ISBN: 978-989-95079-6-8

come equipped with observational mechanisms that permit identifying (through behavioural equivalences) those systems that cannot be taken apart by external observations. In some cases, process algebras have also complete axiomatizations, that capture the relevant identifications.

There has been a huge amount of research work on process algebras carried out during the last 25 years that started with the introduction of CCS [7], CSP [8] and ACP [9].

The main ingredients of a specific process algebra are:

- a minimal set of well thought operators capturing the relevant aspect of systems behaviour and the way systems are composed;
- a transition system associated with the algebra via structural *operational semantics* to describe the evolution of all systems that can be built from the operators;
- an equivalence notion that permits abstracting from irrelevant details of systems descriptions.

Verification of concurrent systems within the process algebraic approach is performed either by resorting to behavioural equivalences or by checking that processes enjoy properties described by some temporal logic's formulae. Equivalences are used for proving conformance of a process to specifications, expressed within the same process algebra notation. Verification with logical formulae is implemented by "model checking", an automatic method to prove properties verification.

In the former case two descriptions of a given system, one very detailed and close to the actual concurrent implementation, the other more abstract describing the abstract tree of relevant actions the system has to perform, are provided and tested for equivalence.

In the latter case, concurrent systems are specified as terms of a process description language while properties are specified as temporal logic formulae. Labelled Transition Systems are associated with terms via a set of structural operational semantics rules and model checking is used to determine whether the transition system associated with those terms enjoys the property specified by the given formulae.

Process algebras and modal logics have been largely used as tools for specifying and verifying properties of concurrent systems. This, also thanks to model checking algorithms, permits verifying whether a given specification satisfies the expected properties.

3 L-Fuzzy Sets

Human perception of real world abounds with concepts without strictly defined constraints (*fat*, *very*, *more*, *slowly*, *old*, etc...). Such concepts can be described by means of Fuzzy Sets: classes of objects in which transit from membership to not membership gradually takes place. A fuzzy set is a simple and intuitive generalization of the classical *crisp*[1] one.

Fuzzy sets are denoted by means of a generalised *membership function* that gives the *membership degree* of each element of the *universe*. This degree usually takes values in $[0, 1]$, the interval of real numbers from 0 to 1 inclusive. Although above range is the one most commonly used for representing membership degrees, any arbitrary set with some natural full or partial ordering can be used. Elements of this set are not required to be numbers as long as the ordering among them can be interpreted as representing various strengths of membership degree [10].

Let U be a universal set and L be a *complete lattice*, a *L-Fuzzy Set* [2, 11] A is denoted by a membership function $\mu_A : U \to L$.

Standard operations on sets and lattices L, like complement, intersection and union, can be generalised to L-Fuzzy Sets. These operations rely on the use of three function $c(\cdot)$, $i(\cdot,\cdot)$ and $u(\cdot,\cdot)$ that, respectively, give the measure of complement, intersection and union of fuzzy degrees.

The complement of a L-Fuzzy Set A, denoted by $\overline{A}$, is specified by a function $c : L \to L$ which assigns a value $\mu_{\overline{A}}(x) = c(\mu_A(x))$ to each membership degree $\mu_A(x)$. This assigned value is interpreted as the membership degree of the element x in the L-Fuzzy Set representing the negation of the concept represented by A.

Intersection and union of two L-Fuzzy Sets A and B are defined using functions $i : L \times L \to L$ and $u : L \times L \to L$. For each element a in the universal set U, these functions take as argument the pair consisting of the membership degrees of a in A and in B, respectively. Function i, also named *t-norm*, yields the membership degree of a in $A \cap B$, while u, also named *t-conorm*, returns the membership degree of a in $A \cup B$. Thus, $\mu_{A\cap B}(a) = i(\mu_A(a), \mu_B(a))$ while $\mu_{A\cup B}(a) = u(\mu_A(a), \mu_B(a))$.

Function c, i and u operating on L-Fuzzy Sets must be *continuous* on L and satisfy all axioms in Table 1, where 0 and 1 denote respectively the least and the greatest element in L while $\leq$ denotes the partial ordering on L. In the rest of this paper we will use $\mathcal{L}$ to denote a tuple $\langle L, c, i, u\rangle$ containing a complete lattice L together with its complement, intersection and union functions used for defining a family of L-Fuzzy Sets.

Table 1: Axioms of fuzzy operations

Axioms for $c(\cdot)$

$$c(1) = 0 \qquad c(0) = 1 \qquad \frac{x \leq y}{c(y) \leq c(x)} \qquad c(c(x)) = x$$

Axioms for $i(\cdot,\cdot)$

$$i(1,1) = 1 \qquad i(0,x) = 0 \qquad i(1,x) = x \qquad i(x,y) = i(y,x)$$

$$\frac{x_1 \leq x_2 \quad y_1 \leq y_2}{i(x_1,y_1) \leq i(x_2,y_2)} \qquad i(i(x,y),z) = i(x,i(y,z))$$

Axioms for $u(\cdot,\cdot)$

$$u(0,0) = 0 \qquad u(0,x) = x \qquad u(1,x) = 1 \qquad u(x,y) = u(y,x)$$

$$\frac{x_1 \leq x_2 \quad y_1 \leq y_2}{u(x_1,y_1) \leq u(x_2,y_2)} \qquad u(u(x,y),z) = u(x,u(y,z))$$

Fuzzy set theory was initially formulated by considering the

[1] Crisp set is defined to split individuals belonging to a certain universe into two groups: members (who surely belong to the set) and not members (who surely do not belong).

ISBN: 978-989-95079-6-8

complete lattice $[0,1]$, denoting the interval of real numbers from 0 to 1 (inclusive), and the following complement, intersection and union functions:

$$c(x) = 1 - x \quad i(x,y) = \min[x,y] \quad u(x,y) = \max[x,y]$$

It is easy to prove that these functions are continuous on $[0,1]$ and satisfy the axioms of Table 1.

4 A Fuzzy Process Algebra

Fuzzy systems are used for handling behaviours that depend on data without precise values that are described by means of variables taking values between 0 and 1. Variables, like temperature or speed, are represented by means of fuzzy sets each of which identifies a different range of values (e.g. *cold*, *warm*, *hot*,...).

As an example, we can consider a *Temperature Control System* (TCS). This is composed of an air conditioner (AC) system and a temperature sensor installed in the room. The TCS regulates the AC power, according to the values read from the sensor, to guarantee a suitable room temperature.

Following the fuzzy approach, room temperature can be modeled by considering different states identifying different range of values. For instance, *cold*, *warm* and *hot* like in figure 1.

Behaviour of TCS is described by a set of rules like: *if the temperature is warm then slightly increase the AC power*, *if the temperature is hot then increase the AC power*.

These systems are classically represented by means of Fuzzy Inference Systems (FIS).

In this section we present a fuzzy variant of CCS (*Calculus of Communicating Processes* [12]), named *Fuzzy CCS* (FCCS). In the new calculus the standard CCS actions are enriched with a fuzzy value modeling the enabling-degree. We aim at defining a formal language that permits compositionally describing fuzzy systems and that can be used for supporting fuzzy reasoning. This, also thanks to the use of standard formal tools like modal logics.

Like other process algebrae, FCCS provides a set of operators that permit describing the complete system starting from the specification of its subcomponents. Following the CCS approach, components interact with each other by means of *actions*, atomic and not interruptible steps, which represent input/output operations on communication ports or internal computations of the system. Let Λ be an infinite numerable set of labels or ports, not containing τ. A FCCS action can be: $a \in \Lambda$, the action to receive a signal on port a; $\bar{a}$ with $a \in \Lambda$, the action to deliver a signal on port a; τ, an internal computation step. We assume $\bar{\bar{\alpha}} \triangleq \alpha$, where $\alpha \in \Lambda \cup \{\bar{a} \mid a \in \Lambda\} \cup \{\tau\}$. Actions $\bar{\alpha}$ and α are said complementary, they represent input and output actions on the same channel.

The fundamental difference from CCS is the introduction of an attribute "x_i", that we define *action execution degree*. It is a fuzzy value able to represent, on a quality level, action behaviour. By this way CCS actions become fuzzy and therefore more representative of real world.

We define FCCS sintax by means of the following grammar:

$$\begin{aligned} Q &::= nil \mid X \mid \sum_{i \in I} (act_i,\, x_i).Q_i \\ P &::= Q \mid P_1 \mid P_2 \mid P\backslash A \mid P\,[f] \\ act &::= \bar{a} \mid a \mid \tau \end{aligned}$$

Now a brief description of operators:

- nil is the *inactive* process.
- X is the *process constant*, if $X \triangleq P$ then X denotes the invocation of process P. It is useful in defining recursive processes.
- $\sum_{i \in I}(act_i,\, x_i).Q_i$ is the *choice or sum* operator and denotes a choice among i possible behaviours that evolve with action act_i and degree x_i.
- $P_1 \mid P_2$ is the *parallel composition* operator and represents the concurrent execution of processes P_1 e P_2. If during the composition two complementary actions match, the resulting composed action is the internal one τ.
- $P\backslash A$ is the *restriction* operator. $A \in \Lambda$ and $P\backslash A$ behaves like P exception made for the impossibility to interact using actions in A.
- $P\,[f]$ is the *relabelling* operator. $f : \Lambda \to \Lambda$ allows relabelling process actions, to ease the description of complex processes.

4.1 Fuzzy Operational Semantics

Operational semantics of FCCS processes is defined in term of Fuzzy Labelled Transition Systems [6]. These generalize Labelled Transition Systems by defining the transition relation in term of a L-Fuzzy Set. This approach permits modeling situations like: "the transition takes place *rarely*" or "the transition occurs *frequently*" which may be distinguished and treated as a consequence.

Definition 4.1 ($\mathcal{L}$-FLTS) *Let $\mathcal{L} = \langle L, c, i, u\rangle$, a Fuzzy Labelled Transition System $\mathcal{F}$ for $\mathcal{L}$ ($\mathcal{L}$-FLTS) is a tuple $\langle Q, A, \chi_{\to}\rangle$ where:*

- *Q is a set whose elements are called states*
- *A is a finite set whose elements represent actions*
- *$\chi_{\to} : (Q \times A \times Q) \to L$ is the total membership function.*

We will write $q_0 \xrightarrow{\alpha}_{\varepsilon} q_1$ to denote that a transition from state q_0 to state q_1 by action α has a membership degree ε to the automaton.

In FLTS next states are selected nondeterministically. The membership degree associated to each transition is used to give a measure to computations. This measure is not *exact* as the probability one induced by PLTS [13], but can be used as the base for *approximate* reasoning in the spirit of Fuzzy Logic. The membership degree associated to a transition can be thought of as a value describing how much this transition is *enabled* in the FLTS.

Semantics for FCCS processes is defined by considering function $\mathcal{N}$ associating to each process P and transition α the fuzzy set $\mathcal{P}$ of processes reachable from P with α; we identify $\mathcal{P}$ with the set

$$\{Q : \varepsilon \mid Q \text{ is reachable from } P \text{ with action } \alpha \text{ and degree } \varepsilon\}$$

ISBN: 978-989-95079-6-8

Function $\mathcal{N}$ is formally defined in Table 2 where we use $\mathcal{P}|Q$ (resp. $Q|\mathcal{P}$) denotes the fuzzy set obtained by composing each element of $\mathcal{P}$ in parallel with Q. Similarly, $\mathcal{P}|\mathcal{Q}$ is the fuzzy set containing the parallel composition of each P in $\mathcal{P}$ with each Q in $\mathcal{Q}$, where the membership degree of $P|Q$ in $\mathcal{P}|\mathcal{Q}$ is defined as $i\left(\mu_{\mathcal{P}}(P), \mu_{\mathcal{Q}}(Q)\right)$.

Table 2: $\mathcal{N}$ext Function

$$\mathcal{N}\left(\langle\alpha,\varepsilon\rangle.P,\beta\right) = \begin{cases} \{P:\varepsilon\} & if\ \alpha=\beta \\ \emptyset & else \end{cases}$$

$$\mathcal{N}\left(P+Q,\alpha\right) = \mathcal{N}\left(P,\alpha\right) \cup \mathcal{N}\left(Q,\alpha\right)$$

$$\mathcal{N}\left(P\backslash L,\alpha\right) = \begin{cases} \mathcal{N}\left(P,\alpha\right)\backslash L & if \alpha \notin L \\ \emptyset & else \end{cases}$$

$$\mathcal{N}\left(P\left[f\right],\alpha\right) = \bigcup_{\beta:f(\beta)=\alpha} \mathcal{N}\left(P,\beta\right)\left[f\right]$$

$$\mathcal{N}\left(P|Q,\alpha\right) = \begin{cases} \left[\mathcal{N}\left(P,\alpha\right)|Q\right] \cup \left[P|\mathcal{N}\left(Q,\alpha\right)\right] & if \alpha \neq \tau \\ \left[\mathcal{N}\left(P,\tau\right)|Q\right] \cup \left[P|\mathcal{N}\left(Q,\tau\right)\right] \cup \left[\bigcup_{\alpha\in\Lambda}\left(\mathcal{N}\left(P,\alpha\right)|\mathcal{N}\left(Q,\bar{\alpha}\right)\right)\right] \cup \left[\bigcup_{\alpha\in\Lambda}\left(\mathcal{N}\left(P,\bar{\alpha}\right)|\mathcal{N}\left(Q,\alpha\right)\right)\right] & if \alpha = \tau \end{cases}$$

$$\mathcal{N}\left(A,\alpha\right) = \mathcal{N}\left(P,\alpha\right) \qquad if\ A \triangleq P$$

We say that P can evolve to Q (written $P \succ Q$) if and only if there exists an action α such that if $\mathcal{P} = \mathcal{N}(P,\alpha)$, $\mathcal{P}(Q) \neq 0$. We use $\succ^*$ to denote the reflexive and transitive closure of $\succ$.

Let P be a FCCS process, we denote with $FLTS(P) = \langle S, \Lambda, \chi_{\rightarrow}\rangle$ the FLTS such that:

- $S = \{Q \mid P \succ^* Q\}$;
- $\chi_{\rightarrow}(P,\alpha,Q) = \mathcal{P}(Q)$, where $\mathcal{P} = \mathcal{N}(P,\alpha)$.

Standard behavioural equivalences, like for instance bisimulation, can be easily generalized in order to take into account fuzziness. This kind of equivalences are useful when one aims at comparing different specifications. Definition of Fuzzy Bisimulation is straightforward and it is somehow reminiscent of Stochastic Bisimulation [14].

Definition 4.2 (Fuzzy Bisimulation) *Let $\langle S, A, \chi_{\rightarrow}\rangle$ a Fuzzy LTS. An equivalence relation $R \subseteq S \times S$ is a* fuzzy bisimulation *if and only if for each p and q in S, for each equivalent class C of R in S, and for each transition label α:*

$$\chi_{\rightarrow}(p,\alpha,C) = \chi_{\rightarrow}(q,\alpha,C)$$

where:

$$\chi_{\rightarrow}(p,\alpha,C) = \bigvee_{p'\in C} \chi_{\rightarrow}(p,\alpha,p')$$

Definition 4.3 (Fuzzy Bisimilarity) *Let $\langle S, A, \chi_{\rightarrow}\rangle$ be a Fuzzy LTS. We say that $p, q \in Q$ are bisimilar ($p \sim_F q$), if there exists a fuzzy bisimulation R such that pRq.*

Relation $\sim_F$ is a *fuzzy bisimilarity* and can be defined as the largest fuzzy bisimulation, namely:

$$\sim_F \triangleq \bigcup \{R \mid R \quad \text{is a fuzzy bisimulation}\}$$

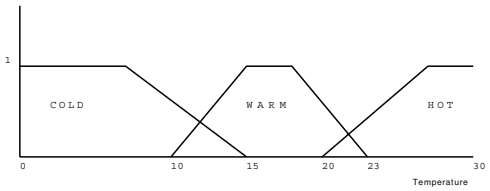

Figure 1: Temperature Fuzzy sets: COLD, NORMAL, HOT

Modeling Fuzzy Systems with FCCS We can now use FCCS for modeling the TCS described in section 4, where we consider three fuzzy sets for describing possible values of the room temperature. These sets are represented in Figure 1. Systems TCS is modeled in FCCS by splitting it into four subcomponents representing behaviours of the system. They "mime" TCS by interacting among each of them. Interactions are the result of synchronization between an input and an output action with the same name. The fuzzy value of the resulting action is calculated following semantics in Tab. 2. Process SYS_{st} is defined as follows:

$$SYS_{st} \triangleq (SENS_{st}|H|N|C)\backslash\{hot, warm, cold, inc, dec, noop\}$$

where st is the starting temperature while process $SENS_t$, which models the behaviour of temperature sensor, is defined as follows:

$$\begin{aligned} SENS_t \triangleq\ & \left\langle \overline{hot}, \mu_{hot}(t)\right\rangle.AC_t \\ & + \left\langle \overline{warm}, \mu_{warm}(t)\right\rangle.AC_t \\ & + \left\langle \overline{cold}, \mu_{cold}(t)\right\rangle.AC_t \\ & + \left\langle temp_t, 1\right\rangle.SENS_t \end{aligned}$$

$$\begin{aligned} AC_t \triangleq\ & \left\langle inc, 1\right\rangle.SENS_{t+1} \\ & + \left\langle dec, 1\right\rangle.SENS_{t-1} \\ & + \left\langle noop, 1\right\rangle.SENS_t \end{aligned}$$

Notice that in the processes above, non-determism is used for modeling the unpredictable changes in room temperature.

Controller behaviour is rendered by means of processes H, N and C that modify the AC power. These processes are defined as follows:

$$\begin{aligned} H &\triangleq \left\langle hot, 1\right\rangle.\left\langle \overline{inc}, 1\right\rangle.H \\ N &\triangleq \left\langle warm, 1\right\rangle.\left\langle \overline{noop}, 1\right\rangle.N \\ C &\triangleq \left\langle cold, 1\right\rangle.\left\langle \overline{dec}, 1\right\rangle.C \end{aligned}$$

For this system one could be interested on verifying that for each fixed starting temperature, the system always is able to reach a state where the room temperature is in a given range. In the next section, we will introduce a modal logic that will permit specifying and verifying properties of fuzzy systems.

An alternative description of this system could be obtained by considering process SYS^2_{st} defined as follows:

$$SYS^2_{st} \triangleq (SENS_{st}|CONT)\backslash\{hot, warm, cold\ inc, dec, noop\}$$

ISBN: 978-989-95079-6-8

where, differently from the previous implementation, the controller is obtained as a single process $CONT$ that nondeterministically can behave like H, N and C defined above:

$$CONT \triangleq (H + N + C).CONT$$

It easy to prove that SYS_{st} and SYS^2_{st} provide the same behaviour. Namely, that $SYS_{st} \sim_F SYS^2_{st}$.

5 Fuzzy Hennessy-Milner Logic

Fuzzy Hennessy-Milner Logic (FHML) [6] is an extension of HML, which aims at specifying properties of concurrent systems whose behavior is detailed by means of FLTS. Let $\mathcal{L} = \langle L, c, i, u\rangle$, $\Phi_{\mathcal{L}}$ be the set of formulas φ defined by the following syntax:

$$\varphi ::= tt \mid \neg\varphi \mid \varphi \bowtie \varepsilon \mid \varphi_1 \wedge \varphi_2 \mid \langle\alpha\rangle\varphi \mid X \mid \nu X.\varphi$$

where $\varepsilon \in L$.

Table 3: Formulae semantics

$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![tt]\!]\delta(p) = 1$$
$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\neg\varphi]\!]\delta(p) = \mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(p)$$
$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi_1 \wedge \varphi_2]\!]\delta(p) = i\left(\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi_1]\!]\delta(p), \mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi_2]\!]\delta(p)\right)$$
$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi \bowtie \varepsilon]\!]\delta(p) = \begin{cases} 1 & if\ \mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(p) \bowtie \varepsilon \\ 0 & else \end{cases}$$
$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\langle\alpha\rangle\varphi]\!]\delta(p) = u_{q\in Q}\left(i\left(\chi_{\rightarrow}(p,\alpha,q), \mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(q)\right)\right)$$
$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![X]\!]\delta = \delta(X)$$
$$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\nu X.\varphi]\!]\delta = \cup\left\{\chi \mid \chi \leq \mathfrak{F}^{\delta,\varphi}_X(\chi)\right\}$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![tt]\!]\delta(p) = 0$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\neg\varphi]\!]\delta(p) = \mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(p)$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi_1 \wedge \varphi_2]\!]\delta(p) = u\left(\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi_1]\!]\delta(p), \mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi_2]\!]\delta(p)\right)$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi \bowtie \varepsilon]\!]\delta(p) = \begin{cases} 1 & if\ \mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(p) \not\bowtie \varepsilon \\ 0 & else \end{cases}$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\langle\alpha\rangle\varphi]\!]\delta(p) = $$
$$= i_{q\in Q}\left(u\left(i\left(\chi_{\rightarrow}(p,\alpha,q), \mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(q)\right), c\left(\chi_{\rightarrow}(p,\alpha,q)\right)\right)\right)$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![X]\!]\delta = \delta(X)$$
$$\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\nu X.\varphi]\!]\delta = \cap\left\{\chi \mid \chi \geq^{\frown} \mathfrak{F}^{\delta,\varphi}_X(\chi)\right\}$$

where

$$\mathfrak{F}^{\delta,\varphi}_X = \mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta[\chi/X] \qquad {}^{\frown}\mathfrak{F}^{\delta,\varphi}_X = \mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta[\chi/X]$$

Operators are usual logical tt (true), $\neg$ (not), $\wedge$ (and). Moreover $\nu X.\varphi$ is Tarski's fixed point and $\langle\alpha\rangle\varphi$ the modal operator representing the property of evolving with action α to a state that behaves like φ. FHML extends HML by considering new operator $\varphi \bowtie \varepsilon$ ($\bowtie \in \{<, >\}$) that states about the satisfaction degree of a given formula in a given state. Such operator makes possible to describe the satisfaction degree of a formula in terms of an upper or a lower bound[2].

[2]This is somehow reminiscent of operator $[\varphi]_p$ proposed by Parma and Segala [15]

Other operators can be defined as macros in FHML. In the rest of this paper we let: $ff = \neg tt$, $\varphi_1 \vee \varphi_2 = \neg(\neg\varphi_1 \wedge \neg\varphi_2)$, $[\alpha]\varphi = \neg\langle\alpha\rangle\neg\varphi$ and $\mu X.\varphi = \neg\nu X\neg\varphi[\neg X/X]$.

Semantics of FHML is defined in term of functions $\mathcal{M}_{\mathcal{L},\mathcal{F}}$ and $\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}$ that for each formula φ yield the L-Fuzzy Set that gives the measure, respectively, of satisfaction and unsatisfaction of φ. This approach permits defining semantics of FHML in a general way without considering any special constraint on the underlying L-Fuzzy Sets. Indeed, in general, standard properties of sets do not hold in the case of L-Fuzzy Sets. For instance, the intersection between a L-fuzzy set and its complement could be not empty. Notice that, in general, $\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\neg\varphi]\!] \neq c\left(\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\right)$.

To give a semantics to recursive formulae, interpretation functions $\mathcal{M}_{\mathcal{L},\mathcal{F}}$ and $\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}$ take also, as a parameter, a function $\delta : Q \rightarrow L$, that associates to each logical variable X a L-fuzzy set.

We assume the usual definitions on positive and negative variables in [6] for guaranteeing well-definedness of interpretation formulae.

Definition 5.1 (Well formed formula) *A formula is well formed if in each subformula of the form $\nu X.\varphi$, variable X occurs positive in φ.*

Interpretation functions are parameterized with respect to $\mathcal{L}$, used for defining the underlying L-Fuzzy Set and the relative operations, and with respect to the $\mathcal{L}$-FLTS $\mathcal{F}$ used for interpreting formulae. Note that, interpretation of FHML coincides with the standard interpretation of HML when considering standard Boolean lattices.

Definition 5.2 (Formulae Semantics) *Let $\mathcal{L} = \langle L, c, i, u\rangle$ and $\mathcal{F}_{\mathcal{L}} = \langle Q, A, \chi_{\rightarrow}\rangle$. Functions $\mathcal{M}_{\mathcal{L},\mathcal{F}} : \Phi_{\mathcal{L}} \rightarrow Q \rightarrow L$ and $\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}} : \Phi_{\mathcal{L}} \rightarrow Q \rightarrow L$ are inductively defined in Table 3.*

$\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!]\delta(q)$ denotes the satisfaction degree of formula φ by q. Formulae tt and ff are satisfied by every state with degree 1 and 0 respectively. A state p satisfies $\neg\varphi$ with degree ε if and only if p *does not satisfy* φ with degree ε. Fuzzy set $\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi_1 \wedge \varphi_2]\!]$ is defined as the intersection between $\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi_1]\!]$ and $\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi_2]\!]$. If a state p satisfies φ with a degree that is $<$ (resp. $>$) of ε then p satisfies $\varphi < \varepsilon$ (resp. $\varphi > \varepsilon$) with degree 1 (resp. 0). $\mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\langle\alpha\rangle\varphi]\!]\delta(p)$, which gives a measure of how p can reach with a transition labelled α a state satisfying φ, is defined as the disjunction, for each q, of $i(\chi_{\rightarrow}(p,\alpha,q), \mathcal{M}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!](q))$. Where $\chi_{\rightarrow}(p,\alpha,q)$ returns the membership degree of the transition from p to q with label α to the behaviour of the system. Finally, interpretation of $\nu X.\varphi$ is defined as greates fixed point of the interpretation of φ ($\mathfrak{F}^{\delta,\varphi}_X$), which is monotone in the complete lattice of Q L-Fuzzy Sets. This, thanks to the Tarski's fixed point theorem [16], guarantees the well-definedness of functions $\mathcal{M}_{\mathcal{L},\mathcal{F}}$ and $\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}$.

The definition of function $\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}$ is similar and straightforward. However, more attention has to be paid for $\mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\langle\alpha\rangle\varphi]\!]$. Each state q, contributes to the unsatisfaction of $\langle\alpha\rangle\varphi$ by p as a factor that depends on the degree of the transition α from p to q and on the unsatisfaction degree of formula φ by q. This value is obtained as a disjunction of: $c\left(\chi_{\rightarrow}(p,\alpha,q)\right)$ and $i\left(\chi_{\rightarrow}(p,\alpha,q), \mathcal{M}^{\frown}_{\mathcal{L},\mathcal{F}}[\![\varphi]\!](q)\right)$. The former indicates how much the transition from p to q with label

ISBN: 978-989-95079-6-8

α *does not belong* to the behaviour of the system. The latter, gives the measure of the unsatisfaction of φ when the action is executed.

Example 5.1 *FHML can be used for specifying that system process SYS_{st} can always reach a configuration where the room temperature is between* 18 *and* 20 *degrees. The following formula states that a configuration where temperature is between* 18 *and* 20 *degrees is eventually reached:*

$$\varphi = \mu X.\langle\overline{temp}_{18}\rangle tt \vee \langle\overline{temp}_{19}\rangle tt \vee \langle\overline{temp}_{20}\rangle tt \vee \langle\tau\rangle X$$

While formula:

$$\nu Y.\varphi \wedge [\tau]Y$$

states that φ is always satisfied.

Logical characterization of Fuzzy Bisimulation Formulae satisfaction induces an equivalence on the interpretation model and two states in a Fuzzy LTS are equivalent if (and only if) they satisfy the same set of formulae. A classical result relating modal logic and behavioural equivalence is the one in [12] showing that the equivalence induced by HML coincides with the bisimulation equivalence. A similar result can be proved when one considers FHML and Fuzzy Bisimulation. However, to prove this correspondence, one has to guarantee that the considered Fuzzy LTS is *finite-branching*.

Definition 5.3 (Finite-branching) *A Fuzzy LTS $\mathcal{F} = \langle S, A, \chi_{\rightarrow}\rangle$ is finite-branching if and only if $\forall p \in S$, $\forall \alpha \in A$ and $\forall \varepsilon \in \chi_{\rightarrow}$, the set $\left\{q' \in Q | q \xrightarrow{\alpha}_{\varepsilon} q'\right\}$ is finite.*

Theorem 1 *Let $\mathcal{F} = \langle S, A, \chi_{\rightarrow}\rangle$ be finite-branching. For each $p, q \in S$,*

$$p \sim_F q \quad \Leftrightarrow \quad \forall \varphi.\, \mathcal{M}[\![\varphi]\!](p) = \varepsilon \Leftrightarrow \mathcal{M}[\![\varphi]\!](q) = \varepsilon \text{ and } \mathcal{M}^{\smile}[\![\varphi]\!](p) = \varepsilon \Leftrightarrow \mathcal{M}^{\smile}[\![\varphi]\!](p) = \varepsilon$$

Due to lack of space, the proof is not reported.

6 Conclusions and Future Works

In this paper we have presented FCCS, a Fuzzy variant of CCS (*Calculus of Communicating Processes*), that aims at compositionally describing fuzzy behaviours. Operational semantics of FCCS has been defined by means of *Fuzzy Labelled Transition Systems* [6] (FLTS). These are an extension of Labelled Transition Systems where fuzziness is used for modeling uncertainty in concurrent systems. In the paper we have also shown how standard process algebras formal tools, like modal logics and behavioural equivalences, can be used for supporting fuzzy reasoning.

The idea to combine process algebrae and fuzzy sets is not new. For instance, in [17] is introduced a model based on interval values, to solve the problem of nondeterministic choices arising in concurrency and communication systems. However, differently from previous approaches, the present work introduces both a behavioural equivalence and a modal logic for reasoning about fuzzy specifications.

As a future work we plan to use the proposed approach for modeling the examples proposed in literature [18, 19, 20] where Fuzzy Theory is used for modeling the behaviour of "systems", like for instance those involving human interactions, where imprecision is a central feature.

Abstract— *In this paper, line search based on Sequential Quadratic Programming is implemented in order to find a solution to Fuzzy Relation Equations. Sequential Quadratic Programming is a gradient-based method that uses a quadratic estimation of the objective function in each iteration's neighborhood. Unlike analytical approaches, the method can handle equations with any combinations of t-norms and t-conorms and at any dimensions. It is assumed that the FRE problem has at least one solution.*

Keywords— Fuzzy Relation Equation (FRE), Fuzzy Triangular Norms, Line Search, Numerical Solution, Sequential Quadratic Programming (SQP).

1 Introduction

Fuzzy Relation Equations were first introduced by Sanchez [1] in 1976. Most of the works done on fuzzy relation equations are focused on specific non-parametric t-norms (min and product) and t-conorms (max and probabilistic sum). Markovskii [2], Shieh [3-5], Molai and Khorram [6], Hana et al. [7], and Perfilieva and Nosková [8] have presented some algorithms for FREs with such compositions. In special cases, an exact solution can be obtained through direct analytical methods. However, for parametric operators like *Schweizer-Sklar*, *Frank*, *Yager*, *Sugeno-Weber*, *Dombi*, and *Dubois-Prade* there is no direct solution available. This is mostly because of the complex non-linear nature of these operators.

An FRE can be formed as:

$$P \circ Q = R \tag{1}$$

where $\circ$ denotes the S-T composition. The problem involves finding P from Q and R.

Stamou and Tzafestas [9] developed a criterion for the existence of minimal solutions, and interpreted a *Fuzzy Inference System* (FIS) as an FRE, indicating that FREs are appropriate for FIS implementation. Shieh [3, 4] recently extended the discussion to a general condition using continuous t-norms. In such cases, when the solution set for (1) is not empty, it can be completely determined by a unique maximum solution and a finite number of minimal solutions.

However, the current models mostly discuss analytical approaches to solve the FRE problem in case-specific conditions—such as max-min or max-product compositions and sizes of $1\times m$ and $1\times n$ for binary fuzzy relations P and R.

In this paper, we propose a new numerical method based on *Sequential Quadratic Programming* (SQP) line search. The proposed model's advantages are solving FREs for any set of parametric operators and capability of handling sizes of $p\times m$ and $p\times n$ for P and R.

It should be noted that the fundamental assumption of this effort is that there exists at least one solution to the FRE problem.

The rest of this paper is organized as follows. In section 2, basic concepts of Fuzzy Relation Equations and Sequential Quadratic Programming are presented. Section 3 describes the method in detail. In section 4, some examples are provided for demonstration of the model's performance. Finally, section 5 gives the conclusions and suggests ideas for future research.

2 Basic Concepts

2.1 Parametric Fuzzy Operators

The most familiar fuzzy operators are max and algebraic sum (as t-conorms or s-norms) and min and product (as t-norms). But they are not limited to these special cases, and can be parametrically constructed.

The advantages of using parametric operators are:

- Most of the parametric operators have the capability to reduce to the aforementioned non-parametric operators, with specific values for the parameters. For example, the Frank t-norm reduces to min when $p = 0$.
- The parameters can be tuned according to the specific requirements of the system in question.

On the other hand, the disadvantage is that the increasing complexity leads to longer running times and more sensitivity to the tuning mechanism.

2.2 Fuzzy Relation Equations

An FRE is as presented in (1), in which $\circ$ acts as the S-T composition, meaning:

$$\bigvee_{j=1}^{m}\left[T\left(p_{ij}, q_{jk}\right)\right] = r_{ik} \tag{2}$$

where P, Q, and R are fuzzy binary relations and p, q, and r are their elements respectively [10]. The Yager series of t-norms and t-conorms are well-known fuzzy operators:

$$T_w(a,b) = 1 - \min\left\{1, \left((1-a)^w + (1-b)^w\right)^{1/w}\right\} \tag{3}$$

$$S_w(a,b) = \min\left\{1, \left(a^w + b^w\right)^{1/w}\right\} \tag{4}$$

ISBN: 978-989-95079-6-8

Equation (3) represents the t-norm and (4) is the t-conorm of Yager operators.

2.3 Sequential Quadratic Programming

SQP methods represent the state of the art in nonlinear programming methods. Schittkowski [11], for example, has implemented and tested a version that outperforms every other tested method in terms of efficiency, accuracy, and percentage of successful solutions, over a large number of test problems.

The method closely mimics Newton's method for constrained optimization just as is done for unconstrained optimization. At each major iteration, an approximation is made of the Hessian of the Lagrangian function using a quasi-Newton updating method. This is then used to generate a Quadratic Programming sub-problem whose solution is used to form a search direction for a line search procedure.

Consider the following general non-linear minimization problem (*P*):

$$Minimize\ f(x)$$

$$subject\ to \begin{cases} h_i(x) = 0; & i = 1,...,l \\ h_j(x) \le 0; & j = l+1,...,m \end{cases}$$

where $x \in R^n, f: R^n \to R, h: R^n \to R^m$.

At *k*th iteration, the SQP algorithm generates a search direction (*d*) solving the definite quadratic sub-problem (*Q*) below:

$$Minimize\ \nabla f_k^T d + \tfrac{1}{2} d^T B_k d$$

$$subject\ to \begin{cases} h_i(x_k) + \nabla h_i^T(x_k) d = 0; & i = 1,...,l \\ h_i(x_k) + \nabla h_i^T(x_k) d \le 0; & j = l+1,...,m \end{cases}$$

where B_k is a positive definite approximation to the Hessian matrix of the Lagrangian function of the original problem (*P*):

$$L(x,\mu) = f(x) + \sum_{i=1}^{m} \mu_i h_i(x) \tag{5}$$

At each major iteration a positive definite quasi-Newton approximation of the Hessian of the Lagrangian function, *L*, is calculated using Broyden–Fletcher–Goldfarb–Shanno (BFGS) method [12].

A detailed description of the SQP method for nonlinear optimization can be found in Fletcher [13], Gill et al. [14], Powell [15], Hock and Schittkowski [16], Nocedal and Wright [17], and Bartholomew-Biggs [18].

3 The Method

SQP, as any other line search method, requires an initial solution to start from. A fairly large random search of the solution space can provide us with this initial solution. Random solutions are generated as matrices of *p*×*m*—dimensions of *P* in (1)—with elements uniformly distributed between 0 and 1.

There are various line search methods for solving nonlinear problems, the most prominent of which are gradient descent, the Newton method, quasi-Newton methods, and Sequential Quadratic Programming. These four were thoroughly tested for our problem and SQP turned out to be the most superior in terms of running time and error measure. So SQP is the line search algorithm of choice for our method.

Since our goal is to minimize the final error, the objective function would rationally be *RMSE*, that is, the root-mean-square of the errors obtained by the difference between the actual *R* and the one calculated from the composition below.

$$R' = P' \circ Q \tag{6}$$

where *P′* is the solution in search of *P*. Thus, the objective function will be as follows.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{p}\sum_{k=1}^{n}(r_{ik} - r'_{ik})^2}{p \times n}} \tag{7}$$

Using (2), we arrive at this formula:

$$RMSE = \sqrt{\frac{\sum_{i=1}^{p}\sum_{k=1}^{n}\left\{\bigcirc\!\!\!\!\!\!\sum_{j=1}^{m}\left[T(p_{ij}, q_{jk})\right] - \bigcirc\!\!\!\!\!\!\sum_{j=1}^{m}\left[T(p'_{ij}, q_{jk})\right]\right\}^2}{p \times n}} \tag{8}$$

Constraints for *P′* elements are obviously the lower band of 0 and the upper band of 1.

This approach guarantees that regardless of the operators chosen, the difference between *R* and *R′* will be minimized. Moreover, continuity and differentiability are necessary conditions for the line search. Specifically, operators containing such terms as $\max\{c, f(a,b)\}$ render SQP unusable. In situations like this, the following substitutions will be used:

$$\max\{c, f(a,b)\} = \frac{c + f(a,b)}{2} + \frac{|c - f(a,b)|}{2} \tag{9}$$

$$\min\{c, f(a,b)\} = \frac{c + f(a,b)}{2} - \frac{|c - f(a,b)|}{2} \tag{10}$$

It's worth mentioning that unlike the "minimum" and "maximum" functions, the "absolute value" function is differentiable using symbolic math—across all its domain except where $u(x) = 0$.

$$\frac{d}{dx}|u(x)| = \frac{|u(x)|}{u(x)} u'_x(x) \tag{11}$$

4 Sample Results

The MATLAB 2008a environment was chosen to implement the proposed method, because of its efficiency in matrix operations and also the built-in functions and methods. The sample M code for Yager's operators can be found in the appendix.

For each run, *P* and *Q* are generated randomly and *R* is obtained through $P \circ Q$ with predetermined t-norm and t-conorm parameters to guarantee the existence of at least one solution for *P*. This initial value of *P* is then discarded so as not to interfere with the search process.

P, *Q*, and *R* are all 5×5 in the samples, since dimensions do not cause any significant change in the method's behavior. The initial random search produces 2000 solutions and chooses the one with the least *RMSE* for the SQP initialization. The stopping criterion for SQP is the number of *RMSE* evaluations, which was determined to be 1500.

ISBN: 978-989-95079-6-8

Operators of the same type (e.g. Dombi) were chosen in each run. Sample results are summarized in Table 1 for the following triangular norms and conorms:

- Frank
- Dombi
- Schweizer & Sklar 1
- Schweizer & Sklar 2
- Schweizer & Sklar 3
- Schweizer & Sklar 4
- Yager

More information on parametric fuzzy operators can be found in [10].

The method was repeated 10 times for each operator, with the best, worst, and average results for *RMSE* reported in the Table 1. Also included is the average running time.

Table 1 shows the performance of the proposed method with various parametric operators. The results imply that the Frank operators provide the most suitable search space for this method.

Table 1: test results for various fuzzy operators

Fuzzy Operator	Worst RMSE	Best RMSE	Average RMSE	Average Running Time
Frank	0.0008	0.00005	0.000313	222.48
Dombi	0.064	0.0009	0.026438	88.11
Schweizer & Sklar 1	0.014	0.0003	0.003795	300.98
Schweizer & Sklar 2	0.064	0.0050	0.018533	188.55
Schweizer & Sklar 3	0.046	0.0006	0.016644	166.08
Schweizer & Sklar 4	0.036	0.0003	0.008164	363.53
Yager	0.072	0.0001	0.020254	1006.42

For the sake of clarity, a numerical example will be fully featured here .Given the following values for Q and R, we want to estimate P such that

$$P \circ Q = R$$

using the Frank norm.

$$Q = \begin{bmatrix} 0.3500 & 0.3500 & 0.2900 & 0.0800 & 0.1300 \\ 0.2000 & 0.8300 & 0.7600 & 0.0500 & 0.5700 \\ 0.2500 & 0.5900 & 0.7500 & 0.5300 & 0.4700 \\ 0.6200 & 0.5500 & 0.3800 & 0.7800 & 0.0100 \\ 0.4700 & 0.9200 & 0.5700 & 0.9300 & 0.3400 \end{bmatrix}$$

$$R = \begin{bmatrix} 0.8551 & 0.9785 & 0.9356 & 0.9769 & 0.6889 \\ 0.6664 & 0.9419 & 0.8942 & 0.6672 & 0.6712 \\ 0.6423 & 0.9227 & 0.8260 & 0.8592 & 0.5874 \\ 0.4230 & 0.8127 & 0.8054 & 0.5878 & 0.5892 \\ 0.6713 & 0.9630 & 0.9023 & 0.9533 & 0.6681 \end{bmatrix}$$

After 57 iterations (1500 evaluations), P' is the estimated value for P.

$$P' = \begin{bmatrix} 0.2921 & 0.4785 & 0.7671 & 0.9538 & 0.8433 \\ 0.6804 & 0.9593 & 0.2627 & 0.5497 & 0.2491 \\ 0.2617 & 0.5455 & 0.3835 & 0.4141 & 0.7563 \\ 0.1811 & 0.5821 & 0.7026 & 0.1342 & 0.2487 \\ 0.0139 & 0.2564 & 0.8796 & 0.3088 & 0.9254 \end{bmatrix}$$

Then, R' is calculated according to (6):

$$R' = P' \circ Q$$

$$R' = \begin{bmatrix} 0.8549 & 0.9785 & 0.9360 & 0.9772 & 0.6888 \\ 0.6664 & 0.9418 & 0.8942 & 0.6672 & 0.6713 \\ 0.6417 & 0.9236 & 0.8279 & 0.8590 & 0.5859 \\ 0.4231 & 0.8125 & 0.8052 & 0.5878 & 0.5894 \\ 0.6715 & 0.9629 & 0.9021 & 0.9536 & 0.6682 \end{bmatrix}$$

And here's the difference between the actual R and the one obtained by the estimation of P (P'), which will lead to our error measure:

$$R' - R = \begin{bmatrix} -0.0002 & 0.0000 & 0.0005 & 0.0003 & -0.0001 \\ 0.0000 & -0.0001 & 0.0000 & 0.0000 & 0.0001 \\ -0.0005 & 0.0009 & 0.0019 & -0.0002 & -0.0015 \\ 0.0001 & -0.0002 & -0.0002 & 0.0000 & 0.0002 \\ 0.0002 & -0.0001 & -0.0002 & 0.0003 & 0.0000 \end{bmatrix}$$

Finally, by applying (7), we arrive at the value of *RMSE* as a universal error measure.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{5}\sum_{k=1}^{5}(r_{ik} - r'_{ik})^2}{5 \times 5}} = 5.5246\text{E-}04$$

5 Conclusions and Future Research

In this paper, we have proposed a new numerical method based on Sequential Quadratic Programming for solving fuzzy relation equations. This work is distinguished from previous methods in that:

- it views the FRE problem in the most general sense, being capable of handling sizes of $p \times m$ and $p \times n$ for P and R; and
- unlike analytical approaches, it can handle equations with any combinations of t-norms and t-conorms and at any dimensions.

However, the proposed method is not capable of tuning the parameters of t-norms and t-conorms. Also, it can be extended to be able to handle systems of Fuzzy Relation Equations. Such improvements can be considered for future research.

Abstract— *In this contribution we propose a multi-objective evolutionary algorithm for Tuning Fuzzy Rule-Based Systems by considering two objectives, accuracy and interpretability. To this aim we define a new objective that allows preserving the interpretability of the system. This new objective is an interpretability index which is the union of three metrics to preserve the original shapes of the membership functions as much as possible while a tuning of the membership function parameters is performed. The proposed method has been compared to a single objective accuracy-guided algorithm in two real problems showing that many solutions in the Pareto front dominate to those obtained by the single objective-based one.*

Keywords— Fuzzy Rule-Based Systems, Tuning, Interpretability, Multi-Objective Evolutionary Algorithms.

1 Introduction

Fuzzy modeling usually tries to improve the accuracy of the system without inclusion of any interpretability measure, an essential aspect of Fuzzy Rule-Based Systems (FRBSs). However, the problem of finding the right trade-off between accuracy and interpretability has achieved a growing interest [1].

One of the most widely-used approaches to enhance the performance of FRBSs is the *tuning* of the Membership Functions (MFs). It consists of refining a previous definition of the Data Base (DB) once the Rule Base (RB) has been obtained. Generally, tuning is a variation in the shape of the MFs that improves their global interaction. Classically, the tuning methods refine the parameters that identify the MFs associated to the labels comprising the DB [2].

For this model, to take into account interpretability issues it is necessary to use a measure to quantify the interpretability of the tuned DB. This kind of measure could be used as an additional objective to maintain the interpretability of the fuzzy partitions when the tuning is carried out.

In the literature, many authors improve the difficult trade-off between accuracy and interpretability of FRBSs, obtaining linguistic models not only accurate but also interpretable. We can distinguish two kinds of approaches for managing the interpretability:

1. The complexity of the model [3, 4, 5, 6] (usually measured as number of rules, variables, labels per rule, etc.)
2. Measuring the interpretability of the fuzzy partitions [4, 7, 8] by means of a semantic interpretability measure.

A way for optimizing both objectives (accuracy and interpretability) is the use of the Multi-Objective Evolutionary Algorithms (MOEAs) [9, 10]. Since this problem presents a multi-objective nature the use of MOEAs to obtain a set of solutions with different degrees of accuracy and interpretability is an interesting way to work [3, 5, 6, 8].

In this work, we focus our attention in measuring the interpretability of the fuzzy partitions. We propose a semantics interpretability index for maintaining the interpretability of the system by means of the aggregation of several metrics, with the aim of preserving the original form of the MFs while a tuning is performed. These metrics try to minimize the displacement of the central point of the MFs, besides maintaining the symmetry and the area of the original MFs associated to the linguistic labels. To this end, we apply a specific MOEA to obtain accurate and interpretable linguistic fuzzy models by performing a tuning of the MFs parameters with two main objectives:

- The system error
- The proposed interpretability index.

This algorithm is based on the well known $SPEA2$ [11] and is called SPEA2$_{SI}$ ($SPEA2$ for Semantic Interpretability). In order to improve its search ability, SPEA2$_{SI}$ implements some concepts as incest prevention and restarting [12]. Moreover, it is focused on the most accurate solutions to finally form a wide Pareto front. Thus, SPEA2$_{SI}$ is aimed at generating a complete set of Pareto-optimum solutions with different trade-offs between accuracy and interpretability. We have not considered the well-known NSGA-II [13] algorithm since in [3], approaches based on SPEA2 were shown to be more effective when performing a tuning of the MFs.

To show the good performance of the proposed method it is compared with a single objective accuracy-guided tuning algorithm [14] by applying both of them to initial linguistics models obtained from automatic learning methods. Two real-world problems with different complexities have been considered showing that the solutions of the accuracy based algorithm are dominated by those obtained by SPEA2$_{SI}$. We can see as both objectives required are certainly contradictory as the obtained Pareto fronts moves clearly from the most accurate solutions to the most interpretable ones.

Next section describes the classic tuning used in this work. Section 3 presents the proposed index to control the interpretability of the MFs. Section 4 presents the SPEA2$_{SI}$ algorithm describing its main characteristics and the genetic operators considered. Section 5 shows the experimental study

ISBN: 978-989-95079-6-8

and the results obtained. Finally, in section 6 we point out some conclusions.

2 Preliminaries: Tuning of MFs

This approach, usually called DB tuning, involves refining the MF shapes from a previous definition once the remaining FRBS components have been obtained [15, 16, 17, 18, 19, 20]. The classic way to refine the MFs is to change their definition parameters. For example, if the following triangular-shape MF is considered:

$$\mu(x) = \begin{cases} \frac{x-a}{b-a}, & \text{if } a \leq x < b \\ \frac{c-x}{c-b}, & \text{if } b \leq x \leq c \\ 0, & \text{otherwise} \end{cases}$$

changing the basic parameters — a, b, and c — will vary the shape of the fuzzy set associated to the MF, thus influencing the FRBS performance (See Figure 1). The same yields for other shapes of MFs (trapezoidal, gaussian, sigmoid, etc.).

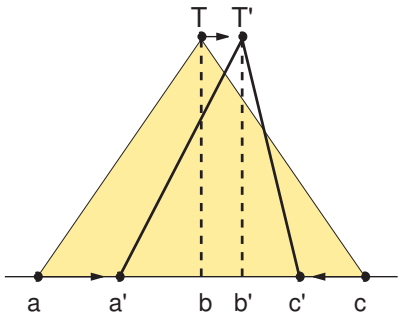

Figure 1: Tuning by changing the basic MF parameters

Tuning involves fitting the characterization of the MFs associated to the primary linguistic terms considered in the system. Thus, the meaning of the linguistic terms is changed from a previous definition (an initial DB). In order to ensure the semantics integrity through the MFs optimization process [1, 21, 22], some researchers have proposed several properties. Considering one or more of these properties several constraints can be applied in the design process in order to obtain a DB maintaining the linguistic model comprehensibility to the higher possible level [15, 23, 24, 25].

In this work we consider strong fuzzy partitions to define the initial MFs. In order to maintain semantics integrity we consider also these constraints by defining the variation intervals for each MF parameter. For each $MF_j = (a_j, b_j, c_j)$ where j=(1,...m) and m is the number of MFs in a given DB, the variation intervals are calculated in the following way:

$$[I^l_{a_j}, I^r_{a_j}] = [a_j - (b_j - a_j)/2, a_j + (b_j - a_j)/2] \ ,$$
$$[I^l_{b_j}, I^r_{b_j}] = [b_j - (b_j - a_j)/2, b_j + (c_j - b_j)/2] \ ,$$
$$[I^l_{c_j}, I^r_{c_j}] = [c_j - (c_j - b_j)/2, c_j + (c_j - b_j)/2] \ .$$

Thanks to these restrictions it is possible to maintain the comprehensibility of MFs to a reasonable level. In any case, it would be very interesting to have a measure for the quality of the tuned MFs. We propose three metrics trying to preserve the original form of the MFs, so improving if possible the trade-off between accuracy and interpretability.

3 An Interpretability Index based on Three Interpretability Metrics

In this section, we propose several metrics to measure the interpretability when a tuning is performed on the DB. At this point, we should remark that these metrics are based on the existence of the variation intervals (integrity constraints) defined in the previous section and, therefore, on the assumption that the initial DB is comprised of triangular uniformly distributed MFs (strong fuzzy partitions) with an associated linguistic meaning. Based on these assumptions, significant changes in the DB can influence negatively in the interpretability. In this way, each metric is proposed to control how good are different desirable aspects of the tuned MFs with respect to the original ones. The metrics proposed are:

- MFs displacements (δ): This metric measures the proximity of the central points of the MFs to the original corresponding ones. It should be higher as closer to the original point.
- MFs symmetry (γ): This metric measures the symmetry of the MFs. It should be higher when the two parts of the support of the MFs (left and right) present more similar lengths.
- MFs area similarity (ρ): This metric measures the similarity of the area of the tuned MFs to the original one. It should be higher when the tuned area and the original area are closer.

In the following subsections the three proposed metrics will be explained in depth.

3.1 MFs displacements (δ)

This metric can control the displacements in the central point of the MFs. It is based on computing the normalized distance between the central point of the tuned MF and the central point of the original MF, and is calculated through keeping the maximum displacement obtained on all the MFs. For each MF_j: $\delta_j = |b_j - b'_j|/I$, where $I = (I^r_{b_j} - I^l_{b_j})/2$ represents the maximum variation for each central parameter. Thus δ^* is defined as: $\delta^* = max_j\{\delta_j\}$.

The δ^* metric takes values between 0 and 1, thereby value near to 1 represent that the MFs present a great displacement. The following transformation is made so this metric represents proximity (maximization):

$$\delta = 1 - \delta^* \ ,$$

3.2 MFs symmetry (γ)

This metric can be used to control the symmetry of the MF shapes. It is based on relating the two parts of the support of the tuned MFs. Let us define that $leftS'_j = |a'_j - b'_j|$ is the length of the left part of the MF support and that $rightS'_j = |b'_j - c'_j|$ is the right part. γ_j is calculated using the following equation:

$$\gamma_j = \frac{min\{leftS'_j, rightS'_j\}}{max\{leftS'_j, rightS'_j\}} \ .$$

Values near to 1 mean that the two parts of the support of the MFs are more similar (higher symmetry). Finally γ is calculated by keeping the minimum value obtained.

$$\gamma = min_j\{\gamma_j\} \ .$$

ISBN: 978-989-95079-6-8

3.3 MFs area similarity (ρ)

This metric can be used to control the area of the MF shapes. It is based on relating the areas of the original and the tuned MFs. Let us define that A_j is the area of the triangle representing the original MF_j, and A'_j is the new area. ρ_j is calculated using the following equation for each MF:

$$\rho_j = \frac{min\{A_j, A'_j\}}{max\{A_j, A'_j\}} \ .$$

Values near to 1 mean that the original area and the tuned area of the MFs are more similar (less changes). The ρ metric is calculated through keeping the minimum value obtained:

$$\rho = min_j\{\rho_j\} \ .$$

3.4 A global Semantics Interpretability index based on the aggregation of the three metrics

We propose an aggregation of the metrics in a global index based on the geometric mean, that is denoted as GM3M index. It is clear that if only one of the proposed metrics has very low values a problem in the interpretability will arise. The aggregation operator should consider this fact:

$$GM3M = \sqrt[3]{\delta * \gamma * \rho}$$

The value of $GM3M$ ranges between 0 (the lowest level of interpretability) and 1 (the highest level of interpretability).

4 Proposed Multi-objective Evolutionary Algorithm

The proposed algorithm performs a parametric tuning to improve the system accuracy as a first objective and uses the $GM3M$ index to try to preserve the interpretability. It is called $SPEA2$ for Semantic Interpretability ($SPEA2_{SI}$) and is based on the well-known $SPEA2$[11] algorithm. In the next subsections the main components of this algorithm are described and the specific characteristics are presented.

4.1 Coding Scheme and Initial Gene Pool

We consider a real coding scheme, being m^i the number of labels of each of the n variables comprising the DB,

$$\begin{array}{l} C_i = (a_1^i, b_1^i, c_1^i, \ldots, a_{m^i}^i, b_{m^i}^i, c_{m^i}^i), \\ \ i = 1, \ldots, n \ , \\ C = C_1 C_2 \ldots C_n \ . \end{array}$$

The initial DB is included as first individual of the initial population. The remaining individuals are generated at random within the corresponding variation intervals defined in the previous section.

