25 **Key message**

26 In the inner-Alpine Aosta Valley, severe growth reductions occurred in Scots pine stands during  
27 1987-1993 and 2003-2005. Trees more sensitive to May precipitation exhibited stronger growth  
28 decline during these periods.

29

30 **Abstract**

31 Over the last decades, Scots pine (*Pinus sylvestris* L.) decline has involved large areas in the  
32 European Alps. Although the species is supposed to be drought-resistant, increased temperatures  
33 and droughts are often indicated as predisposing causes of the decline. Nevertheless, the exact  
34 climate conditions that initiate the decline, and the reasons why they differentially affect  
35 individual trees, are largely unknown. Our aims were to identify climate constraints on Scots pine  
36 growth, and elucidate the effect of individual characteristics, such as tree age, size, crown  
37 condition, mistletoe occurrence, competition, and sensitivity to climate, on tree growth decline  
38 and recovery after repeated climatic stress. We analysed 232 trees in four second-growth stands  
39 located at 985 to 1350 m a.s.l. in the inner-Alpine Aosta Valley, NW Italy. Multi-year growth  
40 declines, occurred in 1987-1993 and 2003-2005, were related to repeated May precipitation  
41 shortage, while temperatures and summer precipitations played a minor role. Growth decline was  
42 stronger in the stand at lower elevation and with higher competition intensity. At the individual  
43 scale, trees more sensitive to May precipitation exhibited lower growth rates during both dry  
44 periods, but not a faster recovery. In the lower elevation stand, tree growth decline was  
45 significantly related to both crown transparency and mistletoe abundance, which was almost  
46 absent in the other stands. We conclude that future variations in the spring precipitation regime  
47 | could threaten Scots pine more than warming *per se*, in ~~inner-inner~~-Alpine valleys around 1000-

48 | 1400 m a.s.l. -Still, different individual sensitivity to precipitation will likely result in patchy  
49 patterns of healthy and declining trees within the same stand.

## 55 **Introduction**

56 Scots pine (*Pinus sylvestris* L.) is the most widespread tree species in Europe, covering more than  
57 20 million hectares from Siberia and Northern Fennoscandia to Southern Europe. During the 20<sup>th</sup>  
58 century, the species has considerably expanded in the European Alps due to its early-seral  
59 character, i.e., a capacity to colonize abandoned fields and grasslands (Barbero et al. 1990). In  
60 ~~inner~~-inner-Alpine valleys characterized by continental climate, a peculiar tolerance to a wide  
61 range of climatic and edaphic stressors (Richardson 1998) allows the species to grow on  
62 southerly-exposed slopes where other species are limited by concomitant low winter and high  
63 summer temperatures, and summer rain shortage (Vacchiano et al. 2012). Therefore, in the  
64 continental sectors, Scots pine can be considered both an early- and late-seral species (Ozenda  
65 1985).

66 However, over the last 20 years, an increasing number of studies have reported a decline of Scots  
67 pine in ~~inner~~-inner-Alpine valleys, especially at medium and low elevations, e.g., in the Austrian  
68 Inn Valley (Oberhuber 2001), Swiss Valais (Bigler et al. 2006), Southern France (Thabeet et al.  
69 2009), and Italy's Aosta Valley (Vacchiano et al. 2012). Symptoms of the decline include stem  
70 growth reduction, crown defoliation, and mortality, eventually leading to shifts in species  
71 composition in favour of other species such as downy oak (*Quercus pubescens* Willd.) (Weber et  
72 al. 2007; Rigling et al. 2013; Vacchiano and Motta 2015).

73 Different biotic agents, including mistletoe (*Viscum album* L.), insects, nematodes, and fungi  
74 have been locally found to act as contributing factors (Manion 1981) for Scots pine defoliation  
75 and mortality (Dobbertin and Rigling 2006; Polomski et al. 2006; Wermelinger et al. 2008;  
76 Gonthier et al. 2010). However, on a broader scale, increased temperatures and more frequent  
77 droughts are indicated as the main drivers (predisposing and inciting factors) of the decline  
78 (Rebetez and Dobbertin 2004). Current climate change scenarios predict further year-round

