Abstract

A novel class of Fe-based nano hydrotalcites as catalysts for Fischer-Tropsch (FT) synthesis, with a focus on CO_2 hydrogenation have been prepared, characterized and tested. These catalysts were synthesized using two green, energy- and time-saving synthesis methods: ultrasound-assisted co-precipitation and solvent-free mechanochemical syntesis. The catalysts demonstrate very satisfactory CO and CO_2 conversion capacities, in particular with good selectivities towards heavy hydrocarbons. The ultrasound-processed variant is particularly noteworthy, displaying about 10% higher activity under specific conditions. The unique physicochemical properties of these catalysts, which were extensively characterized by XRD, TGA, (ATR) FT-IR, ICP-OES, SEM, TEM, BET, and TPR, are responsible for their remarkable potential for CO and CO_2 conversion with varied product distribution. These findings highlight as these iron-based hydrotalcites can be considered as a new promising class of catalyst for CO and CO_2 conversion by Fischer-Tropsch reaction.

Keywords: Fischer Tropsch; Hydrotalcite; Iron; CO_2 conversion; Ultrasound; Ball milling.

32   1. Introduction

33   The need to replace fuels and chemicals derived from refining and converting crude oil is driving the

34   development of industrial processes using alternative sources [1]. Fischer Tropsch synthesis (FT) is

35   a well-established industrial process that can be adapted to meet these needs. For instance, by using

36   syngas (mixture of H_2 and CO) manufactured from CH_4, coal or, as a new trend, biomass [2]. The FT

37   process converts syngas into hydrocarbons in the C_1 to C_{100} range. Common catalysts used for the

38   synthesis are iron-, cobalt- or ruthenium-based, and the resulting products span from hydrocarbon

39   fuels (such as gasoline, diesel fuel and jet fuel) to olefins, waxes, and oxygenated compounds like

40   alcohols. The synthesis, in a nutshell, consists of two main reactions: the formation of alkanes

41   (Equation 1) and that of alkenes (Equation 2) and it is traditionally performed starting from syngas

42   (CO and H_2):

43

$$nCO + (2n + 1)\, H_2 \; \rightarrow \; C_2H_{2n+2} + n\, H_2O \tag{1}$$

$$n\, CO + 2n\, H_2 \; \rightarrow \; C_nH_{2n} + n\, H_2O \tag{2}$$

46

47   These reactions are highly exothermic and the temperature control during the process is a crucial

48   parameter that significantly influences the final products formation and distribution [3].

49   Besides the operating conditions, the composition of the end products depends on the characteristics

50   of the catalysts [4]. Cobalt-based catalysts have long been used for FT due to their long lifetime, high

51   CO conversion and high selectivity towards heavy hydrocarbons [5]. Moreover, these catalysts

52   exhibit low water-gas shift activity, which helps avoiding CO_2 formation. Ruthenium is commonly

53   used in small amounts as an additive to promote cobalt reduction in supported catalysts [6].

54   In recent years, considerable progress has been made in the FT process. This includes new synthetic

55   strategies for catalysts and the use of different raw materials to obtain fuels such as coal (CTL: coal

56   to liquids), natural gas (GTL: gas to liquids) and biomass (BTL: biomass to liquids) [3]. Current

57   research primarily focuses on improving the efficiency of heterogeneous catalysts and on increasing

58 the yield of the FT process. Also appealing is the prospect of using syngas with high CO_2 contents

59 (i.e. for BTL technologies) to produce carbon-neutral fuels [7]. However, the activation of the carbon

60 dioxide molecule is a challenge for the scientific community and the conversion and selectivity

61 reported so far are quite limited [8]. One approach to addressing this technological limit, consists in

62 developing new catalysts based on the same active metals as traditional ones (mainly Fe and Co) but

63 capable of achieving greater activity, higher conversion rate and better selectivity. In this regard, a

64 new class of promising catalysts are nano hydrotalcites (HTlc) [9].

65 HTlc are generally described by the formula $[M(II)_{1-x}M(III)_x(OH)_2]^{x+}[A^{n-}_{x/n}]^{x-}mH_2O$ where M(II) is

66 a divalent cation (Co, Mg, Zn, Ni, or Cu), M(III) is a trivalent cation (Al, Cr, Fe or Ga), A^{n-} is the

67 interlayer anion, and m is the molar amount of co-intercalated water.

68 To date, HTlc-based materials have been used as catalysts in various processes such as

69 transesterification, biodiesel production [10], steam reforming of ethanol for hydrogen production

70 [11], and methane reforming [12]. In recent literature, some studies have been carried out on Co-

71 based hydrotalcites [13], particularly in the use of HTlc as support of the FT catalyst [14] in which

72 the catalytically active metal is dispersed on HTlc surface [15]. HTlc are normally synthesized using

73 traditional methods, such as the co-precipitation or urea methods. Only recently, techniques like

74 ultrasonication and ball milling have been investigated for the preparation of HTlc used as catalysts

75 for CO_2 reduction by methanol synthesis or CO production. These synthetic methods have

76 substantially improved some characteristics of the catalysts promoting a higher dispersion of active

77 sites, particle size control and increased catalyst stability [16].

78 The ultrasound-assisted synthesis is an innovative green technique, which enables the creation of

79 materials with unique textural properties, a more uniform size distribution, higher surface area and

80 better-controlled phase composition [17, 18]. To ensure effective implementation of ultrasound-based

81 syntheses, it is crucial to regulate the emitted power in solution, frequency and sonication duration

82 [19]. Once these parameters are fine-tuned, the benefits are significant. One of the most noteworthy

83 is the improvement in catalytic performance due to a better distribution of the active phases on the

84 inert particles [17]. These improvements are promoted by the formation, growth and implosive

85 collapse of bubbles induced by acoustic cavitation that create local extreme conditions (e.g., ca. 5000

86 °C and 1000 atm followed by cooling rates of more than of 109 Ks^{-1}) that prevent aggregation and

87 crystallization of materials [20-22]. From an energy-saving perspective, the short synthesis duration

88 (a few minutes) must also be considered. The use of ultrasound in the preparation of iron-based

89 Fischer-Tropsch catalysts prepared by impregnation methodology was successfully evaluated in a

90 previous work by observing an increase of the catalytic performance due to a better distribution of

91 the active phases on the inert particle [17].

92 Another alternative emerging and sustainable method to prepare HTlc is the mechanochemistry. In

93 this case, reactions are promoted by mechanical energy generated by a ball mill. This method enables

94 the preparation of HTlc without solvents and with high yield, thereby minimising the environmental

95 impact of the synthesis [23]. The short synthesis duration is another parameter to take into

96 consideration when listing the benefits of this methods.

97 Ultimately, it has to be noted that both the techniques result in catalysts with a porous structure.

98 Recent advancements in the field of microporous and mesoporous materials [24, 25] have shed light

99 on the significant potential of such structures in catalysis. This is particularly relevant in the context

100 of FT synthesis, where the pore structure of catalysts plays a critical role in determining their efficacy.