4.2 Objectives

In this algorithm we use two objectives. They are:

- The interpretability index ($GM3M$) that is a maximization objective representing the geometric mean of the three proposed metrics (interpretability).
- The Mean Squared Error (MSE) that is a minimization objective (accuracy):

$$\text{MSE} = \frac{1}{2 \cdot |E|} \sum_{l=1}^{|E|} (F(x^l) - y^l)^2,$$

with $|E|$ being the data set size, $F(x^l)$ being the output obtained from the FRBS decoded from such chromosome when the l-th example is considered and y^l being the known desired output. The fuzzy inference system considered to obtain $F(x^l)$ is the *center of gravity weighted by the matching* strategy as defuzzification operator and the *minimum t-norm* as implication and conjunctive operators.

4.3 Main Characteristics of $SPEA2_{SI}$

The proposed algorithm makes use of the $SPEA2$ selection mechanism. However in order to improve the search ability of the algorithm the following changes are considered:

- The proposed algorithm includes a mechanism for incest prevention based on the concepts of CHC [12], for maintaining population diversity. This mechanism avoids premature convergence. Only those parents whose hamming distance divided by 4 is higher than a threshold are crossed. The well-known BLX-0.5 [26] crossover is applied to obtain the offspring.

  Since we consider a real coding scheme, we have to transform each gene considering a Gray Code with a fixed number of bits per gene ($BGene$) determined by the system expert. In this way, the threshold value is initialized as:

  $$L = (\#C * BGene)/4,$$

  where $\#C$ is the number of genes of the chromosome.

  At each generation of the algorithm, the threshold value is decremented by one which allows crossing closer solutions. Following the concept of the CHC algorithm that does not used mutation, in our algorithm we do not include mutation operator.

- A restarting operator is applied by maintaining the most accurate individual, and the most interpretable individual as a part of the new population (external population is forced to be empty) and obtaining the remaining individuals with the tuning parameters generated at random within the corresponding variation intervals. This way preserves both the most accurate and the most interpretable solutions obtained.

  Restarting should be applied when we detect that all crossovers are allowed. However in order to avoid premature convergence we apply the first restart if 50 percent of crossovers are detected at any generation. This condition is updated each time restarting is performed as $\%_{Required} = (100 + \%_{Required})/2$. Moreover, the most accurate solution should be improved before each restarting. To preserve a well formed Pareto front at the end, the restarting is not applied in the last evaluations. The number of evaluations without restart can be estimated as the number of evaluations needed to apply the first restart multiplied by 10. Additionally, restart is disabled if it was never applied before reaching the mid of the total number of evaluations.

ISBN: 978-989-95079-6-8

- In each stage of the algorithm (between restarting points), the number of solutions in the external population ($\overline{P}_{t+1}$) considered to form the mating pool is progressively reduced, by focusing only on those with the best accuracy. To do that, the solutions are sorted from the best to the worst (considering accuracy as sorting criterion) and the number of solutions considered for selection is reduced progressively from 100% at the beginning to 50% at the end of each stage by taking into account the value of L.

  In the last evaluations when restart is disabled. This mechanism, whose main objective is focusing on the most accurate solutions, is also disabled in order to obtain a wide well formed Pareto front.

5 Experiments

To evaluate the goodness of the proposed approach, two real-world problems with different complexities (different number of variables and available data) are considered to be solved (these data sets are available at, *http://www.keel.es/*) [27]:

- Estimating the maintenance costs of medium voltage lines in a town (ELE).
- Predicting the Abalone Age (ABA).

In both cases, the well-known *ad hoc* data-driven learning algorithm of Wang and Mendel [28] is applied to obtain an initial set of candidate linguistic rules. To do so, we will consider strong fuzzy partitions of triangular-shaped MFs. Once the initial RB is generated, the proposed post-processing algorithm can be applied.

Methods considered for the experiments are:

- T method performs a classic MFs parameter tuning by only considering the accuracy of the model as the sole objective [14].
- $SPEA2_{SI}$ is the proposed MOEA method for the classic tuning considering two objectives, precision and the semantics interpretability index (GM3M).

5.1 Experimental Set-up

We consider a *5-fold cross-validation model*, i.e., 5 random partitions of data each with 20%, and the combination of 4 of them (80%) as training and the remaining one as test. For each one of the 5 data partitions, the tuning methods have been run 6 times, showing for each problem the averaged results of a total of 30 runs.

In the case of $SPEA2_{SI}$ the averaged values are calculated considering the most accurate solution from each Pareto obtained. In this way, $SPEA2_{SI}$ can be compared with the single objective method T.

The values of the input parameters considered by T are: population size of 61, 100000 evaluations, 0.6 as crossover probability and 0.2 as mutation probability per chromosome. The values of the input parameters considered by $SPEA2_{SI}$ are: population size of 200, external population size of 61, 100000 evaluations and 30 bits per gene for the Gray codification.

5.2 Results and Analysis

Table 1 shows the results obtained with WM, where $\#R$ stands for the number of rules, $\text{MSE}_{tra/tst}$ for the averaged error obtained over the training/test data, σ for their respective standard deviations and $GM3M$ for the interpretability index. This method obtains the initial knowledge bases that will be tuned by T and $SPEA2_{SI}$. For the WM method the interpretability index takes value 1 that is the highest level of interpretability.

Table 1: Results obtained with WM method

Dataset	#R	MSE_{tra}	σ_{tra}	MSE_{tst}	σ_{tst}	GM3M
ELE	65	56136	1498	56359	4685	1
ABA	68	8.407	0.443	8.422	0.545	1

The results obtained by both post-processing methods are shown in Table 2. In addition we also show δ, γ and ρ that represent the individual values of the metrics comprising, and *t* represents the results of applying a *test t-student* (with 95 percent confidence) in order to ascertain whether differences in the performance of the best results are significant when compared with that of the other algorithm in the table. The interpretation of the *t* column is:

- $\star$ represents the best averaged result.
- $+$ means that the best result has better performance than that of the related row.

Analysing the results showed in Table 2, we can highlight the following facts:

- The proposed method obtains the best results in training and test with respect to T in both problems. In the case of the electrical problem, SPEA2_{SI} improves among 7% and 8.5% in training and test respectively and in the abalone problem it obtains an improvement of 1.5%.
- The most accurate solutions from SPEA2_{SI} improve the accuracy and obtain more interpretable models, with 29%(ELE) and 52%(ABA) of improvement in the interpretability index with respect to the T method.

Figure 2 shows the Pareto front obtained with SPEA2_{SI} method, the solution obtained by T and the initial knowledge base obtained by WM in the same data partition and seed of ELE. We can observe that the obtained Pareto front is quite wide. In fact, the number of non dominated solutions is always equal to the external population size. Moreover, the WM solution coincides with the last point of the Pareto front and the solution obtained with T is dominated by several solutions from SPEA2_{SI}. Furthermore there is not overfitting in the results obtained with the proposed method.

The Pareto front obtained allows selecting solutions with different degrees of accuracy and interpretability. Figure 2 presents that an improvement in the interpretability produces lack of precision and an improvement in the precision produces lack of interpretability. This figure clearly shows that

ISBN: 978-989-95079-6-8

Table 2: Results obtained in both problems

Dataset	Method	MSE_{tra}	σ_{tra}	t-test	MSE_{tst}	σ_{tst}	t-test	GM3M	σ_{GM3M}	t-test	δ	γ	ρ
ELE	T	17020	1893	+	21027	4225	=	0.225	0.046	+	0.058	0.337	0.694
	$SPEA2_{SI}$	**15884**	1191	*	**19257**	2893	*	**0.319**	0.170	*	0.225	0.398	0.648
ABA	T	2.688	0.063	+	2.770	0.242	=	0.144	0.051	+	0.032	0.182	0.636
	$SPEA2_{SI}$	**2.648**	0.051	*	**2.744**	0.276	*	**0.298**	0.153	*	0.177	0.392	0.625

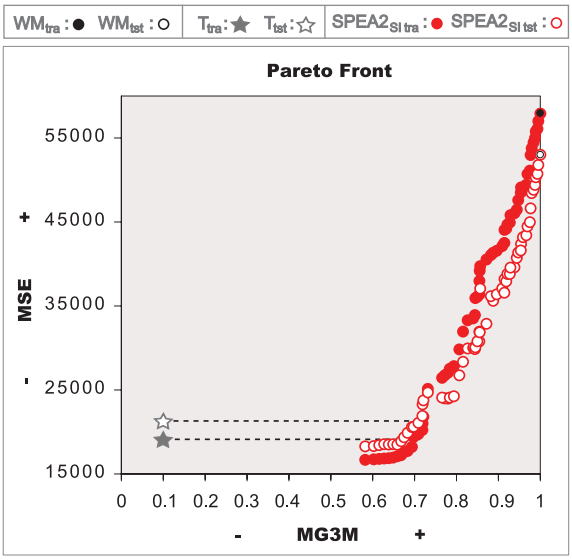

Figure 2: Pareto Front obtained in ELE

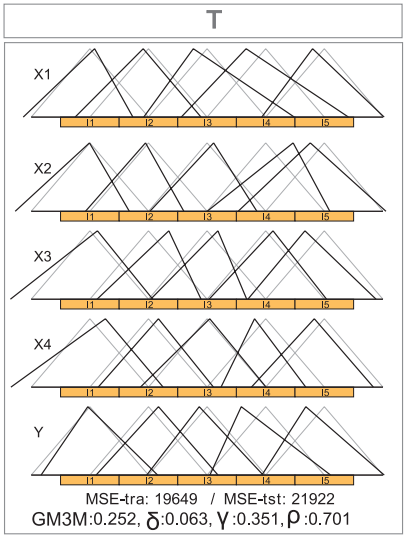

Figure 3: A DB obtained with T method in ELE

both objectives are actually contradictory. In the extremes of the Pareto front an improvement in one objective represents small lost in the other objective. On the contrary in the mid part of the Pareto front improvements in one objective deteriorates the other objective.

Figure 3 presents an illustrative DB obtained with T. Some DBs obtained with $SPEA2_{SI}$, in the same data partition and seed than this shown for T, are shown in Figure 4. This figure includes three DBs, one with the most accurate solution, other with a solution not only accurate but also interpretable and another highly interpretable DB, that obtains 35% of improvement with respect to the WM method with a value of the interpretability index near to 1.

6 Conclusions

The proposed index is useful to preserve the original shape of the MFs, in order to maintain the interpretability and it is a measure of the quality of the DB.

The proposed method obtains wide well formed Pareto fronts that provide a large variety of solutions to select from more accurate solutions to more interpretable ones.

Finally, we can stand out that $SPEA2_{SI}$ algorithm is very competitive and efficient since it is able to maintain the DB interpretability at a better level while accuracy is greatly improved.

Abstract— *We have proposed tolerant fuzzy c-means clustering (TFCM) from the viewpoint of handling data more flexibly. This paper presents a new type of tolerant fuzzy c-means clustering with L_1-regularization. L_1-regularization is well-known as the most successful techniques to induce sparseness. The proposed algorithm is different from the viewpoint of the sparseness for tolerance vector. In the original concept of tolerance, a tolerance vector attributes to each data. This paper develops the concept to handle data flexibly, that is, a tolerance vector attributes not only to each data but also each cluster. First, the new concept of tolerance is introduced into optimization problems. These optimization problems are based on conventional fuzzy c-means clustering (FCM). Second, the optimization problems with tolerance are solved by using Karush-Kuhn-Tucker conditions and an optimization method for L_1-regularization. Third, new clustering algorithms are constructed based on the explicit optimal solutions. Finally, the effectiveness of the proposed algorithm is verified through some numerical examples.*

Keywords— fuzzy c-means clustering, L_1-regularization, optimization, tolerance, uncertainty

1 Introduction

The aim of data mining is to discover important knowledge from a large quantity of data. From this viewpoint, clustering techniques have been actively studied. Clustering is one of the well-known unsupervised classification methods. For example, hard c-means clustering (HCM) is the most basic method. Fuzzy c-means clustering (FCM) is one of the well-known and useful clustering methods. For example, standard fuzzy c-means clustering (sFCM) [1] and entropy regularized fuzzy c-means clustering (eFCM) [2] are representatives. The entropy regularized fuzzy c-means clustering is constructed by regularization with maximum entropy function.

By the way, there are some difficulties of handling a set of data by clustering methods. Some clustering algorithms have been proposed to solve significant problems, for example, data with uncertainty, cluster size, noise or isolated data and so on. When we handle a set of data, data contains inherent uncertainty. For example, errors, ranges or some missing value of attributes are much caused. In these cases, each data is represented by an interval or a set instead of a point. In case of handling data with uncertainty, some significant methods have been proposed [3, 4]. These methods can not only handle data with uncertainty but also obtain high quality results by considering data with uncertainty. Thus, handling data with uncertainty is a very important problem in the field of data mining.

Therefore, some of the authors have proposed the original concept of tolerance [5, 6] which handle data with the above-mentioned uncertainty by using tolerance vector, and constructed some clustering algorithms [7, 8]. In these algorithms, tolerance is defined as hypersphere [5, 6] or hyper-rectangle [7, 8]. In case of hyper-rectangle, the missing value of attributes are handled successfully.

On the other hand, it is difficult to obtain clusters with different size or shape by a single-objective function, e.g., conventional FCM. In general, multi-objective optimization is considered to solve such problems. However, there are some problems by optimization, for example, how to select objective function. We have thought to be solved the above-mentioned problems by introducing a kind of "flexibility" for a pattern space and we have proposed the method to handle such "flexibility" by tolerance vector [9].

It is considered that the constraint for tolerance vector much affects classification results. It means that unsuited parameter makes trivial solutions. Therefore, regularization technique, e.g., Tikhonov's regularization [10] method have been used to solve these ill-posed problems. The quadratic and maximum entropy functions are typical regularization techniques. Moreover, L_1-regularization is the most efficient technique to induce sparseness. In the field of regression models or machine learning, some methods with L_1-regularization have been proposed and given sparse classifiers [12, 13, 14]. In algorithms applied to L_1-regularization, a lot of vari-

ISBN: 978-989-95079-6-8

ables are calculated zero. Non-zero variables are essential to understand classification results.

First, we consider optimization problems of tolerant fuzzy c-means clustering with L_1-regularization. Second, the optimal solutions are derived by Karush-Kuhn-Tucker (KKT) conditions and an optimization method for L_1-regularization . Third, we construct a new clustering algorithm by above-mentioned processes. Finally, the effectiveness of the proposed algorithm is verified through some numerical examples.

2 Preparation

Let data set, cluster and its cluster center be $X = \{x_k \mid x_k = (x_k^1, \ldots, x_k^p)^T \in \Re^p, k = 1 \ldots n\}$, C_i $(i = 1, \ldots, c)$ and $v_i = (v_i^1, \ldots, v_i^p)^T \in \Re^p, (i = 1, \ldots, c)$, respectively. Moreover, u_{ki} is the membership grade of x_k belonging to C_i and we denote the partition matrix $U = (u_{ki})_{k=1\sim n,\ i=1\sim c}$.

2.1 Fuzzy c-means clustering

Fuzzy c-means clustering is based on optimizing an objective function under constraint for membership grade.

We consider following two types of objective functions J_s and J_e.

$$J_s(U,V) = \sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ki})^m \|x_k - v_i\|^2,$$

$$J_e(U,V) = \sum_{k=1}^{n}\sum_{i=1}^{c} u_{ki}\|x_k - v_i\|^2 + \lambda^{-1}\sum_{k=1}^{n}\sum_{i=1}^{c} u_{ki}\log u_{ki}.$$

J_s is a well-known objective function of standard fuzzy c-means clustering (sFCM) proposed by Bezdek [1] and J_e is an entropy regularized fuzzy c-means clustering (eFCM) [2].

The constraint for u_{ki} is as follows :

$$\sum_{i=1}^{c} u_{ki} = 1\ ,\ u_{ki} \in [0,1]\ ,\ {}^{\forall}k.$$

2.2 Regularization

As above-mentioned, regularization is efficient techniques in the field of data mining. Tikhonov's regularization [10] method has been used to solve ill-posed problems. Many data mining algorithms which are applied to regularization have been actively studied to determine a variety of solution [12, 13, 14].

In the field of clustering, many membership regularization techniques have been proposed to obtain a variety of membership functions.

$$\min_U J(U,V) + \lambda\Omega(U),$$

where λ is a regularization parameter and $\Omega(U)$ is a regularization term.

The choice of a regularization term is important to determine a shape of a membership function. The quadratic function and maximum entropy function are typical examples.

$$\Omega(U) = \frac{1}{2}\sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ki})^2,$$

$$\Omega(U) = \sum_{k=1}^{n}\sum_{i=1}^{c} u_{ki}\log u_{ki}.$$

3 The concept of tolerance

In the new concept of tolerance, the vector which attributes not only each data but also cluster center is defined as tolerance vector ε_{ki}. The tolerance κ_{ki} is defined as upper bound of tolerance vector.

From these formulation, the proposed methods can handle data more flexible than conventional methods.

We define κ_{ki}^j as the upper bound of each attribute of tolerance vector $\kappa_{ki} = (\kappa_{11}^1, \ldots, \kappa_{nc}^p) \geq 0$ and tolerance vector $E = \{\varepsilon_{ki} \mid \varepsilon_{ki} = (\varepsilon_{ki}^1, \ldots, \varepsilon_{ki}^p)^T \in \Re^p\ \}$ which mean the admissible range of each data, and the vector within the range of tolerance, respectively. The constraint for ε_{ki}^j is as follows :

$$|\varepsilon_{ki}^j|^2 \leq (\kappa_{ki}^j)^2\ (\kappa_{ki}^j \geq 0), {}^{\forall}k,\ i,\ j.$$

Figure 1 is an illustrative example about the new concept of tolerance defined as hyper-rectangle in $\Re^2$.

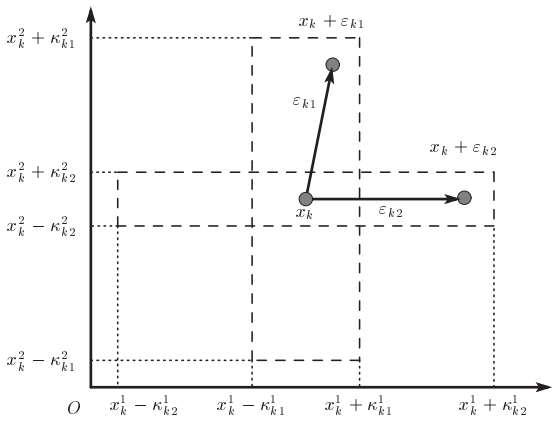

Figure 1: The new concept of tolerance defined as hyper-rectangle in $\Re^2$.

4 Tolerant fuzzy c-means clustering

In this section, we discuss optimization problems for clustering. We formulate the tolerant fuzzy c-means clustering (TFCM) by introducing the notion of tolerance into optimization problems and consider the way

ISBN: 978-989-95079-6-8

to optimize this objective function under the constraints for u_{ki} and ε_{ki}^j. The squared Euclidean-norm is used as dissimilarity, that is,

$$d_{ki} = \|x_k + \varepsilon_{ki} - v_i\|_2^2 = \sum_{j=1}^{p}(x_k^j + \varepsilon_{ki}^j - v_i^j)^2.$$

4.1 Tolerant standard fuzzy c-means clustering

The optimization problem is as follows :

$$J_{ts}(U,E,V) = \sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ki})^m d_{ki}, \tag{1}$$

under the following constraints,

$$\sum_{i=1}^{c} u_{ki} = 1\ ,\ u_{ki} \in [0,1]\ ,\ {}^\forall k, \tag{2}$$

$$|\varepsilon_{ki}^j|^2 \le (\kappa_{ki}^j)^2\ (\kappa_{ki}^j \ge 0), {}^\forall k,\ i,\ j. \tag{3}$$

The goal is to find the solutions which minimize the objective function (1) under the constraints (2) and (3).

From the convexity of (1), we introduce the following Lagrangian function to solve this optimization problem.

The Lagrangian function L_{tsr} is as follows :

$$\begin{aligned} L_{tsr} =& J_{ts}(U,E,V) + \sum_{k=1}^{n}\gamma_k(\sum_{i=1}^{c}u_{ki} - 1) \\ &+ \sum_{k=1}^{n}\sum_{i=1}^{c}\sum_{j=1}^{p}\delta_{ki}^j(|\varepsilon_{ki}^j|^2 - (\kappa_{ki}^j)^2). \end{aligned}$$

Karush-Kuhn-Tucker conditions (KKT conditions) are as follows:

$$\left\{\begin{array}{l} \frac{\partial L_{tsr}}{\partial v_i^j} = 0,\ \frac{\partial L_{tsr}}{\partial \varepsilon_{ki}^j} = 0,\ \frac{\partial L_{tsr}}{\partial u_{ki}} = 0,\ \frac{\partial L_{tsr}}{\partial \gamma_k} = 0, \\ \frac{\partial L_{tsr}}{\partial \delta_{ki}^j} \le 0,\ \delta_{ki}^j\frac{\partial L_{tsr}}{\partial \delta_{ki}^j} = 0,\ \delta_{ki}^j \ge 0. \end{array}\right. \tag{4}$$

First we consider u_{ki}, from $\frac{\partial L_{tsr}}{\partial u_{ki}} = 0$, we have,

$$u_{ki} = \left(\frac{\gamma_k}{m d_{ki}}\right)^{\frac{1}{m-1}}. \tag{5}$$

In addition, from the constraint (2),

$$\sum_{l=1}^{c}\left(\frac{\gamma_k}{m d_{kl}}\right)^{\frac{1}{m-1}} = 1. \tag{6}$$

From (5) and (6), we have,

$$u_{ki} = \frac{\frac{1}{(d_{ki})^{\frac{1}{m-1}}}}{\sum_{l=1}^{c}\frac{1}{(d_{kl})^{\frac{1}{m-1}}}}. \tag{7}$$

If some $x_k + \varepsilon_{ki} = v_i$, we set $u_{ki} = 1/|C'|$. Here, $|C'|$ is number of cluster centers which satisfies $x_k + \varepsilon_{ki} = v_i$.

For v_i^j, from $\frac{\partial L_{tsr}}{\partial v_i^j} = 0$,

$$v_i^j = \frac{\sum_{k=1}^{n}(u_{ki})^m(x_k^j + \varepsilon_{ki}^j)}{\sum_{k=1}^{n}(u_{ki})^m}. \tag{8}$$

For ε_{ki}^j from $\frac{\partial L_{tsr}}{\partial \varepsilon_{ki}^j} = 0$, we can get

$$\varepsilon_{ki}^j = -\frac{(u_{ki})^m(x_k^j - v_i^j)}{(u_{ki})^m + \delta_{ki}^j}. \tag{9}$$

From $\delta_{ki}^j\frac{\partial L_{tsr}}{\partial \delta_{ki}^j} = 0$,

$$\delta_{ki}^j(|\varepsilon_{ki}^j|^2 - (\kappa_{ki}^j)^2) = 0. \tag{10}$$

From (10), we should consider two cases, i.e., $\delta_{ki}^j = 0$ and $|\varepsilon_{ki}^j|^2 = (\kappa_{ki}^j)^2$. First, we consider the case of $\delta_{ki}^j = 0$. In this case, the constraint (3) is not considered. From (9), we can get,

$$\varepsilon_{ki}^j = -(x_k^j - v_i^j).$$

On the other hand, in case that $|\varepsilon_{ki}^j|^2 = (\kappa_{ki}^j)^2$,

$$|\varepsilon_{ki}^j|^2 = |-\frac{(u_{ki})^m(x_k^j - v_i^j)}{(u_{ki})^m + \delta_{ki}^j}|^2 = (\kappa_{ki}^j)^2.$$

From $(u_{ki})^m + \delta_{ki}^j > 0$,

$$\frac{(u_{ki})^m}{(u_{ki})^m + \delta_{ki}^j} = \frac{\kappa_{ki}^j}{|x_k^j - v_i^j|}. \tag{11}$$

From (9), (11),

$$\varepsilon_{ki}^j = \frac{-\kappa_{ki}^j(x_k^j - v_i^j)}{|x_k^j - v_i^j|}.$$

From the above, we can get an optimal solution for ε_{ki}^j as follows :

$$\begin{aligned} \varepsilon_{ki}^j =& -\alpha_{ki}^j(x_k^j - v_i^j), \\ \alpha_{ki}^j =& \min\left\{\frac{\kappa_{ki}^j}{|x_k^j - v_i^j|}, 1\right\}. \end{aligned} \tag{12}$$

4.2 Tolerant entropy regularized fuzzy c-means clustering

The optimization problem is as follows :

$$\begin{aligned} J_{te}(U,E,V) =& \sum_{k=1}^{n}\sum_{i=1}^{c}u_{ki}d_{ki} \\ &+ \lambda^{-1}\sum_{k=1}^{n}\sum_{i=1}^{c}u_{ki}\log u_{ki}. \end{aligned}$$

ISBN: 978-989-95079-6-8

Constraints are same as (2) and (3).
The Lagrangian function L_{er} is as follows :

$$L_{ter} = J_{te}(U,E,V) + \sum_{k=1}^{n}\gamma_k(\sum_{i=1}^{c}u_{ki}-1) + \sum_{k=1}^{n}\sum_{i=1}^{c}\sum_{j=1}^{p}\delta_{ki}^{j}(|\varepsilon_{ki}^{j}|^2-(\kappa_{ki}^{j})^2).$$

KKT conditions are same as (4).
The optimal solutions are derived as follows :

$$u_{ki} = \frac{\exp(-\lambda d_{ki})}{\sum_{l=1}^{c}\exp(-\lambda d_{kl})}, \quad (13)$$

$$v_i^j = \frac{\sum_{k=1}^{n}u_{ki}(x_k^j+\varepsilon_{ki}^j)}{\sum_{k=1}^{n}u_{ki}}, \quad (14)$$

$$\varepsilon_{ki}^j = -\alpha_{ki}^j(x_k^j-v_i^j),$$

$$\alpha_{ki}^j = \min\left\{\frac{\kappa_{ki}^j}{|x_k^j-v_i^j|},1\right\}.$$

5 Tolerant fuzzy c-means clustering with L_1-regularization

In this section, we will consider tolerant fuzzy c-means clustering with L_1-regularization. In this method, constraint for ε_{ki}^j is not considered.

5.1 L_1-regularization

It is well-known that L_1-regularization can induce the strong sparseness of the variables [12, 13, 14]. A lot of ε_{ki}^j become zero, by L_1-regularization described as follows :

$$\Omega(E) = \sum_{k=1}^{n}\sum_{i=1}^{c}\sum_{j=1}^{p}|\varepsilon_{ki}^j|.$$

Here, we will describe objective function with L_1-regularization as J_{tl}. The partial derivatives of J_{tl} which respect to ε_{ki}^j will be uniformly zero, as follows :

$$\left|\frac{\partial J_{tl}}{\partial\varepsilon_{ki}^j}\right| = \nu \qquad \text{if } |\varepsilon_{ki}^j|>0,$$

$$\left|\frac{\partial J_{tl}}{\partial\varepsilon_{ki}^j}\right| < \nu \qquad \text{if } |\varepsilon_{ki}^j|=0.$$

Here, $\nu > 0$ is a regularization parameter. This denotes that if the partial derivatives of J below ν, ε_{ki}^j will be set exactly zero.

5.2 Tolerant standard fuzzy c-means clustering with L_1-regularization

We will consider the following objective function with L_1-regularization.

$$J_{tsl}(U,E,V) = \sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ki})^m d_{ki} + \nu\sum_{k=1}^{n}\sum_{i=1}^{c}\sum_{j=1}^{p}|\varepsilon_{ki}^j|.$$

In the tolerant fuzzy c-means clustering, each tolerance vector can be solved separately. So, we consider the following semi-objective function J_{tsl}^{kij} :

$$J_{tsl}^{kij}(E) = (u_{ki})^m(x_k^j+\varepsilon_{ki}^j-v_i^j)^2 + \nu|\varepsilon_{ki}^j|.$$

To obtain partial derivatives respect to ε_{ki}^j, we will decompose $\varepsilon_{ki}^j = \xi^+ - \xi^-$, where all element of ξ^+ and ξ^- are nonnegative. Thus, the semi-objective function can be written as follows :

$$J_{tsl}^{kij}(E) = (u_{ki})^m(x_k^j+\varepsilon_{ki}^j-v_i^j)^2 + \nu(\xi^+ + \xi^-).$$

The constraints are as follows :

$$\varepsilon_{ki}^j \le \xi^+,$$
$$\varepsilon_{ki}^j \ge -\xi^-,$$
$$\xi^+, \xi^- \ge 0.$$

Introducing the Lagrange multiplier β^+, β^-, δ^+ and $\delta^- \ge 0$, Lagrangian L_{tsl} is as follows :

$$L_{tsl} = (u_{ki})^m(x_k^j+\varepsilon_{ki}^j-v_i^j)^2 + \nu(\xi^+ + \xi^-) + \beta^+(\varepsilon_{ki}^j-\xi^+) + \beta^-(-\varepsilon_{ki}^j-\xi^-) - \delta^+\xi^+ - \delta^-\xi^-.$$

Here,

$$\frac{\partial L_{tsl}}{\partial\xi^+} = \nu-\beta^+-\delta^+, \quad (15)$$

$$\frac{\partial L_{tsl}}{\partial\xi^-} = \nu-\beta^--\delta^-. \quad (16)$$

Since $\delta^+,\ \delta^- \ge 0$, conditions $0 \le \beta^+ \le \nu$ and $0 \le \beta^- \le \nu$ are obtained from (15) and (16), respectively. By using (15) and (16), the Lagrangian L_{tsl} is simplified as follows :

$$L_{tsl} = (u_{ki})^m(x_k^j+\varepsilon_{ki}^j-v_i^j)^2 + \beta\varepsilon_{ki}^j. \quad (17)$$

Here, $\beta = \beta^+ - \beta^-$ and satisfies condition $-\nu \le \beta \le \nu$.
From $\frac{\partial L_{tsl}}{\partial\varepsilon_{ki}^j} = 0$,

$$\frac{\partial L_{tsl}}{\partial\varepsilon_{ki}^j} = 2(u_{ki})^m(x_k^j+\varepsilon_{ki}^j-v_i^j)+\beta = 0.$$

From above,

$$\varepsilon_{ki}^j = -(x_k^j-v_i^j) - \frac{\beta}{2(u_{ki})^m}. \quad (18)$$

Introducing (18) to (17), the Lagrangian dual problem is written as follows :

$$L_{tsld} = -\frac{\beta^2}{4(u_{ki})^m} - \beta(x_k^j-v_i^j).$$

ISBN: 978-989-95079-6-8

This objective function is a quadratic function respect to β. From $\frac{\partial L_{tsld}}{\partial \beta} = 0$, this dual problem is solved as,

$$\beta = -2(u_{ki})^m (x_k^j - v_i^j). \tag{19}$$

From considering (18) and (19), the optimal solution of primal problem is derived. First, if $\beta \leq -\nu$, the optimal solution is $\beta = -\nu$. Second, if $-\nu \leq \beta \leq \nu$, the optimal solution is $\beta = -2(u_{ki})^m (x_k^j - v_i^j)$. Third, if $\nu \leq \beta$, the optimal solution is $\beta = \nu$. Finally, the optimal solution for ε_{ki}^j of L_1-regularized objective function is derived as follows :

$$\varepsilon_{ki}^j = \begin{cases} -(x_k^j - v_i^j) + \frac{\nu}{2(u_{ki})^m} & (\beta \leq -\nu), \\ 0 & (-\nu \leq \beta \leq \nu), \\ -(x_k^j - v_i^j) - \frac{\nu}{2(u_{ki})^m} & (\nu \leq \beta). \end{cases} \tag{20}$$

5.3 Tolerant entropy regularized fuzzy c-means clustering with L_1-regularization

From the same procedure, the optimal solution for ε_{ki}^j of tolerant entropy regularized fuzzy c-means clustering with L_1-regularization is derived as follows :

$$\varepsilon_{ki}^j = \begin{cases} -(x_k^j - v_i^j) + \frac{\nu}{2u_{ki}} & (\beta \leq -\nu), \\ 0 & (-\nu \leq \beta \leq \nu), \\ -(x_k^j - v_i^j) - \frac{\nu}{2u_{ki}} & (\nu \leq \beta). \end{cases} \tag{21}$$

6 Algorithms

Algorithms of TFCM derived in the above section are called as follows. In case of hyper-rectangle, we call these methods TsFCM(R) and TeFCM(R). In case of L_1-regularization, we call these methods TsFCM-L_1R, and TeFCM-L_1R.

Each algorithm of TFCM is calculated according to the following procedure. Eqs. **A**, **B** and **C** used in each algorithm follow **Table 1** .

Algorithm 1

TFCM1 *Set the initial values and parameters.*

TFCM2 *Calculate $u_{ki} \in U$ by Eq.* **A**.

TFCM3 *Calculate $v_i \in V$ by Eq.* **B**.

TFCM4 *Calculate $\varepsilon_{ki} \in E$ by Eq.* **C**. *If convergence criterion is satisfied, stop. Otherwise, go back to* **TFCM2**.

In these algorithms, the convergence criterion is convergence of each variable, value of objective function or number of repetition.

Table 1: The optimal solutions of each algorithm.

Algorithm	Eq.**A**	Eq.**B**	Eq.**C**
TsFCM(R)	(7)	(8)	(12)
TeFCM(R)	(13)	(14)	(12)
TsFCM-L_1R	(7)	(8)	(20)
TeFCM-L_1R	(13)	(14)	(21)

7 Numerical examples

In this section, some numerical examples of classification are shown. In these examples, '$\circ$', '$\triangle$', '$\square$' and '$*$' mean each cluster and cluster centers, respectively. Moreover, tolerance vectors are expressed by arrowed line. The value of each data are normalized between 0 and 10. In addition, $m = 2.0$ in TsFCM and $\lambda = 1.0$ in TeFCM.

A polaris data set is mapped into two dimensional pattern space and consists of 51 points. This data set should be classified into three clusters [1]. Fig. 2 and 3 are classification results of TFCM with L_1-regularization. In Fig. 2, $\nu = 2.0$ and the number of non-zero tolerance vector is 30. In Fig. 3, $\nu = 4.0$ and the number of non-zero tolerance vector is 15. Moreover, Fig. 4 shows the relation between regularization parameter ν and the average of zero parameter ratio out of 1000 trials.

From these results, it is verified that proposed algorithm with L_1-regularization can induce the strong sparseness and its sparseness is controlled by regularization parameter ν.

8 Conclusions

In this paper, we have formulated the optimization problems based on concept of tolerance and derived the optimal solutions of tolerant fuzzy c-means clustering with L_1-regularization. From these results, we have constructed new clustering algorithm. Moreover, we have verified the effectiveness of proposed algorithm through some numerical examples.

The proposed technique is essentially different from the past one from the viewpoint of handling data more "flexible" than conventional methods.

In future works, we will calculate with real data which includes data with uncertainty, e.g., the missing value of attributes. Next, we will consider another type of regularization term or constraint for tolerance vector to induce sparseness.

Abstract— *Quadratic programming can be seen both as a general approach to linear programming and a special class of nonlinear programming. Moreover, Quadratic Programming problems are of utmost importance in a variety of relevant practical fields, such as, portfolio selection. This work presents and develops a novel fuzzy-sets-based method that solves a class of quadratic programming problems with vagueness in the set of constraints. As vagueness is natural and ever-present in real-life situations requiring solutions, it makes perfect sense to attempt to address them using fuzzy quadratic programming. This kind of problem modeling is being applied in an increasing variety of practical fields especially those with logistics problems. Some illustrative numerical examples illustrating the solution approach are solved and analyzed to show the efficiency of this proposed method.*

Keywords— Fuzzy sets, decision making, fuzzy mathematical programming, quadratic optimization.

1 Introduction

In the early sixties, based on the fact that classical logic does not reflect, to the extent that it should, the omnipresent imprecision in the real world, L. A. Zadeh proposed the Theory of Fuzzy Sets and Fuzzy Logic. Nowadays Fuzzy Logic, or rather Soft Computing, is employed with great success in the conception, design, construction and utilization of a wide range of products and systems whose functioning is directly based on how human beings reason. This is specifically patent in the case of optimization problems, and particularly in so called Mathematical Programming problems. Mathematical programming is an area which solves problems that involve minimization (or maximization) of the objective function in a function domain that can be constrained or not. In this area, Quadratic Programming represents a special class where the objective function is a quadratic function and the constraints are linear. This set of problems can be formalized in the following form:

$$\begin{aligned} \min \quad & \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q x} \\ \text{s.t.} \quad & \mathbf{A x} \leq \mathbf{b} \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned} \tag{1}$$

where $\mathbf{c}$ is an n vector, $\mathbf{b}$ is an m vector, $\mathbf{A}$ is an $m \times n$ matrix, and $\mathbf{Q}$ is an $n \times n$ symmetric matrix.

Thus, on the one hand, it is clear that quadratic programming encompasses all linear problems, including applications in scheduling, planning and flow computations, and they may be used to solve some interesting combinatorial optimization problems. On the other hand, quadratic programming is a particular kind of nonlinear programming. There are several classes of problems that are naturally expressed as quadratic problems. Examples of such problems can be found in game theory, engineering modeling, design and control, problems involving economies of scale, facility allocation and location problems, problems in microeconomics amongst others. Several applications and test problems for quadratic programming can be found in [5, 7, 8, 16, 17]. Some traditional methods are available in the literature [2, 24] for solving such problems. An interesting web page about quadratic programming is [6].

Among the several applications, we will present a portfolio selection problem which is an important research field in modern finance. This problem was first introduced by Markowitz [14, 15], and provided a risk investment analysis. Vagueness, approximate values and lack of precision in this problem are very frequent in that context, and quadratic programming problems have shown to be extremely useful in solving a variety of portfolio models. In any case, it is important to point out that the aim of this work is not to solve portfolio models. They are only considered here for the sake of illustrating the fuzzy quadratic programming problems solution approach presented, which in fact is the goal and main aim of this contribution. Some works about portfolio selection problem by using fuzzy approaches can be found in [9, 11, 19, 21, 22].

Moreover, there are some cases where the parameters of the real-world problems are seldom known exactly and have to be estimated by the decision maker. Therefore, the application of Soft Computing, and Fuzzy Logic in particular, has shown, in recent years, great potential for modeling systems which are non-linear, complex, ill-defined and not well understood. Fuzzy Logic is a way to describe this vagueness mathematically and it has found numerous and different applications due to its easy implementation, flexibility, tolerant nature to imprecise data, low cost implementations and ability to model non-linear behavior of arbitrary complexity because of its basis in terms of natural language. The uncertainties can be found in the relation, constants, decision variables or in all parameters of the problem. Some authors have applied Soft Computing methodologies to quadratic programming as can be seen in [1, 3, 4, 12, 13, 18, 20, 23, 25, 26, 27].

With this in mind, the goal of this paper is to present a novel approach that transforms a quadratic programming problem with uncertainties in the coefficients and order relation of the

ISBN: 978-989-95079-6-8

set of constraints into a parametric problem and to obtain a set of optimal solutions of this new problem that belong to the fuzzy solution.

Thus, Problem (1), which is a classic quadratic programming problem, can be rewritten in the following way:

$$\begin{aligned} \min \quad & \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q x} \\ \text{s.t.} \quad & \tilde{\mathbf{A}}\mathbf{x} \leq^f \tilde{\mathbf{b}} \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned} \tag{2}$$

where $\mathbf{x}$ and $\mathbf{c}$ are $n \times 1$ vectores with real numbers and $\tilde{\mathbf{b}}$ is an $m \times 1$ vector with fuzzy numbers, $\mathbf{Q}$ is an $n \times n$ matrix with real numbers and $\tilde{\mathbf{A}}$ is an $m \times n$ matrix with fuzzy components, and the symbol "$\leq^f$" shall mean just that the decision-maker is willing to permit some violations in the accomplishment of the constraints. Both fuzzy numbers and these violations are measured by membership functions $\mu_i : \mathbb{R} \to [0,1],\ i = 1,\ldots,m$ that for each solution provide the decision maker's degree of satisfaction with the accomplishment of each constraint.

The paper is organized as follows: Section 2 demonstrates that a fuzzy quadratic programming problem can be transformed into a parametric quadratic problem and that the solution obtained by traditional techniques is an acceptable fuzzy solution. To illustrate the approach, Section 3 presents a general portfolio selection problem formulated as a fuzzy quadratic programming; Section 4 presents numerical simulations for the proposed problems and an analysis of the results obtained. Finally, in Section 5 some conclusions are pointed out.

2 A general model for fuzzy quadratic programming

In this section, a novel approach is presented to solve quadratic programming problems with uncertainties in the order relation and coefficients in the set of constraints. This approach transforms this fuzzy quadratic problems into a parametric quadratic programming problem. A quadratic programming problem with this fuzzy environment has been formulated in (2) and the following sub-section will show how the uncertainties can be dealt with.

2.1 Parametric ideas for solving a fuzzy quadratic programming problem

The fuzzy coefficients of the quadratic problem (2) are defined with fuzzy nature, that is, some violations in the accomplishment of such restriction functions are permitted. Therefore these fuzzy parameters can be determined by the decision maker.

It is clear that each membership function will give the degree of membership (satisfaction) such that any $\mathbf{x} \in \mathbb{R}^n$ accomplishes the corresponding fuzzy objective function and constraint upon which it is defined. These membership functions can be formulated as follows

$$\mu_i : \mathbb{R} \to (0,1], \quad i \in I$$

where μ is an linear membership function (and formally can also be a non linear one), and I is the set that contains all fuzzy parameters.

In order to solve this problem in a two-phase method, first let us define for each fuzzy constraint, $i \in I$

$$X_i = \left\{ \mathbf{x} \in \mathbb{R}^n \mid \tilde{A}_i \mathbf{x} \leq^f \tilde{b}_i, \mathbf{x} \geq 0 \right\}.$$

If $\mathbf{X} = \bigcap_{i \in I} X_i$ then the former fuzzy quadratic problem can be addressed in a compact form as

$$\min \{ f(\mathbf{x}) \mid \mathbf{x} \in \mathbf{X} \}$$

It is clear that $\forall \alpha, \gamma \in (0,1]$, an (α,γ)-cut of the fuzzy constraint set will be the classical set

$$X(\alpha,\gamma) = \{ \mathbf{x} \in \mathbb{R}^n \mid \mu_X(\mathbf{x}) \geq \min\{\alpha,\gamma\} \}$$

where $\forall \mathbf{x} \in \mathbb{R}^n$,

$$\mu_X(\mathbf{x}) = \inf \mu_i(\mathbf{x}), i \in I$$

Hence an (α,γ)-cut of the i-th constraint will be denoted by $X_i(\alpha,\gamma)$. Therefore, if $\forall \alpha, \gamma \in (0,1]$,

$$S(\alpha,\gamma) = \{ \mathbf{x} \in \mathbb{R}^n \mid f(\mathbf{x}) = \min\ f(\mathbf{y}),\ \mathbf{y} \in X(\alpha,\gamma) \}$$

the fuzzy solution to the problem will therefore be the fuzzy set defined by the following membership function

$$\mu_{S(\alpha,\gamma)}(\mathbf{x}) = \begin{cases} \sup\{\alpha,\gamma : \mathbf{x} \in S(\alpha,\gamma)\} & \mathbf{x} \in \bigcup_\alpha S(\alpha,\gamma) \\ 0 & \text{otherwise.} \end{cases}$$

Provided that $\forall \alpha \in (0,1]$,

$$X(\alpha,\gamma) = \bigcap_{i \in I} \{ \mathbf{x} \in \mathbb{R}^n \mid [(\tilde{A})_\alpha x]_i \leq r_i(\alpha,\gamma), \mathbf{x} \geq 0, \mathbf{x} \in \mathbb{R}^n \}$$

with $r_i(\alpha,\gamma) = [(\tilde{b})_\alpha]_i + [(\tilde{d})_\alpha]_i (1-\gamma)$.

Thus, the operative solution to the former problem can be found, (α,γ)-cut by (α,γ)-cut, by means of the following auxiliary parametric quadratic programming model,

$$\begin{aligned} \min \quad & \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q x} \\ \text{s.t.} \quad & \tilde{\mathbf{A}}_\alpha \mathbf{x} \leq \tilde{\mathbf{b}}_\alpha + \tilde{\mathbf{d}}_\alpha (1-\gamma) \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned} \tag{3}$$

Therefore, the fuzzy quadratic programming problem was parameterized at the end of the first phase. In the second phase, the parametric quadratic programming problem is presented as a multiobjective approach which is solved for each of the different α and γ values using any multiobjective optimization technique. We must find efficient solutions to parametric problem for each α and γ that satisfy Karush-Kuhn-Tucker's necessary efficient optimality conditions.

2.1.1 Methods to solve quadratic programming problems with fuzzy relations

By using the parametric idea described above a general method to solve quadratic programming problems with fuzzy relations is presented here, as described in [18]. This method is an extension of the method that was developed to solve fuzzy linear programming problems;

$$\begin{aligned} \min \quad & \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q x} \\ \text{s.t.} \quad & (Ax)_i \leq b_i + d_i(1-\alpha), i \in I \\ & x_j \geq 0, j \in J, \alpha \in (0,1]. \end{aligned} \tag{4}$$

where d_i is the violation permitted for each constraint i, $\mathbf{Q}$ and $\mathbf{A}$ are an $n \times n$ matrix and an $m \times n$ matrix with real numbers, and $\mathbf{c}$ and $\mathbf{b}$ are an n vector and m vector with real numbers.

ISBN: 978-989-95079-6-8

2.1.2 Methods to solve quadratic programming problems with fuzzy coefficients in the set of constraints

This multiobjective approach was developed in [10] to solve fuzzy nonlinear programming problems. This approach will be used to solve Problem (2) with fuzzy coefficients in the constraints set. The fuzzy solution is obtained by transforming a fuzzy nonlinear programming problem into a parametrical multiobjective nonlinear programming problem in which the parameters $\alpha, \gamma, \beta_{ij} \in [0,1],\ i = 1,\ldots,m, j = 1,\ldots,n+1$ can be treated as new decision variable.

The goal of this parametrical multiobjective problem is to minimize $f(\mathbf{x})$, maximize γ, and maximize and minimize $\alpha, \gamma,\ \beta_{ij},\ i = 1,\ldots,m,\ j = 1,\ldots,n+1$, simultaneously. Therefore, Problem (3) is transformed into a multiobjective quadratic programming problem that is stated as follows:

$$\begin{array}{ll} \min & \left[\mathbf{c^t x} + \frac{1}{2}\mathbf{x^t Q x}, \beta_{11}, 1-\beta_{11}, \ldots, \beta_{m,n+1}, 1-\beta_{m,n+1}\right] \\ \text{s.t.} & \sum_{j=1}^{n}\left((a_\alpha^L)_{ij} + \beta_{ij}\left((a_\alpha^U)_{ij} - (a_\alpha^L)_{ij}\right)\right)x_j \leq (b_\alpha^L + d_\alpha^L)_i + \\ & \quad + \beta_{i,n+1}\left((b_\alpha^U)_i - (b_\alpha^L)_i + \left((d_\alpha^U)_i - (d_\alpha^L)_i\right)(1-\gamma)\right) \\ & \mathbf{x} \geq \mathbf{0}, \alpha, \beta_{ij} \in [0,1],\ i = 1,\ldots,m,\ j = 1,\ldots,n+1 \end{array} \tag{5}$$

where it considers $m(n+3)$ new decision variables α, γ and $\beta_{ij},\ i = 1,\ldots,m,\ j = 1,\ldots,n+1$, to transform the intervals $I_{ij}(\alpha) = [h_{ij}^{-1}(1-\alpha), g_{ij}^{-1}(1-\alpha)]$ into functions of the form $z_{ij}(\alpha, \beta_{ij}) = h_{ij}^{-1}(1-\alpha) + \beta_{ij}(g_{ij}^{-1}(1-\alpha) - h_{ij}^{-1}(1-\alpha))$.

The obtained results for each α and γ value generate a set of solutions $S(\alpha, \gamma)$ and then the Representation Theorem can be used to integrate all these specific alpha-solutions and ending the second phase. Therefore the outlined solution to the parametric method is a valid solution to the fuzzy quadratic problem.

3 Portfolio selection problem

As said previously, in order to illustrate the above described two phases method for solving fuzzy quadratic programming problems, we now focus on general Portfolio Problems. It is important to point out that up to now we have not tried to improve other solution methods for this kind of important problems, but only to show how our solution approach performs. A description of a classical portfolio selection problem that was formulated by Markowitz as a quadratic programming problem is given in [15]. Assume that there are n securities denoted by S_j $(j = 1,\ldots,n)$, then this quadratic problem can be written in the following form:

$$\begin{array}{ll} \min & \mathbf{x^t \Sigma x} \\ \text{s.t.} & \mathbf{x^t E(R)} \geq \rho \\ & \mathbf{1x} = 1 \\ & \mathbf{x} \geq \mathbf{0} \end{array} \tag{6}$$

where $\mathbf{x}$ is an n vector that represents the percentage of money invested in assets, i.e., the proportion of total investment funds devoted to each security; $\mathbf{E(R)}$ is the average vector of returns over m periods because $\mathbf{R} = [r_{ij}]$ is an $m \times n$ matrix that represents the random variables of the returns of assets varying in m discrete times; ρ is a parameter representing the minimal rate of return required by an investor; and $\Sigma = [\sigma_{ij}^2]$ is a covariance $n \times n$ matrix between returns of asset which can be written as:

$$\sigma_{ij}^2 = \sum_{k=1}^{m} \frac{\left(r_{ki} - E(r_i)\right)\left(r_{kj} - E(r_j)\right)}{m-1}. \tag{7}$$

Therefore, the objective of Problem (6) is minimizing the risk variance and the investment diversification subject to a given average return ρ.

The expected return rate, ρ, is a decision maker's value that represents an expert's knowledge, then a fuzzy approach can be used in the constraint of the portfolio selection problem. Problem (6) with the use of fuzzy sets can be formulated in the following form:

$$\begin{array}{ll} \min & \mathbf{x^t \Sigma x} \\ \text{s.t.} & \mathbf{x^t E(R)} \geq^f \rho \\ & \mathbf{1x} = 1 \\ & \mathbf{x} \geq \mathbf{0}. \end{array} \tag{8}$$

Thus, Problem (8) can be rewritten as

$$\begin{array}{ll} \min & \mathbf{x^t \Sigma x} \\ \text{s.t.} & \mathbf{x^t E(R)} \geq \rho - d(1-\alpha) \\ & \mathbf{1x} = 1 \\ & \mathbf{x} \geq \mathbf{0}. \end{array} \tag{9}$$

4 Numerical experiments

The problems we use to evaluate this method are one hypothetic mathematical formulation and one fuzzy portfolio selection problem with the fuzzy approach described in Section 3. Nevertheless, they are efficient in validating the realized study. First, in subsection 4.1 we will show the formulation of the problems. Then in subsection 4.2 the computational results and a comparative analysis of the classic methods and the iterative methods responses will be presented.

The tests were all performed on a PC with two 2.26GHZ Intel® Core(™) 2 Duo processors, 4GB RAM running Ubuntu 8.10 operational system. All the problems presented in this work were resolved using **fminimax** function to solve constraint programming problems of *ToolBox Optimization* of MATLAB® 7.4.0 program.

4.1 Formulation of the numerical examples

We present some real-world and theoretical problems found in the literature with a view to validating the proposed algorithm. We simulate two quadratic programming problems both with uncertainties in the order relation and coefficients in the set of contraints.

Table 1 provides one theoretical quadratic problem that is described in [8]. The optimal solution to the problems without uncertainties is presented in the columns $\bar{\mathbf{x}}'$ and $f(\mathbf{x})$ of table 1.

In order to show the performance of our method, we use the set of historical data shown in Table 2 introduced by Markowitz. The columns 2-10 represent American Tobacco, A.T.&T., United States Steel, General Motors, Atcheson&Topeka&Santa Fe, Coca-Cola, Borden, Firestone and Sharon Steel securities data, respectively. The returns on the nine securities, during the years 1937-54, are presented in Table 2.

This example will consider performances of portfolios with respect to "return" thus defined. This assumes that a dollar of realized or unrealized capital gains is exactly equivalent to a

ISBN: 978-989-95079-6-8

dollar of dividends, no better and no worse. This assumption is appropriate for certain investors, for example, some types of tax-free institutions. Other ways of handling capital gains and dividends, which are appropriate for other investors, can be viewed in [15].By computing the average value of all the years of each column of random variables of Table 2, we obtained the expected values of each return of the securities that are described in (10). Then, using Equation (7), we computed the covariance matrix that is presented in (11).

4.2 Results and Analysis

Here we show the results obtained for the problem by the fuzzy quadratic programming method introduced in Section 2. The problem described in this work was solved by using linear membership functions as presented by Problem (3). Table 3 shows the solution of the theoretical problem described by Table 1, while the solution of the real-world portfolio selection problem, described by Table 2, is presented in Table 4.

Table 3 presents the results of the hypothetical problem with fuzzy coefficients and relation in the constraints set. Each row describes parametrical solutions to different α-cut levels of the fuzzy coefficients and each column represents parametrical solutions to different violations of the fuzzy relation in the set of constraints. Now, by applying the Representation Theorem in these parametrical solutions, we can define a fuzzy solution that describes a satisfactory solution of the fuzzy quadratic programming problem shown in Table (1).

Table 4 presents the results of the fuzzy portfolio selection problem to different α-cut levels of the fuzzy coefficients and violations of the fuzzy relation in the set of constraints. Thus, a fuzzy solution can be defined by applying the Representation Theorem in these parametrical solutions. This fuzzy solution describes a satisfactory solution of the fuzzy portfolio selection problem.

5 Conclusions

Fuzzy quadratic programming problems are of utmost importance in an increasing variety of practical fields because real-world applications inevitably involve some degree of uncertainty or imprecision, for example in logistics management. One of these problems is the portfolio selection problem, where the imperfect knowledge of the returns on the assets and the uncertainty involved in the behaviour of financial markets may be introduced by means of fuzzy quantities and/or fuzzy constraints. In this context this paper has presented an operative and novel method for solving Fuzzy Quadratic Programming problems which is carried out by performing two phases that finally provide the user with a fuzzy solution. The method has been validated by solving a number of practical problems. The solutions obtained aid the authors to follow along this line of research to try to solve real problems in practice, in such a way that oriented Decision Support Systems involving Fuzzy Quadratic Programming problems can be built.

A parametric approach that solve a fuzzy quadratic problem was proposed. The set of optimal solutions obtained by one parametric approach to each $\alpha, \beta, \gamma \in [0, 1]$ constructs the fuzzy solution by using the Representation Theorem. The authors aim is to extend the line of investigation involving Fuzzy Quadratic Programming problems in order to try to solve other practical problems.

Abstract— *In this paper we introduce an application of interval-valued systems to the segmentation of prostate ultrasound images. The system classifies each pixel as prostate or background. The input variables are the values of each pixel in different processed images as proximity, edginess and enhanced image. The system has 20 rules and is trained with ideal images segmented by an expert. Interval-valued fuzzy systems have been used due to their potential to capture uncertainty in a more robust way compared to ordinary fuzzy systems.*

Keywords— Interval-valued fuzzy sets, ultrasound image, image segmentation

1 Introduction

Ultrasound images are used in clinical settings to evaluate anomalies, tissues and organs. Ultrasound imaging is a quite common modality due to its low cost, portability and harmlessness to human body. Transrectal ultrasound images of the prostate in male patients are frequently used for both diagnosis and treatment purposes. Detecting the outline of the prostate – prostate segmentation – is therefore the first step regardless the following step is of diagnostic nature or treatment planning as for brachytherapy of prostate cancer.