79 warming in Southern Europe (IPCC 2013; Jacob et al. 2014), which will likely exacerbate  
80 summer moisture deficits and aggravate drought effects on forest ecosystems (Allen et al. 2010).  
81 On the other hand, precipitation forecasts are less clearcut, especially in the Alpine region:  
82 precipitations may decrease in summer, but changes in spring and fall are expected to be less  
83 pronounced (Gobiet et al. 2014), with uncertain consequences on forest ecosystems (Lindner et  
84 al. 2014). Finally, extreme climate events, such as droughts and/or heat waves, are expected to  
85 increase in Southwestern Europe (IPCC 2013). Single-year droughts certainly affect forest  
86 ecosystems (Bréda et al. 2006), but on drought-adapted species such as Scots pine they generally  
87 cause short-term growth reduction followed by recovery, at least in healthy trees (Pichler and  
88 Oberhuber 2007; Eilmann and Rigling 2012; Eilmann et al. 2013). On the opposite, repeated  
89 droughts lead to irreversible alterations in the xylem hydraulic system (Hereş et al. 2014), and to  
90 progressive depletion of stored carbohydrates (Rigling et al. 2013). This process negatively  
91 affects tree metabolism and resistance to pathogens that are the actual mortality agents, and can  
92 lead to tree death up to several years or even decades after the event (Bigler et al. 2006; Hereş et  
93 al. 2014).

94 However, even in areas with high mortality, declining and vigorous pine trees can co-occur in the  
95 same stand (Bigler et al. 2006), suggesting that individual tree characteristics influence decline.  
96 In this context, analysis at the individual tree level can increase our understanding of processes  
97 behind tree response to long-term stress. Extensive literature reports on the influence of tree age  
98 (Carrer and Urbinati 2004), size (Mérian and Lebourgeois 2011), and local competition intensity  
99 (Pichler and Oberhuber 2007) on growth response to inter-annual climate variations, but tree-  
100 level response to multi-year or repeated climatic stress has been scarcely investigated (Thabeet et  
101 al. 2009; Walter et al. 2013).

102 To investigate Scots pine response to multi-year stress, we analysed growth patterns of 232 trees  
103 in four stands located at different elevations (985 to 1350 m a.s.l.) along the east-west axis of the  
104 Aosta Valley (NW Italy), one of the driest valleys in the Alps. In this region, land use change has  
105 considerably increased forest cover over the last 50 years (+30%, Garbarino et al. 2006), mainly  
106 due to expansion of early-seral species such as Scots pine. However, Scots pine forests have  
107 recently displayed a quick loss of vitality (Gonthier et al. 2010; Vacchiano et al. 2012). The  
108 specific objectives of our analysis were: (1) to identify climatic conditions that determined multi-  
109 year growth decline in Scots pine stands in the period 1965-2005; (2) to assess the influence of  
110 site, stand, tree age, size, competition, and sensitivity to climate on individual tree growth decline  
111 and recovery after repeated climatic stress; and (3) to test whether crown transparency as an  
112 indicator of tree vitality, and mistletoe as an inciting mortality agent, are related to the ability of  
113 trees to respond to climatic stress.

114

115

## 116 **Material and Methods**

### 117 **Study area and sampling**

118 The study area covers the Aosta Valley region in Northwestern Italy (Fig. 1). Climate is warm-  
119 summer continental, with mean annual temperature at the bottom of the valley (Aosta, 45°26' N,  
120 7°11' E, 583 m a.s.l.) of 10.9 °C (years 1961-1990; Biancotti et al. 1998). Mean temperature in  
121 January and July may differ by as much as 22°C. Mean annual precipitation in the central valley  
122 is scarce (494 mm in Aosta, years 1961–1990) compared to other Alpine valleys, and water  
123 deficit may occur at low elevations from June to September. Winter precipitation usually comes  
124 as snow. Aosta Valley exhibits both crystalline (granites) and metamorphic bedrocks, but most  
125 landscape is covered by quaternary deposits of glacial, gravitative, or colluvial origin.

126 Scots pine forests occur on 5,372 ha on both acidic and basic substrates of well-exposed slopes,  
127 from the valley bottom up to 1900 m a.s.l. (Vacchiano et al. 2014). Depending on successional  
128 stage and climatic factors, species composition may range from 100% pine (especially on  
129 recently disturbed sites or on dry, south-facing slopes) to mixtures with other conifers (*Larix*  
130 *decidua* Mill., *Picea abies* L. Karst., *Abies alba* Mill., *Pinus uncinata* Mill.) or broadleaves  
131 (*Quercus pubescens* Willd., *Fagus sylvatica* L., *Quercus petraea* (Mattus.) Liebl., *Castanea*  
132 *sativa* Mill.).