101 The field of catalysis is continually evolving, with novel approaches emerging to enhance the

102 efficiency of chemical processes. Recent advancements, such as the development of catalytic

103 membranes for hydrocracking and hydro-isomerization [26], highlight the diversity and innovation

104 in this field. In a previous work [27] a different kind of hydrotalcite, based on cobalt, was successfully

105 tested for the syngas conversion. In alignment with this trend of catalytic innovation, the present study

106 introduces a potential new kind of catalysts for the Fischer-Tropsch synthesis with particular interest

107 in the application of CO_2 conversion, prepared with two innovative and energy-saving technologies

108 as ultrasound-assisted co-precipitation and solvent-free mechanochemical synthesis.

109   The purpose of our study is to compare the effectiveness of ternary hydrotalcite-like compounds

110   based on iron, copper and magnesium (MgCuFe), synthesized using the aforementioned methods:

111   ultrasound-assisted co-precipitation and the solvent-free mechanochemical synthesis (ball milling).

112   This novel approach aims to harness the unique properties of these materials for efficient CO_2

113   hydrogenation.

114   Activity tests, for CO e CO_2 hydrogenation, were conducted in a continuous packed bed reactor. SiO_2

115   was used as diluent [28, 29] since its presence improves both the activity, especially for Fe-based

116   catalysts and the heat distribution in the reactor. The catalysts were analysed, both before and after

117   the reaction, using FE-SEM-EDX, TEM, BET, TPR, XRD, TGA and (ATR) FT-IR analyses. This

118   allowed us to establish correlations between the textural characteristics of the catalysts and their

119   efficiency towards light and heavy hydrocarbons selectivity and to select the most promising method

120   for synthesizing the best FT catalyst. The results of this research contribute to the growing body of

121   knowledge in sustainable fuel production, showcasing the potential of nano hydrotalcite-based

122   catalysts in environmental catalysis.

123

124   **2. Experimental methods**

125   **2.1 Materials**

126   Chemical reactants and catalysts precursors as $Mg(NO_3)_2·6H_2O$, $Fe(NO_3)_3·9H_2O$, $Cu(NO_3)_2·3H_2O$,

127   NaOH, $NaHCO_3$ and KNO_3 with analytical grade were purchased from Sigma Aldrich. All reagents

128   were used as received without further purification. Reacting gases for FT synthesis were used directly

129   from high purity (99.99%) cylinders purchased from Sapio Company.

130

131   **2.2 Catalyst synthesis**

132 Sample MgCuFe-US was synthesized by means of an ultrasound-assisted co-precipitation method.

133 High power ultrasound irradiation was carried out by an Ultrasonic processors VC750 (Sonics and

134 Materials) provided with a 13 mm diameter tip, operating at a 750 W, 20 kHz and 50 % of amplitude.

135 The synthesis was carried out by adding 50 mL of 1M NaOH and 2M $NaHCO_3$ solution dropwise to

136 56 mL of 1M Mg, Fe, and Cu nitrate salts solution (molar ratio Mg/Fe/Cu=13.2/6/1). During the

137 addition process, the solution was sonicated with ultrasound for 3.5 min, and the sample was

138 maintained at 5°C. A yellow-brown solid immediately precipitated. At the end of the addition 100

139 mL of distilled water was added to suspend the precipitate. The solid was recovered by centrifugation

140 and washed repeatedly with deionized water, then dried in an oven at 60°C in air. The final

141 composition   of   MgCuFe-US,   determined   by   ICP-OES   (Table   1),   is:

142 $[Mg_{0.59}Cu_{0.07}Fe_{0.34}(OH)_2](CO_3)_{0.17}0.5$ H_2O. MgCuFe-BM was synthesized with a solvent-free

143 method by mixing the salts with a proper amount of NaOH pellets. To prepare 1 g of catalyst, 1.96 g

144 of $Mg(NO_3)_2 \cdot 6H_2O$, 0.14 g of $Cu(NO_3)_2 \cdot 3H_2O$, 1.34 g of $Fe(NO_3)_3 \cdot 9H_2O$ and 0.888 g of NaOH (molar

145 ratio Mg/NaOH = 3/1 molar ratio Mg/Fe/Cu=13.2/6/1) were ball milled for 30 minutes at a frequency

146 of 30 Hz in a planetary mill (Retsch MM200 swing mill, capacity 10 mL, provided with agate balls

147 with diameters 10 mm). The solid was collected and transferred in a PTFE bottle filled with 50 mL

148 of distilled water. The precipitate was aged in an oven at 80°C for 3 days. The solid was recovered

149 by centrifugation, washed three times with deionized water and dried at 60°C in air. The MgCuFe-

150 BM   composition,   obtained   by   ICP-OES   measurements   (Table   1),   is:

151 $[Mg_{0.62}Cu_{0.06}Fe_{0.32}(OH)_2](CO_3)_{0.16}$ 0.5 H_2O.

152 **Table 1.** Experimental weight ppm of Mg, Cu and Fe as determined by ICP and the corresponding

153 molar fractions of the fresh and spent catalysts

154

sample	Mg (ppm)	Cu (ppm)	Fe (ppm)	x_{Mg}	x_{Cu}	x_{Fe}
MgCuFe-US **fresh**	8.79	2.73	11.70	0.59	0.07	0.34
MgCuFe-BM **fresh**	8.95	2.09	10.78	0.62	0.06	0.32
MgCuFe-US **spent**	4.46	1.42	5.92	0.59	0.07	0.34
MgCuFe-BM **spent**	6.30	1.71	7.79	0.61	0.06	0.33

155

156   Before the catalytic tests the samples were impregnated with KNO_3. In detail, MgCuFe-US and

157   MgCuFe-BM were soaked for 2 h in a KNO_3 solution (K = 0.5 wt%) at T= 60°C. The samples were

158   dried at 80°C until all water was removed.

159   **2.3 Characterization of Catalysts**

160   The specific surface area (SBET) and porosity distribution were obtained from N_2

161   adsorption/desorption isotherms at 77 K using a Tristar II 3020 (Micromeritics) apparatus and the

162   instrumental software (Version 1.03) and applying Brunauer–Emmett–Teller (BET) and Barrett–

163   Joyner–Halenda analyses, respectively. Prior to measuring, sample powders were thermally pre-

164   treated (T = 150 °C, 4 h, N_2) to remove adsorbed species such as water.

165   X-ray powder diffraction (XRPD) patterns were collected with a Bruker D8 Advance diffractometer

166   (Bruker AXS GmbH, Karlsruhe, Germany) equipped with a Lynxeye XE-T fast detector and CuKa

167   radiation. The operative conditions were 40 kV and 40 mA, with a step size of 0.033° 2θ and a step

168   scan time of 30 s. Phase identification was performed using the Bruker DIFFRAC.EVA V5 software,

169   and a COD database. Quantitative analyses of crystalline phases have been performed applying the

170   Rietveld method with the help of the Bruker AXS Topas Version 6 software.

171   The metal content of the samples, before and after the catalytic tests, was determined by inductively

172   coupled plasma optical emission spectrometry (ICP-OES), using a Varian Liberty Series instrument.