Ultrasound image segmentation is strongly affected by the lower quality of these images. Speckle noise, shadows and prostate inhomogeneity make the segmentation a complicated task. There exist several methods to segment ultrasound images, a complete review can be found in [12]. Some methods use machine learning techniques to extract the objects/lesions. In those methods ideally segmented images created by an expert radiologist are used to train the system. In [18] reinforcement learning is used to train an agent devoted to segment prostate ultrasound images. Zhang et al. [20] optimize the weights of a weighed wavelet to detect microcalcifications in mamographic images. Neural networks were used in [13] to identify possible injuries in liver images and in [5] a genetic algorithm optimizes the weights of a self-organized neural network (Kohonen net).

One of the problems of the Neural Networks is the black box reasoning. In medical applications it is very useful to know how a certain task has been done the process of segmenting the image. Hence, we propose to use a fuzzy logic system to segment ultrasound images since they provide a convenient way of interpreting the tasks/results.

Due to the complexity of the ultrasound images we are going to use interval-valued fuzzy sets enabling us to represent the uncertainty that is within these images. In [9] Mendel proposes an adaptation of the fuzzy rule learning algorithm to interval type 2 fuzzy rules. Note what he called interval type 2 fuzzy sets are the same as interval-valued fuzzy sets in some cases (when $a = 1$, please see section 2). The objective of this paper is to develop an interval-valued fuzzy logic system (from now IT2FLS following the notation given in [9]) to segment prostates in transrectal ultrasound images.

Why to use interval-valued fuzzy systems instead of classical fuzzy systems? When we design a fuzzy system that is going to be trained using typical machine learning algorithms, we must choose the input variables, the output of our system and the number of rules. If we train the system with the past data, we can understand this process as function fitting problem, in which the fuzzy rule base system is a parametrized function and the training process is the modification of said parameters. This means that the output of the system fits the training data. If the system uses interval-valued fuzzy sets instead of classical fuzzy sets, the number of parameters to define an interval fuzzy rule is larger than the one needed for a classical fuzzy rule. So, in the training process, with the same data, the interval fuzzy system has more parameters, more degrees of freedom, which means it can be adjusted in a better way to the data. Some researchers suggest that this is an advantage compared to ordinary fuzzy systems. Therefore it means that for the same linguistic complexity (number of rules and number of variables) interval-valued fuzzy systems can, at least in theory, achieve better accuracy. We have made a comparative study to verify this hypotheses.

This work is organized as follows: first we present an introduction of interval-valued fuzzy logic systems. In section 3 we review Mendel's algorithm to generate an IT2FLS from training data. Later, in section 4 we present the model that we propose to segment ultrasound images. Finally we show some experimental results, conclusions and future research.

2 Interval-valued fuzzy systems

An interval-valued fuzzy set constitutes that the membership degree of every element to the set is given by a closed subinterval of interval [0,1]. The concept of type 2 fuzzy sets was introduced by Zadeh [19] as a generalization of an ordinary

ISBN: 978-989-95079-6-8

fuzzy set. The membership degree of an element to a type 2 fuzzy set is a fuzzy set in [0,1].

An interval type 2 fuzzy set $\overline{\overline{A}}$ in U is defined as

$$\overline{\overline{A}} = \{(u, A(u), \mu_u(x)) | u \in U, A(u) \in L([0,1])\},$$

where $A(u) = [\underline{A}(u), \overline{A}(u)]$ is a membership function; i.e., a closed subinterval is $[0,1]$, and function $\mu_u(x)$ represents the fuzzy set associated with the element $u \in U$ obtained when x is within $[0,1]$; $\mu_u(x)$ is given in the following way:

$$\mu_u(x) = \begin{cases} a \text{ if } \underline{A}(u) \leq x \leq \overline{A}(u) \\ 0 \text{ otherwise} \end{cases},$$

where $0 \leq a \leq 1$.

In [8]–[10], it is proved that an interval type 2 fuzzy set is the same as an interval-valued fuzzy set if $a = 1$.

Example: We can represent an interval-valued fuzzy set by means of an upper bound membership function and a lower bound membership function. In this work, all of the membership functions are going to be represented by a Gaussian function:

$$\mu_k^l(x_k) = exp\left[-\frac{1}{2}\left(\frac{x_k - m_k^l}{\sigma_k^l}\right)\right] \ \sigma_k^l \in [\sigma_{k1}^l, \sigma_{k2}^l] \quad (1)$$

In fig. 1 we show the membership function with parameter $m_k^l = 0.4$. We take $\sigma_{k1}^l = 0.05$ to represent the lower bound and $\sigma_{k2}^l = 0.1$ for the upper bound.

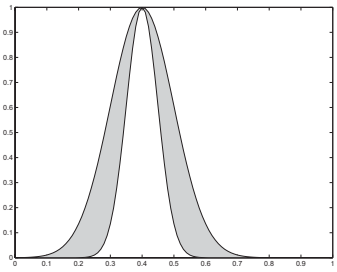

Figure 1: Interval-valued membership function with a Gaussian primary membership function and $m = 0.4$, $\sigma_{k1}^l = 0.05$ y $\sigma_{k2}^l = 0.1$.

An IT2FLS is a rule-based system in which the sets that represent the antecedents and consequents are interval-valued fuzzy sets (or interval type 2 fuzzy sets). In fig. 2 we depict the most important modules of an IT2FLS (see [9]).

The input of the system is a set of values. The fuzzfier transforms the inputs into interval-valued fuzzy sets. Then, the main part of the system, using the rules carries out the inference to generate conclusions, represented by interval-valued fuzzy sets. To use these conclusions (decisions) in the real world, the defuzzifier transforms these sets into crisp values. Commonly, before defuzzification, we can reduce the sets from interval-valued fuzzy sets to classical fuzzy sets, such a way typical defuzzifying techniques could be used to obtain crisp values.

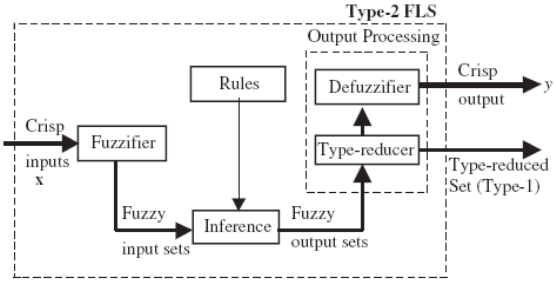

Figure 2: Interval Type 2 Fuzzy Logic System

Considering an IT2FLS with p inputs $x_1 \in X_1, \cdots, x_p \in X_p$ and one output $y \in Y$. Then we assume that the system has M rules in the following way:

$$R^l: \text{ IF } x_1 \text{ is } F_1^l \text{ AND } \ldots \text{ AND } x_p \text{ is } F_p^l, \text{ THEN } y \text{ is } G^l \text{ con } l = 1, \ldots, M \quad (2)$$

where $F_1^l, \ldots, F_p^l, G^l$ are interval-valued fuzzy sets. Each rule is interpreted as an implication:

$$R^l : F_1^l \times F_2^l, \cdots \times F_p^l \rightarrow G^l = A^l \rightarrow G^l \text{ with } l = 1, \ldots, M \quad (3)$$

R^l is described by the membership function $\mu_{R^l}(\mathbf{x}, y) = \mu(x_1, \ldots, x_p, y)$ where,

$$\mu_{R^l}(\mathbf{x}, y) = \mu_{A^l \rightarrow G^l}(\mathbf{x}, y) = \left[\bigcap_{i=1}^{p} \mu_{F_i^l}(x_i)\right] \bigcap \mu_{G^l}(y) \quad (4)$$

Using the extension of the Zadeh's compositional rule to interval-valued fuzzy sets, the consequent is calculated as follows:

$$\mu_{B^l}(y) = \mu_{A^l \circ R^l}(y) = \bigcup_{x \in X} \left[\mu_{A_x}(\mathbf{x}) \bigcap \mu_{R^l}(\mathbf{x}, y)\right] \text{ with } y \in Y, l = 1, \ldots, M \quad (5)$$

There exist several works regarding the inference with interval-valued fuzzy rules [2, 6], but in this work we are going to use the method proposed by Mendel in [9] (for a more detailed study see [10]).

3 Design of Interval-valued fuzzy systems from data

In this section we show how we can design an IT2FLS from training data.

Given a collection of N pairs of input-output data $(\mathbf{x}^{(1)}, y^{(1)}), (\mathbf{x}^{(2)}, y^{(2)}), \cdots (\mathbf{x}^{(N)}, y^{(N)})$ where $\mathbf{x}^{(t)}$ is the input vector and $y^{(t)}$ is the output value of the t training pair, we define the error of the IT2FLS for the t-th input as:

$$e^{(t)} = f_{s2}(\mathbf{x}^{(t)}) - y^{(t)} \quad t = 1, \ldots, N \quad (6)$$

where f_{s2} is the output of the IT2FLS. Such a value depends on the parameters that define the interval-valued fuzzy sets of the antecedents and consequents of the corresponding rules (m_k^l, σ_{k1}^l, σ_{k2}^l, y_l^j and y_r^j, with $k = 1, \ldots, p$, for p inputs, $j = 1, \ldots, M$, for M rules). Also y_l^j and y_r^j represent the bounds of the membership function of the consequent after

ISBN: 978-989-95079-6-8

the type reduction.
We define the quadratic error of the IT2FLS in t-th input as:

$$E^{(t)} = \frac{1}{2}[e^{(t)}]^2 \quad t = 1, \ldots, N \tag{7}$$

and the performance of the system as

$$E = \sum_{i=1}^{N} E^{(t)} \quad t = 1, \ldots, N \tag{8}$$

The training of an IT2FLS aims at finding the optimal values of the parameters that define the system such that equations (7) or (8) are minimized. If we minimize equation (7) (such a method is explained in [9]), the learning process is done in an incremental way, because the parameters are adjusted iteratively after processing every training pair. If we minimize equation (8), as we have done in this work, the learning process is done as a batch processing, because the parameters are adjusted after processing all of the training pairs. When we process all of the N training pairs and modify the parameters it is called a training epoch. In this work, in every epoch the parameters are adjusted proportional to the error gradient $\frac{\partial E}{\partial m_k^l}$, $\frac{\partial E}{\partial \sigma_{k1}^l}$, $\frac{\partial E}{\partial \sigma_{k2}^l}$, $\frac{\partial E}{\partial y_l^j}$ and $\frac{\partial E}{\partial y_r^j}$.

This quantity is calculated using the *resilient backpropagation* algorithm (RPROP, [14]). This algorithm automatically adjusts its own parameters during the training process, and is very easy to implement and can achieve a high convergence speed.

4 Proposed method

The objective of our method is to classify each pixel of the image. That is, decide if each pixel belongs to the important area (prostate) to segment or if it belongs to the background. Since the size and the position of the prostate are subject to change, the user must select the central point of the region (also called the seed point) to avoid false detections (and to focus on the segmentation itself). Therefore, the method is semi-supervised due to user suppling some relevant information. However, automation of this step is quite possible and has been repeatedly reported in literature.

The IT2FLS that we propose has 5 inputs, one output and consists of 20 rules. The inputs are:

1. pos_i: The distance, in pixels, of the pixel considered from the central point in the horizontal axes.
2. pos_j: The distance, in pixels, of the pixel considered from the central point in the vertical axes.
3. $dist$: The proximity of the pixel w.r.t. to the central point, calculated via a flooding algorithm.
4. edg: Edginess of each pixel.
5. mgr: Average gray level of the pixels neighborhood (e.g. 5×5 neighborhoods) in the enhanced image.

In the following subsections we present the techniques used to obtain the values of enhancement, proximity and edginess.

4.1 Enhanced image

The algorithm used to enhance ultrasound images is the one proposed by Sahba et al. [15, 16, 17], in which fuzzy rules such as the following have been used:

IF the pixel does not belong to the prostate,
THEN leave it unchanged
IF the pixel belongs to the prostate AND is dark,
THEN make it darker
IF the pixel belongs to the prostate AND is gray,
THEN make it dark
IF the pixel belongs to the prostate AND is bright,
THEN make it brighter

We use a simplified version of these rules in form of

IF the pixel *belongs* to the object AND is *dark*,
THEN make it *darker*,

or in a even more simple formulation and to save time we can use rules such as:

IF the pixel *belongs* to the object,
THEN make it *darker*,

where the degree of "belonging" of each pixel to the object is a function of its distance to the central point of the object or the inside of an initial/coares segment as proposed by Sahba et al. The main idea of enhancement is to eliminate the noise in the images and enhance the gray levels of selected area (regional contrast enhancement). First the noise is eliminated using a median filter (7×7 or 9×9). Then each pixel is fuzzyfied depending on its intensity with a membership function that is constructed taking into account the mean level of gray of the surroundings and the position of the selected point.

4.2 Proximity image

The proximity image represents the proximity of every pixel to the central point (similar to [7, 15, 16]), but taking into account the edges that separate the different regions of the original image. First we calculate the edges of the enhanced image using the Canny algorithm [4]. Then, starting from the central pixel selected by the user the algorithm labels the pixels with their distance to the central pixel step by step. In the first step the neighbors are labeled with distance 1 and so on (Fig. 3). The pixels marked as edge by the Canny edge detector are used as walls and cannot be labeled, so the proximity values generated are related with areas of the image.

4.3 Edginess

To create the edginess image, we calculate what is commonly called *false edges*. In [3] we presented a method to obtain false edges by means of t-norms and t-conorms. For every pixel a neighborhood matrix is constructed (3×3, 5×5, etc.). Applying t-norms to the elements of the matrix we obtain a lower bound of an interval. Applying t-conorms we obtain the upper bound of that interval. We called the length of the interval, that is the difference between the upper bound and the lower bound of the interval, false edge. The most known case is obtained when using minimum as the t-norm and maximum as the t-conorm.

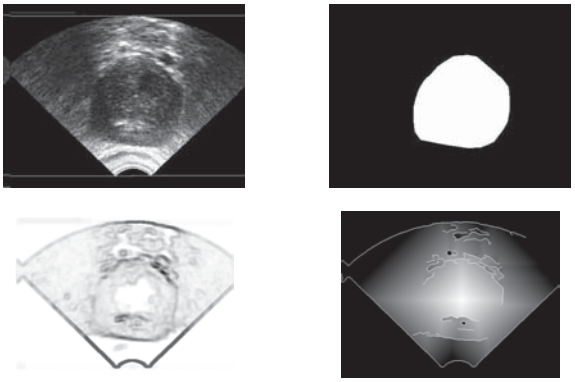

Figure 3: Top left to bottom right: Original image, ideally segmented image, edginess image, proximity image

5 Experimental results

To evaluate the performance of the IT2FLS we have a set of ten prostate ultrasound images with their corresponding ideal segmentation created by an expert. Each image has a central point of the prostate provided by the expert (for many prostate images automated detection of central point is relatively easy [1]). We use two of these images for the training and the other six for the validation. From the two training images we select randomly 200 pixels which are the training data pairs. This training data set is used to adjust the parameters of the system as described in section 3. The data is also split into two groups, the training set (80% of the data pairs) and the validation set (20%). To evaluate the performance of the IT2FLS we use an overlap measure S_A between the areas of the IT2FLS result and the ideally segmented image.

$$S_A = \frac{|Ideal \cap IBF|}{|Ideal \cup IBF|}, \tag{9}$$

where $Ideal$ is the binary image segmented by the expert, IBF is the binary image obtained using our method, $\cap$ and $\cup$ are the intersection and the union between crisp sets, respectively. Due to the initial values of the parameters of the system are selected randomly before training, we can obtain different possible solutions. In Table 1 we show the best ones after 20 trials. In Fig. 4 and 5 we show the binary images obtained by IT2FLS.

Table 1: Area overlap of segmented images with ideally segmented prostates.

Image	1	2	3	4	5	6	7	8	9	10
IVFS S_A(%)	84	61	74	75	77	75	62	64	71	72
Fuzzy S_A	86	67	77	78	77	80	71	72	70	73

Table 2: Percentage of convergence.

System	Percentage of convergence
Fuzzy	90 %
IVFS	30 %

In the experimental results we show that interval-valued fuzzy rule systems perform similar to classical fuzzy systems. The point is that the convergence of IVFS systems is really poor and also the mean performance achieved by these systems is a bit worse than ordinary fuzzy sets. It means that the extra adjustable parameters, if we dont use a specific learning algorithm with the IVFS system, are not worth in this case.

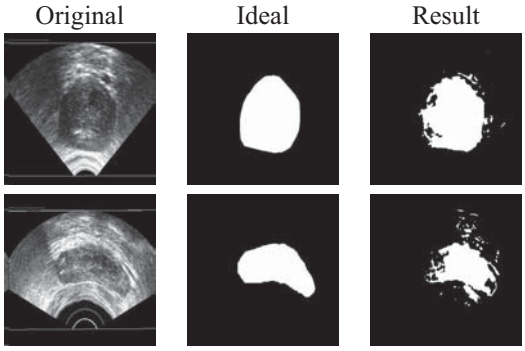

Figure 4: Comparison between ideally segmented images and IT2FLS segmented images used for training.

6 Conclusions and future research

We have proposed a new method to segment ultrasound images using an interval-valued fuzzy system. The system has 5 inputs, 20 rules and one output and can be trained using images previously segmented by an expert. An average overlap of 72% between the segmented area and the ideal segmentation has been reached. Nevertheless the results of the classical fuzzy systems are a bit better than the IVFSs system, mainly due to poor convergence of the learning algorithm.Taking into account the size of the proposed system on one hand and the challenging nature of prostate ultrasound segmentation on the other hand, the results can be regarded as promising.

The results show poor spatial consistency, which could be improved by adding some constraints or rules regarding shape and boundaries of the areas to the system. Also, we want to obtain interval input values to capture the uncertainty existing in the ultrasound images and deal with it via the IT2FLS in order to obtain better results.

Abstract*— *The need for an automatic inference process able to deal with information coming from unreliable sources is becoming a relevant issue both on corporate networks and on the open Web. Mathematical theories to reason with uncertain information have been successfully applied in several situations, but each one of these models is tailored to deal with a specific semantics of uncertainty. In this paper, we put forward the idea of using explicit representations of the different types of uncertainty for partitioning the inference process into parts. By coordinating multiple independent reasoning processes, we are sometimes able to apply a specific model to each type of uncertain information, and recombine the final results via a suitable reconciliation process. We validated our approach applying it to the classic* ***schema matching problem*, and using the* ***Ontology Alignment Evaluation Initiative****, (OAEI) tests to assess the results.*

Keywords— Uncertainty, Ontology Matching, Reasoning, Rules.

1 Introduction

The problem of automatic inference is one of the most challenging problem in computer science [1], becoming even harder when knowledge is uncertain, due to lack of reliability of the source of information, approximation, dependencies and other factors. While many mathematical models for reasoning on uncertain information have been proposed, the general problem of handling and interpretation of uncertain knowledge is still to be solved. In this paper, we put forward the idea of using explicit representations of the different uncertainties present in the knowledge base according to different uncertainty models, coordinating multiple independent reasoning processes. By splitting the inference process into parts, we are able to apply a specific model to each type of uncertain information, recombining the final results via a suitable reconciliation process. Although the interoperability among multiple inference models been studied [2, 3], in the literature we are not aware of any hybrid reasoning processes which can handle the flexible integration of different models. As a proof of concept of this approach we present a semantics-aware matching strategy, that we apply to the well-known problem of ontology alignment [4]. The paper is structured as follows: Section 2 introduces the problem of uncertain information in knowledge management, briefly presenting the different types of uncertainty and the mathematical models used for the inference process. The section also introduces the need for an explicit representation of the various types of uncertainty, referring to the Ontology of Uncertainty [5] proposed by W3C's UR3W-XG incubator group[1]. Section 3 presents a case study, applying our technique to the classic *schema matching problem*, testing it via the Ontology Alignment Evaluation Initiative (OAEI) tests and comparing the results to the participants to the OAEI 2007 contest [4]. Conclusions and future work on our framework are presented in Section 5.

2 Uncertain Information Representation and Reasoning

Experience has shown that the open Web and other platforms for hosting user-generated content can provide little quality control at content production time. As a result, most publicly available information can be considered *uncertain* to some degree. In order to clarify the notion of uncertainty, it is important to distinguish between **degrees of truth** and **degrees of uncertainty** in the information [6]. A degree of truth can be defined as the degree of compatibility between a statement and a knowledge base, which is limited to what the system knows about reality: a statement S is true if this assumption agrees with the set of statements in the knowledge base. Instead, Uncertainty of a statement arises when the knowledge base does not provide sufficient information to decide if a statement is true or false. Therefore uncertainty falls at a meta-level with respect to truth [7]. In case of truth values, we briefly mention two major theories [7]: *Classical two-valued logic* and *Fuzzy Logic*. In the first case, a statement's truth value can only assume one of two values [8], namely `0` or `1`. In the second case [9], truth values belong to the entire interval $[0, 1]$. For uncertainty representation, we distinguish between *Probability* and *Possibility theory*. The degree of probability associated to a statement is a typical example of gradual uncertainty. In sentences like: *"The player tossing a coin* wins *with 50% probability"*, "The player *wins*" is a true statement: it cannot happen that a player "half wins". The "50%" at the end of the sentence is not the statement truth value, but its level of uncertainty. *Possibility theory* is an alternative to probability theory, which separates the uncertainty of statements in possibilities and necessities [7]. Uncertainty can be classified as **Epistemic**, if it comes from the limited knowledge of the agent that generates the assertion or **Aleatory** if it is intrinsic in the observed world. Depending on the features of the agent that generates uncertain statements, is possible to identify two different types of uncertainty: **Objective** if the uncertainty derives from a repeatable observation and **Subjective** if the uncertainty in the information is derived from an informal evaluation. Furthermore, uncertainty can depend on the type of statement it is associated to: **Ambiguous**, **Inconsistent**,**Vague**, **Incomplete** and **Empiric**.

For our purposes, uncertainty can be represented as an annotation about a statement, expressing the level of certainty about it. We shall call "uncertain information" the triple

ISBN: 978-989-95079-6-8

(S, t, l) formed by a statement S, its truth value t and its corresponding uncertainty level l. It is important to remark that in many practical scenarios, we may encounter statements whose uncertainty levels have diverse semantics, especially when uncertain information is generated by multiple unsupervised processes. For example, Web-based weather forecasting services provide uncertain information in different forms; the uncertainty can be possibilistic or probabilistic (*Cloudy:"50%"*, *Rain:"10%"*) while truth value ranges can be classical (*Rainy*, *Fair*) or fuzzy (*Partially Covered*, *Heavy Rain*). Traditional approaches to uncertain reasoning support extensions of logic models dealing with inference on statements and their truth values, including mathematical theories able to deal with the uncertainty levels. In many cases, however, handling uncertainty hs an impact on the complexity and even the decidability of the inference problem. Scientific areas very active in the integration of classical logic with mathematical theories dealing with uncertainty is Artificial Intelligence and Knowledge Representation. Recently the effort was concentrated on the languages for the Web, such as in particular Semantic Web standards. For example, several probabilistic extensions of *Description Logics* (DL) [10] and *First Order Logic* (FOL) are available. Here, we shall focus the discussion on Description Logics, which are the logical model underpinning the OWL-Lite and OWL-DL ontology languages [11] used on the Semantic Web [12]. OWL-Lite and OWL-DL correspond respectively to $\mathcal{SHIF}(\mathbf{D})$ and $\mathcal{SHOIN}(\mathbf{D})$ Description Logics respectively, which are known to be tractable. A sound and complete fragment of $\mathcal{SROIQ}(\mathbf{D})$ is $\mathcal{SHOQ}(\mathbf{D})$ [13]. This fragment can be extended to handle uncertainty; in [14] Lukasiewicz defines a Probabilistic Description Logic $\mathcal{P} - \mathcal{SHOQ}(\mathbf{D})$. Based on Lukasiewicz's Probabilistic Description Logics, Klinov in [15] has implemented the probabilistic reasoner Pronto, that can reason with ontologies where a probability interval is assigned to statements, specifying the probability that a certain statement is true. As far as truth-values are concerned, the work of Straccia and Bobillo [16] extends the classical two-valued Description Logics to fuzzy sets. Namely, the authors present an extension of $\mathcal{SHIF}(\mathbf{D})$ Description Logics to the fuzzy case, dealing with different definitions for the logic operators (Zadeh logic, Lukasiewicz logic and Classical Logic); this approach, moreover, provides support to backward reasoning in case of Classical Logic semantics.

At first sight, one might hope that uncertainty representations and truth value ranges can be freely mixed according to the characteristics of the problem at hand. On the Web, vague information is usually modelled using fuzzy truth-values, knowledge uncertainty due to incomplete or defective observations is represented by Probability theory, and uncertainty arising from common sense knowledge and guessing can be handled with Possibility theory [17].

Unfortunately, the problem of dealing simultaneously with probability-based uncertainty and fuzzy truth values has been widely treated in literature but, as stated in [7] probability and possibility theories are not fully compositional with respect to all the logical connectives, without a relevant loss of expressiveness. This consideration leads to the consequence that uncertain calculi and degrees of truth are not fully compositional either. Nevertheless, some work in this direction has been proposed, by imposing restrictions to the expressiveness of the logics. The most relevant studies are: [18, 19] where the authors define *Probabilistic Description Logics Programs* (PDLP) by combining stratified fuzzy Description Logics programs with respect to degrees of probabilities in a unified framework. In [20] a definition of possibilistic fuzzy Description Logics has been proposed by associating weights, representing degrees of uncertainty, to the fuzzy Description Logic formulas. An extension of the fuzzy Description Logics in the field of Possibility theory has been presented also in [21] by annotating logic axioms with possibilities and necessity measures; by extending the approach presented in [20].

It is also important to underline that different approaches can be used to tackle the same type of uncertainty (i.e. in case of incomplete information is possible to use Possibilistic or Probabilistic theory) the choice of the best theory depends on the context. For instance, in [22] the authors use Dempster-Shafer's beliefs theory to resolve inconsistencies.

2.1 Ontology of Uncertainty

As mentioned in Section 2 uncertainty is generated from different situations and represented under different semantics. it is possible to create a classification of assertions based on several criteria: *nature*, *derivation*, *temporal validity* and *type*. Nature of uncertainty can be divided in *epistemic* and *aleatory*; *objective* and *subjective*; based on the temporal validity of a statement that can be valid for a period of time or can be valid always. A statement is *contingent* if refers to a particular situation or instant; in the second case a statement refers to situations that summarize trends (e.g. laws of physics, common sense knowledge, statistical knowledge) and is classified as *generic* statement. The nature of uncertainty, moreover, also depends on the statement it is attached to. Statements can be *ambiguous* in case the statement can be represented in different worlds with more than one interpretation, *inconsistent* if there is no possible world where the statement can hold, *vague*, and *incomplete* in case the knowledge about the observed world do not provide enough information to take a decision. Finally, a statement is *empiric* when is satisfied at least in one world. A first effort toward capturing all aspects of uncertainty is the *Ontology of Uncertainty*, published by the UR3W-XG incubator group[5]. This ontology tries to capture the nature, type and source of uncertainty that are specific of an assertion and allows moreover to relate the assertion to the correct computational model of inference. Statements, in the Ontology of Uncertainty, are represented by the concept `Sentence`, that provides information about the source (`Agent`) of the assertion, the subject (`World`) of the assertion and the semantics information about the `Uncertainty` model related to the assertions. There is not much to say about the two concepts `Agent` and `World`, which respectively represent the producer and the subject of an assertion. More interesting is the case of concept `Uncertainty`, the central concept of the ontology. This concept is related to all the various elements used to classify a `Sentence` under precise semantics. Other concepts related to `Uncertainty` are then used to describe type, derivation, validity and nature of the statement[2]. The ontology provides a generic meta-model rep-

[2]Currently, the Ontology of Uncertainty defined by the URW3-XG does not include a concept of `Validity` related to the temporal

ISBN: 978-989-95079-6-8

resented in OWL-DL [11] for representing uncertainty associated to various assertions and provides some use case scenarios, where, according to the semantics of the uncertainty, the correct inference model is selected. Unfortunately, the document [5] produced by the URW3-XG incubator group does not specify how to deal with situations where more than one model is involved in the inference process.

2.2 Using the Ontology of Uncertainty to support Reasoning

The Ontology of Uncertainty provides information on which mathematical model of uncertainty can be employed for managing a specific set of statements. When more than one model is involved in the reasoning process, the problem of integrating the results of multiple inference processes arises : if the subsets of statements handled by each model are disjoint, i.e. inferences are independent form each other, however, there are no particular problems in re-conciliating the results of the various reasoning processes;s. Some work in this direction has been carried out by the *Rule Interchange Format* (RIF[3]). In [2] the authors propose a framework for sharing information between three different models of uncertainty, where the fuzzy linguistic truth values are propagated through the three models in a non-monotonic way, by exploiting the extension principle [23] and aggregation of linguistic values. This approach is promising but is grounded to fixed fuzzy values (linguistic truth) that are used by all the different models and then aggregated according to non-monotonic rules.

In our approach, instead, we make use of the Ontology of Uncertainty as a way to model different types of uncertainty in a unified framework. The inference process involves three different steps: the first step is to partition the knowledge base in subsets according to the specific model, the second step is to carry out independent inferences, and the third one aggregates the results of the independent inference processes, following the *First Inference Then Aggregation* (FITA) approach [24], which also supports parallel reasoning. In our strategy the various reasoning processes are independent; we use the Ontology of Uncertainty classification to divide the various matching relations according to the uncertainty model to be used for the reasoning process. This way, the reasoners can be modelled as parallel processes. Directives on how to divide the heterogeneous knowledge base and how to recombine the results of the different reasoning processes are explicitly specified as DL-Safe Horn rules [25].

The knowledge base containing the information for our matching strategy is composed by a set of statements, generated independently by different sources, seen as instances of the concept `Sentence` in the Ontology of Uncertainty. To each statement S, information about uncertainty is associated by instantiating the ontology concept `Uncertainty` that defines the correct semantics. DL-Safe rules and SPARQL queries are largely involved in this process. A first set of DL-Safe rules is used to associate the statements to the correct type of uncertainty, and a set of SPARQL queries is used to divide the knowledge base according to the reasoning model associated to the statement. Finally a third set of rules is used to aggregate the results of the various reasoners. Currently, our approach requires the manual definition of rule sets. However, while the first set of rules is largely application dependent, the set of SPARQL queries and the third set of rules can be reused in many applications[4]. A detailed application of our approach is presented in Section 3.

3 A Semantics-aware Matching Strategy

Schema Matching is the time-honored problem of identifying the relations between the entities of two data source schemata. In case these schemata are represented as ontologies, this problem is also known as Ontology Alignment. In the literature different matching operators for a wide range of situations are available: the most exhaustive survey is [26].

Recent proposals tackle the schema matching problem by considering more than one matching operator at once and combining the final results through a matching strategy [27]. A **Matching Strategy** can be defined as *the process of transformation from a set of Matching Relations* Mr *to a new set* Mr', while a **Matching Operator** can be defined as *a function that takes as input two schema elements and creates as output a Matching Relation between the two elements*.

So far, even if some logic-based approaches are available [28, 29], most strategies proposed in literature neither consider explicitly the semantics of the various matching operators nor the different meanings of the relations that they generate. Instead, our matching strategy explicitly models the semantics of different matching operators as a Description Logic. In our approach, matching relations are stored as instances of a domain ontology, describing our application scenario. This domain ontology is extended with the *Ontology of Uncertainty* [5], which is used to associate the respective uncertainty to the different types of assertions. The *classification* of the various uncertainty types is performed by applying SWRL rules [30, 25] to the knowledge base. Once the classification is performed, the knowledge base is divided (by a *splitting* process) according to the specific uncertainty model. Each one of this inference models is used to perform a classification of the various relations in order to discover the most reliable ones. Finally a *reconciliation* process aggregates the best results[5].

3.1 The Matching Ontology

A matching relation mr_i is a $1:1$ relation associating two elements (concepts or attributes) of the two ontologies to align by a relation r from a collection of set theory operators ($\equiv$,$\subset$,$\supset$,$\cap$,$\neq$) and a degree of matching δ represented as:

$$mr_i = \langle e_h, e_k, r, \delta \rangle \tag{1}$$

The relation r between the elements depends on the particular feature that is analysed by the matching operator: as an example, in case of *JaroWinkler* matching operator, the features are composed by the label of the elements e_h and e_k to

validity of an assertion, but its addition is straightforward.

[3]The mission of the Rule Interchange Format (RIF) Working Group is to produce W3C Recommendations for rules interchange. `http://www.w3.org/2005/rules/wiki/RIF_Working_Group`

[4]Although they may require some fine tuning. This especially true of the third set, which is closely related to the aggregation procedure.

[5]The *classification*, *splitting* and *reconciliation* process in our system are rule driven, but this is not a strict requirement: this phases of the strategy can also be inferred from a Description Logics reasoning process used to classify various instances.

ISBN: 978-989-95079-6-8

match, while in case of an *Instance-based* matching operator the features are composed by the instances related to the elements to match.

We generally consider a matching operator as a process that generates a matching relation mr_i represented by the relation r between the elements e_h, e_k in input, associated with the strength δ of the relation. A matching operator is defined by a function f used to extract a particular feature that is analysed by the operator, a function θ which generates the relation r and a function ϕ that is in charge of the creation of the value δ, which represents the *strength* of the relation:

$$mo = \langle f, \theta, \phi \rangle \qquad (2)$$
$$mo(e_h, e_k) \rightarrow \langle e_h, e_k, r, \delta \rangle$$

Obviously, different matching operators carry different semantics that needs to be considered in the matching generation process. Also, the same relation can be generated by different matching operators; but in this case, the syntax of the relations is identical while the semantics is different. Consequently, different theories can be adopted, in order to infer the most suitable matching relations: the relations generated by the data type based matching operator can be considered as *possibilities*, while the relations generated by the instance based and string based matching operator can be modelled as *necessities* [6]. As we have seen, the Matching Ontology models the information created by the various matching operators, as well as information describing each specific matching operator. The attributes, relations and concepts from the ontologies to align are stored in the Matching Ontology as instances of the concept `Element`, represented by a unique identifier (e.g. URI) which is used by the system to retrieve the element in the original ontologies. The concept `MatchingOperator`, in the Matching Ontology, represents a generic matching operator; the specific matching operators (e.g. JaroWinkler, WordNet, Instances) are modelled as subclasses of this concept. The various matching relations are defined as instances of the concept `MatchingRelation`, which is composed by the concept `RelatedElements` that has a `subject` and an `object` that represent the two elements that have been related by one or more matching operators; and by a `confidence` value representing the strength of the matching relation. Subclasses of the concept `Matching Relation` are created in order to specialize the matching relation according to the specific relation (e.g. `Equivalent`, `Subset`, `Superset`, `Disjoint`, `Intersection`).

Instances of the Matching Ontology are generated during the matching process. The various matching operators generate a set of matching relations in the form $\langle e_h, e_k, r, \delta \rangle$; these relations are stored in the Matching Ontology with a reference to the instance of the matching operator that has generated the relation. When the Matching Ontology is generated in this way, some information is certain (e.g. the information provided by the original ontologies), and some other information in uncertain under different semantics (e.g. the matching relations that can disagree or that may have a probability degree to consider). This consideration motivates the use of additional annotations able to model the semantics of uncertainty of the various matching relations.

3.2 Managing uncertainty in the matching strategy

In a scenario like the one described in Section 3.1, we use the Ontology of Uncertainty to identify situations where is important to explicitly describe the type of uncertainty related to an assertion. First of all, the two ontologies (Matching Ontology and Ontology of Uncertainty) have to be linked somehow. Assertions in the Ontology of Uncertainty are represented by the concept `Sentence`. A sentence is `saidBy` an `Agent`, which we identify with the matching operator; moreover a sentence have also an object of the assertion (`saidAbout`) which is represented by the concept `World`. The two concepts `Agent` and `World` are then the linking point between the two ontologies; the link is defined by declaring `MatchingRelation` and `MatchingOperator` as sub-concepts of `World` and `Agent` respectively. Here, the Ontology of Uncertainty is used basically to drive the reasoning process: each type of uncertainty is processed by its specific reasoner and a final process, based on SWRL rules, integrates the results of the various reasoners. The application flow of the Matching Strategy operates as follows: a process takes as input the uncertain knowledge base generated by the matching operators, afterwards it divides the assertions according to their uncertainty and each sub part of the ontology is processed by its specific reasoner: in the system we consider a Probabilistic Description Logic reasoner, such as *Pronto* [15], a fuzzy Description Logic reasoner such as *FuzzyDL* [16] and a Defeasible Logic Reasoner such as *DR-Prolog* [3], but other models can be easily added. In our scenario the sources of information to be analysed, according to different uncertainty models are independent and no intersections among them has to be managed. This particular case allows a straightforward use of the Ontology of Uncertainty to drive the reasoning process, although in general the assumption of independence among the source of information is a lucky case.

The first part of the matching strategy is to assign to the various assertions (`Sentence`), the correct information about their uncertainty semantics. This information is classified according to a set of pre-defined SWRL rules that assigns the correct semantics in relation to several factors. The assignment is based on: (i) the `Agent` that has generated the relation; as an example: some agents can generate objective or subjective assertions: we can identify objective statements as necessities and subjective as possibilities; (ii) the presence of a degree of probability: as an example, sentences with a degree of probability can be handled with probabilistic theory models or with possibility theories. In this case is important to identify which statements need to be modelled with probability theory and which ones need to be modelled with possibility theory. (iii) the level of inconsistency among matching relations: as an example, if a sentence asserts that two elements are equivalent and another matching relation asserts that they are disjoint; (iv) the trustiness level of the matching operator: some operators are more reliable than others; (v) the level of detail of the assertion: the assertion created by a Data Type matching operator is more vague then an assertion created by a Regular Expression matching operator; (vi) the Data Type

[6] Note that this does not have a direct implication on the mappings to be created by the systems; for instance, it is clear that a necessary matching of strings does not imply a necessary mapping.

ISBN: 978-989-95079-6-8

of the elements to match can be used to establish priorities between operators.

$$\begin{aligned} uncertainty : Sentence(?sentence) \wedge \\ matching : MatchingRelation(?matrel) \wedge \\ uncertainty : saidBy(?sentence, ?operator) \wedge \\ matching : MatchingOperator(?operator) \wedge \\ uncertainty : saidAbout(?sentence, ?matrel) \wedge \\ uncertainty : Objective(?derivation) \wedge \\ uncertainty : Uncertainty(?uncer) \wedge \\ uncertainty : hasUncertainty(?sentence, ?uncer) \rightarrow \\ uncertainty : derivationType(?uncer, ?derivation) \end{aligned} \tag{3}$$

There are one or more rules for each specific uncertainty type, nature, model, derivation and temporal validity. An example of a rule that we use in this step of the matching strategy is reported in (3). In our strategy the rules are applied to the matching ontology with the use of a rule engine such as Jess[7]; the rules we use have to be restricted to the DL-Safe [25] subset to ensure tractable complexity of the reasoning processes. By applying the rules, all the matching relations are associated to their respective uncertainty.

At this point, a set of sub-knowledge bases is created by dividing the various instances of the concept `sentence` according to their uncertainty model. A SPARQL [32] query is used in this case to select the instances of the concept `sentence` that respect the desired restrictions. As an example the following SPARQL query returns the instances of `Sentence` that are associated to a probability theory model.

```
SELECT ?sentence ?type ?derivation ?nature ?model
WHERE {?sentence uncertainty:hasUncertainty ?uncertainty.
?uncertainty uncertainty:nature ?nature.
?uncertainty uncertainty:derivationType ?derivation.
?uncertainty uncertainty:uncertaintyType ?type.
?uncertainty uncertainty:uncertaintyModel ?model.
?probabilistic rdf:type uncertainty:Probability.
FILTER (?model = ?probabilistic)}
```

Once the set of assertions has been partitioned, the parallel reasoning processes can be launched. The reasoning processes are performed locally, exploiting the information provided by each assertion and the information provided by the ontologies to align. According to the information that has been provided to each reasoner, the process has to return back to the matching strategy the set of assertions that they believe to be the most reliable ones. Each reasoning process returns the results as instances of its representative concept (sub-concepts of the concept `Sentence`).

When the parallel reasoning processes come to an end, results are propagated back to the matching ontology by a reconciliation process. This process can be another reasoning process; in the case of our matching strategy we make use of SWRL rules to aggregate the results. Basically the reconciliation process follows the priority between the various reasoners that need to be made explicit. Some models are more reliable than others and this preference is defined in our system by SWRL rules. In our matching strategy we have to deal with inconsistencies because different relations on the same pair of elements can be classified as reliable relations by different reasoning processes. In case the preferences between inference models can not solve this situation we handle inconsistencies by assigning preferences between relations and operators, according to contextual factors: (e.g., analysing the data types of the elements to match. *Equivalence* relations have the highest priority in case of Strings, because Instance-based equivalence between integers is less reliable than the one between Strings). Rules are also used to propagate the best matching relations to other elements of the ontologies exploiting structural information from the original ontologies to match. This case can again be managed using a defeasible rules system such as DR-Prolog [3], which provides different precedences between rules, to help the decision process in inconsistent situations.

[7] in the Java prototype we developed, we have used Jess Rule engine (`http://herzberg.ca.sandia.gov/`) with the support of JessTab [31] and Protégé (`http://protege.stanford.edu/`) to translate SWRL rules and assertions from OWL to Jess and backwards.

4 Experimental Evaluation

Let us now describe the use of OAEI as a validating test for our data integration system. The comparison has been carried out with the results of the 2007 contest [4]. The majority of the participants of the context are based on a linear combination of several matching operators. In some cases this aggregating function is adaptive (Asmov [33], Prior+ [34]), while in some other cases it is fixed and defined by several experimentation (RiMOM [35], Sambo [36], Soda [37], Ola [38], TaxoMap [39], X-Som [40]). Some approaches are based on Possibility theory such as DSSim [28] and OWL-CM [41]. The test is performed using a palette of five semantically different matching operators (*JaroWrinkler Matching Operator, WordNet Label Matching Operator, Description Matching Operator, Type-based Matching Operator* and *Instance-based Matching Operator*). The results are stored in a matching ontology and the most reliable relations are extracted by our matching strategy. Each relation is associated to the respective matching operator. The reasoners that we used are a Fuzzy Description Logic reasoner [16] for the matching relations classified as probabilities (e.g. JaroWinkler matching operator) and a classic Description Logic reasoner [42] to process certain matching relations that the rules classify as necessities (e.g. String matching operator). The matching strategy has been developed as a Java prototype that we used to run the tests.

4.1 Results

The testbed can be divided in five subcategories:

101-104 This test set is the easiest set of tests. The first task is to match the reference ontology 101 with itself, the second test requires to generate a matching from the reference ontology to an ontology totally irrelevant (102 is a wine ontology). The ontology 103 represents a language generalization (unavailable constraints are replaced by their generalization): this ontology is an OWL-Lite generalization of the ontology 101. Finally the ontology 104 represents a language restriction with respect to the reference ontology 101. The constraints that are not available in OWL-Lite are simply removed. In the case of this first set of tests, our algorithm does not generate perfect alignments. In the case of 103 the propagation mechanism of the strategy does not perform well because of the generalization of the ontology. The various matching operators generate several reliable relations that the strategy can not recombine correctly in relation to their priority.

201-210 In this set of test cases, the structure of ontology

ISBN: 978-989-95079-6-8

Test #	Name	Prec.	Rec.	fMeas.
101	Reference Alignment	1	1	1
102	Irrelevant Ontology	NaN	NaN	NaN
103	Language Generalization	0,81	0,56	0,66
104	Language Restriction	0,94	0,94	0,94

is preserved. Syntactical changes are introduced: labels and identifiers are replaced by random names, misspellings, synonyms, language translation and moreover the comments in some cases have been suppressed. Our matching strategy obtains good results in this set of tests, because of the variety of the palette of matching operators that are considered in the strategy. In some cases (202, 209, 210) the Recall value is low, this because in case a matching operator does not create a possible relation this can not be automatically generated by the strategy. SWRL rules are used to propagate the best results to related elements, but if the matching relation is not created by any matching operator the propagation mechanism is not effective.

Test #	Name	Prec.	Rec.	fMeas.
201	No Names	0,92	0,90	0,91
202	No Names, No Comments	0,88	0,15	0,26
203	No Comments	0,97	0,97	0,97
204	Naming Conventions	0,92	0,92	0,92
205	Synonyms	0.91	0,90	0,90
206	Translation	0,96	0,70	0,95
207		0,98	0,70	0,97
208		0,96	0,72	0,82
209		0,87	0,34	0,49
210		0,92	0,12	0,22

221-247 In this case the set of tests can be divided into two subgroups: **221-231** and **232-247**. The first subgroup contains several structural modifications, such as the hierarchy that is flattened or expanded, and individuals, restrictions and data types that are suppressed. Each one of the documents in this subgroup has been modified by a structural change. Because of the fact that the labels and comments are preserved, the modifications have little influence on our system. The use of *Description Matching Operator* and *Name Matching Operator* allows the strategy to find most of the correct alignments using just the labels and comments information. In the second subgroup (232-247), the modifications made by combinations of the single modifications used in 221-231. Our system obtains good results for 232-247 as well.

Note that the observations about the Recall value we made about the previous tests, here are not valid since the ontologies provide sufficient information to the matching operators that can create reliable relations. Also in case of 222 where there is no hierarchy the results are satisfactory because of the information provided by the ontology.

248-266 This set of documents represents the most challenging case. This set combines structural and syntactical suppressions. The single challenges represented by the two previous set of documents are mixed in this set. All labels and identifiers are replaced by random names, and the comments are also suppressed. In this case our system does not perform well because no hierarchical representation is preserved so the strategy can not propagate the few correct matching found. This results in a low level of Recall. However, not enough information is provided in the ontologies, and the matching strategy can only find few alignments. The tests from 254 to 262, are the most difficult since almost all literal (labels and comments) and structural information are removed. In this case the propagation of the results can not take place because the relations that the strategy discovers can not be associated to other elements because of the structural information that is missing. When some structural information is preserved, the strategy can exploit this information in order to create possible matches, starting from the relations discovered by the single matching operators.

301-304 This test set is composed by real ontologies contextually related to the reference ontology 101. The ontologies in this test set represent bibliographical information and they have been defined independently each other. This test represents a real world case of ontology alignment. Our strategy performs in the average with respect to the other systems evaluated. In the case of ontologies 301 our approach finds most of the correct alignments, but it also returns some wrong results. The alignment results for 302 and 303 are far from satisfactory. The reason is that these ontologies do not provide individuals and with shallow class hierarchy, where classes and properties are not related. In this case as well, the recall value is low: the matching operators are very sensible to the noise in data; moreover without a useful hierarchy the few matching relations identified by the matching operators can not be propagated or enforced with the support of hierarchical information. The ontology 304 has similar structure and vocabularies to the reference ontology 101 and in this case, the results are slightly better than the previous alignments.

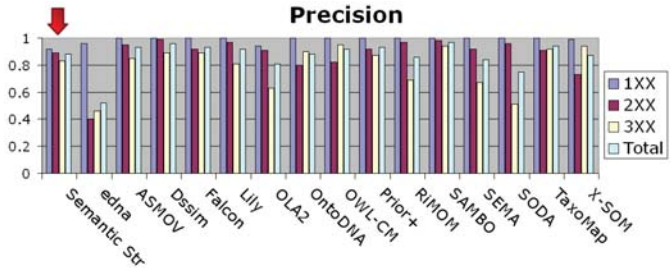

Figure 1: Graph of the Precision values of the different matching algorithms.

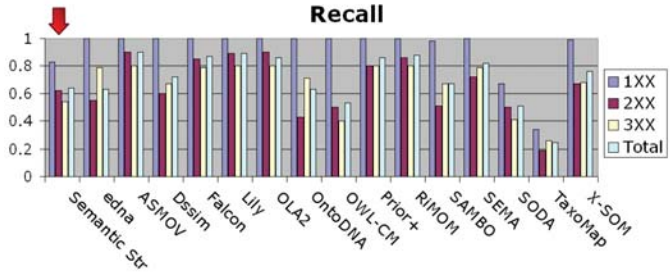

Figure 2: Graph of the Recall values of the different matching algorithms.

As one can see from the graphs in Figure 1 and 2 , our algorithm has acceptable results but under the best scores. These results are anyway reasonably encouraging, because our strategy is neither entailed to a particular reasoning model nor to a set of specific matching operator. More important our strategy does not imply a training phase that is typically required by the other systems. Our semantics-aware strategy is a new approach to ontology matching problem that provide a approach generally valid and not dependent on the domain. At this stage the results are very sensible to factors independent to the strategy; such as the quality of the matching operators and the available reasoners.

For this test we used a Probabilistic Description Logics reasoner and a traditional Description Logic reasoner in case of matching relations without a confidence degree. Moreover the inconsistencies, in the knowledge base, are not treated by a reasoning process but with the use of SWRL rules. As soon as new reasoners or new models appears we can exploit their use with our strategy. Moreover or strategy is highly customizable: if a new matching operator is plugged in the matching strategy is just necessary to create the related concept in the matching ontology and the SWRL rules reacting to the semantics of the new matching operator.

In case of the first series of test the strategy do not obtain the best results but, instead provides results under the average. Even the most simple matching operators, such as Edna, performs better than our strategy. The reason of this behaviour has been identified in the confusion of the strategy that considers the relations generated by different operator all reliable at the same level. We had run the same test only with JaroWinker matching operator and we obtained an average value of Precision 1 and Recall 1 for all the first series; this result confirm our previous assumption. In the case of the second and the third series the results are in the average of the approaches presented to the contest. The graph in Figure 1 shows the comparison of the Precision of our strategy with respect to the other algorithms. As is possible to see the values are very closed to 1, except in some isolated cases (Edna). These results show that the various strategies generate correct relations. The graph in Figure 2 shows the comparison of the Recall of our strategy with respect to the other algorithms. As is possible to see the values this time instead are far from the limit. Only few strategies (Asmonv, Falcon, Lily, OLA2) obtain results around 0.8, while the others still remain over the $0,5$. This generally low value of Recall means that the algorithm does not propagate well the good matching relations by exploiting the structure of the ontologies.

5 Conclusions

In this paper we presented preliminary work on a framework for managing different types of uncertainty and a possible application to the Schema Matching problem. The Ontology of Uncertainty, proposed by the W3C's UR3W-XG incubator group, provides a vocabulary to annotate different sources of information with different types of uncertainty. We argue that such annotations should be clearly mapped to corresponding reasoning and representation strategies. This mapping allows the system to analyse the information on the basis of its uncertainty model, running the inference process according to the respective uncertainty. In this way we can also deal with complex situations that do not tailor to the traditional strategies: as an example, matching relations provided by a user with her specific level of expertise. In our scenario the sources of information analysed, according to different uncertainty models are independent and no intersection among them has to be managed. This particular case allows a straight-forward use of the Ontology of Uncertainty to drive the reasoning process, although in general the assumption of independence among the source of information is a lucky case. The need of additional work on the Ontology of Uncertainty is necessary in order to support reasoning processes when combinations of uncertainty models are applied to a single source of information. This outlook is promising in order to provide more expressive frameworks for reasoning under different types of uncertainties, but definitely the need of more research in this direction is evident.

Fuzzy Descriptions to Identify Temporal Substructure Changes of Cooccurrence Graphs

Matthias Steinbrecher[1] Rudolf Kruse[1]

Abstract— *Cooccurrence graphs easily grow very dense when applied to represent binary association patterns of large amounts of data. Therefore, postprocessing is needed to extract valuable information from them. We propose an approach to identify subgraphs of cooccurrence graphs that show a certain temporal behavior. This behavior is described with linguistic variables and fuzzy connectives defined over the change rate domains of certain graph measures. These measures assess graph properties whose change over time the user is interested in. To justify our proposed method, we are going to present evidence from a real-world dataset.*

Keywords— Cooccurrence graphs, Temporal change, Fuzzy description

1 Introduction

Frequent pattern mining has become a prominent method for identifying patterns in large volumes of data and led to algorithms for postprocessing these patterns [1] or transfer the underlying ideas to other data structures such as graphs [2, 3, 4]. Since the search for frequent patterns necessarily has to deal with subsets of input data, one easily runs into the problem of combinatorial explosion which is reflected by the common problem of finding more patterns than there are input data. We have addressed this issue in previous work [5], arguing that the user requires tools that allow to filter the results in order to identify only those results that meet his criteria (such as interestingness, novelty, etc.). In addition to that we also provided arguments and empirical evidence [6] that patterns usually do not arise all of a sudden but evolve or disappear rather slowly as time passes. In consequence we proposed a method that allows the user to specify linguistically (in terms of fuzzy variables) the temporal behavior of the values of association rules' evaluation measures that he is interested in. The presented algorithm thinned out the entire rule set retaining just those rules that matched the users' concepts (to some degree).

In this paper we develop this idea further while keeping the way of describing temporal behavior (explained in the background section) but transferring it to a different area of application.

This area of application comprises the identification of interesting substructures in cooccurrence graphs. These graphs arise quite naturally wherever, theoretically speaking, one is interested in the fact that two entities share some property with respect to a so-called location (which not necessarily has to be a spatial artifact but often is). Two authors being cited by the same paper [7], two persons having visited the same website [8, 9, 10], or two crimes being committed at the same location are just three examples of cooccurrences. We will elaborate the possible applications later in the future work section. All these examples can be represented by an undirected graph with the node set comprising all possible locations and the weighted edges representing the cooccurrences. A typical graph of a real-world application is depicted in Fig. 1. It represents 100 locations in a 3D gaming environment. Whenever two locations have been visited by the same players, an edge is inserted (which also gets assigned a weight drawn as the width of the edge representing the number of common visitors, but this is omitted here). It is pretty obvious that a user needs some assistance tools that allow him to identify interesting substructures (edge combinations). This becomes even more important if we have multiple such graphs representing the cooccurrences of different time frames (e. g. weeks or months). The focus of this paper is to present a straightforward yet powerful approach how to identify common substructures in a collection of cooccurrence graphs by means of linguistics expressions that address the temporal change in these patterns.

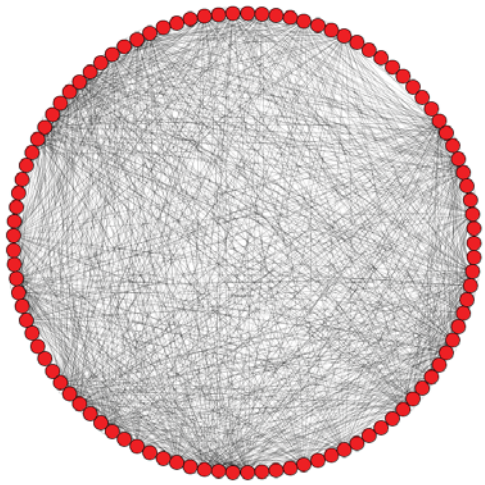

Figure 1: A typical cooccurrence graph with 100 nodes as it arose in a small-sized application (online gaming players that having visited the same locations in a 3D world). It is clear that this representation calls for some means of postprocessing in order to extract usable information from it.