133 In 2005 we selected four Scots pine stands along the east-west axis of the Region: one at  
134 Challand-Saint-Anselme (hereafter Chal), two at Saint Denis (SD1 and SD2), and one at Morgex  
135 (Morg) (Table 1, Fig. 1). All stands originated by natural encroachment after the abandonment of  
136 pastures and meadows in the past century. All of them exhibited visual symptoms of decline such  
137 as a wide range of crown transparencies. In each stand, we established a 70x70m monitoring plot,  
138 where all living trees with diameter at breast height (dbh) > 4 cm were identified, labelled, and  
139 mapped. For each tree, we measured dbh, tree height, and crown radii in four orthogonal  
140 directions, which were then used to calculate crown area, approximated as an ellipse.  
141 Furthermore, we assessed crown transparency on a scale from 0 (healthy crown) to 100  
142 (completely defoliated) by comparison with visual field guides (Müller and Stierlin 1990;  
143 Dobbertin et al. 2004), and recorded mistletoe abundance on a scale from 0 (absent) to 3  
144 (abundant) (Dobbertin and Rigling 2006). One increment core was taken at breast height from all  
145 living trees within a concentric 50x50 m subplot, to avoid edge effects in the calculation of  
146 competition indices (Castagneri et al. 2008).

147

#### 148 **Methodological approach**

149 Radial growth is a good indicator of tree vitality and reaction to environmental stress (Dobbertin  
150 2005). Furthermore, in contrast to other tree vitality indices such as crown transparency, ring  
151 measurement is objective, repeatable, and retrospective (on the whole tree life-span). We  
152 analysed tree-ring series to assess individual tree response to inter-annual climate variations, and  
153 identified protracted growth decline periods. Then we analyzed tree response to inter-annual  
154 climate variations (ring width-climate correlations) and to prolonged stress (i.e. growth rates  
155 during and after the identified decline periods) using tree age, size, competition, mistletoe  
156 abundance, and crown transparency as covariates.

157

#### 158 **Ring-width analysis**

159 Tree cores were prepared using standard dendrochronological techniques (Speer 2010). Tree  
160 rings were measured to the nearest 0.01 mm and cross-dated using TsapWin (Rinntech,  
161 Germany). Cross-dating accuracy was checked using COFECHA (Holmes 1983). Sample size  
162 showed an abrupt reduction prior to 1965, thus 1965-2005 was identified as the investigation  
163 period. Series not entirely overlapping with this period, and those poorly cross-dating, were  
164 excluded from the analyses. Raw ring width (RW) and basal area increment (BAI) series were  
165 built for 54 trees for SD1, 66 for SD2, 73 for Morg, and 39 for Chal, for a total of 232 series  
166 across the study sites.

167 To assess inter-annual growth variations, we removed age-size related trends on RW series by a  
168 double-detrending process using the DetrendeR package (Campelo et al. 2012) for the R  
169 statistical framework 3.1 (R Development Core Team 2014). Detrending was based on a cubic  
170 spline with 50% frequency response at wavelength of 200 years, followed by a cubic spline  
171 function with 32 years response (Fritts 1976); we computed detrended ring width by dividing raw  
172 RW by the value fitted with the splines. We then calculated mean sensitivity (MS) of detrended

173 series to assess high-frequency variations (Fritts 1976), first-order autocorrelation (AC) to  
174 measure the influence of previous year's growth on the current ring, and mean correlation  
175 between trees ( $\bar{R}$ ) to measure the common growth forcing among trees within each plot.  
176 Finally, mean chronologies were calculated for each plot as the bi-weight robust mean of  
177 detrended individual series (Cook 1985).

178

### 179 **Tree-level competition**

180 To assess the competitive status of each tree, we computed distance-dependent and distance-  
181 independent individual-tree based competition indices (CIs) (Tab. 2). We tested different radii (5,  
182 7 and 9 m) of the zone of influence (i.e., the circular area surrounding the subject tree where  
183 competitors are selected) to compute distance-dependent CIs. Moreover, different weights were  
184 applied to species other than Scots pine to account for possible variations in the competitive  
185 pressure of interspecific competitors. Specifically, due to the high number of species in the four  
186 plots, some of which represented by only a few individuals, we gathered them in two groups:  
187 conifers (5 species) and broadleaves (13 species). To test if conifer and/or broadleaf interspecific  
188 competitors had higher or lower competitive pressure on focus trees (always Scots pines)  
189 compared to intraspecific competitors (weight = 1), we assigned different weights to trees  
190 belonging to the two groups—different weights: 0.5 to test for lower (half) competitive pressure; 1  
191 for same pressure; 2 for higher (double) pressure. All possible combinations were tested. The  
192 predictive ability of each combination of CI, zone of influence, and weighting scheme was tested  
193 by a linear regression against cumulative BAI of each tree in the ten years before measurement  
194 (Castagneri et al. 2008). Both predictors and dependent variables were log-transformed to  
195 normalize error distributions. The combination of competition index, radius of the zone of  
196 influence, and weighting scheme producing the highest correlation with BAI (i.e., competition

197 importance) and steepest regression slope (i.e., competition intensity) was used in subsequent  
198 analyses.