173   Thermogravimetric analyses (TGA) were obtained using a Netzsch STA 490 C TG-DTA thermal

174   analyzer, operating at 10 °C/min heating rate and 30 mL/min air flow.

175   Attenuated total reflection (ATR) FT-IR measurements were carried out using a Shimadzu IR-8000

176   spectrophotometer. The spectral range measured was 400 to 4000 cm^{-1}, with a spectral resolution of

177   4 cm^{-1} acquiring 100 scans.

178   The morphology and composition were examined by Field Emission Gun Electron Scanning

179   Microscopy (FE-SEM) LEO 1525 ZEISS. Elemental composition and chemical mapping were

180   determined using a Bruker Quantax EDS.

181 TEM images were obtained using a Philips 208 Transmission Electron Microscope. The samples

182 were prepared by placing a drop of an ethanol dispersion of the catalyst powder on a copper grid pre-

183 coated with a Formvar film and air-dried.

184 Contact angle measurements were performed using water as the medium. The instrument is a Data

185 Physics OCA 150 equipped with a SCA20 version 2.3.9 build 46 software. The analysis was

186 performed to check the hydrophilicity of the two catalysts, both as fresh and after performing the

187 activation. The reported results were determined as average of four measurements.

188 The Temperature Programmed Reduction (TPR) measurements were carried out by placing the

189 catalyst (25 mg) in a quartz reactor heating in a reductive mixture flow (5% H_2/Ar) at a heating rate

190 of 10 °C/min from 25 to 1000 °C. Hydrogen consumption was monitored by a TCD detector with a

191 W/Re filament in the Autosorb IQ instrument.

192 Temperature programmed desorption using CO_2 as a probe molecule (CO_2-TPD) was carried out in

193 a lab-made equipment. Samples (25 mg), previously cleaned in He flow (30 mL/min) at 110 ° C for

194 0,5 h, were inserted in a quart reactor. After cooling to 40 °C, the samples were exposed to CO_2 pulses

195 of 0.44 mL each to achieve over saturation. After cleaning the surface with He flow (30 mL/min) for

196 0.5 h at 40 °C, samples were heated with a temperature rate of 10 °C/min from 40 °C to 1000 °C in

197 He flow (30 mL/min). Gases were monitored by a Gow-Mac TCD detector with a AuW_2 filament.

198 **2.4 Catalytic test**

199 During FT reaction (H_2/CO as reactants) Brooks mass flow controllers were used to measure the

200 amount of H_2 (32 Nml min^{-1}, 99.99% purity), CO (16 Nml min^{-1}, 99.99% purity), and N_2 (internal

201 standard, 5 Nml min^{-1}, 99.99% purity) in a continuous mixer. In the case of carbon dioxide

202 hydrogenation reaction, the H_2/CO_2 ratio was set to 3, with the flow of reactants being 36 Nml min^{-1}

203 ^{1}, 12 Nml min^{-1}, and 5 Nml min^{-1}, for H_2 (99.99% purity), CO_2 (99.99% purity) and N_2 (99.99%

204 purity) respectively.
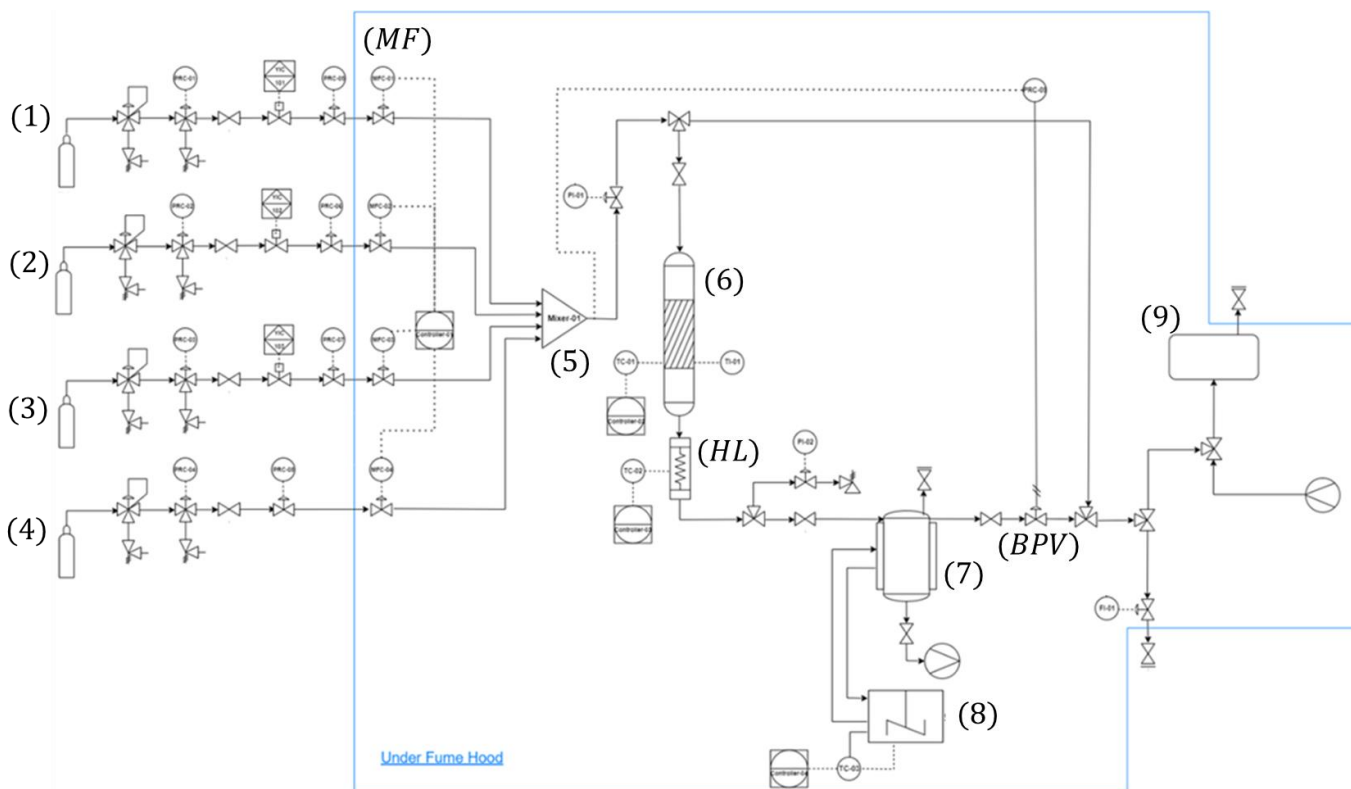

Fig. 1: Laboratory scale plant used for catalytic tests. (1) CO cylinder, (2) H_2 cylinder, (3) N_2 cylinder, (4) CO_2 cylinder, (MF) Mass flowmeters, (5) Mixing chamber, (6) Reactor, (HL) Hot line, (7) Cooling trap, (8) Refrigerator, (BPV) Back pressure valve, (9) In-line Micro-GC analyzer.

The reactor used in the experiment had a 6 mm internal diameter and was packed with 1 g of new catalyst and 0.5 g of SiO_2 as diluent to improve the heat loss [24, 25].