The remainder of this paper is organized as follows: Section 2 introduces the notation used throughout the paper and revisits the linguistic filtering introduced in [6]. Section 3 mo-

ISBN: 978-989-95079-6-8

tivates and presents the method of extracting substructures of cooccurrence graphs that exhibit a certain user-specified temporal behavior. To underpin our proposal, we use a real-world dataset to illustrate the different stages of analysis in Section 4. Since this dataset reveals substructures that could not have been better generated manually, we refrain from handcrafting an artificial dataset and use selected subsets instead. We conclude our paper in Section 5 and propose other applications as well as possible promising extensions.

2 Background and Nomenclature

2.1 Graph Notations

In this paper we are going to deal exclusively with undirected graphs which we model as a tuple $G = (V, E)$ with vertices V and edge set E with

$$E \subseteq V \times V \setminus \{(v, v) \mid v \in V\},$$

and the constraint

$$(u, v) \in E \;\Rightarrow\; (v, u) \in E$$

to emphasize the undirected character. We will interpret the graphs as cooccurrence graphs where edges determine the number of cooccurrences (of whatever kind). This is taken into account with an edge weight function for every edge $e = (u, v)$:

$$w : E \to \mathbb{N}_0 \;\text{ with }\; w(e) = w(u, v) = w(v, u).$$

In the figures, this weight is represented as the edge width, thus we use the notion *width* and *weight* interchangeably. Given a subset $W \subseteq V$, we can induce a subgraph $G_W = (W, E_W)$ with

$$E \supseteq E_W = \{(u, v) \mid u, v \in W \wedge (u, v) \in E\}.$$

In the remainder we will sometimes use such a subset W in the context of a graph; it is G_W that we then refer to. A threshold θ defines the subgraph $G_\theta = (V, E_\theta)$ with

$$E_\theta = \{(u, v) \mid (u, v) \in E \wedge w(u, v) \geq \theta\},$$

i. e., as the graph containing only edges with a weight greater or equal to θ. Both operations can of course be combined, i. e., $G_{W,\theta}$ represents the subgraph of G induced by the node set W after having removed all edges with weight less than θ.

Since we will deal with sequences of graphs, we denote the temporal index as a superscript. All graphs share the same node set V and differ only in their edge sets or edge weights or both. Given a sequence $G^{(1)}, \ldots, G^{(n)}$ of graphs, we define the sum of these graphs as follows: $G_\Sigma = (V, E_\Sigma)$ with

$$E_\Sigma = \bigcup_{i=1}^{n} E^{(i)} \;\text{ and }\; w_\Sigma(u, v) = \sum_{i=1}^{n} w^{(i)}(u, v).$$

2.2 Linguistic Filtering Revisited

As described in [6] it is not only important to find patterns that meet some predefined constraints (such as minimum support or confidence) but also interpret these patterns in terms of temporal change. If a pattern describes a problem in some domain or an interesting customer behavior, it might be of interest to find such evolving patterns early. The underlying idea is as follows: given a pattern, we devise a set of evaluation measures that characterize the particular pattern (in [6] we used association rule measures such as support, lift, confidence, etc.). Next, the time series of a user-selected subset of these measures is calculated for every pattern. Each time series in turn is aggregated to a single value representing the overall trend, if any. The domain of this aggregate (i. e., the change rate domain) is equipped with an adequate fuzzy partition. Given a fuzzy rule antecedent (representing the user's intention of what temporal behavior of which measure(s) he is interested in), for every rule a membership degree to this concept is computed and an ordered list of rules according to these degrees is returned.

3 Spatio-temporal Filtering

3.1 Motivation

The objective of our approach is to answer questions of the following type (given a sequence of cooccurrence graphs):

> "First, what are interesting candidates for subgraphs that it would be worth looking at over time?"

and

> "Second, given a (still intractable large) set of subgraphs, which graphs become more sparse and less balanced over time?"

Before we turn to the algorithmic part of our approach, we need to negotiate which types of substructures within the graphs are most interesting to users. We will exploit the edge weights for this purpose. Several measures are needed to quantify for every subgraph aspects such as size, completeness, edge balance, etc.

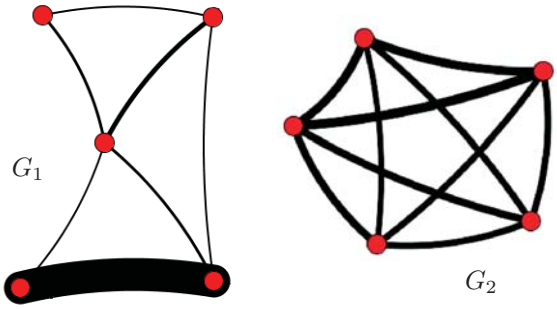
If the cooccurrence graphs represent visits of different web pages within the same online shop portal, then it might be desirable to know whether customers are able to use the web portal as intended by the owners. Are there dead ends where users are stuck? What are the "hot spot" sites, i. e., the pages that attract the most users and are visitors able to find the recently introduced shortcut to related pages? How do the accesses to the support area of the site change after renewing the navigational aids, etc.

We explicitly stress that subgraphs that are heavily interconnected with large edge weights only provide us with a *hint* that there may be an interesting visiting pattern. However, we can never conclude transitivity just from the cooccurrence graph! This is due to the fact that it only represents *binary* cooccurrences. Even a fully connected graph does not tell us anything about individual events. The sets of cooccurring events whose cardinality is represented by the edge weights even might be mutually disjoint. However, these subgraphs are found to be valuable hints that are worth being investigated.

3.2 Graph Measures

Focussing on the before-mentioned type of aspects one can identify highly connected subgraphs with large edge weights to be one type of substructures that are most interesting to users. Another type may be single edges just connecting two nodes or substructures that are highly interconnected but with

ISBN: 978-989-95079-6-8



Measure		G_1	G_2
size	Size	5.0	5.0
comp	Completeness	0.7	1.0
wght	Total Weight	5082.0	7906.0
avg	Average Weight	726.0	790.6
med	Median Weight	257.0	770.0
dev	Std. Dev.	1191.1	129.3

Figure 2: Two graphs with the same number of nodes. G_1 lacks three edges to be complete, therefore the completeness is just 0.7, whereas the clique G_2 yields 1.0. The rather large difference between average weight and median weight for G_1 (in contrast to G_2) indicate an imbalanced edge widths distribution which is strengthened by the large standard deviation value. The two graphs obviously justify this finding. The layout only acts as a visual cue and thus does not have any influence on the graph measures.

a large imbalance in the edge weights. The latter might represent two active sets of websites (large edge weights) between which users are able to navigate back and forth (numerous edges in between but with small weights since not every user is likely to use the offered navigational freedom).

The last arguments call for measures that on the one hand capture the mentioned properties of subgraphs and on the other hand allow to build a fuzzy partition on their domains since we are not going to ask for subgraphs *with 9 nodes and edges with weights greater than 100* but for *large* subgraphs with *moderately sized* edges. We use the following set of (sub)graph measures to quantify different aspects:

$$\begin{aligned}
&\text{Size} && \operatorname{size}(G_W) = |W| \\
&\text{Completeness} && \operatorname{comp}(G_W) = \frac{2\,|E_W|}{|W|^2 - |W|} \\
&\text{Edge Weight} && \operatorname{wght}(G_W) = \sum_{e \in E_W} w(e)
\end{aligned}$$

The size simply represents the number of nodes of the subgraph, whereas completeness refers to the relative number of edges compared to the maximal number. Zero represents an isolated graph (no edges) while a value of 1 designates a clique. Finally, the edge weight simply returns the sum of all edge weights without giving any clue about the distribution of these weights among the edges. Therefore, three additional measures are used: $\operatorname{avg}(G_W)$ calculates the arithmetic mean of all edge weights, $\operatorname{med}(G_W)$ returns the median of the weights and $\operatorname{dev}(G_W)$ represents the standard deviation of the weights. Fig. 2 illustrates these intentions with two graphs of the same size. Note, that these are subgraphs from real-world data and no artificial graphs that were crafted to meet the requirements.

3.3 *Candidate Graph Generation*

As we are now equipped with measures to assess certain aspects of subgraphs that we would like to track over time, the remaining question is how to determine such candidate graphs? It is clear that a brute-force approach (testing all subsets of nodes as potential subgraph node sets) fails immediately due to runtime problems, even for small node sets. We therefore promote the following heuristic: The graphs of all time frames are added as shown in Section 2 to arrive at the sum graph G_Σ (or simply the cooccurrence graph if we ignore the time frames). Next, a threshold θ is chosen and the graph's components (disconnected subgraphs) $\mathcal{C}_{G_\Sigma} = \{C_1, \ldots, C_j, \ldots, C_m\}$ of $G_{\Sigma,\theta}$ are taken as the candidate subgraphs. The choice of θ can be entirely left to the user (e. g. by offering a graphical preview tool that shows the components instantly whenever the user selects a new threshold via a slider) or θ may be determined in such a way to limit either the number of components or the (average) size of the components.

3.4 *Matching Against Linguistic Concepts*

Whatever way of determining the granularity of components is chosen, we are left with a set of mutual disjoint node sets $\mathcal{C}_{G_\Sigma}$ that are used to create a sequence of subgraphs $\left\langle G^{(i)}_{C_j} \right\rangle$, $i = 1, \ldots, n$, $j = 1, \ldots, m$ (one sequence for every subgraph induced by the node set) that are evaluated against the user-specified temporal behavior description. A time series is generated for every measure referenced in this user description. The temporal change within this time series is computed and the degree of membership to the user description is calculated. We will employ a simple regression approach, i. e., we fit a regression line into the time series and interpret its slope as an indicator of decrease, stability and increase.

The example concept from the motivation of this section is repeated here:

"Completeness is decreasing and std. deviation is increasing"

Translated into a linguistic concept, the user may specify

$$\langle\, \Delta_{\text{comp}} \texttt{ is decr} \,\wedge\, \Delta_{\text{dev}} \texttt{ is incr} \,\rangle\,,$$

which is evaluated to

$$\top\left(\mu^{(\text{decr})}_{\Delta_{\text{comp}}}(C_j), \mu^{(\text{incr})}_{\Delta_{\text{dev}}}(C_j)\right),$$

where $\top$ represents a t-norm modelling the fuzzy conjunction (we use $\top_{\min}(a,b) = \min\{a,b\}$ in this paper). Fig. 3 depicts an example subgraph consisting of 9 nodes. Five time frames are shown with the respective edge weights. The graph is obviously becoming less dense with time, i. e., the completeness is decreasing. The chart for this measure is depicted in Fig. 4. In analogy to this, Fig. 5 shows the increasing deviation of the edge weights which is attributed to the emergence of the strong cooccurrence (the sudden appearance in this case can be explained with time frames that were too large to appropriately cover the short period during which this strong cooccurrence emerged). If we equipped the change rate domains

ISBN: 978-989-95079-6-8

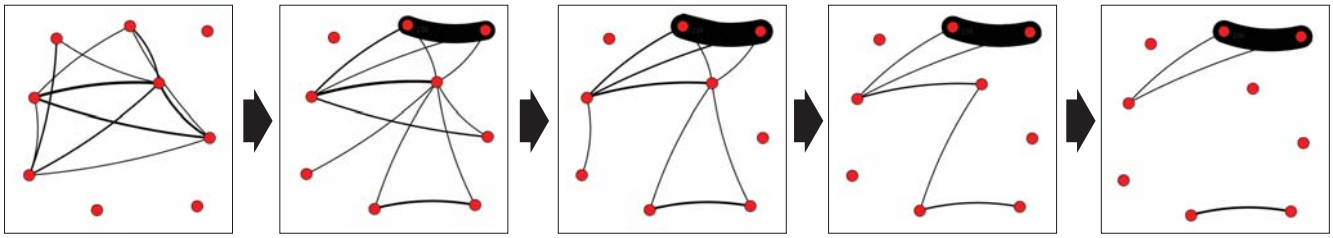


Figure 3: The temporal evolution of the graphs induced by a set of nine nodes. The number of edges is decreasing with time resulting in an almost isolated graph. Simultaneously, the edges that are remaining grow more and more unbalanced, i. e., the deviation of the edge weights is increasing. Both time series of the corresponding measures comp and dev are shown in Fig. 4 and Fig. 5, respectively.

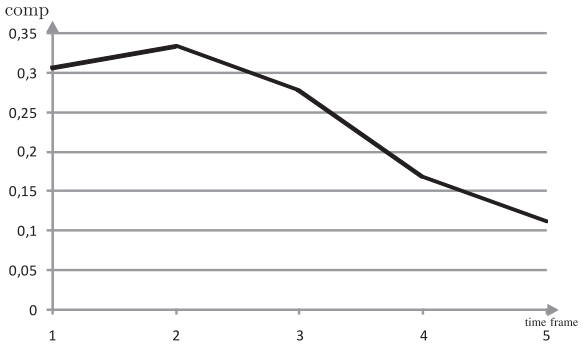

Figure 4: Time series with decreasing trend for the completeness of the edge weights for the five graphs of the time frames depicted in Fig. 3.

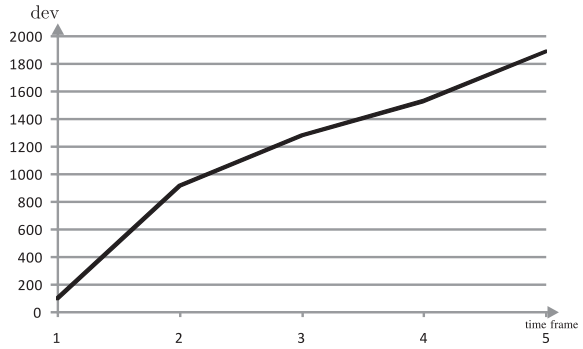

Figure 5: Time series with increasing trend for the standard deviation of the edge weights for the five graphs of the time frames depicted in Fig. 3.

(i. e., domains of the slopes of the regressions lines of the two time series) with appropriate fuzzy partitions (as we will do it in the experiments section) we could calculate the membership degree of this node set to the above-mentioned linguistic concept.

Summarizing, we state the following procedure:

1. Given a sequence $G^{(0)}, \ldots, G^{(n)}$ of cooccurrence graphs with their sum graph being G_Σ.
2. Based on an appropriate value θ, we calculate the candidate graph node sets $\{C_1, \ldots, C_m\}$ which are the vertices of the components of $G_{\Sigma,\theta}$.
3. The user provides a set of linguistic descriptions (fuzzy rule antecedents) that refer to the temporal change of the graph measures.
4. Provide fuzzy partitions for every domain of the change rate of the measures used in the descriptions of step 3.
5. Evaluate for every graph G_{C_j} the degree of membership to the linguistic concepts of step 3.
6. For every linguistic concept sort the graphs in descending order with respect to their membership degrees.

4 Experiments

Now that we have a tool at hand that allows us to determine the structural changes of subgraphs over time, we demonstrate the applicability with a real-world dataset that was already used to illustrate the examples above.

This dataset contains player contacts at certain locations within a 3D environment over a time period of six months. We carefully selected a subset of 100 such locations and discretized month-wise in order to result in a dataset large enough to justify the need for filtering while simultaneously being able to extract subgraphs that exhibit a structure and behavior that could not have been crafted more exemplary by hand. Therefore, we refrain from creating an artificial dataset with just the same structures.

Fig. 6 shows the sum graph of the dataset, i. e., the cooccurrences of six months among 100 locations. The edge weights indicate some subgraphs that are worth looking closer at. The threshold θ has been chosen to be 1000 to induce the candidate node sets.

We will match two linguistic concepts against these graph candidates: first, we are interested in decay, i. e., in graphs that show kind of a dissolving behavior, translating into a decreasing completeness and decreasing total weight. In the sample data this might indicate locations whose attractiveness is diminishing. A second concept that we would like to assess is that of an establishing pattern. An increasing average edge weight and deviation (of edge weight) might point out a phase of initial apparent random visiting of multiple locations which accumulates into a strong favored visiting pattern.

4.1 Concept 1: Decreasing Completeness and Weight

In order to evaluate the membership degrees to the linguistic concept

$$\langle\, \Delta_{\mathrm{comp}} \texttt{ is decr} \wedge \Delta_{\mathrm{wght}} \texttt{ is decr} \,\rangle,$$

ISBN: 978-989-95079-6-8

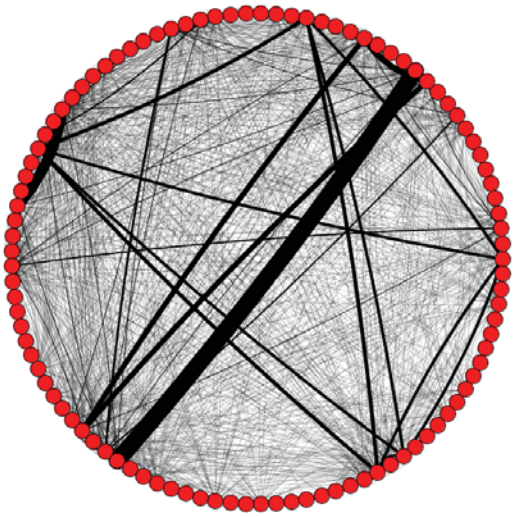

Figure 6: The sum graph of six months of visiting history of players in a 3D environment. We will match the major components (extracted via a user-specified threshold) against two linguistic concepts.

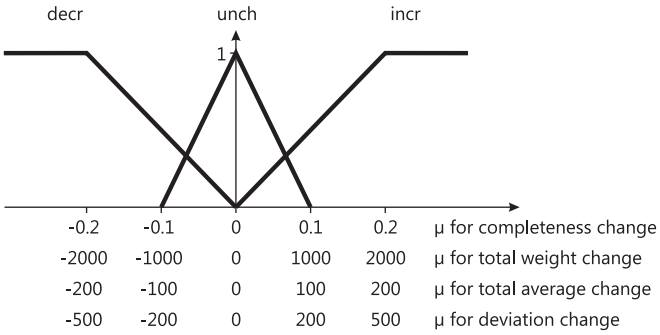

Figure 7: Fuzzy partitions for the four graph measures used in the two experiments.

we need to declare a fuzzy partition on the change rate domains of comp and wght. Fig. 7 displays all used fuzzy partitions. We apply three fuzzy sets. Note the asymmetric slopes of the borders. This setup has proven to be useful in this context since "unchanged" has a more strict semantic to users than the adjectives "decreasing" and "increasing". The respective values that determine the particular fuzzy partition can be read from the four different horizontal scales. These values have been selected with respect to the dataset since the quantity that renders a slope to be highly decreasing or increasing differs, of course, from dataset to dataset.

If we apply the linguistic concept to the candidate graphs and select the one with the highest membership (ignoring the remaining ones here for brevity), the subgraph whose history is depicted in the upper row in Fig. 8 scores 0.71. Most of the high degree can be attributed to the rapid loss of visits in the last two months. The membership degree was evaluated via

$$\min\{\mu^{(\text{decr})}_{\Delta_{\text{comp}}}(C_1), \mu^{(\text{decr})}_{\Delta_{\text{wght}}}(C_1)\} = \min\{0.71, 0.84\} = 0.71,$$

with C_1 being the set containing the five nodes. Data inspection revealed a newly set up structure which was heavily frequented shortly after opening followed by abating excitement.

4.2 Concept 2: Increasing Average and Deviation

We follow the same procedure to find the subgraph that scores best on the concept

$$\langle\, \Delta_{\text{avg}} \texttt{ is incr} \,\wedge\, \Delta_{\text{dev}} \texttt{ is incr} \,\rangle\,.$$

The lower part of Fig. 8 shows the resulting graph with a score of

$$\min\{\mu^{(\text{incr})}_{\Delta_{\text{avg}}}(C_2), \mu^{(\text{incr})}_{\Delta_{\text{dev}}}(C_2)\} = \min\{0.83, 0.89\} = 0.83,$$

The graph shows an establishing link between two nodes in parallel with a weakening in the remaining edges thus rendering the graph history becoming more unbalanced.

5 Conclusion and Future Work

In this paper we discussed the need to postprocess cooccurrence graphs if they grow very dense in practical use. We put forward a heuristic that allows to restrict the candidate node sets, and transferred the fuzzy concept matching approach from [6] to the graphical setting. We provided empirical evidence of the applicability by analyzing a real-world dataset containing six months of game player visits to 100 locations in a 3D environment.

As indicated in the introductory section, there are many other scenarios for which such an analysis might be interesting. We are most interested in applying our method to a web click stream analysis.

Since the used real-world dataset contained time stamps for every event, it is possible to generate a directed graph that also indicates which nodes were the source and target nodes for different users. This requires, of course, some heuristic with which to decide what should be the maximal period in which a user has to commit two visits to different nodes in order to assume that it was a transition and not just two independent visits.

A shortcoming of the presented approach is the heuristic to generate the candidate node sets. It worked well on the underlying datasets but one can imagine that it will return fewer and more interconnected components the more the threshold θ is reduced. Such subgraphs are also referred to as *giant connected components* [11]. To address this problem, we intend to phrase the problem in the setting of the emerging area of graph mining, more specific finding common substructures in a *single* graph [2, 12]. However, we will need a more specific subgraph definition since we have to account for the edge weights and not only the edge presence. This in turn automatically leads to another area of investigation: devising more sophisticated graph measures such as the edge betweenness centrality [13].

Abstract—*The aim of this study is to develop oil content measurement system using transmitted and scattered intensity. Two fluorescence analyses would be suggested with methods that it can use rapidly, continuously, conveniently and accurately in long-distance cruise vessels. The present paper consists of the structure of fluorescence measurement hardware and an interpretative analysis of experimental data. Proposed rule-based fuzzy concentration map offers the possibility of the conversion of fluorescence into oil content. This measurement method would be applied oil discharge monitoring control equipment in cruise vessels.*

Keywords—oil content meter, oil discharge monitoring system, fluorescence analysis, rule-based fuzzy concentration map.

1 Introduction

Maritime pollution controls are effected through the working of the MARPOL Convention and its associated Annexes, as developed by the IMO(international maritime organization) Maritime Environmental Protection Committee, MEPC. The vessel have an OFE(oil filtering equipment) on board. From 6 July 1998, all ships of 400 gross tonnages and above, regardless of age, must be fitted with 15ppm OFE. Some ships were able to use 100ppm OFE, but this is no longer acceptable. According to regulation 10(3)(b) of Annex I processed bilge water from machinery spaces is only allowed to be discharged into the sea through OFE system in a Special Area of Annex I to MARPOL 73/78 Convention [1].

The problem of detecting oil in water has practical significance, especially in the environment [2-3]. Optical measurement techniques are analytical methods commonly used in instrumentation for online measurement of oily water [4-5]. Online optical sensors have been used to monitor for example the coagulation and filtration processes in the water industry [6]. Online nephelometers have been used to measure oily water distributions [7]. In a study of smart nephelometer, artificial neural networks have been used to interpret online nephelometer data [8].

This paper, after working the sensing system with the halogen fluorescence, will attempt to analyze characteristic of the oil content. By comparison with the transmitted and scattered intensity of 25*mg/l* and 1000*mg/l* samples, proposed rule- based fuzzy concentration map is classified into different kinds of oil content. The following section provides a experimental system. Section 3 presents proposed rule-based fuzzy concentration map, section 4 and 5 show experimental result and contains concluding remarks.

2 Experimental System

A fluorescence measurement system is shown in Fig. 1. And system prototype is shown in Fig. 2. The experimental system consists of light emitting part, light receiving part, signal measurement part, and analyzing part.

2.1 Light Emitting Part

The component of the hydrocarbon of oil had strong fluorescence absorbance at the wavelength of about between 600*nm* and 900*nm* [9-10]. The halogen lamp provides the necessary spectral response for emission at between 200*nm* and 900*nm* [11]. So halogen light exhibits high absorption in

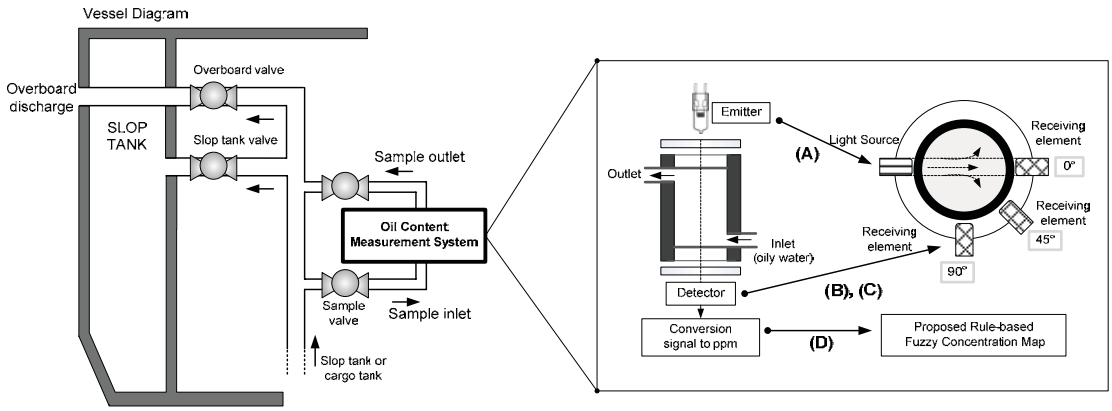

Figure 1: Schematic of fluorescence measurement system,
(A) light emitting part, (B-C) light receiving and signal measurement parts, (D) analyzing part.

ISBN: 978-989-95079-6-8

oil, system prototype was to use halogen lamp as the source of light.

2.2 *Light Receiving Part*

Since the required photo-detector of oily water should detect wavelengths about between 600*nm* and 1000*nm*, the most suitable sensor was found to be the photodiode that spectral response range is between 320*nm* and 1100*nm*. As in the case of the system prototype, voltages are being measured. Since photodiodes generate low current, it is connected to a resistor to transform the measured current to voltage as shown in Fig. 4. And resistor should have a large value in order to attain high voltages the data acquisition board, because there is no amplifier in this system. The transmitted and scattered fluorescence intensities are measured. Each sensor is positioned at 0˚, 45˚, 90˚ as shown in Fig. 1.

2.3 *Signal Measurement Part*

The signal sources of photodiodes are floating or nonreferenced signal source [12]. A floating signal source is not connected to the building ground system, but has an isolated ground-reference point. For examples of floating signal sources are outputs of thermocouples, battery-powered devices, optical isolators, and isolation amplifiers. Since the voltage level of the floating source can move, data acquisition board then saturates, causing erroneous readings. So resistors are used as illustrated in Fig. 3. These resistors, called bias resistors, provide a DC path. V_m is the measurement voltage. In this experiment, light oil samples were prepared with two types, 25*ppm* and 1000*ppm*. The data acquisition were being measured 30 seconds, and sampling rate of 2*kHz*.

2.4 *Analyzing Part*

The experimental results are shown in Fig. 4-5. There is a significant disparity between transmitted and scattered. It shows that the more oil content increases, the more transmitted intensity is decreased. And scattered intensities are increased. Given experimental results, the component of the oil contamination may be seen as absorbing and scattering wavelength based on the hydrocarbon. Although there is not a stark contrast between samples with marked oil content, data-sets have fluorescence patterns to classify. So attention was directed to conversion from fluorescence intensity to oil content using proposed rule-based fuzzy concentration map.

3 Rule-based Fuzzy Concentration Map

Proposed algorithm consist of two variables of fuzzy inference system`s output and one fusion parameter as shown in Fig. 6. ρ_t, ρ_c, ρ_f are predicted oil content, λ is fusion effect ratio, and s_0, s_{45}, s_{90} are optical sensor signals that is positioned 0˚, 45˚, 90˚. The hypothesized relationship between transmitted intensity and scattered intensity is written:

$$\rho_f = (1-\lambda)\rho_t + \lambda\rho_c + \varepsilon \tag{1}$$

where ρ_t, ρ_c denote the independent variables of sub predicted oil content of ANFIS output, ρ_f denotes the final estimated oil content, λ is the fusion effect ratio, and ε is the noise term reflecting other factors that influence content.

The following sections provide proposed structure, fuzzy concentration map and multiple regression analysis.

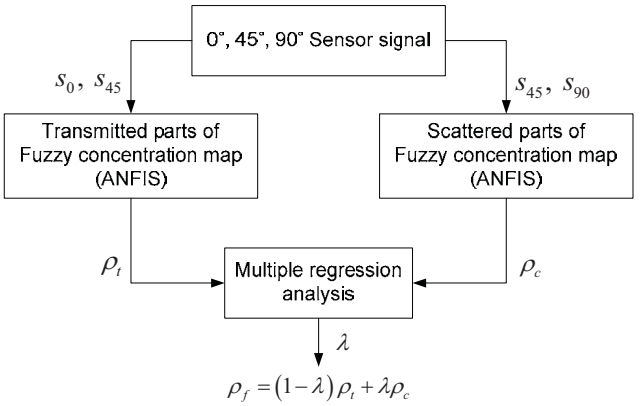

Figure 6: Proposed rule-based fuzzy concentration map.

3.1 Fuzzy Concentration Map

Proposed rule-based fuzzy concentration map presents a modeling method for oil content measuring in the form of ANFIS [13,14]. ANFIS(adaptive neuro-fuzzy inference system) represent TSK(Takagi-Sugeno-Kang) fuzzy models as shown in Fig. 7(a). ANFIS are adaptive networks that are functionally equivalent to TSK fuzzy inference system as shown in Fig. 7(b). *Prod* is the product of all incoming signal or *T*-norm operator that *AND* can be used. *Norm* is the normalized firing weights. The fuzzy concentration map shown in Fig. 7(c) classifies the input space of sensor signal into *n* regions which are assigned a labelled class of oil content. Every *n* region is an adaptive node with a node equation (2).

$$O_i = \bar{w}_i f_i = \bar{w}_i \left(p_i x + q_i y + r_i\right) \tag{2}$$

where $\bar{w}_i$ denotes the normalized firing weight from *i*, and p_i, q_i, r_i are the parameter set of *i* region. These are referred to as consequent parameters.

The fuzzy concentration map predicts oil content of transmitted and scattered part, which computes the overall output as the summation of all *n* regions in (3).

$$\rho_{ppm} = \sum_i O_i = \sum_i \bar{w}_i f_i = \frac{\sum_i w_i f_i}{\sum_i w_i} \tag{3}$$

The ANFIS can be trained by hybrid learning algorithm with combining back propagation and least squares method. In the forward pass the algorithm uses least squares method to identify the consequent parameters. In the backward pass the errors are propagated backward and the premise parameters are updated by gradient descent.

In this paper, proposed method consists of two ANFIS. The two ANFIS have training dataset that is (0˚ sensor, 45˚ sensor, target *ppm*) and (45˚ sensor, 90˚ sensor, target *ppm*). Training was made using MATLAB software.

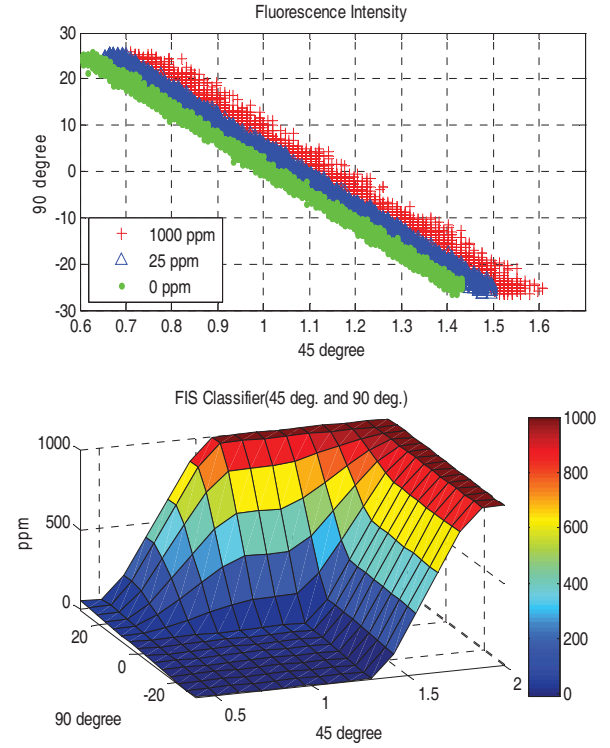
(a)



(b)

Figure 8: Intensity variations and FIS output surfaces; (a) Experimental results and classifier of 0° and 45°, (b) Experimental results and classifier of 45° and 90°.

3.2 Multiple Regression Analysis

Regression analysis is a statistical method for the investigation of relationships between variables [15]. Proposed rule-based fuzzy concentration map is similar to multiple linear regression analysis. Regression analysis is a statistical method for the investigation of relationships between variables. A dependent variable is called response variable or measurement, one or more independent variables are called explanatory variables or predictors in regression analysis. For example, a line in a two dimensional or two-variable space is written:

$$Y = a + bX \tag{4}$$

where a denote term of a constant or intercept, b is a slope as the regression coefficient or B coefficient.

The multiple regression procedures will be estimated in (5).

$$Y = a + b_1 X_1 + b_2 X_2 + \cdots + b_n X_n \tag{5}$$

The purpose of multiple regressions is to learn more about the relationship between several independent or predictor variables and a dependent or criterion variable [16]. The computational problem that needs to be solved in multiple regression analysis is to fit a straight line to number of points. When there is more than one independent variable, the regression line cannot be visualized in the two dimensional space, but can be computed. With n explanatory variables, multiple regression analysis will estimate the equation of a hyper-plane in n-space such that the sum of squared errors has been minimized.

Given experimental data, it shows that the more oil content increases, the more transmitted intensities are decreased, and scattered intensities are increased. Multiple regression analysis provides an update on relation of intensity in (6).

$$\begin{aligned} \rho_f &= b_1 \rho_t + b_2 \rho_c \\ &= (1-\lambda)\rho_t + \lambda \rho_c, \qquad \lambda = 1 - e^{-\eta \bar{\rho}} \end{aligned} \tag{6}$$

where ρ_t, ρ_c denote the independent variables of sub predicted oil content of ANFIS output, ρ_f denotes the final estimated, λ is the fusion effect ratio, η is the gradient scale, and $\bar{\rho}$ is the mean of two predicted oil content.

4 ANFIS Results and Discussion

This paper has attempted to make online measurement system of oil concentration with insufficient samples. It was used samples of 25 *ppm* and 1000 *ppm*, and analyzed contrast between samples with marked oil concentration. Proposed rule-based fuzzy concentration map method was used to convert sensing signal to *ppm*. The generated FIS output surface is shown in Fig. 8. When the measurement voltages are compared to the inference of oil content, this analysis method seems reasonable. After analysis method was established, insufficient content ranges of oil sample were calcu-

ISBN: 978-989-95079-6-8

lated as shown in Table 1. While The output of ANFIS(0° and 45°) was no change in good condition, FIS(45° and 90°) was sensitive. And the more *ppm* increases, the more ANFIS(45° and 90°) increases than ANFIS(0° and 45°). Considered in this relation, λ and η of multiple regression analysis parameters should be updated.

Table 1: Predicted *ppm*(*mg/l*) based on ANFIS.

$[A, B]_x = A \le x \le B$, condition λ=0.5

5 Conclusion

In this paper, we have developed online content measurement system using transmitted and scattered intensity. We attempt to outline an alternative analysis of measurement of oil content using ANFIS. Two part of fluorescence intensities can be used oil content information. Given experimental data-set, it shows that the more oil content increases, the more fluorescence absorbance and scattering of hydrocarbon (-CH) are increased. So transmitted intensity is decreased, and scattered intensities are increased. Proposed rule-based fuzzy concentration map offers the possibility of conversion sensor signal into *ppm*. Because proposed method uses hybrid learning algorithm, the proposed method can provide an input-output mapping. Proposed analysis method and sensing system provide a stepping stone for developing basic technique for designing oil content meter.

Abstract— *This paper presents an entire scheme for the estimation of a sparse disparity map from stereo pair images. In contrary to a dense disparity map, for which disparity values are calculated for each pixel of image, the sparse disparity map is determined only for some distinguished set of pixels from an image. The pixels belong to this set are called features. Therefore, in the first stage the algorithm for determining sparse disparity map has to be able to detect and specify some pixels as the feature pixels. In this article a method for specifying features is introduced. The core of the presented method relies on a fuzzy edges detector. The algorithm of fuzzy edges detection, as well as a manner enabling determination of the features' set, are introduced. The disparity is calculated at the fuzzy domain based on a similarity measure which is the correlation of fuzzy sets. The results of the obtained disparity maps for some benchmark stereo pairs, and the comparison with the well known Marr-Poggio-Grimson algorithm designed for sparse disparity map estimation are presented.*

Keywords— feature points, stereo matching, disparity map, edges detection, fuzzy logic

1 Introduction

Stereo vision is a vivid researched technique of machine vision area which allows to obtain a three dimensional image of a scene observed. Its importance arises from its main characteristics, hence, it is a passive method and the equipment which allows to use it is rather cheap. The estimation of disparity map is one of the central problems of stereo vision application.

In spite of thirty years of research there is no good enough method which always gives a satisfactory solution. The stereo vision and especially the stereo matching research could be divided into two main streams [1, 2]. One of them are algorithms which try to match all pixels from images. As a result of this kind of algorithms the so called dense disparity map is obtained. [3]. The "dense" means that the disparity values are estimated for each pixel of the images. These algorithms, however suffer from the calculation being time consuming and the matching in uniform regions of images being almost impossible. But doubtless the advantage of this group of methods is better model reconstruction possibility. This paper does not consider the methods which produce the dense disparity map.

An alternative approach towards finding a solution to the stereo vision problem is a feature matching strategy. Although, the obtained disparity map has established values in much less amount of pixels, in contrary to the former group of methods, the result can be used in many real tasks as navigation of autonomous robots, manipulation of industrial robots or view morphing. Moreover, the disparity values could be interpolated in the areas where the matching is not made. The disadvantage of this approach is an insufficient amount of disparity values for visually good reconstruction of observed scene. On the other hand, the methods based on features reduce the searching space from full image pixels set to the pixels which were recognized and assigned as the features. It attracts reduction of calculation time and in a natural way, it causes eliminating the ambiguity that may occur inside the uniform regions of images, because in these regions there are usually no feature points.

Each clearly distinct pixel from image can be selected as the features considered for matching task. However, the most popular features taken under consideration are corners [4, 5] and edges [6]. The edges matching techniques are more popular for the reason that the disparity map estimated with dependence only on corners is too sparse. Matching the edges of the images gives a lot of more dense disparity map therefore matching edges is considered in this paper.

In another group of feature based approaches image segmentation is done as the first step. Later, they try to match the segmented regions [7]. This group of methods is not considered here, and the comparison of results would not give meaningful results because the ability of estimation disparity map depends mainly on the segmentation step, which is a totally different issue in machine vision research.

In order to improve results of features stereo matching there is a big group of methods which aim at matching piecewise-linear edge segments [8, 9]. The matching of edge segments has advantages that the error of isolated pixels in edges has very little influence on the position and orientation of the edge segments. There are different modifications in the descriptions of edge segments [10] and the edges could be matched as edge chains [11]. This group of methods is out of our interest because they do not depend on an edge detector and have a different philosophy behind them than matching edges directly.

The well known algorithm for matching features is the Marr-Poggio-Grimson algorithm, MPG in short [12, 13]. This algorithm is an implementation of the human stereo vision theory that was developed by Marr and Poggio [14]. Because the MPG algorithm works mainly with reliance on the edge detection it has been used here as the reference algorithm. All the details of this algorithm are given in the Sec. 5.1.

The paper proceeds in three stages: the first gives a formal statement of the stereo matching problem; the second part contains an algorithm based on fuzzy logic for edges detection and a manner for establishing feature points as well as a method for the calculation of a disparity map; the third part of the paper presents evaluation results of the introduced method and the comparison with the MPG algorithm.

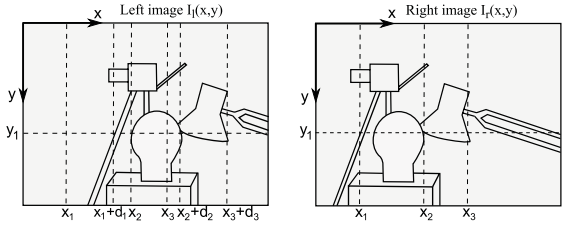

Figure 1: Depiction of the stereo matching problem

2 Problem statement

The stereo vision problem relies on establishing the correspondence between physically the same points in two different images representing the same scene. However, these two images have to be taken under some geometric restrictions in order to ensure they constitute a proper stereo pair [15, 16]. If two images constitute a proper stereo pair then there is a horizontal shift between these two images called *disparity*. Finding this shift is the main aim of almost every stereo matching algorithm. This task is illustrated in Fig. 1 which shows, that the same physical points (x_1, x_2, x_3 in the Fig. 1) in the left and the right images have different abscissa in the image coordinate system. The matching task is usually posed as the problem of finding points in the right image I_r corresponding to the selected points in the left image I_l. The value of abscissa shift of the determined point, called *disparity* is here refereed to as d. The task is to find the proper values of disparity d which correspond to the same physical points.

Usually, the epipolar constraint [15] restricts the search to a horizontal line of images. A further simplification is attained by limiting the maximum possible value of disparity d, for which a good estimate can exist. In this paper we restrict our considerations to a parallel rectified pair of cameras. This means that the searching is done for each line of images and the lines of the left and right images correspond to each other.

3 Features detector

Edge detection is a well known problem for the machine vision community. There are many more or less popular algorithms in the literature considering on image processing tasks [17, 18]. In this paper we used some new kind of an edge detector. This edge detector is based on fuzzy relation and with its characteristic feature being rather fat edges obtained as the detection results [19]. The thickness of the detected edges could be a disadvantage in some applications but in the matching problem has become an advantage, because the edges have more information about themselves and about their neighborhood.

3.1 Edges detection

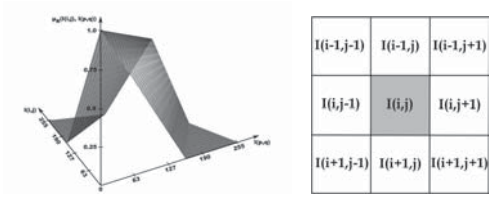
The principle behind the presented algorithm is the fact that for the pixel which belongs to an edge, the neighboring pixels have different values. Therefore if the edge is strong then in the determined small neighborhood of the pixel under consideration there are numerous pixels with the big difference of value.

The distinction between these pixels is made by using the fuzzy relation [20]. As it is pointed in [19] a lot different shapes of fuzzy relation can be used. In this paper we used the fuzzy relation in the triangular form (1). The shape of the triangular similarity relation is shown in Fig. 2(a) and its strength depends mainly on α value.

Formally the triangular fuzzy relation between the pixels $I(i,j)$ and $I(k,l))$ is expressed:

$$\mu_{RT}\left(I\left(i,j\right),I\left(k,l\right),\alpha\right)=\begin{cases}1-\frac{|I(i,j)-I(k,l)|}{\alpha} & if \quad |I\left(i,j\right)-I\left(k,l\right)|<\alpha\\ 0 & if \quad |I\left(i,j\right)-I\left(k,l\right)|\geq\alpha\end{cases} \tag{1}$$

In the edge detection stage the distinctions between one distinguished pixel $I(i,j)$ and its neighbors are calculated. If the differences are big, there are likely big changes in image, and there could be an edge present. The algorithm for edge detection is described as follows:



(a) (b)

Figure 2: The shape of triangular fuzzy relation used for the edge detection (a) and the neighborhood (b) of distinguished pixel.

1. The determination of the differences between the distinguished pixel and its small established neighborhood. This situation of the distinguished pixel and its neighboring pixels is shown in Fig. 2(b). In this case we use the window size eight but many different sizes of this neighborhood can be used [19].
   The vector of homogenity description h_v is defined. The length of homogenity vector h_v is equal to the size of the neighborhood. For each pixel of the image the values of the vector h_v are calculated by (2):
   $$h_v=\bigcup_{k,l=-\rho}^{\rho}\mu_{RT}\left[I\left(i,j\right),I\left(i+k,j+l\right)\right] \tag{2}$$
2. The final response of the edge detector is defined as the sum of the homogenity vector values:
   $$h_e\left(i,j\right)=\sum h_v \tag{3}$$

If the region is uniform, the response of the edge detector would be big because all of the pixels have big similarity close to one. If the region is diverse, and if a strong edge is present in the region, the response of the detector is smaller. The results of the detector working for two images are shown in Fig. 3 and 4. We reverse the colors of the edge images in order to get the better presentation in black in white background. Originally the colors for the edges are brighter, the bigger response of the edge detector while the background is black.

Moreover, the values of the edge detector response called "edginess" could be considered as values of some membership function. The bigger the response, the bigger the pixel's membership function value.

(a) (b)

Figure 4: The left image of an another stereo pair called "Venus" (a) and the result of edges detection (b).

3.2 Edges thinning

The edges detected by the presented edges detection procedure are rather fat therefore we need to further reduce the number of points which are subject to match-making. In order to obtain the reduction of the edge points, a thinning algorithm is executed at the edge images. The thinning is done in three independent steps.

The full thinning algorithm proceeds in the following way:

1. *Thresholding:* The first step of the edge thinning is attenuation of small values by using the global threshold P_{th} with the value given by:

$$P_{th} = a_{th} \times E_{mean} \tag{4}$$

where a_{th} is an arbitrary chosen empirical threshold value. In this work it was set at the value equals 1.25. The term E_{mean} determines the average value of the edges image:

$$E_{mean} = \frac{1}{M \cdot N} \sum_{i=0}^{N-1} \sum_{j=0}^{M-1} e\left(i,j\right) \tag{5}$$

where $e\left(i,j\right)$ is the pixel value of the edge image.

2. *Horizontal non-maximum suppression:* This step has similar idea to the non-maximum suppression algorithm. But in this step, it is made only in the horizontal direction of the image, as carried out:

$$p_e\left(i,j\right) = \begin{cases} p_e\left(i,j\right) & \textbf{if} \quad p_e\left(i,j\right) > p\left(i-1,j\right) \\ & \textbf{and if} \quad p_e\left(i,j\right) > p\left(i+1,j\right) \\ 0 & \textbf{if} \quad else \end{cases} \tag{6}$$

3. *Vertical non-maximum suppression:* The last step is practically the same as the previous step, but it is done in the vertical direction of the image:

$$p_e\left(i,j\right) = \begin{cases} p_e\left(i,j\right) & \textbf{if} \quad p_e\left(i,j\right) > p\left(i,j-1\right) \\ & \textbf{and if} \quad p_e\left(i,j\right) > p\left(i,j+1\right) \\ 0 & \textbf{if} \quad else \end{cases} \tag{7}$$

As the result the images with the edges of one pixel thickness are obtained. In these images the positions of the remaining pixels determine the locations of the features which are to be matched.

The examples of the results obtained by the edge thinning algorithm and the locations of the feature points for the images considered earlier (see Fig. 3 and Fig. 4) are shown in Fig. 5.

(a) (b)

Figure 5: The feature points after edge thinning applied for the images in Fig. 3 (a) and Fig. 4 (b) respectively.

4 Feature points matching

A typical algorithm for finding a stereo matching solution works for an arbitrary range of disparity values from d_{min} to the d_{max}. There are two windows established, one of which, called a reference window is set at a stable position in one (usually left) of the images constituting a stereo pair and the other called a search window moves along the horizontal line in the other image (usually right) within the established disparity range. For each position of the search window some kind of matching measure is calculated. The value of d for which position of the search window the value of measure attains its supreme is taken as the proper value.

The presented algorithm works in the mentioned scheme, that is reference and search windows, but during the matching stage the feature image and the edges images are used. The feature image determines the position of the feature points received after using the edge thinning. It is used for establishing the position of the reference window in the reference edge image exactly at location of the feature point. After establishing the position of the reference window the matching is carried out by moving the search window in the other edge image.

The measure of matching is calculated based on the edge images. For each point which have determined as the feature point in the feature images, the calculation of matching score in the edge images is done. As it was mentioned earlier the values of the edge detector can be interpreted as the values of the membership function which gives the degree of pixel belonging to the "edginess" variable. For this reason the calculation of matching score is done in a fuzzy fashion.

ISBN: 978-989-95079-6-8

The matching measure used in this algorithm is the correlation between fuzzy sets [21]. Let us assume that there is a sequence of paired data $((\mu_A(x_1), \mu_B(x_1)), \ldots, (\mu_A(x_n), \mu_B(x_n)))$ which corresponds to the grades of the membership functions of fuzzy sets A and B defined on X. The correlation coefficient, $f_{A,B}$, between the fuzzy sets A and B is calculated as:

$$r_{A,B} = \frac{\sum_{i=1}^{n} (\mu_A(x_i) - \bar{\mu}_A)(\mu_B(x_i) - \bar{\mu}_B) / (n-1)}{S_A \cdot S_B} \quad (8)$$

where $\bar{\mu}_A$ and $\bar{\mu}_B$ denote the average membership grades of the fuzzy sets A and B according to the dependence:

$$\bar{\mu}_A = \frac{\sum_{i=1}^{n} \mu_A(x_i)}{n} \quad (9)$$

and S_A and S_B are the standard deviations of fuzzy sets A and B calculated as: $S_A = \sqrt{S_A^2}$, where S_A^2 represents the degree of variation of the membership function determined by:

$$S_A^2 = \frac{\sum_{i=1}^{n} (\mu_A(x_i) - \bar{\mu}_A)^2}{n-1} \quad (10)$$

The measure of correlation (8) is simply adapted to the measure of correlation between "edginess" in the reference window and "edginess" in the search window. As in a typical matching algorithm the score is calculated for each shift from the chosen range and the value d_k for which the correlation attains its maximal value is taken as the proper disparity value.

5 Results evaluation and comparison

For the testing purposes we used some benchmark stereo pairs made public accessible [3] from the Middlebury Stereo Vision Page [22]. The big advantage of these stereo pairs is that they have the true disparity map available. This allows to make a reasonable comparison of different algorithm in reference to the true result which should be obtained.

5.1 Reference feature matching algorithm

As the reference algorithm the Marr-Poggio-Grimson (MPG) has been selected. This algorithm is very popular, easy to implementation and gives good results. The implementation which is used here was based on the scheme described in [12, 13].

The MPG algorithm works in the coarse to fine scheme. In the description of this algorithm the word "channel" is used and it refers to image filtering with a specific filter window with established size w. The coarse channel means the filtering with the bigger size of filter window and the finest channel means that the image was filtered by using filter with smaller size.

The typical scheme of the MPG algorithm consists of six steps. The steps are outlined below:

1. *LOG filtering:* Started from the coarsest channel the left and right image of stereo pair is convolved with LOG filter. The LOG is a smoothed second derivative of the image signal and assumes the following form:

$$\nabla^2 (G(x,y)) = \left(\frac{x^2+y^2}{\sigma^2}\right) \exp\left(\frac{-(x^2+y^2)}{2\sigma^2}\right) \quad (11)$$

where ∇^2 is the Laplacian $\nabla^2 = \left(\frac{\partial^2}{\partial x^2}\right) + \left(\frac{\partial^2}{\partial y^2}\right)$ and $G(x,y))$ is the Gaussian function, which acts as a low-pass-filter to the image:

$$G(x,y) = \sigma^2 \exp\left(\frac{-(x^2+y^2)}{2\sigma^2}\right) \quad (12)$$

where the width of the channel "w" is related to σ as follows: $w = \sqrt{2}\sigma$

2. *Zero crossing extraction:* In the filtered image the detection of zero crossing is done by scanning the image horizontally for adjacent elements of opposite sign or for three horizontally adjacent elements, where the middle one is zero. Also the sign of zero crossing is searched. The located position of zero crossing with their signs are remembered.

3. *Matching:* For each scan line in the left image is centered reference window at the founded zero crossing point as the possible candidate to matching. In the right image the search window is moved in established disparity range. If in the right image is a zero crossing point on the search window and has the same sign as the left point, then this zero-crossing point produces a match. The disparity, difference between locations of zero crossing points in the left and right image, is stored in a dynamic buffer.

   Based on the matching process, the left zero crossing is marked as:

   - *unique match*, if only one right image zero crossing is matched with the left one
   - *multiple matches*, if more than one match is found
   - *no match*, if no match is found

4. *Disambiguation:* In this step the disparity map is checked for possible double matches. This kind of ambiguity is resolved by checking the disparities within the same region of the representation at the previous channel. If there is no coarser channel, or there is no a disparity value within this region in the coarser channel, or the disparity is not consistent with coarser level disparity, then the disparity is discarded. The disparity can be approximated by taking the average of the multiple match.

5. *Loop:* When the final map disparity for the current channel has been completed, the process return to the convolution to the next finer representation.

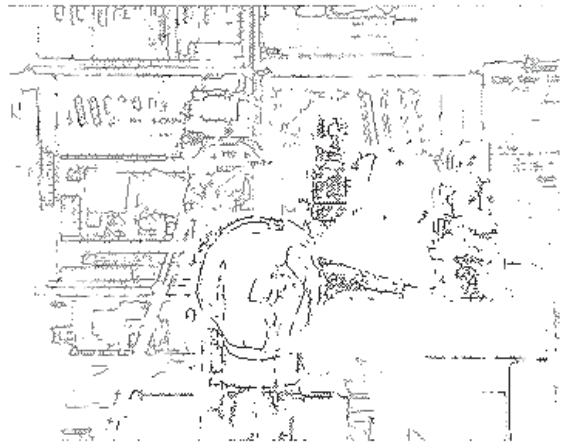
6. *Consistency:* After calculation of disparity in each channel has been completed, there is one final test done. Each disparity value at the finest channel is tested for consistency by checking its value with values at the coarser channel. If the values are inconsistent the matching is eliminated.

In this paper we used, as in the Grimson [12] implementation, four channels with size of 5, 9, 13 and 17 pixels respectively.

ISBN: 978-989-95079-6-8

5.2 *Results evaluation*

The algorithm proposed here and the MPG algorithm were applied for two different stereo pairs. The Fig. 6 presents the estimated disparity maps for "Tsukuba" stereo pair. Similar as in the edge images the colors were reversed for better visual presentation. If the color at the disparity map is darker the original disparity value has bigger value, and the element has bigger disparity value. The second image Fig. 7 presents the disparity maps obtained for the "Venus" stereo pair images.



(a) The result of the proposed algorithm.

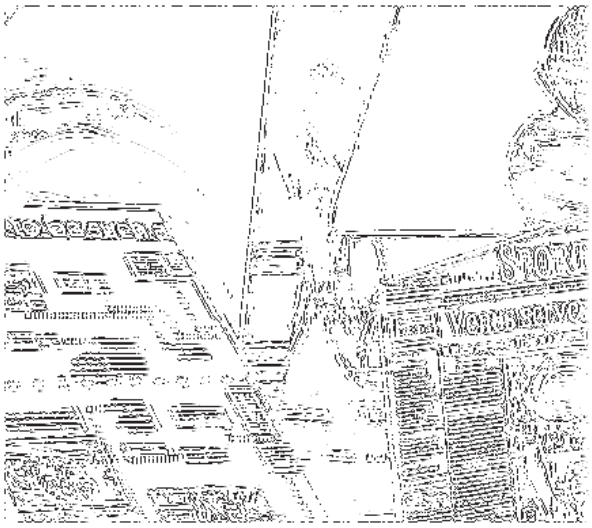
(b) The result of the MPG algorithm.