199

200

### 201 **Climate-growth relationships**

202 The influence of climate on the inter-annual growth variability in the four site chronologies  
203 (years 1965-2005) was assessed by bootstrap correlations using the bootRes package (Zang and  
204 Biondi 2013) for R. Climate variables entered in correlations included: monthly mean  
205 temperature and precipitations sum from May of the previous year to September of the ring  
206 formation year, both retrieved from the CRU TS 3.21 dataset (Harris et al. 2014) accessed via the  
207 KMNI climate explorer (<http://climexp.knmi.nl>); the self-calibrating Palmer Drought Severity  
208 Index (sc-PDSI, CRU TS 3.21 dataset); the ratio between precipitation and potential  
209 evapotranspiration (P/PET) according to Thornthwaite (1948); and the Standardized Precipitation  
210 Evapotranspiration Index (SPEI) (Vicente-Serrano et al. 2010) based on a 6-month integration  
211 period. As PET (and P/PET) was null for winter months due to temperature below 0, while sc-  
212 PDSI and SPEI are incremental, i.e., they incorporate the value of the previous months, these  
213 were computed only for the ~~vegetative period~~growing season (April-August) of the ring  
214 formation year.

215

### 216 **Multi-year growth declines and recovery**

217 Tree growth response to prolonged stress was assessed as follows: (1) for each year in the period  
218 1965-2005, we calculated the number of trees with lower-than-average BAI. Decline periods  
219 were identified as those where two or more consecutive years had lower-than-average BAI in at  
220 least 2/3 of trees. (2) For each of these periods, we computed individual tree growth decline as

221 the ratio between BAI during the period and BAI in the previous five years, and (3) individual  
222 growth recovery as the ratio between BAI in the five years after and BAI during the decline  
223 period (Martín-Benito et al. 2008). We then assessed climate anomalies of each decline and  
224 recovery period (i.e., differences in monthly temperature, precipitation, P/PET, sc-PDSI and  
225 SPEI in decline and recovery periods compared to the reference period), and whether individual  
226 growth decline and recovery differed among stands (Kruskal-Wallis median test, with Mann-  
227 Whitney pairwise comparisons).

228

### 229 **Individual tree responses**

230 To investigate factors influencing individual response to inter-annual climatic variations (i.e.,  
231 ring width-climate correlation coefficients for the most significant climate factors), and  
232 individual growth decline and recovery after prolonged stress (response variables), we used a  
233 linear mixed model approach, with site as a random factor (in both intercept and slope). Growth  
234 decline and recovery were squared-root transformed, while correlation coefficients were  
235 processed by Fisher z-transformation. Independent variables were tree size characteristics (dbh,  
236 height, and crown area), tree age, and competitive status (CI). In the models for growth decline  
237 and recovery, we included as predictors the tree response to inter-annual climatic variations, and  
238 growth decline and recovery in the periods preceding the one being analysed. The effect of each  
239 independent variable was tested first by univariate models, which allowed the identification of  
240 significant predictors. Successively, the latter were used in multivariate models to assess their  
241 relative influence on response variables. Linear mixed effects models were fitted using the  
242 package lme4 (Bates et al. 2014) for R.

243 Finally, we computed generalized linear models (with log-link function and gamma distribution)  
244 to assess the effect of independent variables, plus mistletoe infection where present, on individual  
245 crown transparency in the four stands.

246

247

## 248 **Results**

### 249 **Stand characteristics and competitive status**

250 In the four stands, Scots pine accounted for 75% (SD1) to 100% (SD2) of the total basal area  
251 (Table 1). Other species were mainly downy oak at SD1, downy oak and other broadleaves at  
252 Morg, and larch at Chal. SD1 had the highest total stand density but the lowest basal area and  
253 quadratic mean diameter (QMD). Trees at SD1 were also shorter and younger than in the other  
254 plots.

255 Among different competition indices, the highest correlation with BAI was produced by CAI  
256 (Table 2). Most indices performed better when computed on a 7 m-radius area of influence.  
257 Performance of CIs did not improve when using species-specific weighting coefficients. Despite  
258 having the lowest basal area, SD1 showed the highest correlation and steepest linear regression  
259 coefficient between BAI and CAI, indicating higher importance and intensity of competition at  
260 the local scale.