To prevent any false results, a blank test was conducted to ensure that the inner surfaces of the plant were inactive. The catalyst was held in place by a quartz wool bed divided into two separate sections. The reactor was heated with a furnace and the temperature was measured using a K-type thermocouple. A second K-type thermocouple monitored the reactor temperature.

To activate the catalyst, a 2/1 molar ratio of H_2/CO mixture (53 Nml min^{-1}) was flowed in the reactor for four hours at 350 °C and 0.4 MPa. At 5 °C, liquid products such as water and C_{7+} (i.e., liquid hydrocarbons having more than 7 carbon atoms) were condensed in a 0.13 L cold trap with an external cooling jacket before being examined by gas chromatography.

To maintain a pressure of 2.0 MPa, a pneumatic back pressure regulator was utilized [27, 30, 31].

Permanent gases and non-condensable hydrocarbons went through another condenser and were examined by an Agilent 3000A micro gas chromatograph to calculate CO and CO_2 conversion (X_{CO_2} and X_{CO}). This was based on the peak areas of N_2 and CO_2/CO peak areas (A_{N_2}, A_{CO} and A_{CO_2}), their relative response factor (k), and input (set) flow rate of N_2, CO and CO_2 (F_{in,N_2}, $F_{in,CO}$ and F_{in,CO_2}) (Eq.3 and 4).

$$X_{CO2} = \frac{F_{in,CO2} - F_{in,N_2}}{F_{in,CO2}} \times k \frac{A_{CO2}}{A_{N_2}} \tag{3}$$

$$X_{CO} = \frac{F_{in,CO} - F_{in,N_2}}{F_{in,CO}} \times k \frac{A_{CO}}{A_{N_2}} \tag{4}$$

The oxygenated compounds produced during FT test were assumed to have completely solubilized in the water phase collected in the cold trap. The analysis of this liquid was carried out using a Shimadzu 5000 A Total Organic Carbon instrument.

To ensure accurate measurement of gas compositions during the Fischer-Tropsch tests, a calibration procedure was employed using pure cylinders of CO_2, CO, and H_2. The flow rates of these gases were set by Brooks mass flow controllers and then quantified with a micro-GC analyzer. This calibration was crucial for establishing reliable baseline data for the accurate quantification of reactants and products in the FT tests.

The FT tests with syngas (CO/H_2 mixtures) were performed at temperatures ranging from 200-300C°. More in detail, the furnace temperature was first increased to 200 °C and held for about 18 hours. Then, it was raised to 220 °C and maintained for 24 hours before repeating the process for 250 °C, 270°C, 300°C. Similarly, for the CO_2/H_2 starting feed, the same catalysts were tested at temperatures of 275, 310, 350°C, and at a pressure of 20 bar. The same procedure described above was followed, except for the feed molar ratio CO_2/H_2 of 1:3 instead of CO/H_2 of 1:2.

3. Results and discussion

3.1 Characterization

SEM and TEM images of the MgCuFe-US and MgCuFe-BM samples are shown in Figure 2. In both cases, the crystals appear approximately flat and hexagonal, but the platelet size distribution is not uniform. The samples consist of platelets ranging from 30 to 150 nm, with a greater proportion of small crystals in MgCuFe-US. The synthesis method also affects the crystallinity, which is lower in the ball-milled sample.

Fig. 2: SEM and TEM images of MgCuFe-US (a and c) and MgCuFe-BM (b and d). The scale bars indicate 100 nm.

An indication of the different degree of crystallinity is evidenced by comparing the XRD patterns of the samples, shown in Figure 3. Both samples are characterized by typical hydrotalcite-like compound patterns at 11.6°, 23.3°, 34.3°, 59.6°, and 61.0°, which correspond to *(003)*, *(006)*, *(012)*, *(110)*, and *(013)* crystallographic planes [32]. The interlayer space of HTlc hosts carbonate ions, as evidenced

257 by the position of the first reflection at $2\theta = 11.6°$. The XRD patterns of MgCuFe-BM before and

258 after the thermal treatment suggests that the as-synthesised sample is mostly amorphous, as the peaks

259 are broad and the *(110)* and *(013)* diffraction planes are not clearly distinguished, appearing as a

260 single reflection. Even after the aging process, the reflections of MgCuFe-BM have a larger full width

261 at half maximum than those of MgCuFe-US, indicating the presence of crystallites with smaller size.
262

263 **Fig. 3**: XRD of as synthetised MgCuFe-US (a) and MgCuFe-BM (b).

264

265 The samples were characterized by TGA in order to study their thermal decomposition (Fig. 1 SM).

266 The ATR FT-IR spectra confirmed the formation of HTlc in carbonate form (Fig. 2 SM).

267 After the impregnation with K, the samples were activated by CO/H_2 and analysed by XRD patterns

268 (Figure 4). A quantitative analysis of the phases was also performed (Table 1 SM, Figure 3 SM).

269 Figure 4 shows the XRD patterns of the samples that were activated by CO/H_2 before undergoing the

270 catalytic FT test. This activation procedure involved feeding CO/H_2 syngas mixture at 350°C and 0.4

271 MPa for 4 hours directly in the catalytic reactor. Both diffractograms depict the presence of $MgCO_3$.

272 This phase is formed due to CO_2 activation on the surface of the basic oxide, MgO, which leads to

273 the formation of the carbonate [33]. Additionally, the activating conditions (350 °C and 0.4 MPa),

274 resulted in the detection of Fe_2C_5 (double peak at $2\theta= 43.4°$ and $44.1°$), presumably the active species

275 in the FT process, along with superimposed phases of iron-based spinels such as Fe_3O_4 [34].

276   Moreover, especially in ultrasound-prepared samples, the presence of $Na_2Mg(CO_3)_2$ is evident. This

277   may derive from the trace amount of sodium derivatives already contained in the synthesized samples.

278   The morphology of the samples was investigated using SEM and TEM after CO/H_2 syngas activation.

279   Figure 5 shows the images obtained from the analysis, which reveal that the crystals maintained a flat

280   morphology in all cases. The presence of iron carbide species, as revealed by XRD, is somewhat

281   confirmed by TEM analysis. The TEM images also hint at the presence of a non-specified carbide

282   [35]. This was indicated by the covering layer formed on the surface of the crystals after the

283   activation, as seen in Figures 5c and 5d. This difference is evident when comparing the TEM images

284   of the samples.
Fig. 4: XRD patterns of activated catalysts with Syngas at 350°C: (a) MgCuFe-US and (b) MgCuFe-BM (left). Enlargement in the 40-46 2theta range (right). Fe_3O_4 (magenta line, COD#1532796) and/or $MgFe_2O_4$ (magenta line, COD#1011241), $MgCO_3$ (green line, COD#2101057), Fe_2C_5 (blue line, COD#1521831), $Na_2Mg(CO_3)_2$ (cyan line, COD#9000298).

290
Fig. 5: SEM and TEM images of MgCuFe-US (a and c) and MgCuFe-BM (b and d) activated with

syngas.