Figure 6: Disparity maps for the stereo pair "Tsukuba" (a) estimated by the proposed fuzzy algorithm and the MPG (b).

Visually these results are not so different. In the "Tsukuba" stereo pair can be seen that MPG algorithm gives some different matching but the comparison is very hard to done. Just comparison of numerical statistic given in the Tab.1 gives better view at obtained results. It can be seen that the amount of points classified as the features points is similar in both algorithms but the proposed algorithm based on fuzzy edge detection gives much more true matches. During generation of the results enclosed in Tab. 1 a point was classified as the proper matching point if the difference between its disparity and the true disparity taken from the true disparity map was equal zero or one. In this case the small mistake equal one was allowed. If the difference between estimated disparity value and the true value was bigger than one the matching point was classified as wrongly matched point.

In order to check the characteristics of these algorithms in some more deep manner the second experiment was done. In this case their behavior in the presence of noise in images was investigated. For this reason some amount of Gaussian noise was added to the both images consist of stereo pair. The amount of added noise is determined in the logarithmic scale and was established at $30dB$ value. The value denotes the amount of noise and is calculated by using expression:

(a) The result of the proposed algorithm



(b) The result of the MPG algorithm

Figure 7: Disparity maps for the stereo pair "Venus" (a) estimated by the proposed fuzzy algorithm and the MPG (b).

$$SNR = 10 \cdot \log_{10}\left(\frac{P_{image}}{P_{noise}}\right) \tag{13}$$

For discrete image I with size $M \times N$ and intensities $I(i,j)$ of pixels the power P_{image} is expressed as following:

$$P_{image} = \frac{1}{M \cdot N}\sum_{i,j=1}^{M,N} I^2(i,j) \tag{14}$$

For the purpose to produce the image with assigned SNR to the image the Gaussian noise was added iteratively and the power of noise was calculated for the noise image:

$$I_{noise} = I_{distorted} - I_{original} \tag{15}$$

ISBN: 978-989-95079-6-8

Table 1: The quantitative results of comparison for matching algorithms.

Image	Points	Right	Bad	Right %	Bad %
Results obtained by the fuzzy matching					
Tsukuba	11579	10392	1187	89.8	10.2
Venus	18588	16479	2109	88.7	11.3
In the presence of noise in image; $SNR = 30dB$					
Tsukuba	11898	2629	9269	22.1	77.9
Venus	19269	3313	15956	17.2	82.8

Results obtained by the Marr-Poggio-Grimson algorithm					
Tsukuba	11579	9549	2030	82.4	17.6
Venus	19143	12449	6694	65.1	34.9
In the presence of noise in image; $SNR = 30dB$					
Tsukuba	12345	582	11763	4.7	95.3
Venus	22705	564	22141	2.5	97.5

where the power $I_{original}$ had been calculated (13) before adding noise and the P_{noise} was calculated for the noised image. The amount of noise had been increasing to the moment for which the SNR attained the value equal to $30dB$.

As it is shown in Tab.1 both algorithms have very small resistance at the noise. The number of features does not decrease but the the amount of the proper matching is decreasing very significantly. But the proposed fuzzy approach still give better results.

6 Conclusion

In this paper the full scheme for features stereo matching based on fuzzy edge detection has been presented. The application of fuzzy logic allowed to obtain results better than the good and stable MPG algorithm.

However, both of these algorithms are very sensitive to the noise present in the images under matching consideration. It seems that the most sensitive stage is the edge detection. This aspect of these algorithms should be researched more deeply because the noise is very important in the real applications of stereo vision. In the real world numerous kind of distortions should be considered and this topic should be examined more carefully.

The obtained results are probably also image depended. In the case where the image is more complicated and there are many more edges in an image, as in "Tsukuba" stereo pair, the number of properly matched points is always bigger. In the "Venus" stereo pair, in which long straight edges are present, both algorithms found much more points classified as the feature points but the matching in both cases was worse. In that kind of images probably the algorithms based on segments edge matching would give better results. But when the image encloses a big number of short edges algorithms presented here should have better properties. This is probably a clue for further research but it is out of scope of this paper at this moment.

Abstract— *Choquet integral has proved to be an effective aggregation model in multiple criteria decision analysis when interactions between criteria have to be taken into consideration. Recently, some generalizations of Choquet integral have been proposed to take into account more complex forms of interaction. This is the case of the bipolar Choquet integral and of the level dependent Choquet integral. To apply Choquet integral and its generalizations in decision problems it is necessary to determine one capacity permitting to represent the preferences of the Decision Maker (DM). In general the capacities are determined on the basis of some exemplary decisions supplied by the DM. It has been observed that effectively there is not only one capacity compatible with the DM's preferences, but rather a whole set of capacities. The determination of the whole set of compatible capacities and the consequent definition of proper preference relations is the domain of the non-additive robust ordinal regression. The authors have already proposed a methodology for non-additive robust ordinal regression when dealing with classical Choquet integral in ranking or choice decision problems. In this presentation, we want to give the basis of a general methodology for non-additive robust ordinal regression for Choquet integral and its generalizations (therefore also the bipolar Choquet integral and the level dependent Choquet integral) in the whole spectrum of decision problems (i.e. not only ranking and choice, but also multicriteria classification).*

Keywords— Choquet integral; Bi-Capacity; Bipolar Choquet integral; Level dependent Choquet integral; Non-additive robust ordinal regression.

1 Introduction

In the field of Multiple Criteria Decision Aid (MCDA), the main purpose of the Multi-Attribute Utility Theory (MAUT) [1] is to represent the preferences of the Decision Maker (DM) on a set of alternatives, taking in account different and conflicting points of view, called *criteria*, to get an overall utility function of every alternative.

The principal assumption underlying MAUT is the independence of criteria, not well suited to many real decision problems in which some interactions between criteria should be considered. In this last direction, Choquet integral [2] has proved to be an effective aggregation model in multiple criteria decision analysis when interactions between criteria have to be taken into consideration. Recently, according to some studies in psychology [3], many real decision problems are often based on *affect*. It seems natural to consider the criteria evaluations on a scale going from negative (bad) to positive (good) values, with a central neutral value. Consequently, the criteria are evaluated on a *bipolar* scale, *i.e.* some complex interactions among criteria arise depending on their good or positive values. To handle bipolar scales of criteria, the notion of capacity has been extended to that of bi-capacity by Grabisch and Labreuche in [4] and independently, to the bipolar capacity by Greco, Matarazzo and Słowiński in [5]. As a result, the Choquet integral has been generalized with the bipolar Choquet integral [6].

In this work we also consider a recent generalization of the Choquet integral: the level dependent Choquet integral [7]. The level dependent Choquet integral handles either unipolar scales or bipolar scales and takes into account the fact that importance of criteria depends also on the level of their evaluation.

In this paper, we propose a general framework for *non-additive robust ordinal regression* (see [8]) permitting to determine the capacities of the Choquet integral and of its above generalizations being compatible with the DM's preferences. On the basis of these sets of compatible capacities, we can define appropriate preference relations permitting to give a recommendation in the whole spectrum of decision problems (*i.e.* not only ranking and choice, but also multicriteria classification). Moreover, we propose to help the DM by identifying one capacity being the most representative among the many compatible capacities for the decision problem at hand.

The paper is organized as follows. In Section 2, we present the basic concepts relative to the Choquet integral and its generalizations, the bi-polar Choquet integral and the level dependent Choquet integral. In Section 3, the non-additive robust ordinal regression is extended to such generalizations. Section 4 contains some conclusions.

2 Choquet integral and its generalizations

2.1 Preliminary notation

In a multiple criteria decision analysis, let $X = X_1 \times X_2 \times \cdots X_n$ with $X_1, \cdots, X_i, \cdots, X_n \subseteq \mathbb{R}^n$ be the possible values taken by n criteria describing a finite set X of m alternatives. We denote every alternative $\mathbf{x} \in X$ by the evaluation vector $\mathbf{x} = (x_1, \cdots, x_i, \cdots, x_n) \in X$ and the index set of criteria by $N = \{1, \cdots, i, \cdots n\}$.

2.2 Choquet integral

A *fuzzy measure* (called also capacity) on N is a set function

$$\mu : 2^N \rightarrow [0, 1]$$

with $\mu(\emptyset) = 0$, $\mu(N) = 1$ (*boundary conditions*) and $\forall\ A \subseteq B \subseteq N,\ \mu(A) \leq \mu(B)$ (*monotonicity condition*).

ISBN: 978-989-95079-6-8

In the framework of multicriteria decision problems, the value $\mu(A)$ on the set of criteria A can be interpreted as the importance weight given by the DM to the set of criteria A.

A fuzzy measure is *additive* if $\mu(A \cup B) = \mu(A) + \mu(B)$, for any $A, B \subseteq N$ such that $A \cap B = \emptyset$.

In case of additive fuzzy measures, $\mu(A)$ is simply obtained by $\mu(A) = \sum_{i \in A} \mu(\{i\}), \forall\ A \subseteq N$. In the other cases, we have to define a value $\mu(A)$ for every subset A of N, obtaining 2^n coefficients values.

Given $\mathbf{x} \in X \subseteq \mathbb{R}^n_+$ and μ being a fuzzy measure on N, then the *Choquet integral* [2] is defined by:

$$\begin{array}{l} \mathcal{C}_\mu(\mathbf{x}) = \sum_{i=1}^n \left[x_{(i)} - x_{(i-1)}\right] \mu\left(A_i\right) = \\ = \sum_{i=1}^n x_{(i)} \Big(\mu\left(A_i\right) - \mu\left(A_{i+1}\right) \Big) \end{array}$$

where $_{(\cdot)}$ stands for a permutation of the indices of criteria such that:

$$x_{(1)} \leq x_{(2)} \leq x_{(3)} \leq ... \leq x_{(n)}, \qquad (1)$$

with $A_i = \{(i), ..., (n)\}$ where $A_{n+1} = \{\emptyset\}$ $(i = 1, .., n)$ and $x_{(0)} = 0$.

2.3 Bipolar Choquet integral

Let $\mathcal{S}(N) = \{(C, D)\ :\ C \subseteq N,\ D \subseteq N,\ C \cap D = \emptyset\}$ be the set of pairs of subsets of N.

A *bi-polar capacity*, defined in [5], is a function

$$\breve{\mu}\ :\ \mathcal{S}(N) \rightarrow [0, 1] \times [0, 1]$$

such that,

1. $\breve{\mu}(A, \emptyset) = (a, 0)$ and $\breve{\mu}(\emptyset, B) = (0, b)$, with $A, B \in \mathcal{S}(N)$ and $a, b \in [0, 1]$;
2. $\breve{\mu}(N, \emptyset) = (1, 0)$ and $\breve{\mu}(\emptyset, N) = (0, 1)$;
3. For each $(C, D), (E, F) \in \mathcal{S}(N)$, such that $C \supseteq E$ and $D \subseteq F$, we have $\breve{\mu}(C, D) = (c, d)$ and $\breve{\mu}(E, F) = (e, f)$, $c, d, e, f \in [0, 1]$, with $c \geq e$ and $d \leq f$.

The properties 1) and 2) are the *boundary conditions*, while the property 3) is the *monotonicity condition*.

Given $(C, D) \in \mathcal{S}(N)$ with $\breve{\mu}(C, D) = (c, d)$, we use the following notation, $\breve{\mu}^+(C, D) = c$ and $\breve{\mu}^-(C, D) = d$.

A *bi-capacity*, defined in [4], is a function, $\hat{\mu}\ :\ \mathcal{S}(N) \rightarrow [-1, 1]$ such that,

1. $\hat{\mu}(\emptyset, \emptyset) = 0$ and $\hat{\mu}(N, \emptyset) = 1$ and $\hat{\mu}(\emptyset, N) = -1$ *(boundary conditions)*;
2. If $C \supseteq E$ and $D \subseteq F$, then $\hat{\mu}(C, D) \geq \hat{\mu}(E, F)$ *(monotonicity conditions)*.

From each bi-polar capacity, a corresponding bi-capacity is obtained by

$$\hat{\mu}(C, D) = \breve{\mu}^+(C, D) - \breve{\mu}^-(C, D),\ \ \forall\ (C, D) \in \mathcal{S}(N).$$

Let be $_{(\cdot)}$ a permutation of the elements of N such that,

$$|x_{(1)}| \leq |x_{(2)}| \leq \ldots \leq |x_{(i)}| \leq \ldots \leq |x_{(n)}|,$$

and $|x_{(0)}| = 0$.

Let be the following two subsets of N, $A_i^+ = \{j \in N\ :\ x_j \geq |x_{(i)}|\}$ and $A_i^- = \{j \in N\ :\ x_j < 0,\ -x_j \geq |x_{(i)}|\}$.

The bi-polar Choquet integral of the positive part is defined as,

$$\mathcal{C}^+(\mathbf{x}, \breve{\mu}) = \sum_{i \in N} \Big(|x_{(i)}|\ - |x_{(i-1)}| \Big) \breve{\mu}^+(A_i^+, A_i^-).$$

Analogously, *the bi-polar Choquet integral* of the negative part is defined as,

$$\mathcal{C}^-(\mathbf{x}, \breve{\mu}) = \sum_{i \in N} \Big(|x_{(i)}| - |x_{(i-1)}| \Big) \breve{\mu}^-(A_i^+, A_i^-).$$

The bi-polar Choquet integral is defined (see [5]) as:

$$\mathcal{BC}(\mathbf{x}, \hat{\mu}) = \mathcal{C}^+(\mathbf{x}, \breve{\mu}) - \mathcal{C}^-(\mathbf{x}, \breve{\mu}).$$

$\mathcal{BC}(\mathbf{x}, \hat{\mu})$ can be also formulated in terms of bi-capacities (see [6]), as follows,

$$\mathcal{BC}(\mathbf{x}, \hat{\mu}) = \sum_{i \in N} \Big(|x_{(i)}| - |x_{(i-1)}| \Big) \hat{\mu}(A_i^+, A_i^-).$$

2.4 Some particular submodels

In the bipolar decision making setting, one of the main drawbacks is the huge number of parameters to be elicitated from the DM in order to define the bi-capacity or the bipolar capacity. In fact, since $\mathcal{S}(N)$ is isomorphic to the set of functions from $\mathbb{N}$ to $\{-1, 0, 1\}$, then $|\mathcal{S}(N)| = 3^n$. Let us remark that in this contest the non-additive ordinal regression is particularly useful, because it does not require the elicitation of all the parameters, but it is mainly based on some holistic preferences on a reference set of alternatives from which the whole set of bi-capacities or bipolar capacities compatible with the DM's preferences. Nevertheless, dealing with a model with smaller number of parameters is always useful and for this reason, in the following sections we recall some well-known bipolar submodels, that are interesting from the point of view of applications and a decomposition of the bi-polar capacities, introduced in [9], more meaningful from a DM's point of view.

2.4.1 Decomposable bi-polar measures

We define a $2-$order decomposable bi-polar measure (see [9]) such that

$$\begin{array}{rcl} \mu^+(C, D) & = & \sum_{i \in C} a^+(\{i\}, \emptyset) + \sum_{\{i,j\} \subseteq C} a^+(\{i, j\}, \emptyset) + \\ & & + \sum_{i \in C,\ j \in D} a^+(\{i\}, \{j\}) \end{array}$$

$$\begin{array}{rcl} \mu^-(C, D) & = & \sum_{j \in D} a^-(\emptyset, \{j\}) + \sum_{\{i,j\} \subseteq D} a^-(\emptyset, \{i, j\}) + \\ & & \sum_{i \in C,\ j \in D} a^-(\{i\}, \{j\}) \end{array}$$

ISBN: 978-989-95079-6-8

The above decomposition of the bi-polar capacity has a more manageable and meaningful interpretation according to the DM's preferences.

In fact, $a^{\pm}(\cdot)$ can be interpreted in the following way:

- $a^{+}(\{i\},\emptyset)$, represents the power of the criterion i by itself; this value is always positive.
- $a^{+}(\{i,j\},\emptyset)$, represents the interaction between i and j, when their values are both positive; when its value is zero there is no interaction; on the contrary, when the value is positive there is a synergy effect when putting together i and j; a negative value means that the two criteria are redundant.
- $a^{+}(\{i\},\{j\})$, represents the power of the criterion j against the criterion i, when the criterion i has a positive value and j has a negative value; this provokes always a reduction or no effect on the value of μ^{+} since this value is always non-positive.

Analogous interpretation can be applied to the value of $a^{-}(\emptyset,\{j\})$, $a^{-}(\emptyset,\{i,j\})$, and $a^{-}(\{i\},\{j\})$.

In what follows, for the sake of simplicity, we will use a_i^{+}, a_{ij}^{+}, $a_{i|j}^{+}$, instead of $a^{+}(\{i\},\emptyset)$, $a^{+}(\{i,j\},\emptyset)$, and, $a^{+}(\{i\},\{j\})$, respectively; and a_j^{-}, a_{ij}^{-}, $a_{i|j}^{-}$, instead of $a^{-}(\emptyset,\{j\})$, $a^{-}(\emptyset,\{i,j\})$, and $a^{-}(\{i\},\{j\})$, respectively.

2.5 The level dependent Choquet integral

Let us also recall a recent further generalization of the bi-capacity (see [7]): the generalized capacity. Such measures take in account the fact that importance of criteria depends also on the level of their evaluation.

In particular, we define a *generalized capacity* a function $\mu^{\mathcal{G}}: 2^N \times \mathbb{R}_+ \to [0,1]$ such that

1. for all $t \in \mathbb{R}_+$ and $A, B \subseteq N$, $\mu^{\mathcal{G}}(A,t) \leq \mu^{\mathcal{G}}(B,t)$;
2. for all $t \in \mathbb{R}_+$, $\mu^{\mathcal{G}}(\emptyset,t) = 0$ and $\mu^{\mathcal{G}}(N,t) = 1$;

We define the generalized Choquet integral of $\mathbf{x} = [x_1,\cdots,x_n] \in \mathbb{R}_+^n$, with respect to the generalized capacity $\mu^{\mathcal{G}}$ as follows:

$$\mathcal{GC}(\mathbf{x},\mu^{\mathcal{G}}) = \int_0^{+\infty} \mu^{\mathcal{G}}(A(\mathbf{x},t),t)\,dt$$

where $A(\mathbf{x},t) = \{i \in N\colon x_i \geq t\}$.

Let us remark that the generalized Choquet integral can always be written as:

$$\mathcal{GC}(\mathbf{x},\mu^{\mathcal{G}}) = \sum_{i=1}^{n} \int_{x_{(i-1)}}^{x_{(i)}} \mu^{\mathcal{G}}(A(\mathbf{x},t),t)\,dt.$$

The level dependent Choquet integral can be defined also with respect to a generalized bi-capacity.

In particular, we define a *generalized bi-capacity* a function $\mu^{\mathcal{G}}: \mathcal{S}(N) \times \mathbb{R} \to \mathbb{R}$ such that

1. for all $t \in \mathbb{R}$ and $(A,B),(C,D) \in \mathcal{S}(N)$, $A \subseteq C$, $B \supseteq D$, $\mu^{\mathcal{G}}(A,B,t) \leq \mu^{\mathcal{G}}(C,D,t)$;
2. for all $t \in \mathbb{R}$, $\mu^{\mathcal{G}}(\emptyset,N,t) = 0$ and $\mu^{\mathcal{G}}(N,\emptyset,t) = 1$;

We define the generalized bipolar Choquet integral of $\mathbf{x} = [x_1,\cdots,x_n] \in \mathbb{R}^n$, with respect to the generalized bi-capacity $\mu^{\mathcal{G}}$ as follows:

$$\mathcal{GC}(\mathbf{x},\mu^{\mathcal{G}}) = \int_0^{+\infty} \mu^{\mathcal{G}}(A^{+}(\mathbf{x},t),A^{-}(\mathbf{x}t),t)\,dt$$

where $A^{+}(\mathbf{x},t) = \{i \in N\colon x_i \geq t\}$ and $A^{-}(\mathbf{x},t) = \{i \in N\colon -x_i \geq t\}$.

2.5.1 Interval level dependent capacity

The generalized Choquet integral is quite difficult to calculate and consequently, to be applied since a capacity $\mu^{\mathcal{G}}(A,t)$ is needed for each level $t \in \mathbb{R}$. For this reason in [7], a manageable class of generalized capacities are proposed, namely the *interval level dependent capacities*. For the sake of simplicity, but without loss of the generality, in the following we consider $\mathbf{x} \in [0,1]^n$.

A generalized capacity $\mu^{\mathcal{G}}$ is defined *interval level dependent capacity* if there exist

1. $a_0, a_1, a_2, , a_{m-1}, a_m \in [0,1]$, with m a positive integer such that
$$0 = a_0 < a_1 < a_2 < \cdots < a_{m-1} < a_m = 1$$
2. m capacities $\mu_1,\cdots,\mu_m$ on N.

such that, for all $A \subseteq N$ and all $t \in [0,1]$, $\mu^{\mathcal{G}}(A,t) = \mu_j(A)$ if $t \in]a_{j-1},a_j[$, $j = 1,\cdots,m$. In this case, $\mu^{\mathcal{G}}$ is an interval level dependent capacity relative to the breakpoints $a_0, a_1, a_2, , a_{m-1}, a_m \in]0,1[$ and to the capacities $\mu_1,\cdots,\mu_m$.

Finally, we recall an useful theorem, proposed in [7], which permits to split $\mathcal{GC}(\mathbf{x},\mu^{\mathcal{G}})$ in the sum of a finite number of classical Choquet integrals, more precisely one Choquet integral for each interval $]a_{j-1},a_j[$, $j = 1,\cdots,m$.

Theorem 1 *If $\mu^{\mathcal{G}}$ is the interval level dependent capacity relative to the breakpoints $a_0, a_1, a_2, , a_{m-1}, a_m \in]0,1[$ and to the capacities $\mu_1,\cdots,\mu_m$ then for each $\mathbf{x} \in [0,1]^n$*

$$\mathcal{GC}(\mathbf{x},\mu^{\mathcal{G}}) = \sum_{j=1}^{n} \mathcal{C}_{\mu}(\mathbf{x}^j,\mu_j)$$

where $\mathbf{x}^j \in [0,1]^n$ is the vector having its elements x_i^j , $i = 1,\cdots,n$, defined as follows:

$$x_i^j = \begin{cases} 0 & \text{if} \quad x_i < a_{j-1} \\ x_i - a_{j-1} & \text{if} \quad a_{j-1} \leq x_i \leq a_j \\ a_j - a_{j-1} & \text{if} \quad x_i \geq a_j. \end{cases}$$

3 Non-additive robust ordinal regression

3.1 Sorting problems

Within the multicriteria aggregation-disaggregation framework, *ordinal regression* aims at inducing the parameters of a decision model, for example those of a utility function, which have to represent some holistic preference comparisons of the DM. Usually, among the many utility functions representing the DM's preference information, only one utility function is

ISBN: 978-989-95079-6-8

selected (for example, in the UTA method [10]). In this context we also remember some UTA like-methods within the Choquet integral framework, proposed in [11]. Since such a choice is arbitrary to some extent, recently *additive robust ordinal regression* has been proposed with the purpose of taking into account all the sets of parameters *compatible* with the DM's preference information (for more details, see the multicriteria methodologies UTA$^{\text{GMS}}$ and GRIP proposed, respectively, in [12] and [13]). Let us remark that the principles of the *additive robust ordinal regression* have been applied also in sorting problems (see the UTADIS$^{\text{GMS}}$ method [14]).

Until now, robust ordinal regression has been implemented to additive utility functions under the assumption of criteria independence. In [15], the authors have proposed a *non-additive robust ordinal regression* on a set of alternatives X, whose utility is evaluated in terms of the Choquet integral which permits to represent the interaction among criteria, modeled by the fuzzy measures, parameterizing their approach.

In [15], besides holistic pairwise preference comparisons of alternatives from a subset of reference alternatives $X' \subseteq X$, the DM is also requested to express the intensity of preference on pairs of alternatives from X' and to supply pairwise comparisons on the importance of criteria, and the sign and intensity of interaction among pairs of criteria.

In the following, we recall the binary preference relations on the set of reference alternatives defined in [15].

Let us suppose that the preference of the DM is given by a partial pre-order $\succsim$ on $X' \subseteq X$.

The preference relation $\succsim$ can be decomposed into its symmetric part $\sim$ and into its asymmetric part $\succ$, whose semantics are, respectively:

$$\mathbf{x} \sim \mathbf{y} \;\Leftrightarrow\; \mathbf{x} \text{ is indifferent to } \mathbf{y},$$
$$\mathbf{x} \succ \mathbf{y} \;\Leftrightarrow\; \mathbf{x} \text{ is preferred to } \mathbf{y}, \text{ with } \mathbf{x}, \mathbf{y} \in X'.$$

The relation on the intensity of preference on pairs alternatives is represented by a partial pre-order $\succsim^*$ on $X' \times X'$, whose semantics is: for $\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{t} \in X'$

$$(\mathbf{x}, \mathbf{y}) \succsim^* (\mathbf{z}, \mathbf{t}) \;\Leftrightarrow\; \mathbf{x} \text{ is preferred to } \mathbf{y}$$
$$\text{at least as much as } \mathbf{z} \text{ is preferred to } \mathbf{t}.$$

The following system of linear constraints synthesizes the DM's preference information expressed in the approach proposed in [15].

$$\begin{cases} \mathbf{x} \succsim \mathbf{y} \;\Leftrightarrow\; \mathcal{C}_\mu(\mathbf{x}) \geq \mathcal{C}_\mu(\mathbf{y}), \text{ with } \mathbf{x}, \mathbf{y} \in X', \\ (\mathbf{x}, \mathbf{y}) \succsim^* (\mathbf{z}, \mathbf{t}) \;\Leftrightarrow\; \mathcal{C}_\mu(\mathbf{x}) - \mathcal{C}_\mu(\mathbf{y}) \geq \mathcal{C}_\mu(\mathbf{z}) - \mathcal{C}(\mathbf{t}), \\ \text{with } \mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{t} \in X', \\ \vdots \\ \text{Constraints on the importance and interaction of criteria} \\ \vdots \\ \text{Boundary, monotonicity conditions} \end{cases}$$

The output of the approach defines a set of fuzzy measures (capacities) μ defined *compatible* with the DM's preference information if the Choquet integral, calculated with respect to it, restores the DM's ranking on X', *i.e.*

$$\mathbf{x} \succsim \mathbf{y} \;\Leftrightarrow\; \mathcal{C}_\mu(\mathbf{x}) \geq \mathcal{C}_\mu(\mathbf{y}) \;\; \forall \mathbf{x}, \mathbf{y} \in X'.$$

Moreover, using linear programming, our decision model establishes two preference relations:

- for any $\mathbf{r}, \mathbf{s} \in X$, the *necessary* weak preference relation $\succsim^N$, if for all *compatible* fuzzy measures the utility of $\mathbf{r}$ is not smaller than the utility of $\mathbf{s}$, *i.e.* $\mathbf{r} \succsim^N \mathbf{s} \;\Leftrightarrow\; \mathcal{C}_\mu(\mathbf{r}) \geq \mathcal{C}_\mu(\mathbf{s})$,
- for any $\mathbf{r}, \mathbf{s} \in X$, the *possible* weak preference relation $\succsim^P$, if for at least one *compatible* fuzzy measure the utility of $\mathbf{r}$ is not smaller than the utility of $\mathbf{s}$, *i.e.* $\mathbf{r} \succsim^P \mathbf{s} \;\Leftrightarrow\; \mathcal{C}_\mu(\mathbf{r}) \geq \mathcal{C}_\mu(\mathbf{s})$.

Since as it is shown in literature, bi-capacities are the right tools to represent many decision bipolar behaviors, in this work we suggest to extend the *non-additive robust ordinal regression*, described in [15], to the bipolar decision setting and to the level dependent Choquet integral.

However, the greater flexibility of decision strategies with the criteria on a bipolar scale and level dependent Choquet integral is offset by the huge number of parameters to be elicitated by the DM and the not easy interpretation of the bi-capacities and level dependent capacity for the DM.

Let us remark that in our approach the DM is not compelled to give preference information on all criteria.

Moreover, not all criteria are compulsory on a bipolar scale; some criteria could be on the usual unipolar scale (see for a result in this topic the concept of partially symmetric bi-capacities, introduced in [16]).

The set of constraints relative to the bi-polar Choquet integral is as follows:

2) $$\begin{cases} \mathbf{x} \succsim \mathbf{y} \;\Leftrightarrow\; \mathcal{BC}(\mathbf{x}, \hat{\mu}) \geq \mathcal{BC}(\mathbf{y}, \hat{\mu}), \text{ with } \mathbf{x}, \mathbf{y} \in X', \\ (\mathbf{x}, \mathbf{y}) \succsim^* (\mathbf{z}, \mathbf{t}) \;\Leftrightarrow \\ \mathcal{BC}(\mathbf{x}, \hat{\mu}) - \mathcal{BC}(\mathbf{y}, \hat{\mu}) \geq \mathcal{BC}(\mathbf{z}, \hat{\mu}) - \mathcal{BC}(\mathbf{t}, \mu), \\ \text{with } \mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{t} \in X', \\ \vdots \\ \text{Constraints on the bipolar measures,} \\ \vdots \\ \text{Boundary, monotonicity conditions.} \end{cases}$$

The first set constraints are interpreted in the same way of the first set of constraints of system **1)**, with the only difference that every alternative is evaluated by the bi-polar Choquet integral.

Concerning the constraints on the bipolar measures, we suggest to adopt the decomposition explained in subsection 2.4.1. Such decomposition is more easy for the DM to be interpreted and to be elicitated.

The set of constraints relative to the level dependent Choquet integral is as follows:

3) $$\begin{cases} \mathbf{x} \succsim \mathbf{y} \;\Leftrightarrow \\ \mathcal{GC}(\mathbf{x}, \mu^{\mathcal{G}}) \geq \mathcal{GC}(\mathbf{y}, \mu^{\mathcal{G}}), \text{ with } \mathbf{x}, \mathbf{y} \in X', \\ (\mathbf{x}, \mathbf{y}) \succsim^* (\mathbf{z}, \mathbf{t}) \;\Leftrightarrow \\ \mathcal{GC}(\mathbf{x}, \mu^{\mathcal{G}}) - \mathcal{GC}(\mathbf{y}, \mu^{\mathcal{G}}) \geq \mathcal{GC}(\mathbf{z}, \mu^{\mathcal{G}}) - \mathcal{GC}(\mathbf{t}, \mu^{\mathcal{G}}), \\ \text{with } \mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{t} \in X', \\ \vdots \\ \text{Constraints on the level dependent capacity.} \end{cases}$$

ISBN: 978-989-95079-6-8

In this case, we adopt the interval level dependent capacity defined in Section 2.5.1, since it is more easy for the DM to express some ordinal constraints on such capacities. For example, if $X \subseteq [0,1]^n$ and we split the interval $]0,1[$ in two equal subintervals $I_1 =]0, \frac{1}{2}[$, $I_2 =]\frac{1}{2}, 1[$, DM's preference statement could be that criterion i is more important if the level of evaluation of every alternative is in I_2 than if it is in I_1.

We denote the system of constraints (types **1)**, **2)** and **3)**) on the reference alternatives X' by $E_\varepsilon(X')$.

Since linear programming is not able to handle strict inequalities in $E_\varepsilon(X')$, we put the constraints in the form of weak inequalities, by adding a small arbitrary positive value ε (see [17] for a result on this topic).

$$\textbf{4)} \begin{cases} U(\mathbf{x}) \geq U(\mathbf{y}) + \varepsilon, \text{ with } \mathbf{x}, \mathbf{y} \in X', \\ U(\mathbf{x}) - U(\mathbf{y}) \geq U(\mathbf{z}) - U(\mathbf{t}) + \varepsilon, \\ \text{with } \mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{t} \in X', \\ \vdots \\ \text{Constraints on the bipolar measures,} \\ \vdots \\ \text{Boundary, monotonicity conditions,} \end{cases}$$

where U stands for the aggregation operator than can be the bipolar Choquet integral or the level dependent Choquet integral. A similar approach can be used with the bipolar level dependent Choquet integral.

Once the decision making setting on the set of reference alternatives X' is chosen by the DM (types **1)**, **2)** and **3)**), two different optimization problems arise to establish a *necessary* and *possible* preference relation for any $\mathbf{r}, \mathbf{s} \in X$:

$$\begin{array}{ll} \max & \varepsilon \\ \text{s.t.} & E_\varepsilon^{X'} \quad \text{plus the constraint } U(\mathbf{s}) \geq U(\mathbf{r}) + \varepsilon \end{array} \tag{2}$$

and

$$\begin{array}{ll} \max & \varepsilon \\ \text{s.t.} & E_\varepsilon^{X'} \quad \text{plus the constraint } U(\mathbf{r}) \geq U(\mathbf{s}). \end{array} \tag{3}$$

If the problem (2) finds a solution with $\varepsilon \leq 0$, then $U(\mathbf{r}) \geq U(\mathbf{s})$ for all compatible sets of fuzzy measures, that implies $\mathbf{r} \succsim^N \mathbf{s}$ with $\mathbf{r}, \mathbf{s} \in X$.

On the contrary, if a positive ε solves the linear program indicated in (3), then there exists at least one *compatible* fuzzy measure such that $U(\mathbf{r}) \geq U(\mathbf{s})$, that implies $\mathbf{r} \succsim^P \mathbf{s}$ with $\mathbf{r}, \mathbf{s} \in X$.

3.2 The most representative value function

To consider the whole set of fuzzy measures compatible with the preference expressed by the DM reduces arbitrariness in the decision process. However to take into account one specific fuzzy measure can help the DM in understanding the decision process. As already proposed for robust ordinal regression with additive value functions [18], the most representative fuzzy measure is that one which better represents the necessary ranking maximizing the difference of evaluations between alternatives for which there is a preference in the necessary ranking. As secondary objective, one can consider minimizing the difference of evaluations between actions for which there is not a preference in the necessary ranking.

This comprehensive "most representative" value function can be determined through the following procedure:

1. Determine the necessary and the possible rankings in the considered set of actions.
2. For all pairs of alternatives $(\mathbf{x}, \mathbf{y})$, such that $\mathbf{x}$ is necessarily preferred to $\mathbf{x}$, add the following constraints to the linear programming constraints of types **1)**, **2)** or **3)**: $U(\mathbf{x}) \geq U(\mathbf{y}) + \varepsilon$.
3. Maximize the objective function ε.
4. Add the constraint $\varepsilon = \varepsilon^*$, with $\varepsilon^* = \max \varepsilon$ in the previous point, to the linear programming constraints of robust ordinal regression of types **1)**, **2)** and **3)**.
5. For all pairs of actions $(\mathbf{x}, \mathbf{y})$, such that neither $\mathbf{x}$ is necessarily preferred to $\mathbf{y}$ nor $\mathbf{y}$ is necessarily preferred to $\mathbf{x}$, add the following constraints to the linear programming constraints of of types **1)**, **2)** and **3)** and to the constraints considered in above point 4): $U(\mathbf{x}) - U(\mathbf{y}) \leq \delta$ and $U(\mathbf{y}) - U(\mathbf{x}) \leq \delta$.
6. Minimize the objective function δ.

3.3 Sorting problems

In this section, we briefly illustrate the principles of nonadditive robust ordinal regression to sorting problems in case of nonadditive value function represented by Choquet integral or some of its generalizations.

In MCDA, the sorting problem consists in the assignment of m alternatives of a finite set X into $h = 1, \cdots, k$ homogeneous classes $C_1, \cdots C_h, \cdots C_k$, which are increasingly ordered with respect to preference, i.e. all the elements in the class C_h have a better evaluation than the elements in class C_{h-1}. Let $b_1, b_2, \cdots, b_h$ be a set of thresholds relative to the h classes. We have that $\mathbf{x}$ belongs to class h if $U(\mathbf{x}) \geq b_{h-1}$ and $U(\mathbf{x}) < b_h$, where U stands for the aggregation operator than can be the Choquet integral or one of its generalizations. In this case, the DM's preference information will consist in the assignment of some reference alternatives to some classes. Taking into account the Choquet integral, the proposed approach determines the sets of pairs $(\mu, \mathbf{b})$, where μ is a capacity and $\mathbf{b} = [b_1, b_2, \cdots, b_h]$, compatible with the DM's assignment of the reference alternatives [19]. An alternative $\mathbf{x} \in X$ is said that *possibly belongs to class* C_h if there is at least one pair $(\mu, \mathbf{b})$ for which $\mathcal{C}_\mu(\mathbf{x}) \geq b_{h-1}$ and $\mathcal{C}_\mu(\mathbf{x}) < b_h$. One can deal analogously with the above mentioned extensions of Choquet integral.

As proposed in [20] with respect to robust ordinal regression for sorting problems based on additive value function through the UTADIS$^{\text{GMS}}$ method [14], also in this case we can help the DM with the concept of the "most representative" value function.

The idea is to select among compatible fuzzy measure that one which better highlights the possible sorting which is considered the most stable part of the robust sorting obtained by UTADIS$^{\text{GMS}}$. Thus it is selected the fuzzy measure that maximizes the difference of evaluations between alternatives for

ISBN: 978-989-95079-6-8

which the intervals of possible sorting are disjoints. As secondary objective, one can consider maximize the minimal difference between values of actions **x** and **y**, such that for any compatible fuzzy measure, **x** is assigned to a class not worse than the class of **y**, and for at least one compatible value function, **x** is assigned to a class which is better than the class of **y**. In case there is still more than one such fuzzy measure, the most representative fuzzy measure minimizes the maximal difference between values of alternatives being in the same class for all compatible fuzzy measures, and between values of alternatives for which the order of classes is not univocal.

4 Conclusions

Nonadditive value functions and bipolar decision making are one of the underpinning directions of research within MCDA, as many studies have shown that in a multicriteria decision problem the criteria under consideration could be on a bipolar scale. In such context, we have proposed a multicriteria methodology taking inspiration from some recent approaches based on the principle of the *robust ordinal regression*: the UTA$^{\text{GMS}}$ [12] and GRIP [13] in the context of choice and ranking problems, the UTADIS$^{\text{GMS}}$ method relative to sorting problems [14]. On this basis, with the aim of representing interactions between criteria, we proposed the *non-additive robust ordinal regression* which consists in the extension of the idea of robust ordinal regression to non-additive decision. More precisely, the Choquet integral and its generalizations have been adopted as utility function in different decision problems such as ranking, choice and sorting (for the specific case of Choquet integral applied to ranking and choice problems see [15]). The non-additive robust ordinal regression seems very useful because it permits to take into account the whole set of capacities compatible with the DM's preferences which are expressed through very simple questions such as:

- "is the representative alternative a better than the representative alternative b"?
- "to what class the representative alternative a belongs"?

Towards a unified logical framework of fuzzy implications to compare fuzzy sets

Hoel Le Capitaine Carl Frélicot

La Rochelle, France
Email: {hoel.le_capitaine,carl.frelicot}@univ-lr.fr

Abstract*— *In fuzzy set theory, comparison of fuzzy sets plays an important role. Among the several ways to compare fuzzy sets, we address the logical theoretic approach using fuzzy implications. We propose a general framework allowing to generate many measures of comparison: inclusion, similarity and distance, and study their properties. Since the literature on the use fuzzy implications for defining such measures is abundant, we also attempt to relate this work to existing research.

***Keywords*—** aggregation operators, distance, fuzzy implication, inclusion, similarity

1 Introduction

In fuzzy set theory, inclusion (or subsethood) and similarity measures between fuzzy sets are basic concepts. Among the different approaches to compare fuzzy sets, one finds three categories. The first one is based on measuring a distance between two real functions and do not refer to a specific interpretation, e.g. the Minkowski r-distances. The second category involves set-theoretic operations for fuzzy sets (fuzzy intersection, union, cardinality) [1, 2]. This paper addresses the third category which relies on logical theory, mainly approached by using fuzzy implications. Following the early paper by Bandler and Kohout [3] introducing the use of implications to measure inclusion of fuzzy sets, many authors have proposed new measures satisfying some specific axioms [4, 5, 6].

This paper will be organized as follows. We first recall some basic definitions and theorems on aggregation operators, triangular norms and fuzzy implications that will be used in the sequel in section 2. Next, in section 3 we propose a general framework of comparison measures of fuzzy sets (i.e. inclusion, similarity and distance) based on logical considerations, i.e. using fuzzy implications. A general description of the overall aggregation method is also provided, characterizing each measure belonging to this category. In section 4, we present the existing approaches that could be linked to this general formulation. We finally conclude and mention some application domains we have in mind in section 5.

2 Preliminaries and notations

Aggregating numbers plays an important role in decision-making systems. Values to be aggregated are generally defined on a finite real interval or on ordinal scales. In this paper, we assume with no loss of generality that they come from the unit interval. If not, a simple transformation can be found to make this assumption true. Given n numbers, an aggregation operator is a mapping $\mathcal{A} : [0,1]^n \to [0,1]$, satisfying boundary conditions

$$\mathcal{A}(0,\cdots,0) = 0 \quad \text{and} \quad \mathcal{A}(1,\cdots,1) = 1. \tag{1}$$

and monotonocity

$$\begin{aligned} \forall n \in \mathbb{N}, x_1 \leq y_1, \cdots, x_n \leq y_n \quad &\text{implies} \\ \mathcal{A}(x_1,\cdots,x_n) \leq \mathcal{A}(y_1,\cdots,y_n). \end{aligned} \tag{2}$$

Adding properties like idempotency, continuity, associativity lead to others definitions. In the literature, one finds many aggregation operators, e.g.: triangular norms (t-norms for short), OWA (*Ordered Weighted Averaging*) operators, γ-operators, or fuzzy integrals. They belong to several categories, depending on the way the values are aggregated: conjunctives, disjunctives, compensatory, and weighted operators. Briefly, an aggregation operator is said to be *conjunctive* if its output value is lower than the minimum of the input values, *compensatory* if the output value lies between the minimum and the maximum input value, and *disjunctive* if its output is greater than the maximum value of the inputs, refer to [7] for a large survey on aggregation operators.

Theorem 1. *If $\mathcal{A}$ is a strictly monotonic compensatory aggregation operator, then*

$$\mathcal{A}(x_1,\ldots,x_n) = 1 \Leftrightarrow x_1 = \cdots = x_n = 1 \tag{3}$$

and

$$\mathcal{A}(x_1,\ldots,x_n) = 0 \Leftrightarrow x_1 = \cdots = x_n = 0 \tag{4}$$

Proof.

(3) ($\Leftarrow$) obvious with Eq. (1).
($\Rightarrow$) by contraposition. We show that $\exists i$ such that $x_i < 1$ implies $\mathcal{A}(x_1,\cdots,x_n) < 1$. If $x_i < 1$ for some i, then, since $x_j \leq 1$ for all j, by strict monotonicity of $\mathcal{A}$, we get $\mathcal{A}(x_1,\cdots,x_n) < \mathcal{A}(1,\cdots,1) = 1$, which ends the contraposition.

(4) ($\Leftarrow$) obvious with Eq. (1).
($\Rightarrow$) by contraposition. We show that $\exists i$ such that $x_i > 0$ implies $\mathcal{A}(x_1,\cdots,x_n) > 0$. If $x_i > 0$ for some i, then, since $x_j \geq 0$ for all j, by strict monotonicity of $\mathcal{A}$, we get $\mathcal{A}(x_1,\cdots,x_n) > \mathcal{A}(0,\cdots,0) = 0$, which ends the contraposition.

□

Example 1. *The family of mean operators are strictly monotonic compensatory aggregation operators.*

ISBN: 978-989-95079-6-8

Remark 1. *From Theorem 1, we immediately see that a disjunctive aggregation operator cannot be strictly monotonic.* $\forall j\ x_j \leq 1$, *and* $\exists i,\ x_i < 1$, $\exists k,\ x_k = 1$. *If* $\mathcal{A}$ *is strictly monotonic,* $\mathcal{A}(x_1, \cdots, x_n) < \mathcal{A}(1, \cdots, 1) = 1$. *Since* $\mathcal{A}$ *is disjunctive, i.e.* $\mathcal{A}(x_1, \cdots, x_n) \geq \max(x_1, \cdots, x_n)$, *we have* $1 = \max(x_1, \cdots, x_n) \leq \mathcal{A}(x_1, \cdots, x_n) < 1$, *which is a contradiction.*

A t-norm is an increasing, associative and commutative mapping $\top : [0,1]^2 \to [0,1]$ satisfying the boundary condition $\top(x,1) = x$ for all $x \in [0,1]$. The most popular continuous t-norms are:

- Standard: $\top_S(x,y) = \min(x,y)$
- Algebraic (Product): $\top_A(x,y) = x\,y$
- Łukasiewicz: $\top_L(x,y) = \max(x+y-1, 0)$

Alternatively, the dual operators with respect to a strict negation are called triangular conorms (t-conorms for short). A t-conorm is an increasing, associative and commutative mapping $\perp : [0,1]^2 \to [0,1]$ satisfying the boundary condition $\perp(x,0) = x$ for all $x \in [0,1]$. The most popular continuous t-conorms are:

- Standard: $\perp_S(x,y) = \max(x,y)$
- Algebraic (Product): $\perp_A(x,y) = x + y - x\,y$
- Łukasiewicz: $\perp_L(x,y) = \min(x+y, 1)$

Various parametrical families have been introduced, e.g. the Hamacher family defined by: given $\gamma \in [0, +\infty[$,

- $x \top_H y = \frac{x\,y}{\gamma + (1-\gamma)(x+y-x\,y)}$
- $x \perp_H y = \frac{x+y-x\,y-(1-\gamma)\,x\,y}{1-(1-\gamma)\,x\,y}$.

Such families result in an infinite number of t-norm couples, including non parametrical ones e.g. the Algebraic couple for $\gamma = 1$.

A general problem in fuzzy logic is to handle conditional statements *if* x, *then* y where x and y are fuzzy predicates. A widely used method consists in managing them by mappings $I : [0,1] \times [0,1] \to [0,1]$ such that the truth value of I depends on the initial propositions x and y. We generally speak about an *implication function* if I is non-increasing in the first variable, non-decreasing in the second variable and $I(0,0) = I(1,1) = 1$, and $I(1,0) = 0$, see [8] for a survey on fuzzy implication functions and [9] for a large overview on the use of parametrical implications in fuzzy inference systems. The four most usual implications are:

1. *S-implications*, defined by:
$$I_\perp(x,y) = \perp(x^c, y) \tag{5}$$
where $(.)^c$ is the usual complementation $x^c = 1 - x$. This implication is an immediate generalization of the usual boolean implication $x \to y \equiv x^c \vee y$.

2. *R-(for Residual) implications*, defined by:
$$I_\top(x,y) = \sup_t \{t \in [0,1] | \top(x,t) \leq y\}. \tag{6}$$
Note that if $\top$ is a left-continuous t-norm, the *supremum* operation can be substituted by the *maximum* one.

3. *QL-(for Quantum mechanic Logic) implications*, defined by:
$$I_{QL}(x,y) = \perp(x^c, \top(x,y)). \tag{7}$$

4. *D-implications*, defined by:
$$I_D(x,y) = \perp(\top(x^c, y^c), y) \tag{8}$$
which are the contraposition of QL-implications with respect to the complementation.

In the sequel, we will denote by:

- $X = \{x_1, \cdots, x_n\}$ the (supposed finite) universe of discourse,
- $\mathcal{C}(X)$ and $\mathcal{F}(X)$ the sets of all crisps and fuzzy sets in X, respectively,
- $f_A(x)$, $\forall x \in X$, the membership function of a fuzzy set A over X,
- $[\frac{1}{2}]$ the constant fuzzy set defined by $[\frac{1}{2}](x) = \frac{1}{2}$ for any $x \in X$.

3 General framework

There are several ways to compare fuzzy values or fuzzy quantities. The first one is based on a broad class of measures of equality based on a distance measure which is specified for membership functions of fuzzy sets. This approach takes its roots from studies on how to measure the distance between two real functions and do not refer to any specific interpretation. The general form of a Minkowski r-metric is usually taken and leads to well known distance functions (Hamming, Euclidean, Chebyshev):

$$d_r(A,B) = \left(\sum_{x \in X} |f_A(x) - f_B(x)|^r \right)^{1/r} \tag{9}$$

A second way to compare fuzzy values comes from some basic set-theoretic considerations where union, intersection and complementation are defined for fuzzy sets. Cardinal and possibility based measures belong to this category. In this paper, we will focus our attention on the third way: the logical framework. We present the design a unified logical framework to compare fuzzy sets, which includes usual measures depending the aggregation operators we use. The use of parametrical t-norms and t-conorms to define the implications will enable to obtain parametrical measures of comparison, where the parameters can be set according to user needs.

3.1 Inclusion measures

An inclusion measure is a relation between two fuzzy sets which indicates to which extent one fuzzy set is contained in another one. Since its original definition by $A \subset B$ iff $f_A(x) \leq f_B(x)$, for all x in X, which was crisp assessment, Bandler and Kohout enlarged this point of view by giving a degree of subsetness [3], more in the spirit of the fuzzy theory. Inclusion measures are generally defined by a set of axioms [4] and by using fuzzy implication operators [3, 10].

Definition 1. *A mapping* $\mathcal{I} : \mathcal{F}(X) \times \mathcal{F}(X) \to [0,1]$ *is called an inclusion (or subsethood) measure if it satisfies*

ISBN: 978-989-95079-6-8

(P1) $\mathcal{I}(A,B) = 1$ *iff* $A \subseteq B$, $\quad \forall A, B \in \mathcal{F}(X)$.

(P2) *if* $[\frac{1}{2}] \subseteq A$, *then* $\mathcal{I}(A, A^c) = 0$ *iff* $A = X$.

(P3) $\forall A, B, C \in \mathcal{F}(X)$, *if* $A \subseteq B \subseteq C$, *then* $\mathcal{I}(C,A) \leq \mathcal{I}(B,A)$, *and if* $A \subseteq B$, $\mathcal{I}(C,A) \leq \mathcal{I}(C,B)$.

Note that if a measure $\mathcal{I}$ satisfies only the two last properties, it is called a weak inclusion measure.

Theorem 2. *Let $I_\top$ be a residual implication function. Given X and arbitrary $A, B \in \mathcal{F}(X)$, let*

$$\mathcal{I}(A,B) = \mathop{\mathcal{A}}_{i=1}^{n} I_\top \left(f_A(x_i), f_B(x_i)\right) \tag{10}$$

for all x_i in X, where $\mathcal{A}$ is a conjunctive or a strictly monotonic compensatory aggregation operator satisfying Eqs.(1) and (2). Then $\mathcal{I}$ is an inclusion measure.

Proof.

(P1) ($\Leftarrow$) if $A \subseteq B$, then $f_A(x_i) \leq f_B(x_i)$ for all $x_i \in X$. Since if $x \leq y$ then $I_\top(x,y) = 1$, we have $I_\top(f_A(x_i), f_B(x_i)) = 1$ for all $x_i \in X$, which gives $\mathcal{I}(A,B) = 1$ by boundary condition on $\mathcal{A}$.
($\Rightarrow$) two cases are considered
- if $\mathcal{A}$ is disjunctive, then we obviously have $f_A(x_i) \leq f_B(x_i)$ for all $x_i \in X$, since the minimum value of all implications on X is 1
- if $\mathcal{A}$ is a strictly monotonic compensatory aggregation operator, then by using Theorem 1, we have $I_\top\left(f_A(x_i), f_B(x_i)\right) = 1$ for all $x_i \in X$, giving $A \subseteq B$ by the confinement principle: $x \leq y$ *iff* $I(x,y) = 1$.

(P2) ($\Leftarrow$) if $A = X$, then $I_\top(f_X(x_i), \emptyset(x_i)) = 0$ for all $x_i \in X$. By boundary condition on $\mathcal{A}$, it follows that $\mathcal{I}(A, A^c) = 0$.
($\Rightarrow$) if $\mathcal{I}(A, A^c) = 0$, then $I_\top(f_A(x_i), 1 - f_A(x_i)) = 0$ for all $x_i \in X$ by Theorem 1. Assuming that $A \neq X$, then $\exists i$, x_i such that
$\frac{1}{2} \leq f_A(x_i) < 1$, i.e. $0 < 1 - f_A(x_i) \leq \frac{1}{2}$.
By non-increasingness in the first variable of $I_\top$, we have $I_\top(f_A(x_i), 1 - f_A(x_i)) \geq I_\top(1, 1 - f_A(x_i)) = 1 - f_A(x_i) \neq 0$, since $I_\top$ satisfies the border principle: $I(1,x) = x, \forall x \in [0,1]$. This is a contradiction with $I_\top(f_A(x_i), 1 - f_A(x_i)) = 0$, so that $A = X$.

(P3) if $A \subseteq B \subseteq C$, $f_A(x_i) \leq f_B(x_i) \leq f_C(x_i)$, for all $x_i \in X$. By non-increasingness in the first variable and non-decreasingness in the second variable, it follows that $I_\top(f_C(x_i), f_A(x_i) \leq I_\top(f_B(x_i), f_A(x_i))$ and $I_\top(f_C(x_i), f_A(x_i)) \leq I_\top(f_C(x_i), f_B(x_i))$ for all i. By monotonicity of $\mathcal{A}$, we have $\mathcal{I}(C,A) \leq \mathcal{I}(B,A)$ and $\mathcal{I}(C,A) \leq \mathcal{I}(C,B)$, which concludes the proof.

□

A necessary condition to define a strong inclusion measure $\mathcal{I}$ is that the implication I holds the confinement principle and the border principle. It is easy to show that the four usual implications $I_\top$, $I_\perp$, I_{QL} and I_D satisfy the latter, but only $I_\top$ satisfies the former. Therefore S, QL and $D-$implications define weak inclusion measures while $R-$implications define strong inclusion measures provided the operator $\mathcal{A}$ is not disjunctive, see Remark 1.

3.2 Similarity and distance measures

Definition 2. *A mapping $\mathcal{S} : \mathcal{F}(X) \times \mathcal{F}(X) \to [0,1]$ is called a similarity measure if it satisfies*

(P1) $\mathcal{S}(A,B) = \mathcal{S}(B,A), \quad \forall A, B \in \mathcal{F}(X)$.

(P2) $\mathcal{S}(A,A) = 1$, $\forall A \in \mathcal{F}(X)$.

(P3) $\mathcal{S}(D, D^c) = 0, \quad \forall D \in \mathcal{C}(X)$.