261

### 262 **Climate-growth relationships**

263 Tree-ring series in SD1 showed the highest mean sensitivity, while in Chal they had the highest  
264  $\bar{R}$  (Table 1). In all stands, inter-annual growth variations were strongly affected by spring and  
265 early summer climatic conditions of the ring formation year (Fig. 2), while the climate of other  
266 seasons had a moderate and inconsistent influence (Supplementary Fig. 1). Spring and summer

267 temperature had a negligible effect on growth at SD1 and Morg. A moderately positive effect of  
268 April temperature emerged at SD2, and a negative effect of May and August temperatures at  
269 Chal. May precipitation (or May P/PET in SD1) was the most important factor, and significantly  
270 affected individual growth in 74% of trees (80% at SD1, 82% at SD2, 65% at Morg, 70% at  
271 Chal). Precipitation in other spring and summer months had little influence. Ring-width  
272 correlation with sc-PDSI and SPEI indicated that SD1 was the site most affected by April to  
273 August water deficit.

274

#### 275 **Growth decline and recovery periods**

276 During the investigation period 1965-2005, there were 13 years with at least 2/3 of trees showing  
277 reduced growth rates (i.e., annual BAI lower than average) (Fig. 3 and 4). The first three years  
278 (1965, 1968 and 1976) were isolated events, while the remaining ten clustered in two periods:  
279 1987-1993, where growth was reduced in almost all trees, and 2003-2005 (Fig. 3). As ring-series  
280 ended in 2005, it was not possible to calculate recovery after 2003-2005.

281 May temperature during decline (1987-1993 and 2003-2005) and recovery (1994-1998) periods  
282 was above the 1965-2005 average (Fig. 45), indicating a general warming over the last decades.  
283 May precipitations and P/PET were much lower than average in the growth decline years (except  
284 precipitation in 1988), with a negative peak in 1991. May precipitation during the recovery  
285 period (1994-1998) was above average, except for 1998, while P/PET was below average, due to  
286 high temperatures. Sc-PDSI and SPEI in May evidenced normal conditions during 1987-1993  
287 and drought in 2003-2005, while 1994-1998 period was quite wet. During April and summer  
288 months (June, July and August), temperatures were above average in both the decline and  
289 recovery periods, while precipitations had no evident reduction during 1987-1993

290 (Supplementary Fig. 2). sc-PDSI was consistent with a 2003-2005 drought, whereas conditions  
291 during 1987-1993 were close to average.

292 | All plots experienced a severe growth reduction in 1987-1993 (Fig. 56), but SD1 showed the  
293 | most dramatic decline ( $p < 0.001$ , Kruskal-Wallis median test with Mann-Whitney pairwise  
294 | comparison). Trees at SD1 also experienced the strongest growth recovery among all sites during  
295 | 1994-1998, while in Morg recovery was poor. The 2003-2005 growth decline was less severe  
296 | than the previous in all plots. Again, growth reduction was stronger in SD1, while trees in SD2  
297 | did not show any decline.

298

### 299 **Individual tree response**

300 | In all plots, tree growth was positively affected by May precipitation. However, the effect of May  
301 | precipitation on intra-annual growth variations during 1965-2005 individual tree response was  
302 | not significantly affected by tree age, size, or competitive status (Table 3). Growth decline in  
303 | 1987-1993 was more severe in suppressed trees (those with high CIs) and in trees more sensitive  
304 | to May precipitation in the previous years (Table 4), especially at SD1 and SD2 (Fig. 67). No  
305 | variable appeared to influence growth recovery in 1994-1998, while growth decline in 2003-2005  
306 | was more severe in young trees and, consistently with the previous stress period, in those more  
307 | sensitive to precipitation in the previous years (Tables 3 and 4, Fig. 67).

308

### 309 **Crown transparency**

310 | SD1 exhibited the highest crown transparency among all stands (Fig. 78). Furthermore, several  
311 | trees in SD1 were interested-infested by mistletoe (79%), whereas its occurrence was sporadic in  
312 | SD2 (2%) and null in the other stands. Considering all stands together, we found a scarce  
313 | influence of competition and tree characteristics on crown transparency (Table 3). Crown area

314 had a negative effect on crown transparency, but could not discern whether small crowns were  
315 more defoliated, or defoliation reduced crown size. Individual tree growth decline in 2003-2005  
316 was not related to crown transparency at SD2, Morg, and Chal (results not shown), but it was at  
317 SD1 (Table 5). Furthermore, mistletoe at SD1 was more abundant in trees with higher  
318 transparency – but again, causation between the two variables could be either direction.