Table 2: Specific surface areas

Catalyst	BET surface area (m²/g)	volume of pores (cm³/g)
MgCuFe-US fresh	87	0.34
MgCuFe-US activated	31	0.23
MgCuFe-BM fresh	112	0.30
MgCuFe-BM activated	41	0.19

The specific surface area and pore structure of catalysts play a crucial role in determining their catalytic efficiency, especially in processes like Fischer-Tropsch synthesis. In our study, we measured the BET surface area of the freshly synthesized MgCuFe-BM and MgCuFe-US catalysts, and found them to be 112 m²/g and 87 m²/g, respectively (Table 2). These values are in accordance with those typically observed for hydrotalcite-like compounds [36, 37]. According to IUPAC classification, their isotherms are of type IV (Figure 6) (Table 2) with an H3 hysteresis loop, indicating a mesoporous structure [38]. With non-rigid aggregates of plate-like particles, in agreement with SEM results. This structure favors mass transport of reactants and products within the catalyst.

Upon activation, a decrease in surface area and cumulative pore volume was observed for both catalysts (MgCuFe-US values: 31 m²/g and 0.23 cm³/g, and MgCuFe-BM to 41 m²/g and 0.19 cm³/g). This decrease is likely due to structural changes that occur at high temperatures, particularly close to the activation temperature of 350 °C. These changes cause the collapse of smaller pores, leading to an increase in the average pore width and a decrease in total pore volume. As a result, activation step potentially affects the accessibility of reactant molecules to active sites, ultimately impacting the reaction rate. Nevertheless, both MgCuFe-US and MgCuFe-BM retained their mesoporous structure, as demonstrated by the adsorption isotherms performed on fresh and activated samples (Figure 6).
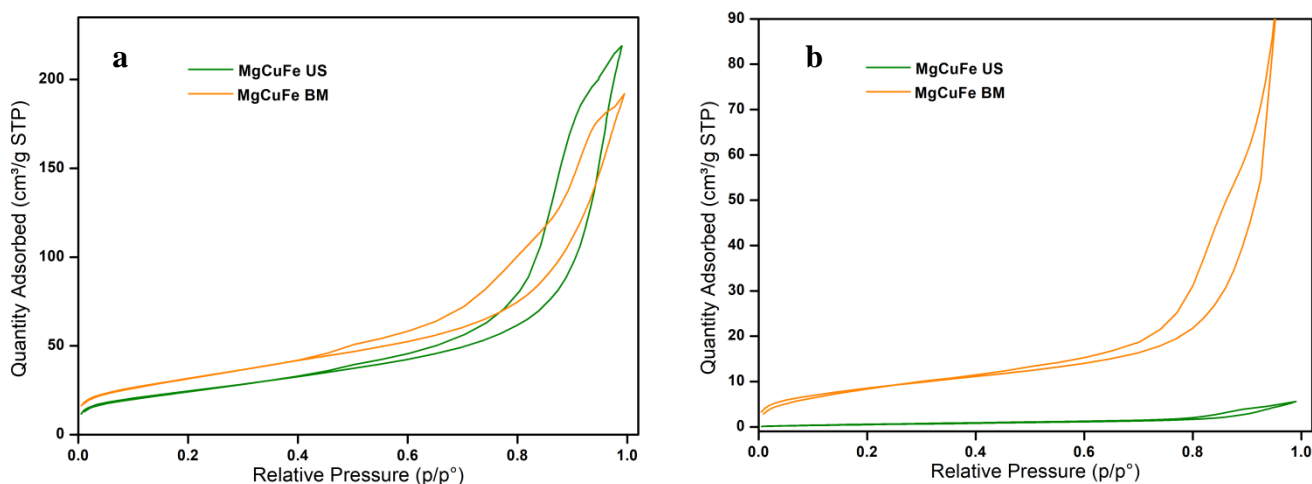

Fig. 6: BET adsorption isotherms a) before the catalytic test, fresh catalyst and b) after activation.

326 These results are in accordance with literature data reporting that sonochemical synthesis typically

327 results in finer, loosely agglomerated particles with larger pores [39, 40], whereas mechanochemical

328 synthesis often leads to denser, more tightly packed agglomerates with smaller pores. The

329 implications of these findings are significant for the catalytic performance of MgCuFe-US and

330 MgCuFe-BM, suggesting that, depending on the desired reaction and on the size of the reactants, it

331 is possible to tune the most effective structure by changing the synthesis method.

332 These results are confirmed by pore size distribution (Table 3), which reveals a difference between

333 the two hydrotalcites and the two synthesis methods. In particular, the as- synthesized ball milled

334 sample contains smaller pores compared to the fresh ultrasound sample, which is constituted by larger

335 pores. This trend is maintained even after the activation. As reported above, such structural

336 differences affect the diffusion of reactant/product molecules, and hence the reaction rate and yield.

337 The largest pores in MgCuFe-US allow easier diffusion and retro-diffusion from catalytic sites,

338 potentially enhancing the reaction rate for larger molecule reactants. Conversely, the smallest pores

339 in MgCuFe-BM could be more effective for reactions involving smaller molecules, as they offer a

340 higher surface area per unit volume, increasing the likelihood of reactant-catalyst interactions. SEM

341 and TEM analysis support this finding, showing that ultrasonic synthesis tends to produce smaller

342 particles and larger pores compared to ball milling.

In FT-CO_2 hydrogenation, water is a byproduct. The hydrophobic nature of catalysts is crucial for efficient operation [41]. Contact angle measurements for the MgCuFe nano hydrotalcites catalysts reveal essential insights. The fresh MgCuFe-US catalyst has a contact angle of 75.81°, indicating moderate hydrophilicity. However, after activation, this angle decreases to 57.92°, suggesting increased hydrophilicity, which might be less desirable in CO_2 hydrogenation due to potential challenges in water removal.

In contrast, the fresh MgCuFe-BM catalyst starts at a hydrophilic 59.92°, but after activation, it shifts to a slightly more hydrophobic angle of 62.65°. This subtle increase in hydrophobicity could be advantageous for CO_2 hydrogenation, as it implies better water management, maintaining catalyst efficiency and preventing deactivation.

Overall, the observed changes in contact angles indicate the significant impact of synthesis and activation methods on the catalysts' surface properties. While initial hydrophilicity might offer some benefits, a trend towards hydrophobicity, particularly after activation, aligns more effectively with the needs of CO_2 hydrogenation. These insights highlight the importance of tailoring surface properties, prioritizing hydrophobic characteristics to optimize performance in reactions where efficient water management is crucial.

3.2 FT Activity test

The main products of the Fischer-Tropsch reaction are CH_4, CO_2, H_2O and C_xH_y in the range of C_1 to C_{100}. The distribution of C_xH_y follows the so-called Anderson-Schulz-Flory distribution (Eq. n°5). According to this theory, the mass distribution (w) depends on two factors: the number of monomer units (k) and an empirical factor, the α value which is a number from 0 to 1:

$$w_n\,(n) = \alpha^{n-1}n(1-\alpha)^2 \tag{5}$$

From Eq. 5 it is possible to obtain a linear relationship (Eq. 6) between the carbon number of a product and its relative weight fraction.

$$\ln\left(\frac{w_n}{n}\right) = \ln(1-\alpha)^2 + (n-1)\cdot\ln\alpha \tag{6}$$

The length of the hydrocarbon chain depends on the chain growth probability (α), which can be determined by analysing the semilogarithmic graphs and it defines the products obtained. The higher the α, the longer the hydrocarbons chains.