(P4) $\forall A, B, C \in \mathcal{F}(X)$, *if* $A \subseteq B \subseteq C$, *then* $\mathcal{S}(A,C) \leq \mathcal{S}(A,B) \wedge \mathcal{S}(B,C)$
or, equivalently
$\forall A, B, C, D \in \mathcal{F}(X)$, *if* $A \subseteq B \subseteq C \subseteq D$, *then* $\mathcal{S}(A,D) \leq \mathcal{S}(B,C)$

However, the symmetry property (P1) is still subject to experimental investigation: if $\mathcal{S}(x,y)$ is the answer to the question *how is x similar to y?*, then, when making comparisons, subjects focus more on the feature x than on y. This corresponds to the notion of saliency [1] of x and y: if y is more salient than x, then x is more similar to y than vice versa, which is experimentally confirmed. Accordingly to [11], for a certain element of the universe of discourse X, a degree of equality of two fuzzy elements x and y can be defined by using implications as follows:

$$(x \equiv y) = \frac{1}{2}\big((x \to y) \wedge (y \to x) + (x^c \to y^c) \wedge (y^c \to x^c)\big) \tag{11}$$

where $\wedge$ stands for minimum, $\to$ is an R-implication.
Then applying Eq. (6) with $x \geq y$, gives

$$(x \equiv y) = \frac{1}{2}\big((x \to y) + (y^c \to x^c)\big) \tag{12}$$

since 1 is the neutral element of t-norms.
Furthermore, due to the opposition law: $I(x,y) = I(y^c, x^c)$, we obtain

$$(x \equiv y) = (x \to y) \tag{13}$$

A convenient way to define a similarity measure is to quantify to which extent two fuzzy membership degrees are similar, so that it is closely related to the problem of matching fuzzy quantities, or fuzzy sets similarity. So we propose to use fuzzy implication functions as similarity measures by the following theorem:

Theorem 3. *Let $I_\top$ be a residual implication function. For arbitrary $A, B \in \mathcal{F}(X)$, let*

$$\mathcal{S}(A,B) = \mathop{\mathcal{A}}_{i=1}^{n} I_\top \left(f_{(1)}(x_i), f_{(2)}(x_i)\right) \tag{14}$$

for all x_i in X, where $f_{(.)}$ is a permutation of f_A and f_B such that $f_{(1)}(x_i) = (f_A \cup f_B)(x_i)$, $f_{(2)}(x_i) = (f_A \cap f_B)(x_i)$, and $\mathcal{A}$ an aggregation operator satisfying Eqs. (1) and (2). Then $\mathcal{S}$ is a similarity measure.

Proof.

(P1) we have $I_\top(x,x) = 1$, for any $x \in [0,1]$. By boundary conditions on $\mathcal{A}$, see Eq. (1), we obtain $\mathcal{S}(A,A) = 1$.

ISBN: 978-989-95079-6-8

(P2) by commutativity of union and intersection of fuzzy sets, we have

$$\begin{aligned}\mathcal{S}(A,B) &= \mathop{\mathcal{A}}_{i=1}^{n} I_\top\left((f_A \cup f_B)(x_i), (f_A \cap f_B)(x_i)\right)\\ &= \mathop{\mathcal{A}}_{i=1}^{n} I_\top\left((f_B \cup f_A)(x_i), (f_B \cap f_A)(x_i)\right)\\ &= \mathcal{S}(B,A)\end{aligned}$$

(P3) by definition, $I(1,0)=0$. By boundary conditions on $\mathcal{A}$, see Eq. (1), we obtain $\mathcal{S}(D,D^c)=0$.

(P4) since $A \subseteq B \subseteq C \subseteq D$, we have for all $x_i \in X$

$$f_D(x_i) \geq f_C(x_i) \tag{15}$$
$$f_B(x_i) \geq f_A(x_i) \tag{16}$$

By non-increasingness in the first variable and non-decreasingness in the second variable of $I_\top$, we obtain for all $x_i \in X$

$I_\top(f_D(x_i), f_A(x_i)) \leq I_\top(f_C(x_i), f_A(x_i))$ by Eq. (15)

$I_\top(f_C(x_i), f_A(x_i)) \leq I_\top(f_C(x_i), f_B(x_i))$ by Eq. (16)

Last, monotonicity of $\mathcal{A}$, see Eq. (2), gives $\mathcal{S}(A,D) \leq \mathcal{S}(B,C)$ which concludes the proof.

□

In contrast to inclusion measures, no restriction is imposed to the $\mathcal{A}$ operator, it can be freely chosen provided Eqs.(1) and (2) are satisfied. On another hand, here again, the confinement principle is necessary to obtain property (P1) of similarity measures. Since $\mathcal{S}(A,B)$ is reflexive and symmetrical, i.e. $\mathcal{S}(A,A)=1$ and $\mathcal{S}(A,B)=\mathcal{S}(B,A)$ hold for any $A,B \in \mathcal{F}(X)$, $\mathcal{S}$ is a proximity relation on $\mathcal{F}(X)$.

Definition 3. *A mapping $\mathcal{D}: \mathcal{F}(X)\times\mathcal{F}(X) \to [0,1]$ is called a distance measure if $\mathcal{D}$ has the following properties*

(P1) $\mathcal{D}(A,B) = \mathcal{D}(B,A), \quad \forall A,B \in \mathcal{F}(X)$.

(P2) $\mathcal{D}(A,A) = 0, \forall A \in \mathcal{F}(X)$.

(P3) $\mathcal{D}(D,D^c) = 1, \quad \forall D \in \mathcal{C}(X)$.

(P4) $\forall A,B,C \in \mathcal{F}(X)$, *if* $A \subseteq B \subseteq C$, *then* $\mathcal{D}(A,B) \leq \mathcal{D}(A,C)$ *and* $\mathcal{D}(B,C) \leq \mathcal{D}(A,C)$

Proposition 1. *For arbitrary $A,B \in \mathcal{F}(X)$, and $\mathcal{S}(A,B)$ a similarity measure defined by Eq. (14), then the mapping $\mathcal{D}: \mathcal{F}(X)\times\mathcal{F}(X) \to [0,1]$ defined by $\mathcal{D}(A,B) = \mathcal{S}^c(A,B)$ is a distance measure between A and B.*

3.3 Examples

Some examples of inclusion and similarity measures of the literature, and the new Hamacher inclusion and similarity measures, all obtained through the proposed general logical framework are given in Table 1. Moreover, this table shows how it is easy to check wether an inclusion measure is strong (non disjunctive $\mathcal{A}$ and $I_\top$) or weak (non disjunctive $\mathcal{A}$), see Definition 1, as well as the proper definition of a similarity measure (any $\mathcal{A}$ and $I_\top$), see Theorem 3.

For illustration purpose, Fig. 1 shows some examples of fuzzy similarity measures as well as the influence of the parameter γ for Hamacher residual implications, which are defined by:

$$I_{\top_{H_\gamma}}(x,y) = \begin{cases} 1 & \text{if } y \geq x \\ \frac{y(\gamma+x-\gamma x)}{y(\gamma+x-\gamma x)+x-y} & \text{if } y \leq x \end{cases} \tag{17}$$

where $\gamma \in [0,+\infty[$. The different plots show the similarity value of a given fuzzy set $A = \{0.4/x_1, 0.3/x_2\}$ to all the possible two-dimensional fuzzy sets B for various $I_\top$. As one could expect, the closer to x_1 or x_2 the higher the similarity. One can also note that different $I_\top$ lead to different shapes for isosurfaces of the similarity.

4 Related works

Let us relate, as far as possible, the proposed framework to some works issued from the abundant literature on the use of fuzzy implications for defining inclusion measures. In their seminal paper [3], Bandler and Kohout propose to use implication functions in order to quantify the inclusion of each element in another, and then aggregate these individual measures by a conjunctive operator: the minimum. Some years later, Hirota and Pedrycz propose to use implications for matching fuzzy quantities [11]. They aggregate the different implication truth values over X by a Choquet integral, computing the fuzzy measure with the help of a family of fuzzy sets taken as fuzzy prototypes. They also propose an entropy measure based on this matching measure, which gives an *impression concerning the uncertainty of matching*. In [14], Kosko criticizes the original definition of fuzzy set containment: B contains A if and only if $f_A(x) \leq f_B(x)$ for all x in X by Zadeh, pointing out that *if this inequality holds for all but just a few x, we can still consider A to be a subset of B to some degree*. So he proposes a second definition based on fuzzy intersection of two fuzzy sets which can be seen as the conditional probability $P(B|A)$ under certain circumstances. Furthermore, he defines the fuzziness of a fuzzy set A as the inclusion measure of $A \cup A^c$ in $A \cap A^c$, which satisfies the axioms of fuzzy entropy of De Luca and Termini [15]. Inclusion and similarity measures from a general set-theoretic point of view, coming from the proposition of Tversky [1], are described by Bouchon-Meunier *et al.* in [2]. The authors introduce a general framework for similitude, satisfiability and inclusion measures, also study the aggregation of measures of comparison, but take only two examples for the aggregation operator $\mathcal{A}$: a t-norm and the OWA operator. In this paper, we propose a study of the properties of $\mathcal{A}$ in its more general meaning. The same remark applies to the work by Young [4] proposing an axiomatization of inclusion measures and their connection to implication operators since she restricts herself to both the minimum and the arithmetical mean for $\mathcal{A}$. Furthermore, this work do not give necessary conditions on implications for the definition of strong or weak inclusion measure whereas our's does (Definition 1). Wang [13] presents two similarity measures which can be viewed as particular cases of the framework we propose. He enlarges his definition to the similarity of fuzzy elements belonging to various fuzzy sets. Again, the framework we propose allows to obtain a similarity between fuzzy elements since we compute implications for each element. Starting from Kosko and Young observations, Botana [16] presents a set of new measures derived

Table 1: Inclusion and similarity measures of the literature, and the new Hamacher inclusion and similarity measures, all obtained through the proposed general logical framework.

Inclusion Measure $\mathcal{I}$	**Aggregation Operator** $\mathcal{A}$	**Implication** I
$\mathcal{I}(A,B) = \min_{x\in X}(\min(1, 1 - f_A(x) + f_B(x)))$ as defined in [12]	min	$I_{\top_L}$
$\mathcal{I}(A,B) = \frac{1}{n}\sum_{x\in X}\min(1, 1 - f_A(x) + f_B(x))$	arithmetical mean	$I_{\top_L}$
$\mathcal{I}(A,B) = \frac{1}{n}\sum_{x\in X}\max(1 - f_A(x), f_B(x))$	arithmetical mean	$I_{\perp_S}$
$\mathcal{I}(A,B) = \frac{1}{n}\sum_{x\in X} 1 - f_A(x) + f_A(x)\, f_B(x)$ as defined in [4]	arithmetical mean	$I_{\perp_A}$
$\mathcal{I}(A,B) = \frac{1}{n}\sum_{x\in X}\frac{f_B(x)(\gamma + f_A(x) - \gamma f_A(x))}{f_B(x)(\gamma + f_A(x) - \gamma f_A(x)) + f_A(x) - f_B(x)}$	arithmetical mean	$I_{\top_{H_\gamma}}$
Similarity Measure $\mathcal{S}$	**Aggregation Operator** $\mathcal{A}$	**Implication** I
$\mathcal{S}(A,B) = \frac{1}{n}\sum_{x\in X}\frac{\min(f_A(x), f_B(x))}{\max(f_A(x), f_B(x))}$ as defined in [13]	arithmetical mean	$I_{\top_A}$
$\mathcal{S}(A,B) = \frac{1}{n}\sum_{x\in X} 1 - \lvert f_A(x) - f_B(x)\rvert$ as defined in [13]	arithmetical mean	$I_{\top_L}$
$\mathcal{S}(A,B) = \max_{x\in X}\min(f_A(x), f_B(x))$	max	$I_{\top_S}$
$\mathcal{S}(A,B) = 1 - \max_{x\in X}\lvert f_A(x) - f_B(x)\rvert$	min	$I_{\top_L}$
$\mathcal{S}(A,B) = \frac{1}{n}\sum_{x\in X}\frac{f_{(2)}(x)(\gamma + f_{(1)}(x) - \gamma f_{(1)}(x))}{f_{(2)}(x)(\gamma + f_{(1)}(x) - \gamma f_{(1)}(x)) + f_{(1)}(x) - f_{(2)}(x)}$	arithmetical mean	$I_{\top_{H_\gamma}}$

from fuzzy implications. He studies whether the introduced inclusion measures satisfy Young's axioms [4] and/or those in [12] when using Wu, Goguen, modified Goguen, Gödel and Standard strict implications. He also gives the formulation of the corresponding entropy in the sense of [15, 14]. Another approach to aggregation operators is proposed in [17] consisting in combining implication truth values through respectively disjunctive and conjunctive functions for an optimistic and pessimistic aggregation. Fan et al. discuss the links between inclusion, entropy and fuzzy implications, and propose some new axioms for these measures [5]. Burillo et al. present a family of implication operators derived from the Łukasiewicz implication in order to define a family of inclusion grade operators [6] using the minimum operator for $\mathcal{A}$. In [18], Kehagias and Konstantinidou introduce L-fuzzy valued inclusion, similarity and distance measures, i.e. mappings $\mathcal{I}, \mathcal{S}, \mathcal{D} : \mathcal{F}(X) \times \mathcal{F}(X) \to [0,1]^n$, but restrict the output to crisp values. As pointed out by the authors, the vector output can lead to a difficult interpretation of the result. Furthermore, as vectors are partially ordered they are even harder to compare, they require a new measure to compare outputs. The framework we propose can provide a vector output since an implication on each element of X is computed. By contrast to [18], it would be a *fuzzy L-fuzzy valued* measure. More recently [19, 20], a distance between fuzzy operators, fuzzy implication functions in particular, is proposed. It leads to normalized tensor-norms which allow to define a similarity of fuzzy sets, and present an heuristic to choose the most suitable implication function to a fuzzy inference system. Zhang and Zhang propose an hybrid inclusion measure in [10] and use it to define similarity and distance measures of fuzzy sets. They restrict themselves to the weighted mean for $\mathcal{A}$, so it can be viewed as a special case of the work we propose, but contrarily to Young the involved implications satisfy the confinement and the border principle. Let us finally mention the work by Fono et al. [21] where as many difference operations as many implications are used to define measures of comparison of fuzzy sets in the set-theoretic framework, but we remind that such measures are out of the scope of this paper.

5 Conclusion and perspectives

In this paper, we propose a unified logical framework to compare fuzzy sets as well as fuzzy elements. Within this framework, new measures of inclusion, similarity and distance can be easily derived. These measures depend on any fuzzy implication I, provided it satisfies the necessary conditions we give (the border and the confinement principles) and any aggregation operator $\mathcal{A}$ (for similarity and distance) or any conjunctive and strictly monotonic compensatory aggregation operator $\mathcal{A}$ (for inclusion). Choosing specific $(\mathcal{A}, I)$ enables to retrieve most of the measures of the literature.
We hope that results of this work would be of great help to set comparison functions in many fields: fuzzy mathematical morphology [6], cluster validity [5], as well as other domains e.g. image retrieval or feature selection.

Preservation of properties of interval-valued fuzzy relations

B. Pękala
Institute of Mathematics, University of Rzeszów
Rejtana 16a, 35-310 Rzeszów, Poland
Email: bpekala@univ.rzeszow.pl

Abstract— *The goal of this paper is to consider properties of the composition of interval-valued fuzzy relations which were introduced by L.A. Zadeh in 1975. Fuzzy set theory turned out to be a useful tool to describe situations in which the data are imprecise or vague. Interval-valued fuzzy set theory is a generalization of fuzzy set theory which was introduced also by Zadeh in 1965. This paper generalizes some properties of interval matrices considered by Pękala (2007) on these of interval-valued fuzzy relations.*

Keywords— Fuzzy relations, interval-valued fuzzy relations, properties of interval-valued fuzzy relations

1 Introduction

The idea of a fuzzy relation was defined in [28]. An extension of fuzzy set theory is interval-valued fuzzy set theory. Any interval-valued fuzzy set is defined by an interval-valued membership function: a mapping from the given universe to the set of all closed subintervals of [0,1] (it means that information is incomplete). In this paper we study properties of the composition of interval-valued fuzzy relations. Consideration of diverse properties of the composition is interesting not only from a theoretical point of view but also for the applications, since the composition of interval-valued fuzzy relations has proved to be useful in several fields, see for example, [20] (performance evaluation), [27] (genetic algorithm), [19] (approximate reasoning) or in other (see [1, 16]). In Section 2, we recall elementary properties of the composition of interval-valued fuzzy relations. Next, we consider preservation of properties of interval-valued fuzzy relations by the composition and lattice operations.

We give the following definition. Let X, Y, Z be crisp finite non-empty sets.

Definition 1 (cf. [29, 26]). Let $Int([0,1])$ be the set of all closed subintervals of $[0,1]$. An interval-valued fuzzy relation R in a universe X, Y is a mapping $R : X \times Y \to Int([0,1])$ such that $R(x,y) = [\underline{R}(x,y), \overline{R}(x,y)] \in Int([0,1])$, for all pairs $(x,y) \in (X \times Y)$. The class of interval-valued fuzzy relations in a universe $X \times Y$ will be denoted by $IVFR(X \times Y)$ or $IVFR(X)$ for $X = Y$.

Interval-valued fuzzy relations reflect the idea that membership grades are often not precise and the intervals represent such uncertainty.

The boundary elements in $IVFR(X \times Y)$ are $\mathbf{1} = [1,1]$ and $\mathbf{0} = [0,0]$. The relation R^{-1} between Y and X is defined by $R^{-1}(y,x) = R(x,y)$ for all $(x,y) \in (X \times Y)$ which we will call the inverse relation of R.

Let us look at immediate properties for interval-valued fuzzy relations: Let $P, R \in IVFR(X \times Y)$.

Then for every $(x,y) \in (X \times Y)$ we can define

$$P(x,y) \leq R(x,y) \Leftrightarrow \underline{P}(x,y) \leq \underline{R}(x,y), \overline{P}(x,y) \leq \overline{R}(x,y),$$

$$(P \vee R)(x,y) = [\max(\underline{P}(x,y), \underline{R}(x,y)), \max(\overline{P}(x,y), \overline{R}(x,y))],$$

$$(P \wedge R)(x,y) = [\min(\underline{P}(x,y), \underline{R}(x,y)), \min(\overline{P}(x,y), \overline{R}(x,y))],$$

where operations $\vee$ and $\wedge$ are the supremum and the infimum in $IVFR(X \times Y)$, respectively. For arbitrary set $T \neq \emptyset$ similarly we use

$$(\bigvee_{t \in T} R_t)(x,y) = [\bigvee_{t \in T} \underline{R_t}(x,y), \bigvee_{t \in T} \overline{R_t}(x,y)],$$

$$(\bigwedge_{t \in T} R_t)(x,y) = [\bigwedge_{t \in T} \underline{R_t}(x,y), \bigwedge_{t \in T} \overline{R_t}(x,y)].$$

We know that $([0,1], \max, \min)$ is a complete, distributive lattice, and therefore $(IVFR(X \times Y), \vee, \wedge)$ is also a complete, distributive lattice. So it is a particular case of lattices considered by Goguen in [18].

Interval-valued fuzzy relations (sets) are equivalent to some other extensions of fuzzy relations (sets) (see [12]). Among others, interval-valued fuzzy relations are isomorphic to Atanassov's fuzzy relations. This fact was noticed by several authors [5, 11, 12]. An Atanassov's fuzzy relation is a pair of fuzzy relations, namely a membership and a nonmembership functions, which represent positive and negative aspects of the given information. This objects introduced by Atanassov and originally called intuitionistic fuzzy relations were recently suggested to be called Atanassov's intuitionistic fuzzy relations or just bipolar fuzzy relations [15]. An Atanassov's fuzzy set theory is also widely applied in solving real-life problems. An example of such application is the optimization in Atanassov's intuitionistic fuzzy environment (an extension of fuzzy optimization and an application of bipolar fuzzy sets) where by applying this concept it is possible to reformulate the optimization problem by using degrees of rejection of constraints and values of the objective which are non-admissible. This concept allows one to define a degree of rejection which cannot be simply a complement of the degree of acceptance [2]. The idea of a positive and negative information was confirmed by psychological investigations [9]. Moreover, multiattribute decision making using Atanassov's intuitionistic fuzzy sets is possible (see [22, 23]).

Definition 2 (cf. [3]). Let $X \neq \emptyset$, $\mathfrak{R},\ \mathfrak{R}^d : X \times Y \to [0,1]$ be fuzzy relations fulfilling the condition

$$\mathfrak{R}(x,y) + \mathfrak{R}^d(x,y) \leqslant 1, \quad (x,y) \in (X \times Y).$$

A pair $\rho = (\mathfrak{R}, \mathfrak{R}^d)$ is called an Atanassov's intuitionistic fuzzy relation. The family of all Atanassov's intuitionistic fuzzy relations described in a given sets X, Y is denoted by $AIFR(X \times Y)$.

ISBN: 978-989-95079-6-8

Basic operations on Atanassov's intuitionistic fuzzy relations $\rho = (\mathfrak{R}, \mathfrak{R}^d)$, $\sigma = (\mathfrak{S}, \mathfrak{S}^d)$ are defined in the following way

$$\rho \cup \sigma = (\max(\mathfrak{R}, \mathfrak{S}), \min(\mathfrak{R}^d, \mathfrak{S}^d)),$$

$$\rho \cap \sigma = (\min(\mathfrak{R}, \mathfrak{S}), \max(\mathfrak{R}^d, \mathfrak{S}^d)),$$

$$\rho \leqslant \sigma \ \Leftrightarrow \ (\mathfrak{R} \leq \mathfrak{S}, \ \mathfrak{S}^d \leq \mathfrak{R}^d).$$

The isomorphism which proves the equivalence between Atanassov's intuitionistic fuzzy relations and interval-valued fuzzy relations is the following

Theorem 1 (cf. [11]). *The mapping $\psi : IVFR(X \times Y) \to AIFR(X \times Y)$, such that $R \to \rho$ is an isomorphism between the lattices $(IVFR(X \times Y), \vee, \wedge)$ and $(AIFR(X \times Y), \cup, \cap)$, where $R(x,y) = [\underline{R}(x,y), \overline{R}(x,y)]$, $R \in IVFR(X \times Y)$ and $\rho(x,y) = (\underline{R}(x,y), 1 - \overline{R}(x,y))$, $(x,y) \in (X \times Y)$.*

2 Composition of interval-valued fuzzy relations

Now, we consider the composition of interval-valued fuzzy relations.

Definition 3 (cf. [8]). Let $* : [0,1]^2 \to [0,1]$,
$P \in IVFR(X \times Y)$, $R \in IVFR(Y \times Z)$.
By the $\sup -*$ composition of relations P and R we call the relation $P \circ R \in IVFR(X \times Z)$,

$$(P \circ R)(x,z) = [(\underline{P} \circ \underline{R})(x,z), (\overline{P} \circ \overline{R})(x,z)], \quad (1)$$

where

$$(\underline{P} \circ \underline{R})(x,z) = \bigvee_{y \in Y} (\underline{P}(x,y) * \underline{R}(y,z)),$$

$$(\overline{P} \circ \overline{R})(x,z) = \bigvee_{y \in Y} (\overline{P}(x,y) * \overline{R}(y,z))$$

and $(\underline{P} \circ \underline{R})(x,z) \leq (\overline{P} \circ \overline{R})(x,z)$.

Other types of compositions may be also considered. For example, the composition of interval-valued fuzzy relations with supremum and $*$ being a triangular norm or a triangular conorm is examined in [8].

Definition 4 (cf. [24]). A triangular norm T (conorm S) is an increasing, commutative, associative operation
$T(S) : [0,1]^2 \to [0,1]$ with a neutral element 1 (0).

In [8] it was proved, for finite sets X, Y, Z, that compositions mentioned there are associative if and only if the first operation in composition is $\vee$ or $\wedge$ and the second is an arbitrary triangular norm or conorm. This is why the choice of the first operation in the composition (1) is reasonable.

For our further considerations we need the following properties

Definition 5 (cf. [18]). Let $* : [0,1]^2 \to [0,1]$. Operation $*$ is infinitely sup-distributive, if

$$\bigvee_{t \in T} (x_t * y) = (\bigvee_{t \in T} x_t) * y, \quad \bigvee_{t \in T} (y * x_t) = y * (\bigvee_{t \in T} x_t).$$

Definition 6 (cf. [6]). Operation $* : [0,1]^2 \to [0,1]$ is isotone if it fulfils the condition:

$$\underset{x,y,z \in [0,1]}{\forall} x \leq y \Rightarrow x * z \leq y * z, z * x \leq z * y.$$

By generalization of the results of the papers [14, 25] and using [13] we obtain

Lemma 1. *If $*$ is isotonic, then $\sup -*$ composition is also isotonic.*

Proof. Let $*$ be left side isotonic.
For $P, R \in IVFR(X \times Y), Q \in IVFR(Y \times Z)$

$$P \leq R \Leftrightarrow [\underline{P}, \overline{P}] \leq [\underline{R}, \overline{R}] \Leftrightarrow$$

$$\underset{x,y \in X \times Y}{\forall} \underline{P}(x,y) \leq \underline{R}(x,y), \overline{P}(x,y) \leq \overline{R}(x,y)$$

by isotonicity of the $*$ and supremum we have for
$x \in X, y \in Y, z \in Z$

$$\bigvee_{y \in X} (\underline{P}(x,y) * \underline{Q}(y,z)) \leq \bigvee_{y \in X} (\underline{R}(x,y) * \underline{Q}(y,z)),$$

$$\bigvee_{y \in X} (\overline{P}(x,y) * \overline{Q}(y,z) \leq \bigvee_{y \in X} (\overline{R}(x,y) * \overline{Q}(y,z)) \Leftrightarrow$$

$$\underline{P} \circ \underline{Q} \leq \underline{R} \circ \underline{Q}, \overline{P} \circ \overline{Q} \leq \overline{R} \circ \overline{Q} \Leftrightarrow P \circ Q \leq R \circ Q.$$

The right side isotonicity of $\circ$ may be proved similarly. □

Lemma 2. *Let the operation $*$ have a zero element z. If $*$ has a neutral element e, then $\sup -*$ composition has a neutral element $\mathbf{S}_e = [S_e, S_e]$,*

$$S_e(x,y) = \begin{cases} e & if \ x = y \\ z & if \ x \neq y \end{cases} \quad for \ x \in X, y \in Y.$$

Proof. Let $*$ operation have a zero element z and a neutral element e.

$$(\mathbf{S}_e \circ R)(x,y) =$$

$$[\bigvee_{z \in X} (S_e(x,z) * \underline{R}(z,y)), \bigvee_{z \in X} (S_e(x,z) * \overline{R}(z,y))] =$$

$$[(e * \underline{R}(x,y)) \vee \bigvee_{x \neq z} (z * \underline{R}(z,y)), (e * \overline{R}(x,y)) \vee \bigvee_{x \neq z} (z * \overline{R}(z,y))] =$$

$$[e * \underline{R}(x,y), e * \overline{R}(x,y)] = [\underline{R}(x,y), \overline{R}(x,y)] = R(x,y).$$

The proof for $R \circ \mathbf{S}_e = R$ is similar. □

If $*$ is an isotonic operation, then we may prove

$$\bigvee_{t \in T} (P_t \circ R) \leq (\bigvee_{t \in T} P_t) \circ R, \ \bigwedge_{t \in T} (P_t \circ R) \geq (\bigwedge_{t \in T} P_t) \circ R. \quad (2)$$

Now we examine the problem of sup-distributivity. Authors [8] in Theorem 6 present condition for sup-distributivity by $*$ equal to any t-norm or t-conorm and by finite non-empty X, Y. By generalization we obtain

Lemma 3. *If an operation $*$ is infinitely sup-distributive, then $\sup -*$ composition is also infinitely sup-distributive i.e., for $P_t \in IVFR(X \times Y), R \in IVFR(Y \times Z)$*

$$\bigvee_{t \in T} (P_t \circ R) = (\bigvee_{t \in T} P_t) \circ R. \quad (3)$$

ISBN: 978-989-95079-6-8

Proof. Let $*$ be sup-distributive, $x \in X, y \in Y, z \in Z$. Then

$$((\bigvee_{t\in T} P_t) \circ R)(x,z) =$$

$$[\bigvee_{y\in Y}((\bigvee_{t\in T}\underline{P_t})(x,y)*\underline{R}(y,z)), \bigvee_{y\in Y}((\bigvee_{t\in T}\overline{P_t})(x,y)*\overline{R}(y,z))] =$$

$$[\bigvee_{y\in Y}(\bigvee_{t\in T}(\underline{P_t}(x,y)*\underline{R}(y,z))), \bigvee_{y\in Y}(\bigvee_{t\in T}(\overline{P_t}(x,y)*\overline{R}(y,z)))] =$$

$$[\bigvee_{t\in T}(\bigvee_{y\in Y}(\underline{P_t}(x,y)*\underline{R}(y,z))), \bigvee_{t\in T}(\bigvee_{y\in Y}(\overline{P_t}(x,y)*\overline{R}(y,z)))] =$$

$$[\bigvee_{t\in T}(\underline{P_t}\circ\underline{R})(x,z), \bigvee_{t\in T}(\overline{P_t}\circ\overline{R})(x,z)] = \bigvee_{t\in T}(P_t\circ R)(x,z).$$

□

Here we discuss the most important property of binary operations, i.e. the associativity. The associativity of $*$ is not sufficient for the associativity of the $\sup -*$ composition. Some results of this problem we see in ([8], Theorem 9) for t-norms or t-conorms on finite sets. As a result the question about the associativity of the composition of interval-valued fuzzy relations we get for arbitrary sets X, Y, Z, U the following lemmas.

Lemma 4. *If an operation $*$ is associative and infinitely sup-distributive, then* $\sup -*$ *composition is associative.*

Proof. Let operation $*$ be associative and infinitely sup-distributive, $P \in IVFR(X\times Y), R \in IVFR(Y\times Z)$, $Q \in IVFR(Z\times U)$ and $x \in X, y \in Y, z \in Z, u \in U$.

$$((P\circ R)\circ Q)(x,u) = [((\underline{P}\circ\underline{R})\circ\underline{Q})(x,u), ((\overline{P}\circ\overline{R})\circ\overline{Q})(x,u)] =$$

$$[\bigvee_z(\underline{P}\circ\underline{R})(x,z)*\underline{Q}(z,u), \bigvee_z(\overline{P}\circ\overline{R})(x,z)*\overline{Q}(z,u)] =$$

$$[\bigvee_z(\bigvee_y(\underline{P}(x,y)*\underline{R}(y,z))*\underline{Q}(z,u)),$$

$$\bigvee_z(\bigvee_y(\overline{P}(x,y)*\overline{R}(y,z))*\overline{Q}(z,u))] =$$

$$[\bigvee_z\bigvee_y(\underline{P}(x,y)*(\underline{R}(y,z)*\underline{Q}(z,u))),$$

$$\bigvee_z\bigvee_y(\overline{P}(x,y)*(\overline{R}(y,z)*\overline{Q}(z,u)))] =$$

$$[\bigvee_y(\underline{P}(x,y)*\bigvee_z(\underline{R}(y,z)*\underline{Q}(z,u))),$$

$$\bigvee_y(\overline{P}(x,y)*\bigvee_z(\overline{R}(y,z)*\overline{Q}(z,u)))] =$$

$$[(\underline{P}\circ(\underline{R}\circ\underline{Q}))(x,u), (\overline{P}\circ(\overline{R}\circ\overline{Q}))(x,u)] = (P\circ(R\circ Q))(x,u).$$

□

As a direct consequence of the above lemmas we observed that set of all interval-valued fuzzy relations with the composition (1) create a semigroup.

Proposition 1. *If $*$ is associative, infinitely sup-distributive operation with a zero element z=0 and a neutral element e=1, then $(IVFR(X),\circ)$ is an ordered semigroup with the identity $\boldsymbol{I} = [I, I]$.*

In the sequel we denote by D the set of all binary operations $* : [0,1]^2 \to [0,1]$ which are associative and infinitely sup-distributive (these conditions imply that $*$ is isotonic). As a result a special case of $*$ may be a left-continous triangular norm or conorm. If $* \in D$, then in a semigroup $(IVFR(X),\circ)$ we can consider the powers of its elements, i.e. relations R^n for $R \in IVFR(X)$, $n \in \mathbb{N}$. By analogy to [21] we define

Definition 7. By the powers of a relation $R \in IVFR(X)$ we call interval-valued fuzzy relations

$$R^1 = R,\ R^{m+1} = R^m \circ R, \text{ where } m = 1, 2, \ldots .$$

By the upper closure $R^\vee$ and the lower closure $R^\wedge$ of the relation R we call, respectively

$$R^\vee = \bigvee_{k=1}^{\infty} R^k,\ \ R^\wedge = \bigwedge_{k=1}^{\infty} R^k, \text{ where } R^k = [\underline{R}^k, \overline{R}^k]. \quad (4)$$

Proposition 2. *If $* \in D$ and $P, R \in IVFR(X)$, then*

$$\bigvee_{n\in\mathbb{N}}(P\vee R)^n \geq P^n \vee R^n,\ \ (P\wedge R)^n \leq P^n \wedge R^n, \quad (5)$$

$$(P\vee R)^\vee \geq P^\vee \vee R^\vee,\ \ (P\wedge R)^\vee \leq P^\vee \wedge R^\vee, \quad (6)$$

$$(P\vee R)^\wedge \geq P^\wedge \vee R^\wedge,\ \ (P\wedge R)^\wedge \leq P^\wedge \wedge R^\wedge. \quad (7)$$

Proof. Let $n \in \mathbb{N}$. From the isotonicity of $*$ and the Lemma 1 we know that the $\sup -*$ composition is also isotonic. As a result we obtain the isotonicity for powers. Then by

$$P\vee R \geq P,\ P\vee R \geq R$$

$$(\underline{P}\vee\underline{R} \geq \underline{P},\ \underline{P}\vee\underline{R} \geq \underline{R},\ \overline{P}\vee\overline{R} \geq \overline{P},\ \overline{P}\vee\overline{R} \geq \overline{R})$$

we have

$$(\underline{P}\vee\underline{R})^n \geq \underline{P}^n,\ (\underline{P}\vee\underline{R})^n \geq \underline{R}^n \text{ and}$$

$$(\overline{P}\vee\overline{R})^n \geq \overline{P}^n,\ (\overline{P}\vee\overline{R})^n \geq \overline{R}^n,$$

so we obtain

$$(P\vee R)^n \geq P^n,\ (P\vee R)^n \geq R^n \Rightarrow (P\vee R)^n \geq P^n \vee R^n.$$

Similarly, we can prove $(P\wedge R)^n \leq P^n \wedge R^n$. Moreover, supremum and infimum are isotonic, so from the condition (5) also closures have this property
$P^\vee \leq (P\vee R)^\vee$, $R^\vee \leq (P\vee R)^\vee \Rightarrow P^\vee \vee R^\vee \leq (P\vee R)^\vee$,
$(P\wedge R)^\vee \leq P^\vee$, $(P\wedge R)^\vee \leq R^\vee \Rightarrow (P\wedge R)^\vee \leq P^\vee \wedge R^\vee$.
Similarly, we may prove the inequalities in (7). □

Proposition 3. *Let $* \in D$ and $P, R \in IVFR(X)$.*
If $P\circ R = R\circ P$, then

$$\bigvee_{n\in\mathbb{N}}(P\circ R)^n = P^n \circ R^n, \quad (8)$$

$$(P\circ R)^\vee \leq P^\vee \circ R^\vee,\ \ (P\circ R)^\wedge \geq P^\wedge \circ R^\wedge. \quad (9)$$

ISBN: 978-989-95079-6-8

Proof. The given equality in (8) may be proved by the mathematical induction and associativity of $*$ and commutativity of powers, which is implied by commutativity of P and R. Then

$$(P \circ R)^{\vee} = \bigvee_{k=1}^{\infty} (P \circ R)^k = [\bigvee_{k=1}^{\infty} (\underline{P}^k \circ \underline{R}^k), \bigvee_{k=1}^{\infty} (\overline{P}^k \circ \overline{R}^k)],$$

by (3), (2) and isotonicity of the operation $\sup - *$ we have

$$[\bigvee_{k=1}^{\infty} (\underline{P}^k \circ \underline{R}^k), \bigvee_{k=1}^{\infty} (\overline{P}^k \circ \overline{R}^k)] \leq [\bigvee_{k=1}^{\infty} (\underline{P}^{\vee} \circ \underline{R}^k), \bigvee_{k=1}^{\infty} (\overline{P}^{\vee} \circ \overline{R}^k)]$$

$$\leq [\underline{P}^{\vee} \circ \bigvee_{k=1}^{\infty} \underline{R}^k, \overline{P}^{\vee} \circ \bigvee_{k=1}^{\infty} \overline{R}^k] = [\underline{P}^{\vee} \circ \underline{R}^{\vee}, \overline{P}^{\vee} \circ \overline{R}^{\vee}] = P^{\vee} \circ R^{\vee},$$

which proves the first condition in (9). The second condition in (9) one may be justified in a similar way. □

3 Properties of interval-valued fuzzy relations

Now, we will examine whether the given properties are preserved by the composition of interval-valued fuzzy relations. We see that many properties of the $*$ operation are transposed to the operation of $\sup - *$ composition but not all of them. Namely, if $* = \min$, then $\sup - \min$ composition is not commutative. Now, we examine very interesting properties, namely subidempotency and superidempotency. These properties are of the large interest for example in economy where they are applied in valuation of supply and demand. Similarly to definitions of properties of fuzzy relations in [21] we have

Definition 8. Let $R \in IVFR(X)$. The relation R is called idempotent, subidempotent (transitive) or superidempotent if $R^2 = R,\ R^2 \leq R,\ R^2 \geq R$, respectively.

For the Boolean matrices of dimension $n \times n$ the following computations hold true

Table 1: The subidempotent relations in the family of all relations.

n	all	subidempotent	%
2	16	13	81,25000
3	512	171	33,39844
4	65536	3994	6,09436
5	33554432	154303	0,45986

A similar situation takes place in any distributive and bounded lattice, it means that the percentage of the subidempotent matrices is rapidly decreasing with the growth of n. This is why the consideration and determination of the upper closure $R^{\vee}$ is very important.

Theorem 2. *Let $* \in D$ and $R \in IVFR(X)$. $R^{\vee}$ is the least subidempotent relation greater than or equal to R. Moreover, the relation R is subidempotent if and only if $R = R^{\vee}$.*

Proof. Let $R, S, Q \in IVFR(X)$. If R is subidempotent, then

$$\bigwedge_{n \in \mathbb{N}} R^n \leq R \text{ and } R \leq R^{\vee} = \bigvee_{n \in \mathbb{N}} R^n \leq R,$$

so we obtain $R^{\vee} = R$.
If $R^{\vee} = R$, then for $S = R^{\vee}$ we have

$$S^2 = \bigvee_{k=2}^{\infty} R^k \leq R^{\vee} = S$$

and $R^{\vee}$ is subidempotent.
We show that if there exists $Q = [\underline{Q}, \overline{Q}]$ such that

$$[\underline{R}, \overline{R}] \leq [\underline{Q}, \overline{Q}] \text{ and } [\underline{Q}^2, \overline{Q}^2] \leq [\underline{Q}, \overline{Q}],$$

then by isotonicity the $\sup - *$ composition (Lemma 1) we obtain

$$[\underline{R}^2, \overline{R}^2] \leq [\underline{R} \circ \underline{Q}, \overline{R} \circ \overline{Q}] \leq [\underline{Q}^2, \overline{Q}^2]$$

thus

$$[\underline{R}^k, \overline{R}^k] \leq [\underline{Q}^k, \overline{Q}^k] \leq [\underline{Q}, \overline{Q}] \text{ for } k \in \mathbb{N}.$$

So by isotonicity of the supremum $R^{\vee} \leq Q$. □

The closures and powers of interval-valued fuzzy relations also preserve some properties of such relations.

Theorem 3. *Let an operation $* \in D$ be commutative and $R \in IVFR(X)$. If R is subidempotent (superidempotent), then R^n, $R^{\wedge}$ ($R^{\vee}$) are subidempotent (superidempotent).*

Proof. Let $R^2 \leq R$. Then R^n are also subidempotent, $n \in \mathbb{N}$. By (2) and subidempotency of R we have

$$(R^{\wedge})^2 \leq (R^2)^{\wedge} \leq R^{\wedge},$$

so $R^{\wedge}$ is subidempotent. The property of superidempotency may be proved analogously. □

Theorem 4. *Let $T \neq \emptyset$ and $* \in D$ and $R_t \in IVFR(X)$, $t \in T$. If $(R_t)_{t \in T}$ is a family of subidempotent relations, then the relation $R = \bigwedge_{t \in T} R_t$ is subidempotent.*

Proof. Let $R_t^2 \leq R_t$, $t \in T$, then by (2)

$$R^2 = (\bigwedge_{t \in T} R_t)^2 = (\bigwedge_{s \in T} R_s) \circ (\bigwedge_{t \in T} R_t) \leq$$

$$\bigwedge_{t \in T} ((\bigwedge_{s \in T} R_s) \circ R_t) \leq \bigwedge_{s,t \in T} (R_s \circ R_t) \leq \bigwedge_{t \in T} R_t = R$$

i.e., the relation R is subidempotent. □

Theorem 5. *Let $* \in D$ and $P, R \in IVFR(X)$. If P, R are subidempotent, then $P \vee R$ is subidempotent if and only if $P \circ R \vee R \circ P \leq P \vee R$.*

Proof. Since $P^2 \leq P$, $R^2 \leq R$ so by (3) we obtain

$$(P \vee R)^2 = [(\underline{P} \vee \underline{R}) \circ (\underline{P} \vee \underline{R}), (\overline{P} \vee \overline{R}) \circ (\overline{P} \vee \overline{R})] =$$

$$[(\underline{P} \circ \underline{P}) \vee (\underline{R} \circ \underline{P}) \vee (\underline{P} \circ \underline{R}) \vee (\underline{R} \circ \underline{R}),$$
$$(\overline{P} \circ \overline{P}) \vee (\overline{R} \circ \overline{P}) \vee (\overline{P} \circ \overline{R}) \vee (\overline{R} \circ \overline{R})] \leq$$

$$[\underline{P} \vee (\underline{R} \circ \underline{P}) \vee (\underline{P} \circ \underline{R}) \vee \underline{R}, \overline{P} \vee (\overline{R} \circ \overline{P}) \vee (\overline{P} \circ \overline{R}) \vee \overline{R}] =$$

$$[\underline{P} \vee \underline{R} \vee (\underline{R} \circ \underline{P}) \vee (\underline{P} \circ \underline{R}), \overline{P} \vee \overline{R} \vee (\overline{R} \circ \overline{P}) \vee (\overline{P} \circ \overline{R})],$$

as a result

$$(P \vee R)^2 \leq P \vee R \Leftrightarrow P \circ R \vee R \circ P \leq P \vee R,$$

because

$$P \leq R \Leftrightarrow P \vee R = R.$$

□

ISBN: 978-989-95079-6-8

Theorem 6. *Let $* \in D$ and $P, R \in IVFR(X)$. If P, R are subidempotent (superidempotent) and $P \circ R = R \circ P$, then $P \circ R$ is subidempotent (superidempotent).*

Proof. If $\underline{P} \circ \underline{R} = \underline{R} \circ \underline{P}$ and $\overline{P} \circ \overline{R} = \overline{R} \circ \overline{P}$, $P^2 \leq P$, $R^2 \leq R$, then by the associativity and monotonicity of the $\sup -*$ composition we have

$$(P \circ R)^2 = [(\underline{P} \circ \underline{R})^2, (\overline{P} \circ \overline{R})^2] =$$

$$[\underline{P} \circ (\underline{R} \circ \underline{P}) \circ \underline{R}, \overline{P} \circ (\overline{R} \circ \overline{P}) \circ \overline{R}] =$$

$$[\underline{P} \circ \underline{P} \circ \underline{R} \circ \underline{R}, \overline{P} \circ \overline{P} \circ \overline{R} \circ \overline{R}] = [\underline{P}^2 \circ \underline{R}^2, \overline{P}^2 \circ \overline{R}^2] \leq$$

$$[\underline{P} \circ \underline{R}, \overline{P} \circ \overline{R}] = P \circ R.$$

As a result $P \circ R$ is subidempotent. The proof for superidempotency is similar. □

4 Conclusion

In this work we present only some problems connected with the preservation of interval-valued fuzzy relation properties by the $\sup -*$ composition and related to it operation. We can also consider preservation of other properties (for example, symmetry, asymmetry, antisymmetry, reflexivity, irreflexivity, connectedness) by the composition of interval-valued fuzzy relations and also by its powers and lattice operations.
We may consider dual composition to the one defined in (1). This is the $\inf -*'$ composition with the dual binary operation $*'$, where $x *' y = 1 - (1 - x) * (1 - y)$ for $x, y \in [0, 1]$. The properties of this composition may be deduced from the $\sup -*$ composition.
Moreover, we may study interval-valued t-norms and t-conorms as operations on *Int*([0,1]) which are important functions because they are useful in approximate reasoning, in medical diagnosis and information retrieval. For example, the authors of [7, 10] examine the construction of t-norms and t-conorms in the lattice $(Int[0, 1], \vee, \wedge)$ and analyze some properties of them.

A fuzzy approach for the model of sliding window. An application to behaviour patterns mining

María Ros, Miguel Delgado, Amparo M. Vila[1]

1.Department of Computer Science and A.I. University of Granada, España
Email: {marosiz, mdelgado, vila}@decsai.ugr.es

Abstract— *Many traditional environment applications base their operations on using sensor. For instance, the Tagged World uses the information from sensors to identify user behaviour and to provide services. We present a method to limit an user behaviour through external user knowledge: a Temporal Window. However, an user behaviour has random imprecision by definition. Thus, we have adapted the method to manage the imprecision, Fuzzy Temporal Window, which includes Fuzzy Logic concepts. As an application, we present a method to extract behaviour patterns on time defined by a Fuzzy Temporal Window.*

Keywords— Behaviour, Fuzzy Windows, Quantified Sentences, Tagged World, Frequent Itemsets

1 Introduction

In the last years, Smart Computers have suffered a great evolution that is transforming the world. *Ubiquitous Computing*[1] uses them to make user daily life easier. Computers are included on daily life without disturbing normal user activities. Different devices are added in traditional environment from common PDA or Mobile Phone to sensors. Nowadays, the last trend in *Ubiquitous Computing* is to provide the environment with different mechanisms to get information.

Sensors are devices that are able to know what is happening in the environment. There are many kind of sensors from temperature sensor to mechanical one. We also find RFID sensors [2] that identify every object in the environment with an unique number by means of radio frequency. Placing RFID tags in an environment we get to construct an intelligent space in which everyone can enjoy services. An intelligent space obtains user position, user behaviour, and environment information around a user and so on by a sensor network [3]. Other example about these spaces can be found in [4]. We find an intelligent space that provides services in a variety of scenes, but hardly ever, without reasoning or inference. The development of these projects is the Tagged World concept.

In [5, 3], the Tagged World project is presented. This project is developed in the University of Ritsumeikan, Japan and consists on providing appropriate personalized services for each user, to make their life easier and safer by recognizing and reasoning the human behaviour. They use a wearable computer as a Pocket Assistant that compares an access log with patterns to recognize human activities. The system is based on a Bayesian network and obtains results with a probability value for every extracted behaviour.

Other alternative is proposed by Philipose and et al. [6]. They proposed a system to infer Activities of Daily Living in a Tagged World. They present a new paradigm for ADL inferencing leverage radio-frequency-identification technology, data mining and a probabilistic inference engine to recognize ADLs based on objects that people use. As sensor, they use RFID technology with other sensor streams to fill in the gaps. The system represents activities as linear sequences of activity stages, and annotates each stage with the involved objects and the probability of their involvement.

In [7][8] is proposed a system to identify correct behaviour using Data Mining Techniques. The system is divided into two main parts: inductive learning mechanism, which produces a behaviour database and a reasoning system for the recognition of sequences that uses this database. The first stage uses Frequent Itemsets, while the second one does Regular Grammar.

This paper is organized in six main sections. In Section 2 we present the formal problem to solve. In Section 3, Fuzzy Temporal Window concept is explained. Section 4 presents the method that manage problem uncertainty. In section 5, we show some empirical results, comparing crisp and fuzzy models. Finally, the conclusions and future works are reported in section 6.

2 Formal Problem

This section defines the formal problem: to obtain sequence patterns to identify user behaviour that are defined on a specific domain and context. Thus, we have to define some basic concepts which are the objectives of the system.

DEFINITION **2.1 (Action)** *An action, a, is an activity that happens using a specific object.*

However, it results very interesting to know when an action happens on time.

DEFINITION **2.2 (Action on time)** *An action on time, a, is an activity that happens over a specific object in a known time and it is denoted as a pattern $a = (h, l)$, where h is a fact and l is a temporal label that defines the time of the action.*

These definitions give us a basic element to work, but our aim is to find different actions that make a behaviour up.

DEFINITION **2.3 (Behaviour)** *Let $A = \{a_1, ..., a_n\}$ be set of possible user actions in some situations or domains. An user behaviour is a finite set of actions:*

$$\beta = \{\alpha_1, \alpha_2, , ...\alpha_{p(\beta)}\}$$

with $\alpha_j \in A \forall j$, and where α_j is performed before α_k iif $j \leq k$.

ISBN: 978-989-95079-6-8

In this definition, we do not pay attention on the time, although, in general, a behaviour happens in a specific moment on time.

DEFINITION **2.4 (Behaviour on time)** *Let $A = \{a_1, ..., a_n\}$ be set of possible user actions in some situations or domains. Let τ be the temporal line, then A user behaviour on time is a finite set of pair such as:*

$$b_I = \{(\alpha_1, t_1), ...(\alpha_{n(b)}, t_{n(b)})\}$$

where $\alpha_j \in A \forall j$, where α_j is performed before α_k iif $j \leq k$, $t_j \in [0, \tau]$ $\forall t_i < t_j$ if $i \geq j$, with $I = [t_1, t_{n(b)}]$

The System is based on a database about user actions. This database has been obtained from user observation, i.e., from actions that user has done. In rest of this document, we name this database as Observation Data Base (ODB).

The representation of ODB is a transactional database T, where every row is an observation over an user. Normally, we study his activity in a whole day; and every column is a possible action from A set, $A = \{a_1, ..., a_n\}$.

3 Fuzzy Temporal Windows. Extract behaviour patterns tool.

In previous section, we have presented behaviour sequence pattern problem. In [7][8] we study behaviours in a crisp way, however the human behaviour is not crisp. Human activity has random imprecision by definition.

3.1 Motivations

In [7][8] we present a process to obtain correct sequence patterns of actions from user behaviour. This method extracts from a particular ODB common actions. A general ODB contains actions that a user has realized for a whole day. For this reason, we do not know where a behaviour starts or ends. The proposed method needs an expert to indicate when a behaviour is performed. This proposal is not applicable in a real system, since every person has his/her specific activities and habits.

Therefore, we have to design a mechanism to identify the interval of the ODB that we have to study. In this point, we use a knowledge about the behaviour :generally, there exist some behaviours that are realized by user at the same time every day.

EXAMPLE **3.1** *Luis leaves home at 8:30 o'clock.*

We use this knowledge to situate an interval on the temporal line. The result is a subset from particular ODB to the studied behaviour.

In spite of this fact, nobody usually does an action at the exactly moment every day. They usually do actions roughly at the same moment. This raises a new problem: how we fix the interval's ranges to detect a specific activity. Ranges should consider random imprecision of the situations.

EXAMPLE **3.2** *Let us suppose that* Luis often leaves home at 8:30 o'clock*, then we could control actions that happen about 8:30 (from 8:20 to 8:40, for instance).*

We name the interval defined over temporal line as *Temporal Window*. It permits to get a subset from each ODB tuple (See figure 1). In this subset, we know that actions have not the same degree of importance, since actions are about the specific time are more important than actions far from the interval centre. So, we could assign a degree of importance at each action, in function of its situation in the interval. Then, we can define the interval as a fuzzy set and name it as *Fuzzy Temporal Window* (See figure 2).

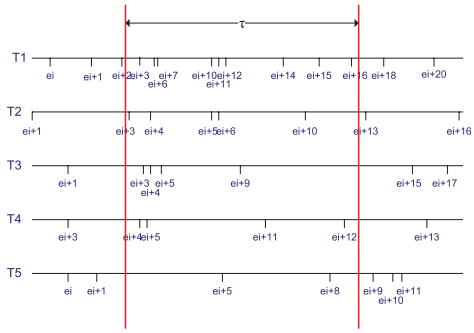

Figure 1: Temporal Window over a ODB

3.2 Model Formulation

In this section we present a formal representation to *Temporal Window* and *Fuzzy Temporal Window*.

DEFINITION **3.1 (Temporal Window, W)** *Let I be a interval from the temporal line τ, ODB the Observation Data Base and $t \in ODB$ a tuple from ODB. Let i_j be an action $i_j = (h_j, l_j)$, then a Temporal Window, W, for a specific behaviour, which happens in interval I of τ, is defined as a subset of t where*

$$\forall i_j \in W(t) \text{ then } i_j \in t \text{ and } l_j \in I$$

DEFINITION **3.2 (Fuzzy Temporal Window, FW)** *Let I be a interval from the temporal line τ, ODB the Observation Data Base and $t \in ODB$ a tuple from ODB. Let i_j be an action $i_j = (h_j, l_j)$ and a Temporal Window, W, to a specific behaviour. Let fs be a fuzzy set over τ, then it defines a* Fuzzy Temporal Window*, FW, as a Temporal Window where*

$$\forall i_j \in W(t)\ \mu_{FW}(i_j) = \mu_{fs}(l_j)$$

If we apply a Fuzzy Temporal Window over the ODB, we obtain an image where each item has its membership degree. As we have represented an ODB as a Transactional Database, we obtain a Transactional Database image too.

DEFINITION **3.3 (Fuzzy ODB applying W)** *Let ODB be an Observation DataBase and W a Fuzzy Temporal Window, it defines $\tilde{ODB}$ as a Fuzzy Observation Data Base constructs as W(ODB) such as*

$$\forall t \in ODB, W(t) \in \tilde{ODB}$$

DEFINITION **3.4 (Fuzzy Transactional Data Base)** *Let T be a Transactional Data Base and W a Fuzzy Temporal Window, it defines $\tilde{T}$ as a Fuzzy Transactional Data Base constructs as W(t) $\forall t \in T$.*

We represent the Fuzzy Transactional DataBase as a table where for every row and column we have membership degree corresponding to the Fuzzy Temporal Window.

ISBN: 978-989-95079-6-8

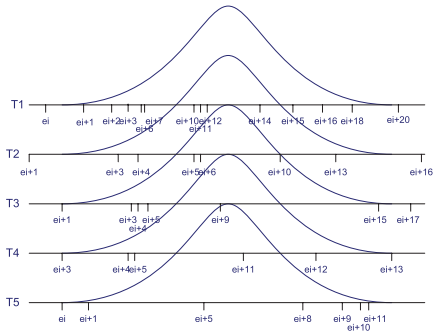

Figure 2: Fuzzy Temporal Window over a ODB

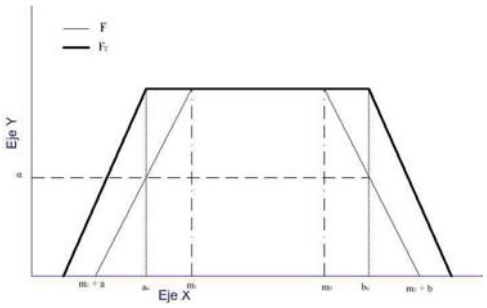

Figure 3: Transformations over a Trapezoidal Fuzzy Temporal Windows

3.3 Extending the Fuzzy Temporal Windows.

Until this point, we establish a Fuzzy Temporal Window with previous behaviour knowledge. We suppose this knowledge is completely true, although this statement always is not correct.