319

320

## 321 **Discussion**

### 322 **Climate influence on Scots pine growth**

323 Scots pine is characterized by great ecological plasticity, which allows the species to grow in a  
324 variety of environmental conditions. In Northern Europe, radial growth is mainly limited by  
325 temperature during the short growing season (Gunnarson and Linderholm 2002), while in Central  
326 and Southern Europe growth is often controlled by water availability in April, May, June or July-  
327 August, depending on the region (Zang et al. 2012; Panayotov et al. 2013; Schuster and  
328 Oberhuber 2013; Morán-López et al. 2014; Merlin et al. 2015). In all analysed stands, May  
329 precipitation was the main climate factor influencing Scots pine growth, while precipitation and  
330 summer temperature, often indicated as major climate stressors in dry sites, had a negligible  
331 effect. Recent studies on Scots pine cambial activity on similar environmental conditions could  
332 help interpreting the observed patterns. In the dry valley of the Inn River (Austria), Gruber et al.  
333 (2010) and Swidrak et al. (2014) evidenced that cambial activity in Scots pine lasts from  
334 early/mid-April to the end of June/early July, with a peak cell production in early to mid-May.  
335 Similarly, Eilmann et al. (2013) indicated that tree rings in Valais (Switzerland) are mostly  
336 completed already in June, before the dry period occurs in July and August. We can therefore  
337 assume that, in the analysed sites, rings are mostly formed in May, when temperature is relatively

338 low and, generally, does not determine high evapotranspiration. Thus, May precipitation is the  
339 limiting factor here. Summer climate has a negligible effect, as most of xylem cells differentiate  
340 before June.

341 Here, we provided empirical evidence that reduced May precipitations over several years induced  
342 prolonged growth depressions, being very reduced during both 1987-1993 and 2003-2005, and  
343 abundant in the recovery period 1994-1998. On the other hand May temperature, and summer  
344 precipitations and temperatures, were neither unusual during 1987-1993, nor favourable in the  
345 successive recovery period, indicating a secondary role of such climate factors. This result is  
346 critical for the definition of climatic stress for the species. Increased temperature, heat waves and  
347 summer drought events are often indicated as a major threat for forest ecosystems (Allen et al.  
348 2010; Huang et al. 2015), but do not seem to have influenced Scots pine growth in the inner-  
349 Alpine Aosta Valley. However, we cannot exclude influence of warming and summer droughts  
350 on other tree physiological processes (e.g., root growth, Brunner et al. 2009; nonstructural  
351 carbohydrates accumulation, Galiano et al. 2011), or on biotic agents of Scots pine decline (e.g.,  
352 insects and nematodes, Rebetez and Dobbertin 2004; mistletoe, Dobbertin et al. 2005).  
353 After dry years, when May precipitation returned to average values, Scots pine trees recovered  
354 rapidly. In the five years following the drought of 1987-1993, growth increased by 40% (Morg)  
355 to 130% (SD1). In 1995, almost 2/3 of trees showed higher-than-average growth. Good recovery  
356 capacity indicates adaptation of the species to climate variations, especially in the site more  
357 affected by drought (SD1).

358

### 359 **Individual tree response**

360 The classical dendrochronological method is based on the selection of large, healthy, and  
361 possibly isolated trees to create a mean chronology representative of the population

362 (Schweingruber et al. 1990). However, over the last decade, an increased interest in the  
363 individual response to climate emerged (Carrer 2011). Each tree has its own characteristics, and  
364 experiences different ecological conditions, which can potentially influence tree response to  
365 environmental variations (Tessier et al. 1997; Castagneri and Motta 2009). We observed a large  
366 variability in Scots pine individual response to climate, growth decline during stress periods,  
367 growth recovery, and crown transparency. However, the investigated tree characteristics scarcely  
368 explained such differences. Tree age was the only characteristic that partially influenced growth  
369 decline, but with no generalized effects. Indeed, age influenced growth decline during 2003-  
370 2005, but had neither influence during the former event, nor affected growth recovery and crown  
371 transparency. In past studies, tree characteristics such as age, stem diameter, height, and crown  
372 size have been shown to affect tree response to inter-annual climate variations, but observations  
373 were not consistent (e.g., for age effect see Szeicz and MacDonald 1994; Carrer and Urbinati  
374 2004; Esper et al. 2008; Dorado Liñán et al. 2012; Rozas 2014). Our data suggest that the  
375 influence of tree characteristics on growth responses to climate (both inter-annual variations and  
376 long-term stress) depends on the peculiar characteristics of the stand, species, and climate event  
377 (Merlin et al. 2015), and a general pattern cannot be defined.