MgCuFe-BM and MgCuFe-US catalysts were tested both for classical FT reaction (CO and H_2 as feed) and CO_2 hydrogenation (CO_2 and H_2 as feed) for the production of hydrocarbons. The results will be presented based on CO and CO_2 conversion rates, as well as the selectivity towards methane, carbon dioxide, light hydrocarbons (C_{2-6}), and heavy hydrocarbons (C_{7+}). The total yield to C_{2+} hydrocarbons is calculated by combining the results of both conversions and product selectivity as calculated by Equations (7) and (8). Methane and carbon dioxide will not be considered in the total yield calculation since they are usually regarded as undesired products in the FT process.

399   C_{2+} *total yield = CO conversion X (selectivity $<C_7$ + selectivity $>C_7$) x 10^{-2}*   (7)

400

401   C_{2+} *total yield = CO_2 conversion X (selectivity $<C_7$ + selectivity $>C_7$) x 10^{-2}*   (8)

402

403   All the data presented in this paper pertains only to the steady state conditions of the experimental

404   plant. It took 14 hours for the FT reactor to reach this state, during which the flow rate and

405   composition remained constant with respect to reaction time. Therefore, we only provide data

406   collected after this initialization period.

407   It is important to note that the activation step directly performed in the reactor before starting the FT

408   test, strongly influences the catalyst's performance.

409   In particular, it is well-known that iron carbide, a highly active species in FT, can be formed by using

410   a mixture of H_2 and CO for activation [42]. To investigate this, we performed TPR and CO_2-TPD

411   analyses on these catalysts activated by pure H_2 or H_2/CO mixture and found no significant

412   differences in the results (see Fig. 4-5 SM), these analyses were discussed in the Supporting Materials.

413   Based on these findings, all the catalysts used in this paper, were activated by means of a flowing

414   mixture of H_2/CO in the reactor.

415   Regarding conversions obtained, Figures 8 and 9 illustrate the ultrasound and ball milled catalysts

416   used in the study.
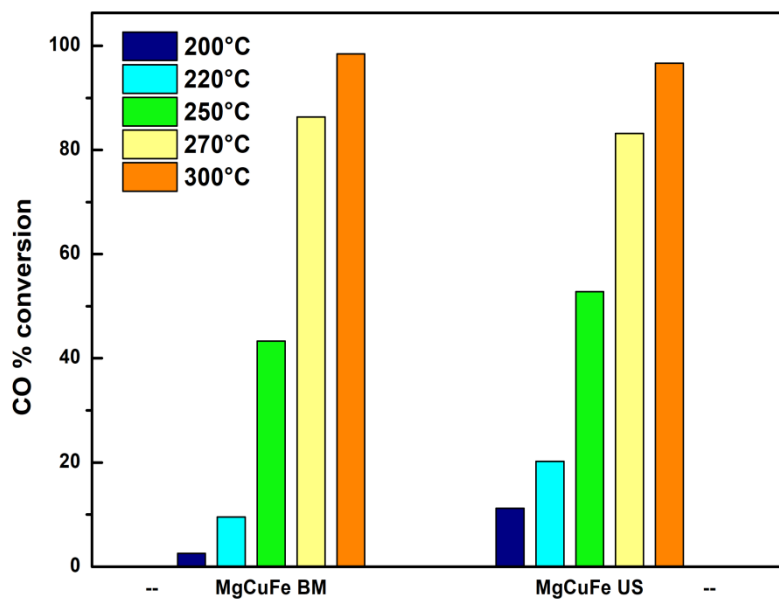

417 **Fig. 7**: CO conversions at different temperatures using MgCuFe-BM and MgCuFe-US catalysts.

	300	51.3	50.2

428

429

430   Results of TOC analyses showed that oxygenated compounds had a very low concentration (<0.5%)

431   in all the catalytic tests. GC-Mass analysis of the condensed phases corroborated the TOC results,

432   confirming that the alcohol content was below 0.5% by weight. The catalysts containing integrated

433   iron in the HTlc structure were proven to be highly active for CO and CO$_2$ hydrogenation in FT

434   synthesis, as demonstrated by the satisfactory results presented in Table 4 and Figures 8 and 9. This

435   is not commonly observed in other studies in the literature [43], where iron is mostly utilized in its

436   metallic form in Fe-supported catalysts.

437   By feeding CO/H$_2$ mixtures, increasing the reactor temperature, the activity of both catalysts

438   increases, as expected, leading to higher CO conversion and greater selectivity towards CO$_2$, CH$_4$,

439   and light hydrocarbons. In particular, CH$_4$ percentage swings from 1-2% up to 6% while CO$_2$ starts

at 20% at 200°C increasing gradually to ca 40% at 300°C. The maximum conversion is observed for both MgCuFe-US and MgCuFe-BM at 300 °C (Fig 8), with difference in activity detected at lower temperatures. In fact, at temperatures ranging from 200 to 250 °C, the MgCuFe-US sample exhibits a CO conversion rate roughly 10% higher than that of the MgCuFe-BM sample. The same phenomenon is observed during CO_2 hydrogenation reaction with US reaching ca. 20% increase in CO_2 conversion at 275 °C.

Significant variation is observed in terms of lighter hydrocarbon cut (C_{2-6}) and heavier one (C_{7+} fractions). As the temperature increases, the MgCuFe-BM sample has a higher C_{2-6} yield than the MgCuFe-US sample, while the latter exhibits a higher selectivity towards C_{7+} hydrocarbons [44]. This can be explained considering that the MgCuFe-BM sample showed a higher concentration of lower pore size particles both in fresh and activated form, while the ultrasound sample displayed greater predominance of larger pore size particles, thus yielding longer hydrocarbon chains as products. The correlation between catalysts pore size and catalytic activity has been investigated in literature and is line with the above-mentioned results [45]. The fact that the total C_{2+} yield has comparable values demonstrates that, even if the conversions are almost equal, the selectivity towards short and long hydrocarbon chains is proven to be distinct between the two-iron based hydrotalcites. In the case of CO_2/H_2 as feed, similar trends were observed (Table 5), with the MgCuFe-US catalysts still showing higher selectivity for C_{7+} hydrocarbons in all evaluated temperatures, while the MgCuFe-BM catalysts showed higher selectivity for C_{2-6} hydrocarbons. The selectivity to methane and carbon monoxide remained stable and under 20% for the CO and 12% for methane.

Table 5: Hydrocarbon selectivities with starting feed CO_2/H_2

| Temperature °C	MgCuFe-BM		MgCuFe-US	
	%C2-6	%C7+	%C2-6	%C7+
275	33.9	32.8	37.3	42.5
310	42.4	33.5	34.5	36.2
350	51.9	31.2	48.6	33.4

462

463   The differences in selectivity are confirmed through the evaluation of the hydrocarbon distribution

464   (α) obtained from the cooled trap by GC analysis of the heavier cut.