EXAMPLE **3.3** *Let us suppose that we want to check the behaviour* `Luis leaves home at 8:30 o'clock`. *However, we know that Luis sometimes arrives late at work. So, we can affirm that* `Luis leaves home at time almost always`.

In the example 3.3, we give a quantified adjective to actions of a behaviour to express certain. We employ a semantic approach based on evaluation of quantified sentences [9]. A quantified sentence is an expression of the form "Q of F are G", where F and G are two fuzzy subsets of a finite set X, and Q is a relative fuzzy quantifier. Some examples could be (The most times, Luis leaves home, 8:30), (Almost never, Luis leaves home, on time), (Almost all times, Luis leaves home, 8:30).

This knowledge is used to expand the Fuzzy Temporal Window size. We use the method presented in [10]. This method transforms the used function to define a specific behaviour according with the knowledge expressed by a quantified sentence. The proposed process obtains a new window F' in two steps:

1. Firstly, they truncate a fuzzy number, our Fuzzy Temporal Window, using the certainty degree α associated to the fuzzy value A. After this operation, we obtain a non normalized fuzzy set A^{α}.
2. Secondly, they normalize the fuzzy set. The authors assume that uncertainty is being translated into imprecision under the condition of the amount of information provided by the fuzzy number remains equal before and after normalization process.

The transformation function is defined as:

DEFINITION **3.5** *Let $A \in \tau$ be a fuzzy number such that $A = \{(m_1, m_2, a, b), \alpha_A\}$, where m_1, m_2, a, b are the values that defines a trapezoidal fuzzy number and α_A is the height of A. Let $\alpha \in (0, 1]$. We will denote $\triangle(\alpha_A, \alpha) = \triangle$ and define*

$$T_{\alpha}(A) = \left\{ \left(m_1, m_2, a + \frac{\triangle}{k}, b + \frac{\triangle}{k} \right), \alpha \right\} \quad (1)$$

for those α in which the transformation makes sense.

To use the definition 3.5, we need to define two basic parameters:

- k.- scale parameter
- α.- value for doing the transformation

In figure 3 we represent the followed process over a trapezoidal window.

In this point, we introduced the quantified sentences over a Fuzzy Temporal Windows, using their evaluation to know α value. When we have this value, we transform A set in its α version (A^{α}), which is the basis of the final transformation A^{T}. Example 3.4 shows the followed process. We use a trapezoidal Fuzzy Temporal Window for the sake of clarity.

EXAMPLE **3.4** *Let us suppose that we want to check the behaviour* `Luis hardly ever leaves home at 8:30 o'clock`. *Thus, our Fuzzy Temporal Windows, represented as a lr-number as $F = (m_1, m_2, a, b)$ where m_1, m_2 is the higher points of a trapezoidal fuzzy number, and a, b are the time to establish the lower points.*

$$F = (8:25, 8:35, 0:05, 0:05) \quad (2)$$

Firstly, we have to evaluate a quantified sentence to find out the α-value. There exists a lot of ways to evaluate it. Here we have selected the basic way, but not the best: Zadeh. The expression of the Zadeh Cardinal is $\alpha_A = \frac{P(A)}{|X|}$ where $P(A) = sum_{x \in X} A(x)$ and $|X|$ is the X set cardinal.

So, $\alpha_A = \frac{15}{20} = 0.75$. The evaluation of the quantified sentence is $Z_Q(A) = Q(\alpha_A) = 0.53$.

Next, we do the transformation of our windows using α value.

$$F = \{(8:25, 8:35, 0:05, 0:05), 1\} \rightarrow \quad (3)$$

$$F^{\alpha} = \left\{ \begin{pmatrix} 8:25 - 0:05(1-\alpha), 8:35 - \\ 0:05(1-\alpha), 0:05\alpha, 0:05\alpha \end{pmatrix}, \alpha \right\} \rightarrow \quad (4)$$

$$F^{T} = \left\{ \begin{pmatrix} 8:25 - 0:05(1-\alpha), 8:35 - 0:05 \\ (1-\alpha), 0:05\alpha - \frac{1-\alpha}{k\alpha}, 0:05\alpha - \frac{1-\alpha}{k\alpha} \end{pmatrix}, \alpha \right\} \quad (5)$$

Replacing α value with $Z_Q(A)$, i.e., $\alpha = 0.53$ we expand our Fuzzy Temporal Windows to

$$F = (8:23, 8:37, 0:08, 0:08) \quad (6)$$

ISBN: 978-989-95079-6-8

4 Fuzzy method to extract behaviour patterns. Obtaining sequence patterns by alpha-cuts

Once we have information, we should get common actions and valid sequences for every behaviour. However, we can not apply the method explained in [7] [8] directly, because we have to manage membership degree corresponded to the Fuzzy Temporal Window.

Here, we cannot present our Crisp model but we have to clarify some basic concepts of it that are need to can understand the process.

4.1 Previous concepts

In this section, we want to specify some important concepts: common actions and valid sequences.

1. Common actions: We define the common actions as a sequence of events that occurs more often in the observed knowledge. We can identify the common actions with the concept of Frequent Itemset: every frequent itemset corresponds to a particular common behaviour [8]. However, an itemset is a set and, so, it has not order relationship among its elements. However, a basic condition for a behaviour is the existence of this relationship. Since, we have to control which sequences of these itemsets are valid.

2. Valid/Correct sequences We define the valid sequences as the permutations of the set whose order relationship among their elements appear in the knowledge of the *ODB*. We use the permutation concept and an designed algorithm to determine if a sequence is valid or not, since not all permutation will be accepted as a pattern sequence.

4.2 Changes to manage the random imprecision

In this subsection, we present the different changes to manage the random imprecision. Thus, the objective is to develop a system that obtains stimulation from user who realizes some actions sequentially. The problem consists on extracting the sequence patterns to specific behaviour when we have a Fuzzy ODB $O\tilde{D}B$, represented as $\tilde{T}$, and a Fuzzy Temporal Window W defined from user knowledge.

Firstly, we have to transform a fuzzy problem to a crisp problem to apply the method explained in [7] [8]. We could use α-cut set [11]. By the α-cut, we would have a new crisp image of $\tilde{T}$, T^{α} where every value is in $\{0, 1\}$. Then, we apply classical method to T^{α}, obtaining frequent itemsets and sequence patterns to specific α value (I^{α} and P^{α}, respectively). After extracting all sequence patterns, we create a fuzzy set **P** by sequence patterns which have obtained to every α-value applying the Representation Theorem.

As we use frequent itemsets, we need to represent extracted frequent itemsets as an unique fuzzy set. Thus, we have to ensure *consistent restriction* between every α frequent itemset I^{α_i}. For sequence patterns representation is the same. The proof of these statements can be studied in [8].

4.3 An illustrative example

In this example we want to show the operation of the method. We start from ODB which is collected from the touched object by the user in the daily activity[1].

Let W a Fuzzy Temporal Window defines by the following fuzzy set over temporal line τ:

$$W = \left\{ \begin{array}{c} \frac{0}{8:20}, \frac{0,2}{8:21}, \frac{0,4}{8:22}, \frac{0,6}{8:23}, \frac{0,8}{8:24}, \frac{1}{8:25}, \frac{1}{8:26} \\ \frac{1}{8:27}, \frac{1}{8:28}, \frac{1}{8:29}, \frac{1}{8:30}, \frac{1}{8:31}, \frac{1}{8:32}, \frac{1}{8:33}, \frac{1}{8:34} \\ \frac{1}{8:35}, \frac{0,8}{8:36}, \frac{0,6}{8:37}, \frac{0,4}{8:38}, \frac{0,2}{8:39}, \frac{0}{8:40} \end{array} \right\} \quad (7)$$

Then, we apply W over T and obtain a Fuzzy T $\tilde{T}$ where every time of actions is replaced with the membership degree value in W. We apply the α-cut for α values α_1 = 0.4, α_2 = 0.6, α_3 = 0.8, α_4 = 1.0. We obtain for each α values the T^{α}, the result of apply the α-cut in $\tilde{T}$. After these operations, we have transformed the fuzzy problem to a crisp problem. Now, we extract frequent itemsets and sequence patterns with the model explained in [7] and [8].

We have executed the Apriori Algorithm with two support values: *minsup = 0.8 and minsup = 0.9*. The results are showed in tables 1 and table 2.

Since we have the common actions to specific behaviour, the next stage consists of obtaining the valid sequences patterns and the final representation as a fuzzy set applying the Identity Principle. The valid patterns are showed in table 3 and table 4. And the final pattern representation in equation 8 to minsup = 0.8 and equation 9 to minsup = 0.9.

5 Performance Evaluation

In this section, our objective is to evaluate fuzzy model versus crisp model presented in [7][8]. In other hand, we present advantages of modifying the windows using quantified sentences. To do this proof, we used a database that represents daily activities of the user. To be precise, we focus study on the analysis of Leave Home behaviour, to simplify the process. We study two databases. These databases try to force the temporal model, thus they imply different temporal relations between their items. In the first one, the interval between two consecutive actions is always the same. In the second database, we break this temporal relation.

With these experiments, we want to control the fuzzy window influence over the database.

As well as, we need a goodness measure to analyze obtained outcomes. We design a measure to evaluate the method that works with a sequence of words. So, we have to design a way to transform these sequences in a numerical way. We have to design this measure because it tries to pay attention all important aspects: correction, rubbish, alpha, minsup, time, etc.

Therefore, we have to define a goodness measure that makes the result evaluation easier:

$$c = \alpha_1 correction + \alpha_2 alpha + \alpha_3 \frac{1}{time} \quad (10)$$

where,

- correction.- similarity measure of every pattern to the correct pattern. We define a function that associates a numeric value with sequences that a higher value indicates greater similarity.
- alpha.- mean of the alpha-values used for the α-cut for every pattern.
- time.- amount of millisecond that the method inverts in obtaining results.

Goodness measure is inversely proportion with time raises to the power of minus one and directly proportion with the correction and confidence measure. So, if the absolute value of the correction gets bigger, the absolute value of goodness measure gets bigger too.

For the experiments, we use a specific values for α. We have chosen this values because we believe they are rougher to the reality. We use: α_1 and α_2 equals 0.3 and α_3 equals 0.4.

5.1 Crisp model vs Fuzzy model

We were evaluating our system with three different fuzzy distribution: a trapezoidal distribution, a the Gauss bell shape

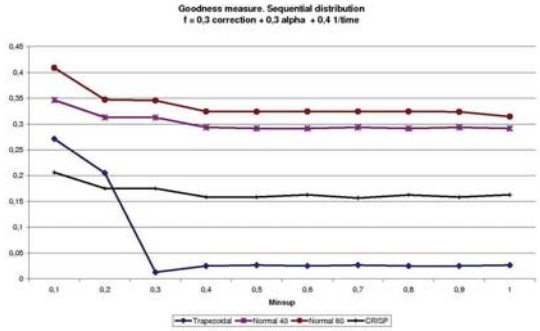

Figure 4: Crisp vs Fuzzy. Database a

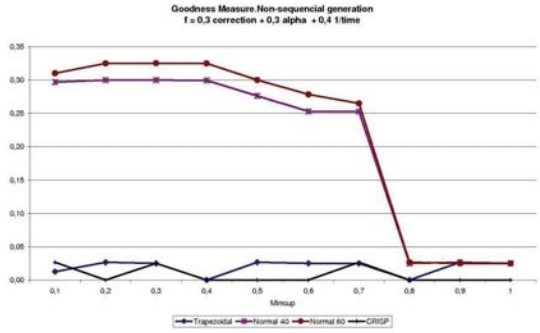

Figure 5: Crisp vs Fuzzy. Database b

with mean 40 minutes and a the Gauss bell shape with mean 60 minutes. We have used some distributions more, however we believe these distributions show the most interesting results. In figure 4 and 5, two graphics show goodness measure for every window. In addition, we show results of crisp model to compare the methods. If we observe results, we extract some conclusions which are convenient to study:

- In general, we conclude that the Fuzzy model obtains better results than the Crisp one. The Fuzzy method includes a way to provide importance to some actions that are key but are irregular. On the other hand, the Crisp method consider all actions at the same importance, and can lose this key actions. In addition, the Crisp method has to study all the data, while the Fuzzy method can reduce the size of transactions and can do the elements become frequent, minimizing the computational cost. This reduction could be very interesting when we have a forgetful user, because we would have a database with many mistakes that we would have to avoid. Moreover, this size reduction of the database makes it easier to find if the order of the sequences are valid.
- Among the Fuzzy Temporal Windows, the best results are obtained with the Gauss bell shape. It relaxes the degree of membership of their elements to the fuzzy window. When we perform the cut with a specific α, we include more items to study. Instead, in the trapezoidal shape the α-cuts are more abrupt, then more elements are lost.
- For the second database, the Crisp method provide good results: if we study all possible data, you always get

ISBN: 978-989-95079-6-8

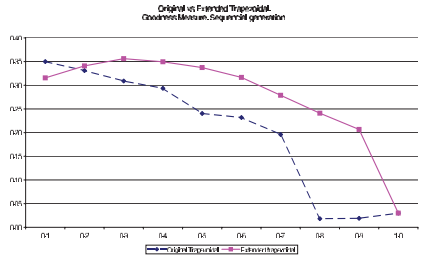

Figure 6: Original vs Extended Trapezoidal. Database a

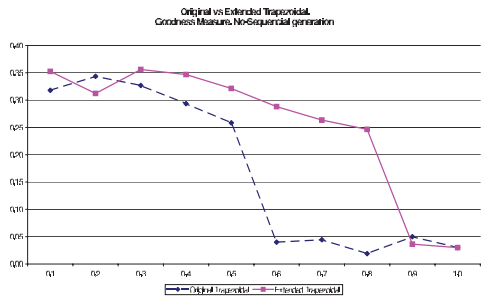

Figure 7: Original vs Extended Trapezoidal. Database b

key actions. However, with any Fuzzy Temporal Window with a Gauss bell shape we can extract almost the same results than the Crisp model minimizing the computational cost. Other alternative is to extend the variance of the fuzzy window, as we will see in the next subsection.

- Thus, the outcomes obtained with the fuzzy model are better than using crisp model.

5.2 *Analysis of process of extending the Fuzzy Temporal Window*

Once we have checked our fuzzy method, we analysed the process of extending the Fuzzy Temporal Window from a knowledge expressed as a quantified sentence. We are going to continue with example 3.4 that we proposed on section 3.3. We applied original Trapezoidal Temporal Window over two databases used in the previous section, and the new window obtained after expanding the window. Goodness measure is represented on figures 6 and 7: From these graphics, we observe that sometimes we extract results with the second window where the first window do not. This event happens because with the second window we have expanded the amount of data we studied to obtain the results. Although, always, we studied less data than the Crisp Method. Therefore, we adjusted the window to get better results than original window, without studying the whole interval.

6 Conclusions

In this paper, we have presented a method to detect user behaviour. As we have indicated, this problem is random imprecision by definition, because we do not know the interval of the time in which the action happen. Imprecision appears due of a behaviour is not static on a context or domain and is specific for every user. Thus, we have designed a method which uses fuzzy logic to limit events in a specific behaviour using a Fuzzy Temporal Window. With a Window, we can assign a membership degree for every event for the studied behaviour. In addition, we extend the Fuzzy Temporal Window concept, to adjust the interval using the knowledge from user we have. This adjustment is made with quantified sentences. With this adjustment we solve the possibility of a person changes his habits.

System's output is the fuzzy pattern sequences which define the behaviour. To manage non-random imprecision, we use the α-cuts and the Decomposition Theorem to obtain a fuzzy result applying the crisp method.

We have demonstrated that the fuzzy method is better than crisp method and that the fuzzy method obtains better outcomes than crisp one. As well as we conclude that results depend on the type of window we use. In addition, we have studied that outcomes are independent from the database.

In future work, we want to distinguish between three problems of our system:

- Non-random imprecision
- Uncertainty, because it could exists an error in the sensor reading. There are many reasons to provoke mistakes in sensors reading: the sensors or the reader could fail, the environment affects to the sensors, sensors damage, etc.
- Uncertainty in the Fuzzy Temporal Window, because the behaviour does no always happen exactly equal.

Our objective consists on extracting patterns that could control these kinds of problems, obtaining an adjusted pattern.

Abstract— *In this paper a fuzzy model based on Adaptive Neuro-Fuzzy Inference System (ANFIS) is introduced for calculating the level of risk in managerial problems. In this model, affecting factors on the level of risk are considered as inputs and the level of risk as the output. Using the fuzzy model, the risky condition changes smoothly in a fuzzy environment as it is the case in the real world; while in classic models, we may have some stepwise changes in the state of the system caused by an infinity small deviations in input parameters. The main advantage of the introduced model is that for continuous values of input factors, the counters of risk surface represent a more realistic behavior for different systems. The model is designed for a system of three inputs (probability, impact and ability to react) and one output (risky situation). The ability of using historical data as well as experts' knowledge and flexibility of adaptation to unusual risky situations are some benefits of the introduced model. This model which is originally used in strategic management system to analyze the external environment and the level of threats can also be used in contingency management for incidents (CMI) or as a tool for Comprehensive Emergency Management Program (CEMP). The strategic Risk of Roche is considered as the bench mark for comparing the difference between fuzzy and classic systems.*

Keywords— Risk assessment, Adaptive Neuro-Fuzzy Inference System, Risk Counters, Impact, Ability to react,

1 Introduction

Risk management has many applications in different fields such as financial management, industrial engineering, military and manufacturing systems as a Meta-disciplinary field. Companies and organizations have to monitor, scan and investigate the environmental factors and to update their strategic plans based on the level of recognized threats to select appropriate policies and strategies for reducing the risks. There are several steps for implementation of global risk management, starting with risk identification and calculation of its level for taking an appropriate decision. One of the most important sub-processes for this purpose is the methodology of calculation of risk and comparison of risky factors to determine the priorities. Considerable quantitative models have been introduced for this purpose in literature, where it is tried to calculate the level of the risk, which is simply defined as the rate of threat or future deficit of any system imposed by controllable or uncontrollable variables (Chavas, 2004; Doherty, 2000). Several factors such as probability of occurrence, impact, severity and ability to react are introduced as effecting factors on the risk. Then it is tried to find the mathematical relation between affecting factors and the value (level) of the risk (McNeil and Frey and Embrechts 2005; Li and Liao, 2007). The concept of risk is considerably wide. It can contain strategic, financial, operational or any other type of the risk. Based on literature review, the models which are mostly used in different fields of risk analysis can be classified to three types:

a) Data oriented models
b) Analytical models
c) Models based on judgment

Although it should be mentioned that this classification is not only related to Risk analysis, but in general it can be applied to system identification tasks.

a) Data oriented models:

In these models the structure is not needed to be known and the only important issue is the system's behavior. Some of the features of this type of models are: dependence to historical data, being behavioral, and storing experience and knowledge, based on the recognition of the input and output patterns of the system. Artificial intelligent models such as ANFIS and Neural Networks as well as statistical methods by concept of math average approach can be classified as this type of models. The more the number of the historical data is, the more reliable the models and their results would be. Figure 1 presents this type of model which is considered as a black box.

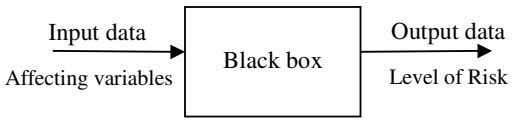

Figure. 1. Data-based System as a black box

This black box shows that there is no information on the analytical model of the system. It means that the relation among the variables as well as the way they affect each other is still unknown for user.

b) Analytical models.

In these systems it is possible to design a homomorphous model based on the system analysis process and structure of the problem. Being structure-based, analytical and independent from the data, are some of the features of this class of models. Many of the existing mathematical models,

ISBN: 978-989-95079-6-8

System Dynamics and a variety system analysis models are included in this class (Marrison2002). In this type of systems the structures must be recognized. It means that components and their relations must be identified to develop the analytical model. Figure 2 represents the concept of a structure based system. As it is mentioned the component and their relations must be recognized for developing an analytical model of the system.

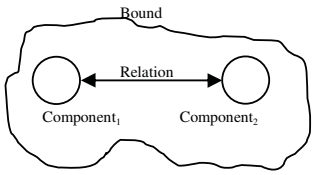

Figure. 2:. Structure-Based Systems (analysis)

For example if component$_1$ is Risk of investment when constructing a building, and component$_2$ represent the probability of earthquake in the region, the relation between them can be presented as :
Risk of investment=f (probability of earthquake)
Although it is a dream for researches to find an analytical model for such problems, however the major weakness of this kind of models is that they need precise data for modeling and the process of verification is considerably hard.

c) Models based on judgment

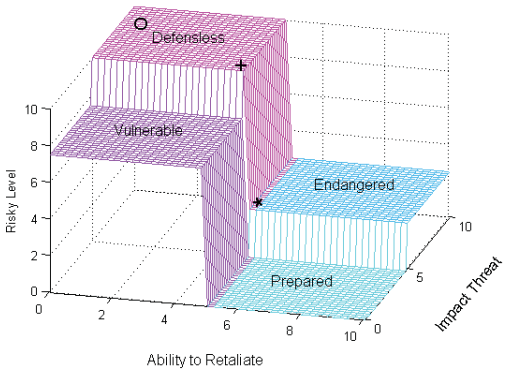
As it is mentioned, sometimes the first and second methods can not be used in real world problems. For example when the risk is based on the human behavior as a complex system, it is impossible for researches to find a pattern or mathematical model for it with available tools. So the judgment and knowledge of experts can help us to determine the level of risk and to find suitable solutions for risk management.

In this type of models, it is tried to overcome the major weakness of the first type consisting their uselessness in the case of no preexisting patterns. The growth of environmental dangers and the rapid increase of their variations as well as the increase of demand for such models by insurance companies have caused rapid and accelerated developments of such models (Roberets, 2005; Michael, 2004; Bernadell and CArdon and Coche and Diebold and Manganelli, 2004). This classification will help us to use the appropriate model in different situations.

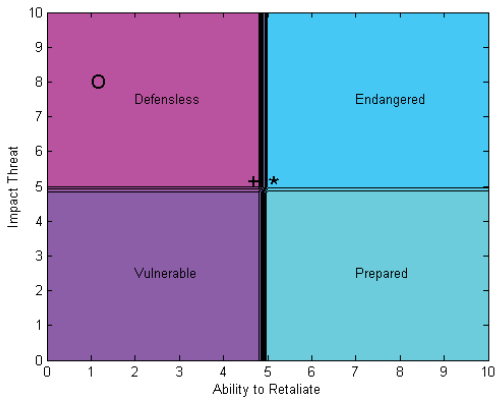
In this paper, the classic models of second type, commonly used in risk assessment of threats in strategic planning, are analyzed and criticized. Afterward a new model based on fuzzy inference is introduced for calculation of risk levels.

2. Problem Statement

Figure 3 shows a classic model of risk analysis. It consists of two factors: Impact threat and the ability to retaliate. In this model the risk value is classified in four groups. Each group represents a risky condition for the organization. During the implementation, first the opinions of the experts on the impact threat and the ability to retaliate are processed by means of any appropriate method such as group decision making, Delphi, …, and then the risky situation of organization is recognized. The distributions of the points with the same risk levels (contours of different levels) are also presented in Fig. 3(b), Points O and + represent the risky situation for two organizations with ability to retaliate and impact threats of (1, 8) and (4.9, 5.1) respectively.



(a)



(b)

Figure 3: (a) Risky situations classified in 4 levels, (b) counters

This model is very simple, but it has some structural drawbacks. For example the organization + which is in Endangered situation will change to completely opposite condition (Vulnerable) point(*) with infinity small deviations (A-da) in ability to retaliate. Also because of its geometrical structure, this model suffers from the lack of considering additional parameters such as ability to react.

Another method which has gained more attraction in the risk analysis literature is the model based on the linear combination of ability to retaliate and impact threat as:

$$Risk = (\text{ability to retaliate}) \times (\text{impact threat}) \quad (1)$$

Figure 4 represents a practical continuous increasing surface (levels), instead of stepwise levels for risk values. Two particular levels are shown by the cutting planes K1 and K2. Positions O, + and * are also presented in this figure. Figure 4(b) shows some contours of risky surface. As it is seen, in this model any small change in the values of probability and severity will cause a very small deviation in its risky level of organization. Also sometimes the risky level remains unchanged. This model is more realistic than the one

ISBN: 978-989-95079-6-8

presented by figure 3. However, it also has its limitations for real world applications because it simplifies the complicated relation between different factors that affect the risky conditions of organizations to a simple multiplication of two factors (ability to retaliate and impact threat).

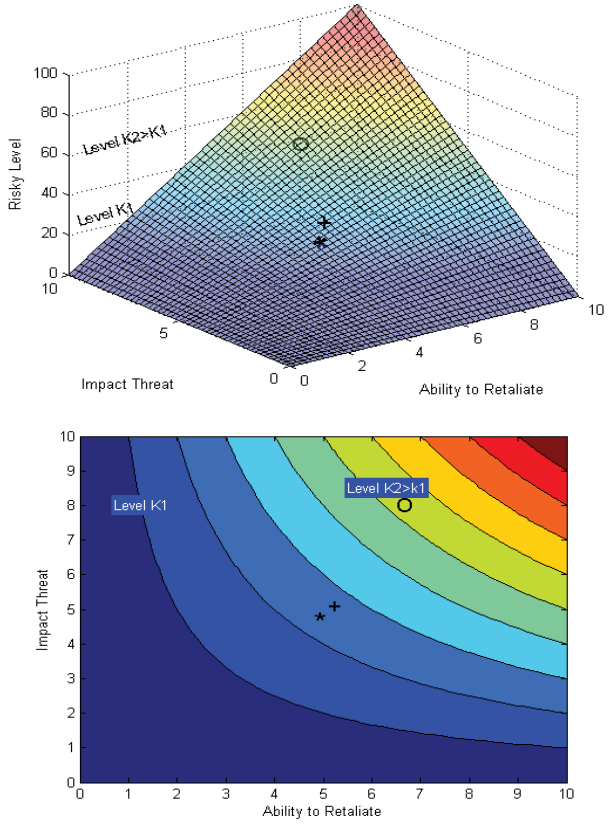


Figure. 4: Continuous surface for risk levels and counters

These kinds of models suffer from some weaknesses such as considering the relation between variables as a linear relation. Also when the number of inputs increases, the complexity of the system will increase dramatically while the accuracy of the model will decrease. Moreover due to inflexibility of the model, it can not be improved considering our experiences based on real world situations or the growth of experts' knowledge.

Hence we can formulate our problem as an input output system by:

$$R=F(X) \qquad (2)$$

Where X is the set of input variables which affect the level of the risk, R is the level of the risk and F(.) is a nonlinear function (Kreinovich and Nguyen, 2000).

The problem here is to find an appropriate solution by which the level of risk of the system (Organization) can be determined in complex situations when there is no access to all data, or the historical data is useless.

In this paper we try to develop a rule based model by using fuzzy inference system.

3. Fuzzy model

Fuzzy inference systems (FIS) are rule-based systems with concepts and operations associated with fuzzy set theory (Zadeh, 1965) and fuzzy logic (Ross, 2004; Mendel, 2001). These systems are mappings from an input space to an output state; therefore, they allow constructing structures that can be used to generate responses (outputs) to certain stimulations (inputs), based on stored knowledge on how the responses and stimulations are related. Sometimes this knowledge is obtained by eliciting information from specialists, in which case these systems are known as fuzzy expert systems (Takács, 2004). A fuzzy system also can be created to mach any set of input-output data. Adaptive Neuro-fuzzy Inference System (ANFIS) is one of the well known methods for creating Input-Output based models. (Krus , Gebhart and Palm, 1994). ANFIS only support Sugeno systems (Sugeno, 1985) subject to the structure of the system such as unit weight for each rule. Since its introduction, ANFIS has successfully been proved in many engineering applications (Jang, 1993). Another common denomination for FIS is fuzzy control systems (see for example (Mendel, 2001)).

FIS are usually divided in two categories (Mendel, 2001; Takagi and Sugeno, 1985): multiple input, multiple output (MIMO) systems, where the system returns several outputs based on the inputs it receives; and multiple input, single output (MISO) systems, where only one output is returned from multiple inputs. Since MIMO systems can be decomposed into a set of MISO systems working in parallel, all that follows will be exposed from a MISO point of view (Mamdani and Assilian, 1999).

FIS suffers of adjusting the linguistic knowledge of the expert with available data; so in this paper a fuzzy model based on ANFIS is introduced for calculating the risky situations of organizations by considering different factors such as probability, Impact threat and ability to retaliate (Nguene and Finger, 2007; Hyo and Hyun, and Yoon, 2002). This model is developed in three phases. To clarify the process of modeling in different phases a benchmark case study adopted from "strategic management by Rowe, et all" (Row et all, 1999) is used as a test example.

Phase 1: Data generation

The expert s' judgments may be extracted by means of different group decision making methods. Our experience in this work shows that the Delphi method as well as Nominal group is more practical. In case there are hard data as a result of historical behavior, a similar methodology can be used. By the way combination of hard data and information extracted from expertise can be used to develop first table which is necessary for next step.

Table 1 shows the set of generated data for test example.

Table.1

Probability	Impact	Ability to React	Risk (Vulnerability)
1	10	4	7.5
0	0	10	0
.5	5	5	1
1	5	5	3
.2	5	2	0
.8	2	8	5
.4	7	3	1

ISBN: 978-989-95079-6-8

1	0	5	0
.7	8	2	4
.8	8	7	2
.2	9	5	.5
.2	3	5	0
.7	10	3	4.5
.5	10	2	2.5
.5	10	10	0
1	8	0	10
1	2	8	.5
.6	10	4	3
.1	2	6	0
.3	6	8	0

Phase 2: Rule making

In this step the Adaptive Neuro-Fuzzy Inference System (ANFIS) is used for generating the rules.

Figure 5 Shows the surfaces of the rule base system adapted for the data of table 1 with:

numMFs = 25

mfType = gaussmf

epoch_n = 20

After constructing rule-base surface the model is improved by investigating the critical states (which are not approved by expert or when there is illogical behavior). Then by adding more rules or by imposing some minor deviations to data set the final rules may be obtained as shown in figure.5. By this way any specific behaviors cause by unusual relation between some particular inputs and output of the system can be supported which is significant advantage benefit of introduced model compare to other model such as Neural Network.

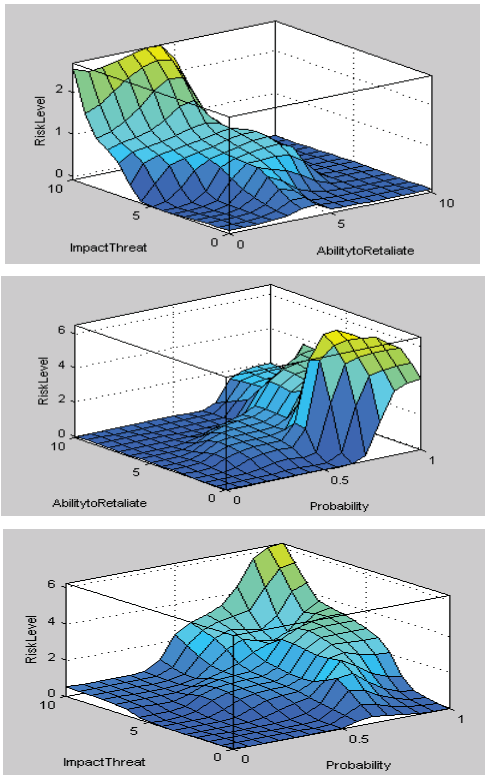

Figure.5: Surfaces of generated rules.

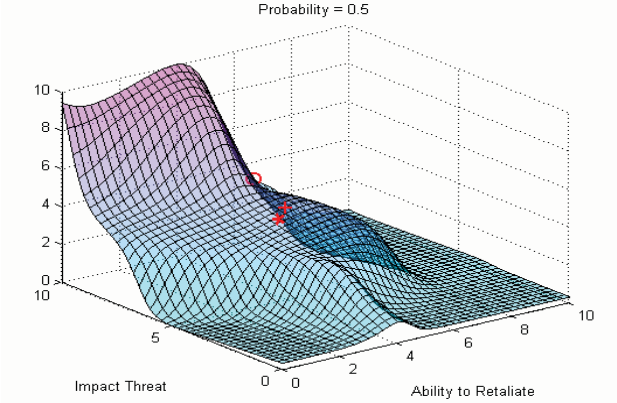
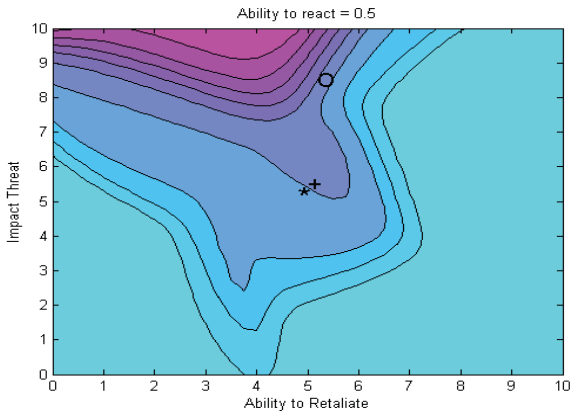
Phase 3. Implementation

This model is implemented to the simple example of section one to have an idea on the main difference between this method and the classic model. Figure 6 shows the surface and counters of risky levels of organizations +, and O. The results are shown for 50% of probability of impact to visualize the obtained results.





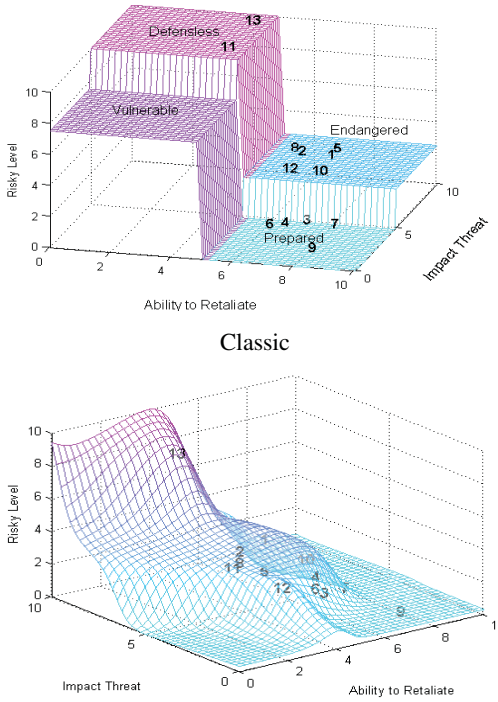
(b)

Figure. 6: (a) Risky surfaces, (b) counters for simple example

As it is seen, organization + which is appropriately Endangered situation will change to appropriately defenseless, point(*), with infinity small deviations (A-da) and (T-dt) in ability to retaliate and impact threat which is more realistic than the classic one.

The vulnerability analysis for Roche Company is also considered as a benchmark for implementing and comparing the obtained results with the classic methods. Figures 7 and 8 compare the results obtained by implementing the introduced model. Note that in the rest of paper only the surfaces and counters for probability of 50% are shown.

ISBN: 978-989-95079-6-8



Classic

Fuzzy

Figure.7: application of classic and fuzzy models for vulnerability analysis of Roche Company

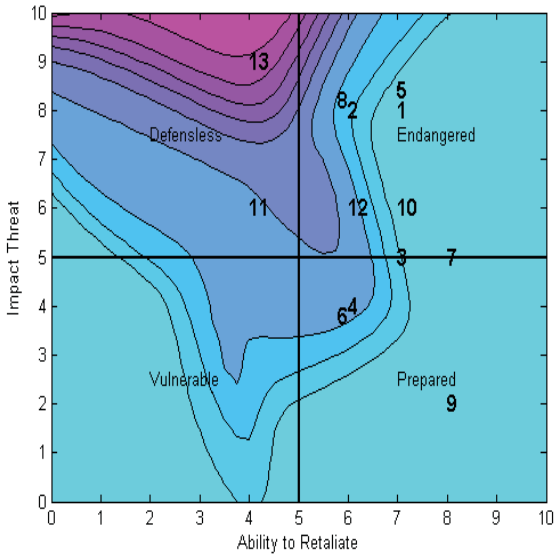


Figure 8: Risky levels of Roche by using classic and fuzzy models

Table 2 compares the results of this method by the classic one.

Table 2

Assumptions	Impact 0-10	Probability 0-1	Capability 0-10	Vulnerability Assessment Strategic management Approach	Vulnerability Assessment Classic	Vulnerability Assessment Fuzzy
1. Needs and wants served by products	8	0.7	7	Endangered	2.5	1.9960
2. Resources and Assets	8	0.6	6	Endangered	2.5	1.6119
3. Cost position relative to competition	5	0.4	7	Prepared	0	0.1490
4. Customer base	4	0.5	6	Prepared	0	1.9093
5. Technologies	8	0.4	7	Endangered	2.5	0.0446
6. Special skills	4	0.4	6	Prepared	0	1.1455
7. Corporate identity	5	0.5	8	Prepared	0	0.0298
8. Institutional barriers to competition	8	0.4	6	Endangered	2.5	0.8793
9. Social values	2	0.2	8	Prepared	0	0.0015
10. Sanctions, supports, and incentives	6	0.7	7	Endangered	2.5	1.7019
11. Customer goodwill	6	0.5	4	Defenseless	10	2.1834
12. Complementary products or services	6	0.3	6	Vulnerable	7.5	0.2943
13. Regulatory agencies	9	0.7	4	Defenseless	10	7.8129

It is seen that using the fuzzy method appropriate continues vulnerability levels are obtained to analyze the risky levels.

As it can be seen in Table.2 the Result of Vulnerability assessment by using Strategic management approach (as shown in fig.3) is stepwise and limited to 4 categories; hence the real value of risk is unclear. The second model (Classic Vulnerability Assessment) suffers from rigidity and can not be customized in different situations. So its efficiency can not be improved by considering available data and knowledge of experts. It is why in real world applications the decision Makers are not generally satisfied (trust the model) by the results obtained by this method.

ISBN: 978-989-95079-6-8

The introduced fuzzy based method overcomes the mentioned drawbacks. For example considering rows 1,2,5,8,10 in table.2, by using classical method as well as strategic management approach the same levels of risk are obtained for different assumptions where by using introduced method different level of risk is determined.

4. Conclusion

In this paper the fuzzy risk analysis procedure is compared with classic methods. It is demonstrated that the fuzzy analysis seems to be more reasonable and applicable because of its smoothness in calculating the risky situations. By fuzzy analysis the dynamic (time dependent) behavior of risk conditions can be defined and used for convenient and reliable decision makings. The model presented in this paper has some features as follows: a) Relations between variables in real life are nonlinear. Abstracting the situation and simplifying the problem to a linear model will cause the missing of some vital data where by utilizing the introduced model the relation between Risk and variables can be considered as a nonlinear function. b) Using FIS brings the advantage of developing and improving the model based on historical data. It is noted that the original model is constructed only based on the experts' knowledge due to lack of historical data. c) The model can be extended to be used for any number of inputs, where expanding the classic models to more inputs is not an easy task. d) This model considers probability as an input where other models usually solve the problem in a probabilistic environment. e) Any Specific behavior caused by unusual relation between some particular inputs and output of the system can be supported by imposing new rules to the model.

Abstract— *Possibilitic networks, which are compact representations of possibility distributions, are powerful tools for representing and reasoning with uncertain and incomplete knowledge. According to the operator conditioning is based on, there are two possibilistic settings: quantitative and qualitative. This paper deals with qualitative possibilistic network classifiers under uncertain inputs. More precisely, we first present and analyze Jeffrey's rule for revising possibility distributions by uncertain observations in the qualitative setting. Then, we propose an efficient algorithm for revising possibility distributions encoded by naive possibilistic networks for classification purposes. This algorithm consists in a series of efficient and equivalent transformations of initial naive possibilistic classifiers.*

Keywords— Min-based possibilistic networks, classification under uncertain inputs

1 Introduction

Graphical models such as Bayesian networks [1][2], influence diagrams and possibilistic networks [3][4] are well-known formalisms widely used for representing and reasoning with uncertain and incomplete knowledge. Possibilistic networks are like Bayesian ones but lie on possibility theory [5][6] to handle imprecise and incomplete knowledge. They allow to factor a global joint possibility distribution into a set of local possibility distributions. There are two types of possibilistic networks: quantitative and qualitative. In the former, conditioning is based on the $product$ operator while it is based on the min-operator in the latter.

Classification is an important task in many real world applications consisting in predicting the class instance corresponding to an observation. This task is a special kind of inference: given an observed instance of each observable variable A_i, it is required to determine the class instance c_k for the instance to classify among a predefined set of class labels. It is important to note that possibilistic classifiers have not been sufficiently studied in spite of the fact that they are very appropriate for problems where knowledge is imprecise or missing as in real-time classification problems or problems where some inputs are missing or uncertain. These problems require classifiers under uncertain inputs. However, only few works used possibilistic classifiers [7][8][9][10] and to the best of our knowledge, there is only one preliminary work [11] addressing possibilistic network classifiers under uncertain inputs in the quantitative setting. More precisely, this work proposes an algorithm suitable of classification under uncertain inputs using product-based possibilistic networks.

This paper also addresses possibilistic-based classification with uncertain observations but in the qualitative setting. While quantitative possibilistic networks are quite similar to the Bayesian ones, the qualitative ones show significant differences. For instance, normalizing conditional possibility distributions in product-based possibilistic networks is the same as in the probabilistic setting while it is significantly different in min-based networks. We first recall the qualitative possibilistic counterpart of Jeffrey's rule [12] for revising possibility distributions by uncertain observations and show that this rule cannot be directly applied for revising possibilistic knowledge encoded by a possibilistic network. Indeed, classification by directly using the possibilistic counterpart of Jeffrey's rule is exponential in the number of attributes and attribute domains. Then, we proposed an efficient method for revising naive min-based possibilistic networks suitable for classification with uncertain inputs. This algorithm is based on a series of equivalent and polynomial transformations of initial possibilistic networks taking into account uncertain inputs.

The rest of this paper is organized as follows: Section 2 briefly presents basic background about possibility theory and possibilistic networks. In section 3, we address possibilistic belief revision based on the possibilistic counterpart of Jeffrey's rule. Section 4 proposes a new efficient algorithm for naive possibilistic network classification with uncertain inputs. Finally, section 5 concludes this paper.

2 Basic background on possibility theory and possibilistic networks

Let us first fix our notations: V=$\{A_1, A_2, .., A_n\}$ denotes the set of variables. D_A=$\{a_1, a_2, .., a_m\}$ denotes the finite domain of variable A. a_i denotes an instance (value) of variable A_i. A, X,.. denote subsets of variables from V. D_X=$\times_{A_i \in X} D_{A_i}$ represents the cartesian product relative to variables A_i involved in subset X. Ω=$\times_{A_i \in V} D_{A_i}$ denotes the universe of discourse and consists in the cartesian product of all variable domains involved in V. A tuple w=$(a_1, a_2, .., a_n)$ or w=$a_1 a_2 .. a_n$ which is an instance of Ω represents a possible state of the world. ϕ, φ denote subsets of Ω called events while $\overline{\phi}$ denotes the complementary of ϕ in Ω ($\overline{\phi}$=Ω-ϕ).

2.1 Possibility theory

Possibility theory was introduced by Zadeh [5] and developed by Dubois and Prade [6]. It is an uncertainty theory based on a pair of dual measures in order to evaluate knowledge/ignorance relative to event in hand. The concept of possibility distribution π is one of the important building blocks of possibility theory: It is a mapping from the universe of discourse Ω to the unit scale $[0, 1]$ which can be either quantitative or qualitative. In both these settings, a possibility degree $\pi(w_i)$ expresses to what extent it is consistent that w_i can be

ISBN: 978-989-95079-6-8

the actual state of the world. In particular, $\pi(w_i)$=1 means that w_i is totally possible and $\pi(w_i)$=0 denotes an impossible event. The relation $\pi(w_i)>\pi(w_j)$ means that w_i is more possible than w_j. A possibility distribution π is said to be normalized if $max_{w_i \in \Omega}(\pi(w_i))$=1. It is said to be sub-normalized otherwise.

The second important concept in possibility theory is the one of possibility measure denoted $\Pi(\phi)$ and computing the possibility degree relative to an event $\phi \subseteq \Omega$. It evaluates to what extent ϕ is consistent with the current knowledge encoded by possibility distribution π on Ω. It is defined as follows:

$$\Pi(\phi) = max_{w_i \in \phi}(\pi(w_i)). \quad (1)$$

The term $\Pi(\phi)$ denotes the possibility degree relative to having one of the events involved in ϕ as the actual state of the world.

The necessity measure is the dual of possibility measure and evaluates the certainty implied by the current knowledge of the world. Namely, $N(\phi)$=1-$\Pi(\overline{\phi})$ where $\overline{\phi}$ denotes the complementary of ϕ.

Given a possibility distribution π on Ω, marginal distributions π_X relative to subset of variables X ($X \subseteq V$) are computed using the max operator as follows:

$$\pi_X(x) = max_{w_i \in \Omega}(\pi(w_i) : w_i[X] = x), \quad (2)$$

where term $w_i[X] = x$ denotes the fact that x is the instantiation of X in w_i.

According to the interpretation underlying the possibilistic scale [0,1], there are two variants of possibility theory:

- **Qualitative possibility theory**: In this case, the possibility distribution is a mapping from the universe of discourse Ω to an "ordinal" scale where only the "ordering" of values is important.
- **Quantitative possibility theory**: In this case, the possibilistic scale [0,1] is numerical and possibility degrees are like numeric values that can be manipulated by arithmetic operators.

In this paper, we only focus on qualitative setting. Conditioning is a fundamental notion concerned with updating the current knowledge (encoded by a possibility distribution π) when an evidence (a sure event) is observed.

In the qualitative setting, conditional possibility degree of w_i given an event ϕ is computed as follows (we assume that $\Pi(\phi) \neq 0$) [13]:

$$\pi_m(w_i|\phi) \begin{cases} 1 & \text{if } \pi(w_i)=\Pi(\phi) \text{ and } w_i \in \phi; \\ \pi(w_i) & \text{if } \pi(w_i)< \Pi(\phi) \text{ and } w_i \in \phi; \\ 0 & \text{otherwise.} \end{cases} \quad (3)$$

2.2 Brief description of possibilistic networks

Like Bayesian networks, possibilistic ones [4] involves two components:

1. A graphical component consisting in a DAG[1] which encodes direct influence relationships existing between domain variables.

2. A numerical component which is a "numerical" component composed of a set of local a priori and conditional possibility distributions. The latter measure the influence endured by each domain variable A_i in the context of its parents U_{A_i}. Local possibility distributions should satisfy the normalization condition denoted as follows:

$$max_{a_{ij} \in D_{A_i}}(\pi(a_{ij}|U_{A_i})) = 1 \quad (4)$$

The joint possibility distribution encoded by the network is computed using the min-based chain rule. Namely,

$$\Pi(A_1, A_2, .., A_n) = min_{i=1..n}(\pi(A_i|U_{A_i})) \quad (5)$$

In classification problems, there exists one node associated with the class variable C which is not observable (it is the target variable) while the remaining nodes represent the attributes A_1, A_2,..,A_n that may be observable. Classification is ensured by computing the most plausible class instance given the instance to classify. Namely, given an observation denoted A=(a_1,a_2,..,a_n) of $\{A1, A_2, .., A_n\}$, the predicted class c is determined as follows:

$$c = argmax_{c_k \in D_C}(\Pi(c_k|A)) \quad (6)$$

Note that term $\Pi(c_k|A)$ denotes the possibility degree of having c_k the actual class instance given the observation A=(a_1,a_2,..,a_n). It is important to note that a class instance c_k is candidate for a given observation $a_1..a_n$ implies that $\Pi(c_k|a_1..a_n)$=1. Note also that several class instances may be totally possible for the observation to classify.

2.3 Min-based naive possibilistic network classifiers

A naive network classifier is the simplest form of possibilistic network classifiers. It lies on the strong independence assumption of attributes in the context of the parent node: attributes are assumed independent in the context of the class node. As it is shown in Figure 1, the only dependencies allowed in naive classifiers are from the class node C to each attribute A_i. As for the quantitative component of a naive possibilistic network, it involves the prior possibility distribution relative to the class node and the conditional possibility distributions relative to attributes given the class node. Figure 2 gives the joint possibility distribution encoded by network of Figure 1.

Figure 1: Naive possibilistic network structure

Classification is ensured using min-based conditioning (see Equation 3) by computing the a posteriori possibility degree for each class instance c_k given the observation $A_1..A_n$ (namely $\Pi(c_k|A_1..A_n)$). Namely,

$$\Pi(c_k|A_1..A_n) = min(\pi(c_k, A_1..A_n), \Pi(A_1..A_n)) \quad (7)$$

Figure 2: Joint possibility distribution encoded by naive classifier of Figure 1

Note that according to min-based conditioning, Equation 7 is only valid when term $\pi(c_k, A_1..A_n) < \Pi(A_1..A_n)$ (See min-based conditioning of Equation 3). To the best of our knowledge, there is no work that addresses the problem of classification under uncertain inputs using min-based possibilistic networks.

3 Min-based revision for classification under uncertain inputs

In our context, uncertainty relative to uncertain/missing attribute A_i is represented by a possibility distribution π'_{A_i} given for example by the expert. Moreover, uncertainty can bear on any attribute subset or on the whole attribute set.
Jeffrey proposed in [12] a method based on probability kinematics for revising a probability distribution p into p' given uncertainty bearing on a set of mutually exclusive and exhaustive events λ_i. In this method, uncertainty is of the form (λ_i, α_i) with α_i=$p'(\lambda_i)$. Jeffrey's rule states that although there is uncertainty about events λ_i, conditional probability of any event $\phi \subseteq \Omega$ given any uncertain event λ_i. The possibilistic counterpart of this rule has been investigated in [14]. In the possibilistic framework, revised possibility distribution π' must comply with the principle stating that uncertainty about events λ_i must not alter the conditional possibility degree of any event $\phi \subseteq \Omega$ given any event λ_i. Namely,

$$\forall \lambda_i \in \Omega, \quad \forall \phi \subseteq \Omega, \Pi'(\phi|\lambda_i) = \Pi(\phi|\lambda_i) \tag{8}$$

Note that contrary to the probabilistic and quantitative possibilistic settings, Equation 8 may have several solutions. In this case, the least specific distribution is selected according to the principle stating that if an event is not explicitly discarded, then it must remain possible. Min-based conditioning allows to obtain from Equation 8 the following one:

$$\forall \phi, \Pi'(\phi) = max_{\lambda_i}(min(\pi'(\lambda_i, \phi), \pi(\lambda_i, \phi), \Pi(\phi)) \tag{9}$$

In classification with uncertain inputs problems, the possibilistic counterpart of Jeffrey's rule cannot directly be applied to revise the possibility distribution encoded by the classifier because of two major problems:
1- The first problem concerns the fact that Jeffrey's rule can be applied only if uncertainty bears on a set of exhaustive and mutually exclusive events while in classification with uncertain inputs problems, uncertainty is bearing on a set of attributes A_i which are not mutually exclusive. Indeed, if inputs A_1,..,A_n are uncertain, then this uncertainty is encoded by $\pi'(A_1)$,..,$\pi'(A_n)$ respectively. In order to apply Jeffrey's rule, we must compute a joint possibility distribution $\pi'(A_1..A_n)$ relative to $A_1..A_n$ where uncertain events $a_1..a_n$ are exhaustive and mutually exclusive. Obviously, the term $\pi'(A_1..A_n)$ is function of $\pi'(A_1)$,..,$\pi'(A_n)$ and will be henceforth denoted by $\pi'(A_1..A_n)$=$f(\pi'(A_1)$,..,$\pi'(A_n))$. Uncertain inputs $\pi'(A_1)$,..,$\pi'(A_n)$ can be combined using a combination operator according to the problem constraints and objectives. It is important to note that the algorithm we propose in next section works regardless the combination function f provided that this latter satisfies the following natural propriety (called henceforth unanimity):
i) If $\forall$i=1..n, $\pi'(a_i)$=1 then $\pi'(a_1..a_n)$=1.
ii) If $\exists a_i \in D_{A_i}$ such that $\pi'(a_i)$=α<1, then $\pi'(a_1..a_i..a_n)$<1 whatever are the possibility degrees of the other variable values.
One can easily check that the $product$ and min (and more generally t-$norm$ operators), which are the most used combination operators in the possibilistic framework satisfy this natural propriety. However, max and more generally, t-$conorm$ operators do not satisfy it. In this paper, we will use the min operator in order to induce the joint possibility distribution $\pi'(A_1..A_n)$ from uncertain inputs $\pi'(A_1)$,..,$\pi'(A_n)$. Namely,

$$\pi'(a_1..a_n) = min_{k=1..n}(\pi'(a_k)) \tag{10}$$

2- The second problem concerns the computational complexity of performing classification under uncertain inputs based on revising the possibility distribution encoded by the classifier by uncertain inputs using the possibilistic counterpart of Jeffrey's rule. Namely, given the initial possibility degrees of class instances c_k, we want to revise this possibility distribution given uncertain attributes A_1,..,A_n using Jeffrey's rule. More precisely, we need to compute $\pi'(c_k)$=$\pi(c_k|\pi'(A_1, .., A_n))$ defined as follows:

$$\pi'(c_k) = max_{A_1..A_n}(min(\Pi(c_k|A_1..A_n), \pi'(A_1..A_n))) \tag{11}$$

It is clear that Equation 11 cannot be used to compute $\pi'(c_k)$ because this computation is exponential in the number of attributes and attribute domains.

Example:
Let us illustrate possibilistic classification with uncertain inputs using Jeffrey's rule on the naive possibilistic classifier of Figure 1. The uncertain inputs to classify are provided by Figure 3. Classification is ensured by determining the most

plausible class instance(s) given these uncertain inputs. Figure 4 gives the results of revising the initial joint possibility distribution (see Figure 2) using the possibilistic counterpart of Jeffrey's rule (see Equation 11). One can easily deduce from joint possibility distribution π' of Figure 4 that only class instance c_2 is totally plausible ($\pi'(c_2)$=1) given the uncertain observations of Figure 3. However, in order to obtain such a result, we computed the revised joint possibility distribution. We would like to ensure the same classification without computing the joint possibility distribution. Next section proposes

Figure 4: Revised joint possibility distribution π'

an efficient algorithm suitable for naive min-based possibilistic network classification with uncertain inputs.

4 A polynomial algorithm for naive possibilistic classifier under uncertain inputs

Classification based on possibilistic networks is ensured by determining if each class instance $c_k \in D_C$ is totally possible given the inputs ($\Pi(c_k|A_1..A_n)$=1). This is the basic idea of our algorithm: only search for class instances having a posteriori possibility degrees equal to 1 on the basis of uncertain inputs. Our algorithm ensures this search through a series of equivalent transformations on the initial possibilistic network taking into account the inputs to classify. The five steps of our algorithm are detailed in the following.