378 Beside tree characteristics, also inter-tree competition can influence tree response to climate, as it  
379 affects light and water availability, resource uptake, and growth efficiency (Gersonde and O'Hara  
380 2005; Castagneri and Motta 2009). It is often assumed that trees in denser stands have a weaker  
381 climate signal (Schweingruber et al. 1990), as supported by comparative studies (Hurteau et al.  
382 2007; Castagneri et al. 2012). However, high competition can increase sensitivity to drought as it  
383 exacerbates water stress (Martín-Benito et al. 2011; Martínez-Vilalta et al. 2012; Madrigal-  
384 González and Zavala 2014). In his seminal work on tree decline diseases, Manion (1981)  
385 indicated competition as a slow “predisposing” factor, while particularly dry years can be the

386 “contributing” or “inciting” cause of mortality of weakened trees. This was partially confirmed  
387 by our results, as SDI was at the same time the stand with more intense competition (despite a  
388 low basal area), the most sensitive to summer drought, and the most affected by prolonged  
389 climate stress. At the tree level, however, the effect of competition on climate-growth  
390 relationships was less clear. Competition appeared to exacerbate drought effects during 1987-  
391 1993, but did not influence growth recovery, nor decline in 2003-2005. As discussed for age/size  
392 effect, we believe that competition-drought interactions at the tree level are extremely complex  
393 and do not comply with general rules, as shown by the inconsistency of previous findings (Piutti  
394 and Cescatti 1997; Pichler and Oberhuber 2007; Martín-Benito et al. 2008; Camarero et al. 2011;  
395 Rozas 2014).

396 In the analysed stands, trees more sensitive to May precipitation (during the years previous the  
397 droughts) had lower growth rates in 1987-1993 and 2003-2005. However, they were not able to  
398 recover faster than other trees during 1994-1998. Therefore, high correlation between growth and  
399 climate did not indicate high tree plasticity, i.e., a capacity to reduce growth under unfavourable  
400 climate and to take advantage of positive conditions. Instead, within stands, some trees were  
401 simply more susceptible to precipitation shortage. Individual difference could be possibly related  
402 to genetics (Taeger et al. 2013), morphology (e.g., the wood anatomy, Hereş et al. 2014; root  
403 system architecture, Mickovski and Ennos 2002), physiology (e.g., carbon storage in sapwood  
404 and needles, Camarero et al. 2015), or micro-site soil conditions (Gruber et al. 2010).

405

#### 406 **Crown conditions**

407 Crown transparency is widely used to monitor anthropogenic, soil, or climate stress in forest  
408 stands. Still, to date, it has been scarcely used to investigate individual response to stress. As both  
409 tree growth and crown transparency are not cause-specific indicators of stress, their assessment

410 may complement each other (Dobbertin 2005; Camarero et al. 2015). Among the four  
411 investigated stands, the highest crown transparency was found at SD1, where repeated May  
412 droughts had the strongest effect on growth. Here, we also observed a relationship between  
413 individual growth decline and crown transparency, suggesting that these stress indicators were  
414 responding to a common limiting factor, i.e. spring water ~~balance~~availability, while tree  
415 characteristics and perceived competition played a minor role. SD1 was also affected by  
416 mistletoe, which occurred only sporadically in the other stands. Within the stand, trees with high  
417 infestation had the highest crown transparency (as observed by Dobbertin and Rigling 2006). In  
418 accordance to Rigling et al. (2010), we did not observe a direct effect of mistletoe on growth  
419 decline, but rather crown degradation, enhanced by mistletoe infection, can result in higher  
420 sensitivity to drought stress.

421

422

### 423 **Conclusion and future perspectives**

424 Along the east-west axis of the inner-Alpine Aosta Valley, at elevations between 985 and 1350 m  
425 a.s.l., repeated precipitation shortage in May caused prolonged growth reductions in Scots pine  
426 second-growth stands, while there was no evidence of summer climate constraint on growth  
427 patterns. However, we cannot exclude that the forecasted general warming (IPCC 2013) will  
428 increase Scots pine sensitivity to May precipitation, as we observed more severe growth  
429 reductions at lower elevations. The species is certainly adapted to water stress, and able to  
430 recover even after seven years of precipitation shortage. Nevertheless, in the most stressful  
431 condition (dense stands at low elevation), prolonged reductions of growth and high crown  
432 transparency aggravated by mistletoe infestation can compromise tree functioning and increase  
433 mortality risk (Bigler et al. 2006; Rigling et al. 2010; Hereş et al. 2012). Thinning to reduce

434 competition for water could moderate drought stress, and thus Scots pine decline (Rigling et al.  
435 2013; Fernández-de-Uña et al. 2015). Otherwise, similarly to what forecasted for other Alpine  
436 valleys, we can expect pine to be replaced by more drought tolerant species such as downy oak  
437 (Weber et al. 2007; Vacchiano and Motta 2015). However, uncertainty in future precipitation  
438 regime in the Alpine area (IPCC 2013) complicates predictions of species performance in the  
439 next decades.