465   When working with CO/H_2 as initial feed, α values are substantially different between the two

466   catalysts, being 0.86 for the MgCuFe-US and 0.79 for the MgCuFe-BM.
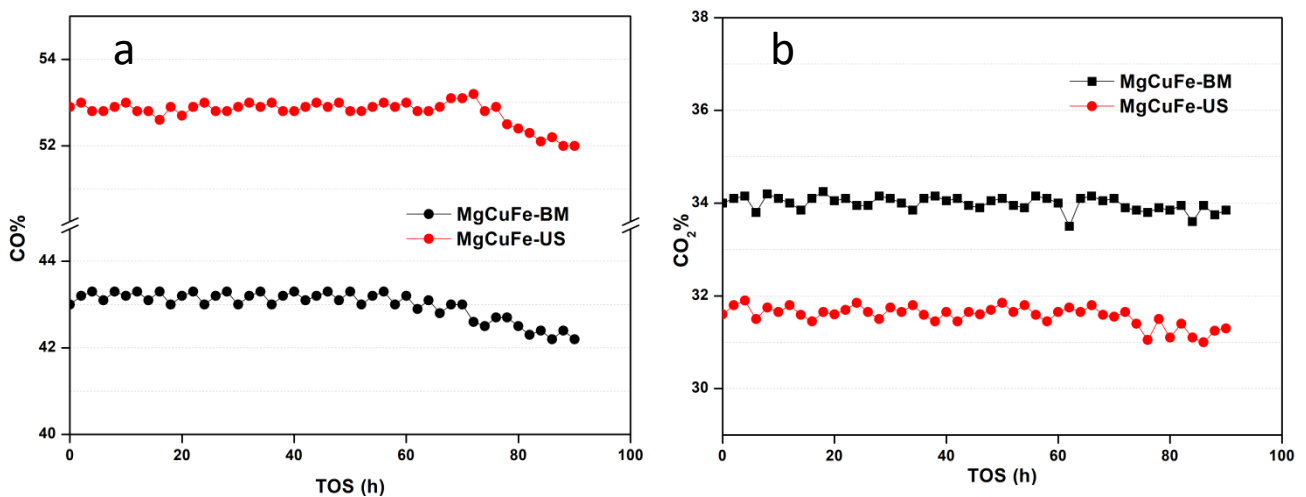

467   The same phenomenon was investigated for the tests performed after the CO_2 hydrogenation (Fig 9).

468   In the case of MgCuFe-US sample, the α value of 0.62 is significantly higher than 0.51 which was

469   obtained using the MgCuFe-BM catalyst.
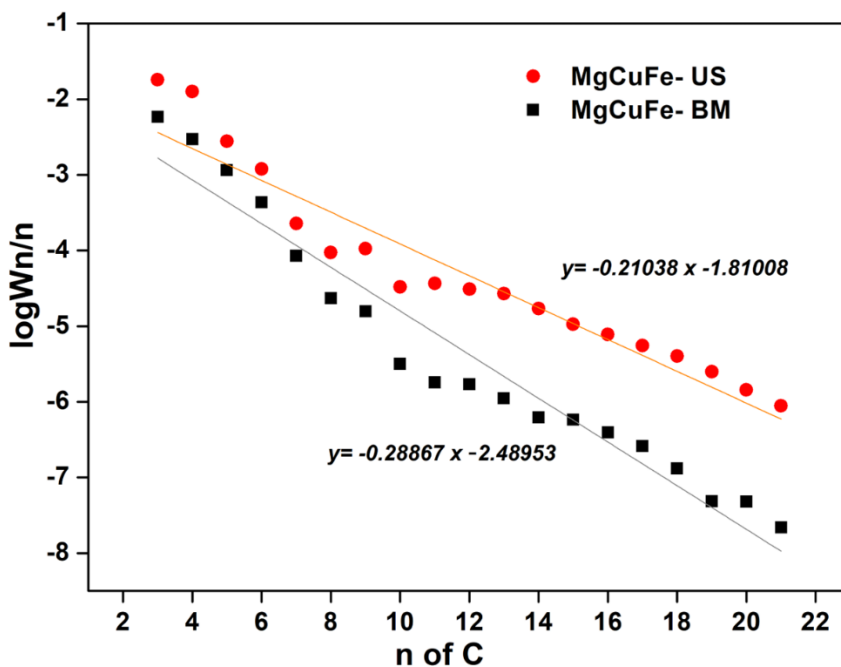

470   .

471   **Fig. 9**: Chain propagation probability α, at 310°C and CO_2/H_2 feed.

472

Fig. 10: Catalytic stability of the two samples with different feeding mixtures, TOS = time on stream,

474 a) isotherm catalytic test at 250 °C, CO% =carbon monoxide conversion. b) isotherm catalytic test at

475 310°C, CO_2% =carbon dioxide conversion.

476

477 Taking into consideration the composition of activated catalysts and the results of surface area and

478 contact angle, we can make assumptions about how the surface of the catalyst interacts with the

479 substrate and explain its reactivity. During the activation phase, the catalyst is heated for four hours

480 in the reactor. The heat causes HTlc to dehydrate and to progressively dehydroxylate. As a

481 consequence, the HTlc structure partially collapses, making the basic sites composed of M-OH

482 (M=Mg, Fe, Cu) more accessible to the syngas as confirmed by CO_2-TPD (Fig. 5 SM). As the

483 temperature increases, HTlc converts to mixed oxides that act as Lewis acid-basic pairs and interact

484 with syngas starting the synthesis [46]. Among the oxides, Fe_3O_4 is responsible for the reverse water-

485 gas shift (RWGS) reaction, which is crucial in the reduction step of CO_2 to CO in the CO_2-FT reaction.

486 As indicated by the XRD patterns in Figure 4, another product of HTlc activation is Fe_2C_5, which

487 drives the subsequent hydrogenation of CO through the classical FT reaction [47]. The RWGS step

488 is endothermic, meaning it is favored at higher temperatures. This is demonstrated by the increased

489 conversion rate at correspondingly increased activation temperature.

490 The different yields at lower temperatures can be explained based on the degree of aggregation and

491 surface roughness of the two HTlcs. These parameters influence the contact angles. HTlcs produced

492 through ball milling have a more disordered structure and agglomerated particles. This results in a

493 denser product with less interparticle space, which leads to reduced water permeability and

494 hydrophilicity. On the other hand, the sample prepared through ultrasonication has a more crystalline

495 structure and larger spaces between particles, which improves wettability. Upon activation, the

496 disparity in value between the two contact angles reduces significantly (from 15.89° to 4.73°) as

497 compared to the fresh samples. Additionally, the yields obtained from both samples are almost

498 identical. This indicates that activation process partially eliminates the initial differences that were

499 caused by the distinct synthesis methods.

500 Together with the morphological stability revealed by XRD analysis, an activity evaluation was also

501 performed. Considering the two experiments, performed at different temperatures, as reference cases,

502 a 90-hour catalytic run was performed to assess the stability of CO and CO_2 conversion over time. As

503 evidenced by Figure 10, the conversions remain consistent throughout the TOS, with negligible

504 discrepancies of less than 1% for both samples. This suggests satisfactory stability in the catalytic

505 activity over prolonged use, whether CO or CO_2 is used as a starting reagent. Moreover, the

506 composition of the catalysts recovered after the reaction was analysed via ICP-OES, and it was found

507 that there was no change in comparison to the pristine samples (the molar fractions vary by maximum

508 3%, Table 1). The active phases (Fe_5C_2 and Fe_3O_4) are still present in the spent compounds as evinced

509 by the phase analysis (Table 2 SM and Figure 6 SM). In addition, metallic Fe and Cu were detected

510 only in MgCuFe-US, graphite in MgCuFe-BM while $FeCO_3$ is common in both the samples and

511 $Na_2Mg(CO_3)_2$ disappears.

512 Studies on other iron-based compounds were compared with the investigated hydrotalcite

513 performance, revealing that the catalyst exhibited a higher catalytic activity than classical silica-

514 supported iron catalysts like FeSi or FeSBA-15 [42], but slightly lower performance than the

515 expensive iron-based metallosilicates like $Fe/Ce/SiO_2$ and $Fe/Zr/SiO_2$ [26, 48-51]. For instance, at

516 280 °C and 1.5 MPa, the Fe15Si catalyst achieved 50% CO conversion, with a heavy hydrocarbon

517 cut selectivity below 40% [48-50, 52]. This comparison highlights the enhanced efficacy of our

518 catalysts, especially in achieving higher conversion rates and balanced selectivity towards heavier

519 hydrocarbons under similar reaction conditions. On the other hand, the previously mentioned

520 metallosilicates exhibit CO conversion ranges between 50 and 60% at 250°C and 2.0 MPa, with heavy

521 phase selectivity between 55 and 65% [46]. This comparison indicates that while our hydrotalcite-

522 based catalysts surpass traditional iron-based catalysts in terms of activity, there is still room for

523 optimization to reach the efficiency levels of the latest metallosilicates.

The performance of our MgCuFe US and MgCuFe BM catalysts was also compared with various iron-based catalysts reported in the literature for CO_2 hydrogenation. As benchmark for the comparison, results achieved at 310°C, 20 bar, and a GHSV of 3200 ml gcat^{-1} h^{-1} were considered.

The MgCuFe BM catalyst exhibited a CO_2 conversion of 34.4% and a C_{2+} selectivity of 75.9%, while the MgCuFe US catalyst showed a CO_2 conversion of 31.9% and a C_{2+} selectivity of 70.7%.

Comparatively, the 92.6Fe7.4K catalyst [53] achieved a CO_2 conversion of 41.7% and a C_{2+} selectivity of 83.8%, and the 10Fe0.8K0.53Co catalyst [54]] showed higher CO_2 conversion of 54.6% with a selectivity of 79.1%. Both were tested at 300°C and 25 bar with a GHSV of 560 ml gcat^{-1} h^{-1}.

The K-Fe15 catalyst [55], at 300°C and 10 bar, reported a CO_2 conversion of 48.5% and a selectivity of 74.4%.

Other catalysts, such as the 1wt% Na-10 wt % Fe/ZrO$_2$ [56], showed lower selectivity (46.6%) and similar conversion (39%) at 340°C and 20 bar, while the 10Fe3Zn1K/Al$_2$O$_3$ [57] had a CO_2 conversion of 38.6% but much lower selectivity (30.9%) at 400°C and 30 bar.

The CuFeO$_2$-12 catalyst [7] had a lower CO_2 conversion (18.1%) and selectivity (65.4%) compared to our catalysts. Similarly, the 5Na/Fe catalyst [56] at 340°C and 20 bar showed lower conversion (24%) and selectivity (47.3%).

The 20Fe-1K/m-ZrO$_2$ catalyst [58] and ZnFeO$_x$-4.25Na catalyst [59] also demonstrated lower performance in terms of selectivity compared to our catalysts, with 30% and 75.2% C_{2+} selectivity, respectively.

Overall, our MgCuFe BM and MgCuFe US catalysts show competitive CO_2 conversion rates and high selectivity towards C_{2+} hydrocarbons, outperforming several reported catalysts, particularly in terms of selectivity. This demonstrates the effectiveness of our synthesis methods and the potential of these catalysts for CO_2 hydrogenation applications and opens the possibility to evaluate with interest the application of these materials, scarcely investigated till now for the Fischer Tropsch synthesis, for CO and CO_2 hydrogenation processes. The list of catalysts taken from literature is represented in Table 3 SM in the Supplementary material.

550   These findings underscore the potential of MgCuFe-US and MgCuFe-BM catalysts in the context of

551   sustainable and cost-effective Fischer-Tropsch synthesis. They offer a competitive alternative to

552   traditional catalysts, balancing performance with economic feasibility, which is crucial for industrial

553   applications. Future enhancements, possibly through modification of synthesis methods or

554   compositional tuning, could bridge the gap in performance with high-end metallosilicates, while

555   maintaining the advantages of lower cost and simpler synthesis associated with hydrotalcite-based

556   catalysts.

557

558   4. Conclusions

559   In this study we synthesized new Fe-based hydrotalcites and used them as catalysts in both Fischer–

560   Tropsch synthesis and CO_2 hydrogenation. We examined the catalytic activity of the materials under

561   different temperatures by using two distinct synthesis routes: ball milling and ultrasonic processing.

562   Our studies showed that specific preparation procedure significantly influences catalytic the activity

563   of the materials and that it is temperature dependent.

564   Both MgCuFe-BM and MgCuFe-US catalysts demonstrated comparable CO conversion capacity at

565   higher temperatures, but they exhibited different product distribution, primarily due to different pore

566   size distribution. However, under 250 °C, the ultrasound processed Fe-based catalyst exhibited

567   roughly 10% higher catalytic activity. Similar trends were observed for CO_2 hydrogenation, with the

568   MgCuFe-US catalysts showing higher selectivity for C_{7+} hydrocarbons in all evaluated temperatures,

569   while the MgCuFe-BM catalysts showed higher selectivity for C_{2-6} hydrocarbons.

570   The experiments conducted at 300 °C yielded the greatest C_{2+} production and conversions (up to

571   98.5%) among the reactions carried out at various temperatures for both CO and CO_2 feeds. This

572   resulted in 50.2% for the ball milled sample and 51.3% for the ultrasound-processed sample in the

573   case of CO hydrogenation. Interestingly, during CO_2 hydrogenation, the MgCuFe-US sample

maintained a higher alpha value, indicating a higher selectivity towards longer chain hydrocarbons compared to the MgCuFe-BM sample.

Our study offers promising insights into the performance of iron-based hydrotalcite catalysts in both CO and CO_2 hydrogenation reactions, suggesting a versatile utility for such catalysts in diverse application conditions. Following these encouraging findings, further research will be conducted on this class of hydrotalcite catalysts in different CO_2/H_2 feed ratios and conditions to further explore and optimize their potential in sustainable chemical production.