440 Our individual-level analysis showed that trees more sensitive to inter-annual precipitation  
441 variations had lower growth rates than other trees during repeated precipitation shortages, but  
442 were not able to recover faster, i.e., they were less able to cope with adverse climate conditions.  
443 However, we did not identify a unique tree characteristic influencing tree response to climate.  
444 Extensive literature suggests that individual size/age/competition effect on response to climate is  
445 related to specific site, stand, and climate conditions. More detailed analyses on Scots pine tree  
446 genetics, and on physiological adjustment to stress, could shed light on why trees within a stand  
447 respond differently to climate stress. Future variations in spring precipitation regime in the Alps,  
448 which is less predictable compared to temperature (IPCC 2013), could threaten Scots pine in  
449 inner-Alpine valleys at intermediate elevation around 1000-1400 m a.s.l. in inner Alpine valleys.  
450 Still, different individual sensitivity to precipitation will probably result in patchy patterns, with  
451 healthy trees close to individuals with declining growth rates, and defoliated crowns infested by  
452 mistletoe.

718 **FIGURE CAPTIONS**

719 **Fig. 1** Location of the four study sites, Challand-Saint-Anselme (Chal), Saint Denis low (SD1)  
720 and high (SD2) elevation, Morgex (Morg), and the Region's capital city (Aosta), within the  
721 Aosta Valley Region, Northwestern Italy. Green indicates forested area

722 **Fig. 2** Bootstrap correlation coefficients between the four stand chronologies and April to August  
723 climate variables. TEMP = temperature, PRCP = precipitation, P/PET = ratio between  
724 precipitation and potential evapotranspiration, sc-PDSI = self-calibrating Palmer Drought  
725 Severity Index, SPEI = Standardized Precipitation Evapotranspiration Index. Dark bars indicate  
726 correlation coefficients significant at  $p < 0.05$

727 **Fig. 3** Mean Basal Area Increment (BAI) in the four study sites during 1965-2005

728 **Fig. 3-4** Percentage of trees with annual BAI below the 1965-2005 average (all plots). Years with  
729 more than 2/3 of trees with BAI lower than average are indicated with red bars

730 **Fig. 4-5** May climate anomalies in 1987-1993, 1994-1998, and 2003-2005 relative to the  
731 reference period 1965-2005 (equal to 1). TEMP = temperature, PRCP = precipitation, P/PET =  
732 ratio between precipitation and potential evapotranspiration, sc-PDSI = self-calibrating Palmer  
733 Drought Severity Index, SPEI = Standardized Precipitation Evapotranspiration Index

734 **Fig. 5-6** Median growth (BAI) decline in 1987-1993, 2003-2005, and recovery in 1994-1998.  
735 Different letters indicate different growth response between stands in the same period, according  
736 to Kruskal-Wallis median test with Mann-Whitney pairwise comparisons

737 **Fig. 6-7** Relationship between individual tree growth decline in 1987-1993 (a) and 2003-2005  
738 (b), and response to May precipitation in the previous period in the four stands

739 **Fig. 7-8** Percentage crown transparency in the four study stands during 2005

740

741 **SUPPLEMENTARY FIGURE CAPTIONS**

742 **Fig. 1** Bootstrap correlation coefficients between the four stand chronologies and **temperature**  
743 **precipitation**-climate variables from May of the previous year to September of the ring formation  
744 year. Dark bars indicate correlation coefficients significant at  $p < 0.05$

745 **Fig. 2** April, June, July and August climate anomalies in 1987-1993, 1994-1998, and 2003-2005  
746 relative to the reference period 1965-2005 (equal to 1). TEMP = temperature, PRCP =  
747 precipitation, P/PET = ratio between precipitation and potential evapotranspiration, PDSI = self-  
748 calibrating Palmer Drought Severity Index, SPEI = Standardized Precipitation Evapotranspiration  
749 Index

761 **Table 1** Site and stand characteristics, and tree-ring statistics, for the four stands. For site  
 762 characteristics, Elevation is the mean plot elevation, Slope is the mean percent slope, and Aspect  
 763 is the main exposition. For stand characteristics, all referred to one hectare. Trees pine is the  
 764 number of Scots pine trees, Trees total is the total tree number (i.e., including all the species), BA  
 765 pine is Basal Area of Scots pine, BA total is the total Basal Area, QMD pine is the quadratic  
 766 mean diameter of Scots pine, Height pine is the mean height of all measured Scots pine trees,  
 767 Age pine is the mean number of years at breast height, estimated to the pith, of the cored Scots  
 768 pine trees. For tree-ring series, it is reported the number of successfully cross-dated cores, the  
 769 mean sensitivity (MS), the autocorrelation (AC), and the mean correlation between trees (Rbar)  
 770