4.1 Step 1: Eliminating not totally possible observations

In our context, classification is ensured by revising the possibility distribution encoded by the classifier according to the possibilistic counterpart of Jeffrey's rule (using Equation 11). Since we are only interested in determining if a given class label c_k has an a posteriori possibility degree equal to 1, it is possible to discard all instances of $A_1A_2..A_n$ where $\pi'(A_1A_2..A_n)$<1 because such instances force the value of $\pi'(c_k)$ to be less than 1. According to the *unanimity* propriety, each input $a_i \in D_{A_i}$ which is not totally possible ($\pi'(a_i)$<1) will prevent every input configuration $a_1..a_i..a_n$ from being totally possible. It is clear that such configurations are useless for the classification task and can be discarded. This leads to eliminating from each attribute domain $D_{A_i}^{\Pi G}$ (relative to attribute A_i in initial network ΠG) values whose possibility degrees in π'_{A_i} are less than 1. In this step, attribute domain $D_{A_i}^{\Pi G}$ is changed to $D_{A_i}^{\Pi G_{S_1}}$ which denotes A_i's domain in network ΠG^{S_1} obtained from ΠG after Step 1. Namely, $D_{A_i}^{\Pi G_{S_1}} = D_{A_i}^{\Pi G} - \{a_i, if\ \ \pi'_{A_i}(a_i)<1\}$. All the remaining attribute instances are totally possible after this step. Then we have the following proposition:

Proposition 1 Let ΠG be the naive possibilistic classifier encoding the initial knowledge and π'_{A_1}, π'_{A_2},..,π'_{A_n} be the possibility distributions encoding uncertainty relative to attributes A_1, A_2,.., A_n respectively. Let ΠG^{S_1} be the naive possibilistic network obtained by eliminating not totally possible instances. Then,
$\pi'^{\Pi G}(c_k) = max_{A_1..A_n}(\Pi^{\Pi G}(c_k|a_1..a_n) * \pi'(a_1..a_n))$=1
if and only if
$\pi^{\Pi G_{S_1}}(c_k) = max_{A_1..A_n}(\Pi^{\Pi G_{S_1}}(c_k|a_1..a_n)) = 1$

This proposition states that if there is a class instance c_k which is totally possible in the initial network ΠG given the uncertain inputs then it is also totally possible in network ΠG^{S_1} obtained after eliminating not totaly possible inputs.

Example (continued): Network of Figure 5 is obtained by respectively substituting $D_{A_1}^{\Pi G}$=$\{a_{11}, a_{12}, a_{13}\}$, $D_{A_2}^{\Pi G}$=$\{a_{21}, a_{22}\}$ and $D_{A_3}^{\Pi G}$=$\{a_{31}, a_{32}\}$ by $D_{A_1}^{\Pi G_{S_1}}$=$\{a_{11}, a_{13}\}$, $D_{A_2}^{\Pi G^{S_1}}$= $\{a_{21}, a_{22}\}$ and $D_{A_3}^{\Pi G^{S_1}}$=$\{a_{31}\}$.

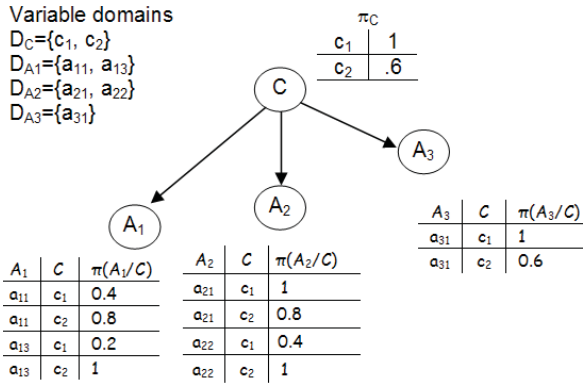

Figure 5: ΠG^{S_1}: Possibilistic network after Step 1

It is important to note that the possibility distribution relative to node C in ΠG^{S_1} is exactly the same as in ΠG.

4.2 Step 2: Eliminating unary variables

After the instance elimination step, some attributes may have their domains only containing one instance. In the example of Figure 5, attribute A_3's domain $D_{A_3}^{\Pi G_{S_1}}$ exactly contains one element (which is a_{31}). Such unary variables can be eliminated provided that class node distribution is adapted to keep the joint possibility distribution unchanged. The possibility degree of any instance $c_k a_1 a_2..a_n$ in network ΠG^{S_1} is computed using the min-based chain rule as follows:

$$\Pi^{\Pi G_{S_1}}(c_k a_1..a_n) = min(\pi^{\Pi G_{S_1}}(c_k), \pi^{\Pi G_{S_1}}(a_1|c_k), .., \pi^{\Pi G_{S_1}}(a_n|c_k)) \quad (12)$$

Unary attributes can be eliminated giving a new network ΠG^{S_2} where class node distribution has to be adjusted in order to guarantee that $\pi^{\Pi G_{S_1}}(c_k a_1..a_n)$ and $\pi^{\Pi G_{S_2}}(c_k a_1..a_n)$ remain equal. Hence, for an unary attribute A_i whose domain $D_{A_i}^{\Pi G_{S_1}}$ contains only one value a_i, it is possible to achieve this transformation by substituting each $\pi^{\Pi G_{S_1}}(c_k)$ with $\pi^{\Pi G_{S_2}}(c_k)$=min($\pi^{\Pi G_{S_1}}(c_k), \pi^{\Pi G_{S_1}}(a_i|c_k)$). This finding is formalized by the following proposition:

Proposition 2 Let ΠG^{S_1} be the naive possibilistic classifier whose nodes involve class node C and attribute nodes A_1, A_2,..,A_n. Assume that A_1 is a unary attribute whose domain only contains the instance a_1 and let ΠG^{S_2} be the naive possibilistic network involving C, A_2,..,A_n such that: $\pi^{\Pi G_{S_2}}(a_i)$= $\pi^{\Pi G_{S_1}}(a_i)$ for i=2,..,n and $\pi^{\Pi G_{S_2}}(c_k)$=min($\pi^{\Pi G_{S_1}}(a_1|c_k), \pi^{\Pi G_{S_1}}(c_k)$). Then,
$\forall c_k \in D_C, \forall a_i \in D_{A_i}^{\Pi G_{S_1}}$ for i=1..n,
$\pi^{\Pi G_{S_1}}(c_k a_1 a_2..a_n)$=$\pi^{\Pi G_{S_2}}(c_k a_2..a_n)$.

Example (continued): Let us continue our example. In network of Figure 5, attribute A_3 is unary and will be removed. After Step 2, we obtain network of Figure 6.

ISBN: 978-989-95079-6-8

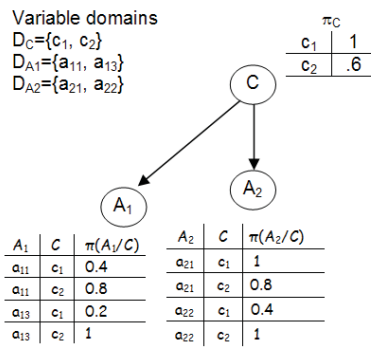

Figure 6: ΠG^{S_2}: Possibilistic network after Step 2

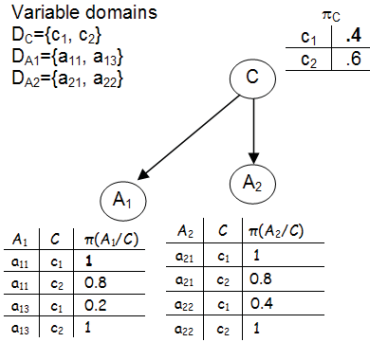

Figure 7: ΠG^{S_3}: Possibilistic network example after Step 3

4.3 Step 3: Re-normalizing local possibility distributions

As a consequence of the instance elimination step (Steps 1), local possibility distributions of some attributes might not be normalized. Indeed, it may exist a variable A_i and a class label c_k such that $max_{A_i}(\pi^{\Pi G_{S_2}}(a_i|c_k))=\alpha$ ($\alpha<1$). Step 3 deals with this problem considering two cases:

- If $\alpha=0$, then $\forall a_i \in D_{A_i}^{\Pi G_{S_2}}$, $\pi^{\Pi G_{S_2}}(c_k a_1..a_i..a_n)=0$ meaning that whatever is the value of A_i, this forces $\pi^{\Pi G_{S_2}}(c_k a_1 a_2..a_n)=0$. Hence, the class c_k cannot be among plausible ones, and can be removed from $D_C^{\Pi G_{S_2}}$.
- If $0<\alpha<1$, re-normalizing the conditional possibility distribution relative to attribute A_i can be done by building a new network ΠG^{S_3} by substituting $\pi^{\Pi G_{S_2}}(a_i|c_k)$ with

$$\begin{cases} 1 & \text{if } \pi(a_i|c_k)=max_{a_j \in D_{A_i}}(\pi^{\Pi G_{S_2}}(a_j|c_k)); \\ \pi(a_i|c_k) & \text{otherwise.} \end{cases}$$

and substituting $\pi^{\Pi G_{S_2}}(c_k)$ with $min(\pi^{\Pi G_{S_2}}(c_k), max_{a_j \in D_{A_i}}(\pi^{\Pi G_{S_2}}(a_j|c_k)))$. After this transformation, $\pi^{\Pi G_{S_3}}(c_k a_1..a_n)$ is conserved while sub-normalized local possibility distribution becomes normalized.

Proposition 3 Let ΠG^{S_2} be the naive possibilistic network involving nodes C,A_1,A_2,..,A_n obtained from Step 2. Assume that conditional possibility distribution relative to node A_1 is not normalized ($\exists c_k$ such that $max_{A_1}(\pi^{\Pi G_{S_2}}(a_1|c_k))=\alpha$ and $0<\alpha<1$). Let ΠG^{S_3} be the naive possibilistic network having same structure as ΠG^{S_2} where $\pi^{\Pi G_{S_3}}(a_1|c_k)=1$ if $\pi(wa_i|c_k)=max_{a_j \in D_{A_i}}(\pi^{\Pi G_{S_2}}(a_j|c_k))$, $\pi(a_i|c_k)$ otherwise and $\pi^{\Pi G_{S_3}}(a_i|c_k)=\pi^{\Pi G_{S_2}}(a_i|c_k)$ for i=2,..,n and $\pi^{\Pi G_{S_3}}(c_k)$=min$(\pi^{\Pi G_{S_2}}(c_k), max_{a_j \in D_{A_i}}(\pi^{\Pi G_{S_2}}(a_j|c_k)))$. Then, $\forall c_k \in D_C^{\Pi G_{S_3}}$, $\forall a_i \in D_{A_i}^{\Pi G_{S_3}}$, $\pi^{\Pi G_{S_3}}(c_k a_1 a_2..a_n)=\pi^{\Pi G_{S_2}}(c_k a_1 a_2..a_n)$

Note that contrary to product-based possibilistic networks, normalizing conditional possibility distribution of min-based networks is significantly different from normalizing local probability distributions of Bayesian networks.

Example (continued): In network ΠG^{S_2} of Figure 6, local possibility distribution of attribute A_1 is not normalized ($max_{a_i \in D_{A_1}}(\pi^{\Pi G_{S_2}}(a_i|c_1))$=.4). After re-normalizing ΠG^{S_2}, we obtain network of Figure 7. Possibility distribution relative to A_1 has been re-normalized and possibility distribution relative to class node C has been adjusted accordingly. One can easily check that joint possibility distributions encoded by networks of Figure 6 and Figure 7 are equal.

4.4 Step 4: Prior totally possible class lookup

The aim of Steps 1, 2 and 3 is simplifying and re-normalizing the initial network. Step 4 allows to search for class instances which are totally possible in network NP^{S_3}. Once the network is simplified and re-normalized, it is immediate that each class instance c_k having the utmost prior possibility degree in network NP^{S_3} (c_k=$argmax_{c_j \in D_C^{NP_{S_3}}}(\pi^{NP_{S_3}}(c_j))$, is totally possible given the uncertain inputs to classify. In particular, if $\pi^{NP_{S_3}}(c_k)$=1, then we can assert that there exists an attribute configuration $a_1..a_n$ allowing c_k to be totally plausible. This result is formalized in the following proposition:

Proposition 4 Let NP^{S_3} be the naive possibilistic network obtained after Steps 1, 2 and 3. Then, $\forall c_k \in D_C^{\Pi G_{S_3}}$ such that $\pi^{\Pi G_{S_3}}(c_k)$=1 or c_k=$argmax_{c_j \in D_C^{NP_{S_3}}}(\pi^{NP_{S_3}}(c_j))$, then $max_{A_1..A_n}(\pi^{\Pi G_{S_3}}(c_k|a_1..a_n))=1$

The attribute configuration guaranteeing that c_k is totally possible is the one where $\pi^{\Pi G_{S_3}}(a_i|c_k)$=1 for i=1..n.

Example (continued): Proposition 4 allows to assert that in network ΠG^{S_3} of Figure 7, class instance c_2 is totally possible since c_2=$argmax_{c_j \in D_C^{NP_{S_3}}}(\pi^{NP_{S_3}}(c_j))$. The attribute configuration allowing this result is $a_{13}a_{22}$. One can easily check that $\Pi^{\Pi G_{S_3}}(c_2|a_{13}a_{22})$=1.

4.5 Step 5: Conditionally totally possible class lookup

We assume in this step that the class variable C is a binary variable (namely, $D_C^{\Pi G_{S_3}}$={c_1, c_2}) and class label c_2 is totally possible ($\pi^{\Pi G_{S_3}}(c_2)>\pi^{\Pi G_{S_3}}(c_1)$).

In Step 4, only a subset of plausible class instances are found. Indeed, other class instances c_k having $\pi^{\Pi G_{S_3}}(c_k)=\alpha$ ($0<\alpha<1$) and $c_k \neq argmax_{c_j \in D_C^{NP_{S_3}}}(\pi^{NP_{S_3}}(c_j))$ can be totally possible given the uncertain inputs to classify. Namely, it may exist an attribute configuration $a_1 a_2..a_n$ such that $\Pi^{\Pi G_{S_3}}(c_k|a_1 a_2..a_n)$=1 even if $\pi^{\Pi G_{S_3}}(c_k)<1$ and $c_k \neq argmax_{c_j \in D_C^{NP_{S_3}}}(\pi^{NP_{S_3}}(c_j))$. Hence, there is a need to check if every class instance c_k which is not found totaly possible in Step 4 can be conditionally totally possible without exploring all configurations of $\Pi^{\Pi G_{S_3}}(c_k|a_1 a_2..a_n)$. If class instance c_1 is totally possible, then this implies

ISBN: 978-989-95079-6-8

that there exists an attribute configuration $a_1..a_n$ where $\Pi^{\Pi G_{S_3}}(c_1|a_1a_2..a_n)$=1. In order to find such a configuration, we can use the following decomposition:
$\Pi^{\Pi G_{S_3}}(c_1|a_1..a_n)$=1 if and only if
$\pi^{\Pi G_{S_3}}(c_1a_1..a_n)$=$\Pi^{\Pi G_{S_3}}(a_1..a_n)$. Recall that
$\Pi^{\Pi G_{S_3}}(a_1..a_n)$=$max(\pi^{\Pi G_{S_3}}(c_1a_1..a_n), \pi^{\Pi G_{S_3}}(c_2a_1..a_n))$
Hence, $\pi^{\Pi G_{S_3}}(c_1a_1..a_n)\geq\pi^{\Pi G_{S_3}}(c_2a_1..a_n)$. Then
$\frac{min(\pi(c_1),\pi(a_1|c_1),..,\pi(a_n|c_1)}{min(\pi(c_2),\pi(a_1|c_2),..,\pi(a_n|c_2)}\geq 1$.
Let us define $\pi_{c_1}(a_i/c_1)$=1 if
$\pi(a_i|c_1)\geq\pi(a_i|c_2)$ and $\pi_{c_1}(a_i/c_1)$=$\pi(a_i|c_2)$ otherwise. Then
$\frac{min(\pi(c_1),\pi(a_1|c_1),..,\pi(a_n|c_1)}{min(\pi(c_2),\pi(a_1|c_2),..,\pi(a_n|c_2)}\geq 1$ implies that

$$\pi(c_1) \leq min(\pi_{c_1}(a_1|c_1),..,\pi_{c_1}(a_n|c_1)). \qquad (13)$$

Decomposition of Equation 13 can be used to build a new network ΠG^{S_5} by transforming conditional possibility distributions relative to each attribute A_i in ΠG^{S_3} by substituting every term $\pi^{\Pi G_{S_3}}(a_i|c_1)$ by 1 if $\pi^{\pi G_{S_5}}(a_i|c_1)\geq\pi^{\Pi G_{S_3}}(a_i|c_2))$ and by $\pi^{\Pi G_{S_5}}(a_i|c_1)$ otherwise and discarding c_2 since it is known to be totally possible. After this transformation, some local conditional possibility distributions in network ΠG may not be normalized. Repeating Step 2 (Re-normalization) on sub-normalized local distributions in network ΠG^{S_5}) allows to re-normalize them. Once re-normalization accomplished, the new possibility distribution $\pi_C^{\Pi G_{S_5}}$ relative to class node shows whether class instance c_1 is totally possible. Then we have the following proposition:

Proposition 5 Let ΠG^{S_3} be the naive possibilistic network obtained after Steps 1, 2 and 3, and let $D_C^{\Pi G_{S_3}}$=$\{c_1, c_2\}$, $\pi^{\Pi G_{S_3}}(c_1)$<$\pi^{\Pi G_{S_3}}(c_2)$. Let ΠG be the possibilistic network having same structure as ΠG^{S_3} where $D_C^{\Pi G^{S_5}}$=$\{c_1\}$. Let for i=1..n $\pi^{\Pi G^{S_5}}(a_i|c_2)$=1 if $\pi^{\Pi G_{S_3}}(a_i|c_1)\geq\pi^{\Pi G_{S_3}}(a_i|c_2))$ and $\pi^{\Pi G^{S_5}}(a_i|c_2)$= $\pi^{\Pi G^{S_3}}(a_i|c_2)$ otherwise. Then, $\pi^{\Pi G^{S_5}}(c_1)$=1 if and only if there exists an attribute configuration $a_1..a_n$ such that $\Pi^{\Pi G_{S_3}}(c_1|a_1..a_n)$=1.

It is important to note that in comparison with the lookup for conditionally totally possible class instances in product-based networks (see [11]), this step shows significant differences in min-based networks.

Example (continued): Transformation of Step 5 on network ΠG^{S_3} and its re-normalization gives network ΠG^{S_5} of Figure 8 where network of the left side gives the network obtained after Step 5 before re-normalization while network of right side represents ΠG^{S_5} after re-normalization according to Step 3. After this transformation, we can assert that class instance c_1 is not totally possible ($\pi^{\Pi G^{S_5}}(c_1) < 1$). This result confirms the one obtained by directly applying the possibilistic counterpart of Jeffrey's rule (see Figure 4).

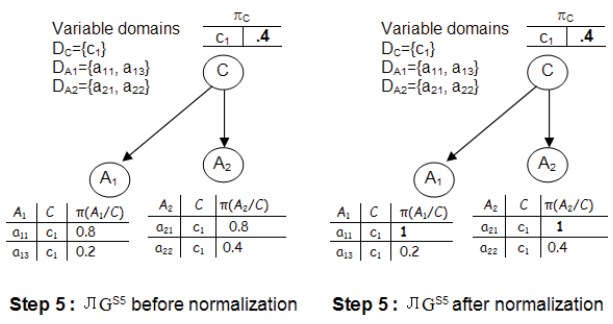

Figure 8: ΠG^{S_5}: Possibilistic network after Step 5

5 Conclusion

This paper dealt with min-based possibilistic network classifiers under uncertain inputs. It first addressed the min-based possibilistic counterpart of Jeffrey's rule for revising possibilistic knowledge encoded by a qualitative naive possibilistic network. After showing that classification based on the min-based revision of a possibility distribution encoded by a qualitative possibilistic classifier is exponential in the number of uncertain inputs, we proposed a polynomial algorithm for revising a naive min-based possibilistic network given uncertain inputs. This algorithm applies a series of equivalent and polynomial transformations on the initial network taking into account the uncertain evidence to classify. In future works, we will address general possibilistic classifiers under uncertain inputs.

Abstract— *Although simple and based on physical realizable color primaries, the RGB color space cannot allow the direct definition of a topology-preserving, perceptually-compatible inter-color distance. The classical normalized inter-color distances are rather complex to implement and tune and do not account for the natural incertitude and confusion regarding both the numerical color values and the color perception. We propose the use of a planar color representation plot, derived from multivariate data visualization, which allows the introduction of a luminance-invariant, geometry-based fuzzy inter-color distance, used with good results in the implementation of distance-based color filters and edge detectors.*

Keywords— fuzzy distance, fuzzy color, fuzzy image filtering.

1 Introduction

The classical inter-color distances are based on standard colorimetric representations, being metrics (or almost metrics) in the color gamut space (a subset of $\mathbf{R}^3$). We propose to investigate a new approach, inspired by the reduced ordering principle of Barnett [1] and also used in multivariate data visualization [2]: namely, the multivariate data (colors) are mapped to some familiar, two-dimensional objects, that can be grouped, compared, and plotted with more ease and are more suited for human perception. Examples of such mappings are the Chernoff faces [3], the Andrews curves [4] and their possible extensions [5], the basic and modified parallel coordinates [6] and the star glyphs [2]. Previous work showed that we could extend the geometric distance between simplified, plane color representations (such as the star glyphs) to color distances [7].

This work proposes the embedding of the uncertainty regarding the exact values of the color components describing the color into a fuzzy color distance, inspired by the two-dimensional geometrical representation of the color by means of the parallel coordinates.

The remainder of the paper is organized as follows: section 2 describes the basic parallel coordinates representation of multivariate data and its application to the representation of colors, section 3 introduces the distance between colors based on their parallel coordinates representation, section 4 introduces the fuzzy extension of the inter-color distance and, finally, section 5 presents some applications of the proposed fuzzy distance in non-linear color image filtering and color edge extraction.

2 Parallel coordinates: the basics

The parallel coordinates representation is a visualization technique that basically allows plotting n-dimensional points and patterns into the bi-dimensional plane. Thus, the parallel coordinates representation transforms multidimensional problems into two-dimensional patterns, without loss of information.

Let us consider a n-dimensional data point $\mathbf{x} = (x_1, x_2, \ldots, x_n)$, originally represented in a Cartesian coordinate system. If each of the n axes of the coordinate system are lined up in parallel with all others into the plane, separated by a fixed distance Δ, we obtain the parallel coordinates system (as presented in Fig. 1) [6]. Obviously, the approach is scalable with respect to the data dimension, n. Visualization is facilitated by viewing the two-dimensional representation of the n-dimensional data points as lines, crossing the n parallel axes, each of them representing one dimension of the original feature space. A n-dimensional point $\mathbf{x}$ is represented in the plane by the series of $n-1$ connected line segments defined by the end points $[(kD, x_1), ((k+1)D, x_2)]$, $[((k+1)D, x_2), ((k+2)D, x_3)]$, , $[((k+n-2)D, x_{n-1}), ((k+n-1)D, x_n)]$ (as shown in Fig. 1).

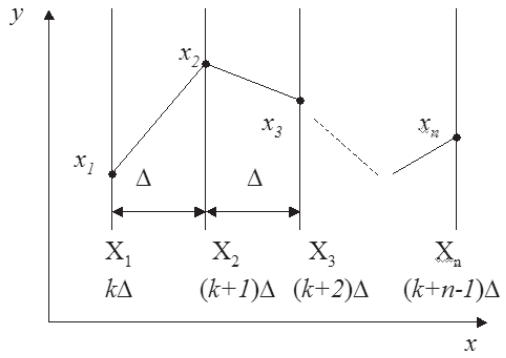

Figure 1: Basic parallel coordinates representation of a n-dimensional data point.

Several interesting mathematical results have been proven for the parallel coordinates representation [6], [8] and several applications were proposed, such as clustering [9], fuzzy rule representation [10], air traffic control [8], and color image filtering [11] based on the independent processing of the points along the individual coordinates axes.

We may notice the strong resemblance of the parallel coordinate representation with the Andrews curves [4], [2] representation method. The Andrews curve representation maps each n-dimensional point into a continuous, analytical curve, obtained as a n-term series expansion having the point coordinates as coefficients, according to a fixed functional basis. The original method uses the Fourier expansion (sine and cosines functions), but modifications were also proposed (e.g. the use of Haar wavelets for color image filtering [5]). For a discrete representation of the Andrews curves, the continuous basis functions are sampled at regular intervals, similar to the

ISBN: 978-989-95079-6-8

use of some parallel axes.

In the following of the paper, we will focus on the representation of colors - three-dimensional data points. Thus, each data point is a triple, $\mathbf{x} = (x_1, x_2, x_3)$. This representation is straightforward for the representation of RGB color data, due to the similar nature of the RGB components; thus, the data points will be $\mathbf{x} = (R, G, B)$, as proposed in [11]. Still, we propose to use a slight modification of the classical model, by using a four-dimensional data vector for the representation of the color, namely $\mathbf{x} = (R, G, B, R)$ as shown in Fig. 2. A color will be thus represented by the polygonal line or by the subgraph (lower limited by the horizontal axis) of that polygonal line, which is itself a polygon and will be subsequently named color polygon.

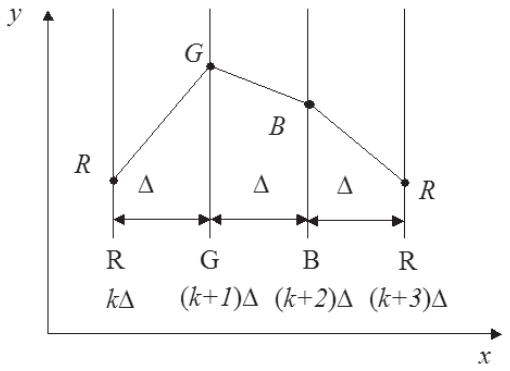

Figure 2: Proposed parallel coordinates representation of a RGB color, viewed as a 4-dimensional data vector.

3 Computing color distances

Color is represented by a three-component vector; the basic representation is the RGB model, for which the vector components are the relative amounts of normalized red, green and blue that additively mix in order to produce that color. Although simple and based on physical realizable color primaries, the RGB color space cannot allow the direct definition of a topology-preserving, perceptually-compatible inter-color distance. The same observation holds for the spectral color representations as well. As normalized by CIE (Commission Internationale de l'Eclairage), perceptual-compatible inter-color distances are obtainable from the Lab color representation. For any two colors $C_1 = (L_1, a_1, b_1)$ and $C_2 = (L_2, a_2, b_2)$, the simplest inter-color distance is the Euclidean distance in the Lab color gamut [12].

Advanced color difference formulas (such as the CMC, BFD or CIE94 [12]) have been introduced, since the basic Lab Euclidean metric do not accurately quantify small-to-medium-sized color differences. Such correctly-measured (as correlated to the subjective estimation) color difference are very complex and untractable for general-use in color image processing. Furthermore, they are not invariant to the change or luminance.

Obviously, the parallel coordinates polygon's shape is related to the nature of the color (properties like hue, saturation, colorfulness, etc.) and the overall area of the polygon relates to the luminance or brightness of the color. It can be accepted that a similarity measure between colors is given by the area of intersection of the two associated parallel coordinates polygons. In order to construct a symmetrical and normalized measure, we will follow an approach similar to the definition of the Canberra distance: the normalization is performed with respect to the average area of the two color polygons. Thus, the distance between colors C_1 and C_2, represented by their corresponding parallel coordinates polygons P_1 and P_2 can be introduced as:

$$d(C_1, C_2) = 2\frac{Area_{P_1 \nabla P_2}}{Area_{P_2} + Area_{P_2}} \tag{1}$$

From simple plane geometry considerations one can easily show that the distance in (1) can be approximately put in the form of:

$$d(C_1, C_2) = \left(D_{RG} + D_{GB} + D_{BR}\right)/3 \tag{2}$$

where D_{RG} is given in (3) and D_{GB} and D_{BR} have similar forms.

$$D_{RG} = 2\begin{cases} \frac{|R_1-R_2|+|G_1-G_2|}{R_1+R_2+G_1+G_2} & if \Delta R \Delta G \geq 0 \\ \frac{(R_1-R_2)^2+(G_1-G_2)^2}{(R_1+R_2)^2-(G_1+G_2)^2} & if \Delta R \Delta G < 0 \end{cases} \tag{3}$$

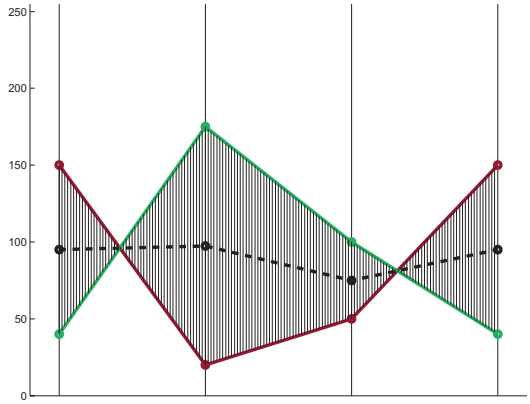

Figure 3: Proposed parallel coordinates distance for two colors (red with $RGB = (150, 25, 50)$ and green with $RGB = (40, 170, 110)$): the hashed area is the uncommon area of the parallel coordinates polygons associated to the colors; the dashed central line is the parallel coordinates polygon having the average area.

It can be easily shown that for unsaturated colors (grays), the proposed inter-color distance is the Canberra distance. The distance in (2) is normalized in the $[0; 1]$ range. It can be easily shown that the proposed distance is invariant to luminance changes, that is $d(C_1, C_2) = d(\alpha C_1, \alpha C_2), \forall \alpha \in \mathbf{R}$.

4 The fuzzy color distance

All image processing algorithms must deal with the imprecision and vagueness that naturally arise in the digital representation of visual information. Noise, quantization and sampling errors, the tolerance of the human visual system are the cause of this imprecision. This strongly suggests that fuzzy models may be used for taking them into account.

In the case of color images, color attributes and color differences play a particularly important role in the perception of

ISBN: 978-989-95079-6-8

object boundaries. The process of measuring color differences must be designed to maintain a balance between the computed and the perceived difference. Still, the simple use of any given color representation does not account for the similarity perception and the visual confusion of colors. We propose to deal with this factors in the framework of a fuzzy representation of the basic RGB color components and obtain a fuzzy distance between colors based on the parallel coordinate representation of the fuzzy colors.

The assumed model means that we will consider each of the R, G, and B color components as fuzzy numbers, centered at their ideal (correct, crisp) value. Thus, the polygonal line representing the given color in the parallel coordinates system will evolve into some fuzzy polygonal line, composed by fuzzy line segments.

We will define the fuzzy distance $\widetilde{D}$ between two fuzzy colors by means of its α-cuts. The corresponding α-cuts of any fuzzy color component are closed intervals along the corresponding parallel coordinate axes. Under these circumstances we can easily determine (from basic geometrical considerations) the minimal and maximal common areas of the corresponding color parallel coordinates polygon and thus to determine the lower and upper bounds of the corresponding α-cut of the fuzzy distance $\widetilde{D}$.

In the particular case of modelling the fuzzy RGB components by fuzzy triangular numbers, the limits of the α-cut intervals of the fuzzy distance are particulary simple to obtain. We will assume that the fuzzy color components $\widetilde{V}_i$ (where V_i is any of the RGB components) are defined by triangular fuzzy membership functions around their crisp value V_{i0}:

$$\mu_{\widetilde{V}_i}(V) = max(0, 1 - \frac{|V - V_{i0}|}{2 * \delta}) \tag{4}$$

In equation (4) above, δ is the support of the membership function, measuring its width around the crisp (correct) value and being thus the direct measure of the incertitude regarding the correct component value V_{i0}.

The α-cuts of any of the terms that sum to the color distance defined in (2) are bounded intervals, like $[D^-_{XY}(\alpha); D^-_{XY}(\alpha)]$. These upper and lower bounds of the α-cuts intervals of color distance terms are given by the expressions in (5) and (6) (for the D_{RG} term given in (3)), according to the cases when the line segments within two successive parallel coordinate axes intersect (corresponding to $\Delta R \Delta G < 0$) or not ($\Delta R \Delta G \geq 0$).

$$D^{\pm}_{RG}(\alpha) = 2\frac{|R_1 - R_2| + |G_1 - G_2| \pm 4(1-\alpha)\delta}{R_1 + R_2 + G_1 + G_2} \tag{5}$$

$$\begin{aligned} P_1 &= (R_1 + R_2 + G_1 + G_2 \mp 4(1-\alpha)\delta) \\ P_2 &= (|R_1 - R_2| + |G_1 - G_2| \mp 4(1-\alpha)\delta) \\ U_1 &= (R_1 - R_2 \pm 2(1-\alpha)\delta)^2 \\ U_2 &= (G_1 - G_2 \pm 2(1-\alpha)\delta)^2 \\ D^{\pm}_{RG}(\alpha) &= 2\frac{U_1 + U_2}{P_1 P_2} \end{aligned} \tag{6}$$

The fuzzy color distance is obtained by its α-cuts, by summing the α-cuts of the corresponding D_{XY} terms in (2). The choice of the width δ of the triangular membership function that models the RGB color components and the discrete nature of the component values imply that the number of distinct α-cuts of the color distance is limited to the rounded value of $\delta + 1$. For instance, the fuzzy distance between the two colors represented in parallel coordinates in figure 3 (red with $RGB = (150, 25, 50)$ and green with $RGB = (40, 170, 110)$) computed according to $\delta = 2.2$ is defined by three α-cuts: 2.53 for $\alpha = 1$, $[2.49; 2.58]$ for $\alpha \in [0.55; 1)$ and $[2.44; 2.62]$ for $\alpha \in [0.09; 0.55)$.

5 Applications

A significant part of nonlinear filters for color images are distance-based, i.e. they rely on the computation of inter-color distances between the colors selected by the filtering window. We shall prove the use of the proposed fuzzy inter-color distance in both smoothing filters (such as the vector median filter) and edge extraction filters, such as standard derivative-based filters.

5.1 Vector median filtering using the fuzzy inter-color distance

The classical VMF (Vector Median Filter) [13] defines the vector (or color) median as the vector characterized by a minimal aggregated distance with respect to all other vectors in the filtering neighborhood; this ordering of the color vectors is an instance of the reduced ordering principle [1]. Usually, the distance between color is computed as a L^k norm of the RGB color vectors. We will show here that the use of the proposed fuzzy inter-color distance provides good filtering results.

The fuzzy aggregate distance associate to each color vector within the filtering window is computed based on the α-cuts of the individual inter-color distances. Finally, the aggregated distances (which are also fuzzy numbers defined by their α-cuts) are ranked, and the minimal fuzzy aggregated distance corresponds to the median color.

The ranking of the fuzzy numbers (the fuzzy aggregated distances) is performed according to the classical total integral value. The total integral value of a fuzzy number $\widetilde{D}$ was introduced in [14] as:

$$I_T(\widetilde{D}) = \int_0^1 \mu^{-1}_{\widetilde{D}}(y)dy \tag{7}$$

According to the ranking proposed in [14], the smallest fuzzy number has the smallest total integral value (we may also notice that this ranking is an instance of Barnett's reduced ordering principle [1]).

Figure 4 presents the result of a fuzzy-VMF filter applied for impulsive noise reduction in a color image.

5.2 Fuzzy color edge detection

Basically, all edge detection operators rely on the computation of an edge intensity map, which is further thresholded in order to obtain a binary edge map. The edge intensity map exhibits important values for the pixels that are on the boundaries of uniform regions, characterized by a discontinuity (or variation) of their colors.

One of the simplest contour extraction methods is the image Laplacian. We shall use the luminance-invariant fuzzy inter-color distance introduced in (2) for the implementation

a) b)

Figure 4: a) 5% Impulsive noise degraded image and b) fuzzy-VMF filtered image within a 3×3 window, with a fuzzy color model characterized by $\delta = 2.2$.

of a fuzzy color Laplacian operator L. The proposed operator is a modification of the classical (derivative-type) V4-neighborhood Laplacian operator; the color Laplacian is the average inter-color distance within the color at the current processed location (i, j) and its immediate neighboring colors from the color image f. Mathematically we can express the proposed fuzzy Laplacian at location (i, j) as:

$$\widetilde{L}(i,j) = \frac{1}{4} \sum_{(k,l) \in V_4} \widetilde{D}(f(i+k, j+l), f(i,j)) \qquad (8)$$

The fuzzy Laplacian will be defined by the use of fuzzy color distances in (8). The summation of the fuzzy color distance is performed via the corresponding summation of the limits of their α-cut intervals, yielding an α-cut definition of the fuzzy color Laplacian at each image location.

The extraction of the binary edge map image implies the thresholding of the fuzzy Laplacian edge intensity map. According to the desired level of detail that we want to extract form the image, we may use as color edge intensity map either the lower or the upper limit of a specified α-cut interval, as shown in figures 5 and 6. The choice of a particular value of α acts as trimming parameter for the extraction of a more accurate and detailed or a more rough binary edge map, while keeping a same fixed general threshold. This is not possible when using a non-fuzzy color distance, either in RGB or Lab or other color representations.

6 Conclusions

In this contribution we presented a new fuzzy inter-color distance measure, derived from geometrical considerations related to a plane, two-dimensional, reversible color representation. This color representation by parallel coordinates (representing a color as a an open polygonal line) was primarily used in multivariate data representation. The proposed fuzzy inter-color distance can be used with good results in the median (non-linear) filtering of color images and fuzzy edge detection.

Abstract— *Pareto-optimality conditions are crucial when dealing with classic multi-objective optimization problems because we need to find out a set of optimal solutions rather than only one optimal solution to optimization problem with a single objective. Extensions of these conditions to the fuzzy domain have been discussed and addressed in recent literature. This work presents a novel approach based on the use of possibility theory as a comparison index to define a fuzzily ordered set with a view to generating the necessary conditions for the Pareto-optimality of candidate solutions in the fuzzy domain. Making use of the conditions generated, one can characterize fuzzy efficient solutions by means of carefully chosen single-objective problems. The uncertainties are inserted into the formulation of the studied fuzzy multi-objective optimization problem by means of fuzzy coefficients in the objective function. Some numerical examples are analytically solved to illustrate the efficiency of the proposed approach.*

Keywords— Possibility theory, multi-objective optimization, fuzzy Pareto-optimality conditions, fuzzy mathematical programming.

1 Introduction

One of the most significant characteristics of human beings is the decision making of day-by-day problems. This characteristics is used to solve several practical problems including economic, environmental, social and technical. These problems are multidimensional and have multiple objectives that are often non-commensurable and conflict with each other. Thus, they are inserted in the set of problems that are solved by using the theory of multi-objective optimization which is a generalization of traditional single objective optimization. Although multi-objective optimization problems differ from single objective problems only in the plurality of objective functions, it is important to realize that the notion of optimality condition change because now the decision maker must find solutions that satisfy or create a compromise among the multiple objectives. These solutions are called Pareto optimal or efficient or non-dominated solutions.

Optimization is a procedure of finding and comparing feasible solutions until no better solution can be found. These solutions are defined good or bad in terms of one or several objectives when is used any optimization model. The optimization models often use classical mathematical programming, which attempts to develop an exact model to the optimization problem of interest. Such modeling may overlook ambiguities that all too frequently exist in actual optimization operations. In recent years, Fuzzy Logic [16] has showed great potential for modeling systems which are non-linear, complex, ill-defined and not well understood. Fuzzy Logic has found numerous applications due to its ease of implementation, flexibility, tolerant nature to imprecise data, and ability to model non-linear behavior of arbitrary complexity because of its basis in terms of natural language. In [18] is discussed the use of fuzzy logic that is a precise logic of imprecision and approximate reasoning. We refer to [6, 10, 19], for some applications in the fields of pattern recognition, data analysis, optimal control, economics and operational research, among others.

The representation and arithmetic manipulation of uncertain numerical quantities can be defined by means of fuzzy sets. Unfortunately, the comparison among two or more fuzzy numbers, intervals and/or sets is not easy. Some approaches to compare them (see some examples in [2, 6, 9, 10, 14]) were developed, each one being based upon a different point of view. The possibility theory, which is analogous to the probability theory, was proposed by Zadeh [17] to aggregate the concept of a possibility distribution to the theory of fuzzy sets. Comparison indexes to rank fuzzy numbers and intervals employing possibility theory were proposed in [7]. Their importance stems from the fact that much of the information on which human decisions rely upon have a possibilistic, rather than a probabilistic nature. On the other hand, some works describe a fuzzy optimization problem in a classical problem and they use the classical theory to find the Pareto optimal set. [8] transform a fuzzy single objective problem into a classical multiple objective one where the number of objectives is defined by fuzzy coefficients from the fuzzy problem.

Possibility theory emerged from the notion of fuzzy sets and his concept tries to take account of the fact that an object may more or less correspond to a certain category in which one attempts to place it. In the calculus of degree of possibility emphasizes the double relationship between possibility theory and set theory and the concept of measure, respectively. One merit of possibility theory is to represent imprecision and to quantify uncertainty at the same time.

This work is organized as follows. Section 2 presents an overview about the formulation of classical multi-objective programming problems and classical concepts to obtain the set of Pareto optimal solutions. Also, it is shown an extension of these concepts to Pareto optimal solutions of fuzzy multi-objective programming problems. Section 3 introduces a novel approach to fuzzy Pareto-optimality. A fuzzily ordered set is defined by using a possibility distribution function as a comparison measure. This section also presents the characterization of the efficient solutions through the use of well defined scalar problems. This relation between efficient solutions and scalar problems can be determined by certain theorems. To clarify the above developments, two numerical

ISBN: 978-989-95079-6-8

examples are analyzed in section 4. Finally, conclusions are presented in Section 5.

2 Multiobjective programming problem formulation and concepts

Choosing the goal to be optimized is a critical step in the process of modeling real-world problems. The local or global optimal solution depends totally upon this choice. In the vast majority of real-world problems, various objective functions could be defined. Many times these functions are conflicting and/or non-measurable. Multi-objective optimization is the branch of mathematical optimization theory devoted to developing methods to solve problems with various objective functions. A classical multi-objective problem can be formulated as follows:

$$\begin{array}{ll} \min & F(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in \Omega \end{array} \tag{1}$$

where $F = (f_1, f_2, \ldots, f_m),\ (m \geq 2)$ is a vector of objectives and $\Omega \subset \mathbb{R}^n$ is the set of feasible solutions.

Due to the issue of conflicting objectives, the classical concept of optimality that are used to obtain the optimal solution to optimization problems with an objective function does not fit into the multi-objective framework. Hence, in such a framework, one settles for the so-called efficient, non-dominated or Pareto-optimal solution.

The classical works [12] and [13], by Vilfredo Pareto, introduced the concept of Pareto-optimality and started the field of multi-objective optimization. A solution $x^* \in \Omega$ is said to be *Pareto-optimal* or *non-dominated* if there exists no alternative solution in Ω that improves some of the objective functions without degrading at least another objective function. Then, we can define mathematically a non-dominated solution as

Definition 1 (Pareto optimal solution) $\mathbf{x}^* \in \Omega$ *is said to be a* non-dominated solution *of Problem (1) if there exists no other feasible* $\mathbf{x} \in \Omega$ *such that* $f_i(\mathbf{x}) \leq f_i(\mathbf{x}^*),\ \forall\ i = 1, \ldots, m$ *with strict inequality for at least one* i.

However, when non-linear programming problems with single objective are solved by any non-linear programming method, only local optimal solutions are guaranteed in practical. Then, the concept of local non-dominated solution can be defined in the following way:

Definition 2 (local Pareto optimal solution) $\mathbf{x}^* \in \Omega$ *is said to be a* local non-dominated solution *of Problem (1) if and only if there exists a real number* $\delta > 0$ *such that* $\mathbf{x}^*$ *is non-dominated in* $\Omega \bigcap \mathcal{N}(\mathbf{x}^*, \delta)$*, i.e., there does not exist another feasible* $\mathbf{x} \in \Omega \bigcap \mathcal{N}(\mathbf{x}^*, \delta)$ *such that* $f_i(\mathbf{x}) \leq f_i(\mathbf{x}^*),\ \forall\ i = 1, \ldots, m$ *with strict inequality for at least one* i.

where $\mathcal{N}(\mathbf{x}^*, \delta)$ denotes the δ neighbourhood of $\mathbf{x}^*$ defined by $\{\mathbf{x} \in \mathbb{R} \| \|\mathbf{x} - \mathbf{x}^*\| < \delta\}$. Thus, it is possible to see by these definitions that the solution of a multi-objective programming problem consists of an infinite number of points.

Many methods to solve multi-objective programming problems were proposed and some specific methods can be found in [4]. These methods are classified according to the instant the decision maker applies their criteria. Three methods are proposed: (i) *a-Priori method*, where the decision maker assigns weights to the objective functions a-priori, thus obtaining a single mono-objective criterion; (ii) *a-Posteriori method*, where the decision maker strives to create some type of efficient solutions to chose from a-posteriori; and (iii) *interactive methods*, where the decision maker informs their preferences during the search process of an efficient solution.

Although the mathematical formulation of optimization problems with multiple objectives be well defined, some values of the real-world problems have vagueness, imprecision and uncertainty. These values which have been estimated by decision maker are parameters in the set of constraints and in one or several objective functions. These uncertainties can be formulated by logic fuzzy which is a way to describe this vagueness mathematically and it has found numerous and different applications due to its easy implementation, flexibility, tolerant nature to imprecise data, low cost implementations and ability to model non-linear behavior of arbitrary complexity because of its basis in terms of natural language. The concept of fuzzy decision to obtain a solution to fuzzy programming problems was introduced by Bellman and Zadeh[1] which proved that the fuzzy programming problems can be reduced to a conventional programming problem under some assumptions determined by decision maker.

Based on this work, many researches developed methods that solve optimization problems under fuzzy environment and in [15] is used α-cut sets to define a non-dominated solution to multi-objective programming problems with fuzzy parameters which is called α-Pareto optimal solution. In this case, the fuzzy parameters can be inserted in Problem (1) and it is transformed in the following way:

$$\begin{array}{ll} \min & F(\tilde{\mathbf{a}}; \mathbf{x}) = (f_1(\tilde{\mathbf{a}}_1; \mathbf{x}), \ldots, f_m(\tilde{\mathbf{a}}_m; \mathbf{x})) \\ \text{s.t.} & \mathbf{x} \in X(\tilde{\mathbf{b}}) \triangleq \{x \in \mathbb{R}^n | g_i(\tilde{\mathbf{b}}_i; \mathbf{x}) \leq 0, i = 1, \ldots, p\} \end{array} \tag{2}$$

where $\tilde{\mathbf{a}}_i$ and $\tilde{\mathbf{b}}_i$ represent a vector of fuzzy parameters involved in the objective functions and in the functions that form the set of constraints, respectively. These fuzzy parameters which reflect the expert's ambiguous understanding of the nature of the parameters in the problem formulation process, are assumed to be characterized as fuzzy numbers.

Definition 3 (α-level set) *The* α*-level set of the fuzzy numbers* $\tilde{c}$ *and* $\tilde{d}$ *is defined as the ordinary set* $(\tilde{c}, \tilde{d})_\alpha$ *for which the degree of their membership functions exceeds the level* α*:*

$$(\tilde{c}, \tilde{d})_\alpha = \{(c, d) | \mu_{\tilde{c}}(c) \geq \alpha \text{ and } \mu_{\tilde{d}}(d) \geq \alpha\}.$$

Now, suppose that the decision maker considers that the degree of all of the membership functions of the fuzzy numbers involved in Problem (2) should be greater than or equal to a certain value of α. Then, for such a degree α, Problem (2) can be interpreted as a conventional multi-objective programming problems in the following way:

$$\begin{array}{ll} \min & F(\mathbf{a}; \mathbf{x}) = (f_1(\mathbf{a}_1; \mathbf{x}), \ldots, f_m(\mathbf{a}_m; \mathbf{x})) \\ \text{s.t.} & \mathbf{x} \in X(\mathbf{b}) \triangleq \{x \in \mathbb{R}^n | g_i(x, b_i) \leq 0, i = 1, \ldots, p\} \\ & (\mathbf{a}, \mathbf{b}) \in (\tilde{\mathbf{a}}, \tilde{\mathbf{b}})_\alpha \end{array} \tag{3}$$

where the coefficient vector $(\mathbf{a}, \mathbf{b}) \in (\tilde{\mathbf{a}}, \tilde{\mathbf{b}})_\alpha$ and $(\mathbf{a}, \mathbf{b})$ are arbitrary for any value in $(\tilde{\mathbf{a}}, \tilde{\mathbf{b}})_\alpha$. This fuzzy subset is formatted for all the vectors whose degree of each membership function exceeds the level α. Here, it is possible to observe that the parameters $(\mathbf{a}, \mathbf{b})$ are treated as decision variables of Problem (3) rather than constants of Problem (2). Through the

ISBN: 978-989-95079-6-8

description of Problem (3), the concepts of (local) α-Pareto optimality is defined as follows.

Definition 4 ((Local) α-Pareto optimal solution) *$x^* \in X(b)$ is said to be a (local) α-Pareto-optimal solution to the α-MONLP(Multi-Objective Non-Linear programming) if and only if there exists no other $x \in X(b)(\bigcap \mathcal{N}(x^*, r))$ and $(a, b) \in (A, B)_\alpha(\bigcap \mathcal{N}(a^*, b^*, r'))$ such that $f_i(x, a_i) \leq f_i(x^*, a_i^*)$, $i = 1, 2, \ldots, k$, with strict inequality holding for at least one i, where the corresponding values of parameters a^* and b^* are called α-level optimal parameters (and $\mathcal{N}(x^*, r) \triangleq \{x \in \mathbb{R}^n | \|x - x^*\| < r\}$ denote the r neighborhood of x^*).*

The (local) α-Pareto-optimal solutions can be obtained through a direct application of the scalarization methods, which transform a multi-objective programming problem into a single-objective programming problem, and the optimal solution obtained is formed by point $(\mathbf{x}, \mathbf{a}, \mathbf{b})$. These set of solutions, however, generally comprises an infinite number of points and the decision should select a single (local) solution based on a subjective criterion.

3 The use of possibility theory in multi-objective optimization under fuzzy environment

Normally, when a multi-objective optimization problems is formulated, many parameters need to be assigned by the decision maker and they may be described by possible values. In most practical situations, it is natural to consider that the possible values of these parameters are often only vaguely known and it is appropriated to interpret them by the decision maker's understanding. This parameters can be represented by fuzzy numbers which intent to describe the possible values that are inserted in the real-world problems. Then, the resulting multi-objective programming problem with fuzzy parameters would be viewed as the more realistic version of the conventional one. In addition, it is necessary to define a model for the quantification of the imprecise data that interpret the decision maker's judgment. There are many comparison approaches among fuzzy numbers and one of them is the possibility theory which was chosen in this work.

3.1 Fuzzy basic concepts

Mathematical programming problems need a precise definition of both the constraints and the objective function to be optimized. Fuzzy sets help handle uncertainties when multi-objective programming problems are formalized in the following form:

$$\begin{array}{ll} \widetilde{\min} & F(\tilde{\mathbf{a}}; \mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in \tilde{\Omega} \end{array} \tag{4}$$

where $F = (f_1, f_2, \ldots, f_m)(m \geq 2)$ is a vector of objectives, $\tilde{\mathbf{a}} \in \mathbb{F}(\mathbb{R}^{n \times m})$ represent the fuzzy parameters in the objective functions and $\tilde{\Omega} \subset \mathbb{F}(\mathbb{R}^n)$ is a subset of feasible solutions. $\mathbb{F}(\mathbb{R})$ defines the set of fuzzy numbers, $\mathbb{F}(\mathbb{R}^n)$ defines the set of n-dimensional vector with fuzzy parameters and $\mathbb{F}(\mathbb{R}^{n \times m})$ defines the set of $n \times m$-dimensional matrix with fuzzy parameters. However, we shall only address the uncertainties of the parameters in the objective functions, in this work.

In order to be able to sort fuzzy numbers in an increasing (decreasing) order, one has to opt for a comparison measure, therefore a possibility measure is used which is defined as:

Definition 5 (Possibility measure) *Let A be a fuzzy subset of U and let $\prod_X$ be a possibility distribution associated with a variable X which takes values in U. The* possibility measure*, $\pi(A)$, of A is defined by*

$$Poss\{X \text{ is } A\} \triangleq \pi(A) \triangleq \sup_{u \in U} \min(\mu_A(u), \pi_X(u)) \tag{5}$$

where μ_A is the membership function of A and π_X is the possibility distribution function of X. It can be interpreted as the possibility that the value X belongs to the set A *and it is defined to be numerically equal to the membership function of X.*

Then, it is possible define a way to compare two fuzzy numbers and this index can be formulated as follows

$$Poss\{\tilde{a}_1 \leq \tilde{a}_2\} = \sup_{u, v \in U; u \leq v} \min(\mu_{\tilde{a}_1}(u), \mu_{\tilde{a}_2}(v))$$

where $\mu_{\tilde{a}_1}$ and $\mu_{\tilde{a}_2}$ are membership functions of $\tilde{a}_1$ and $\tilde{a}_2$. Possibility degree $Poss\{\tilde{a}_1 \leq \tilde{a}_2\}$ shows to what extent $\tilde{a}_1$ is possibly less than or equal to $\tilde{a}_2$, as described in [7, 11].

The definition above enables one to define a fuzzily ordered set $\mathbb{F}(\mathbb{R})$ that is an extension of the classical ordered set. A set is said to be *completely ordered* if it satisfies the following conditions:

Definition 6 (Ordered fuzzily set) *A fuzzy subset $A \subset \mathbb{F}(\mathbb{R})$ is fuzzily ordered with respect to the possibility measure if each element in A satisfies the following basic properties:*

1. $Poss[\tilde{\mathbf{a}}_1 \leq \tilde{\mathbf{a}}_1] = 1$;
2. $Poss[\tilde{\mathbf{a}}_1 \leq \tilde{\mathbf{a}}_2] \geq \alpha_1$ *and* $Poss[\tilde{\mathbf{a}}_2 \leq \tilde{\mathbf{a}}_3] \geq \alpha_2 \Rightarrow$ $Poss[\tilde{\mathbf{a}}_1 \leq \tilde{\mathbf{a}}_3] \geq \min\{\alpha_1, \alpha_2\}$;
3. $Poss[\tilde{\mathbf{a}}_1 \leq \tilde{\mathbf{a}}_2] \geq \alpha_1$ *and* $Poss[\tilde{\mathbf{a}}_2 \leq \tilde{\mathbf{a}}_1] \geq \alpha_2 \Rightarrow$ $Poss[\tilde{\mathbf{a}}_1 = \tilde{\mathbf{a}}_2] \geq \min\{\alpha_1, \alpha_2\}$;

$\forall\, \tilde{\mathbf{a}}_1, \tilde{\mathbf{a}}_2, \tilde{\mathbf{a}}_3 \in A$ *and* $\forall\, \alpha_1, \alpha_2 \in [0, 1]$.

According to the expressions above, a fuzzy subset $A \subset \mathbb{F}(\mathbb{R})$ is completely ordered. However, a fuzzy subset of $\mathbb{F}(\mathbb{R}^m)$ is only partially ordered. Therefore, the concept of optimal solution for single objective problems, which was defined in [3, 15], does no fit into the multi-objective formulation, unless the problem admits the so-called *ideal solution*, i.e. a single solution that simultaneously minimizes all objective functions as below:

Definition 7 (Ideal solution) *The ideal solution $\tilde{\mathbf{y}}$ of the multi-objective problem is defined as*

$$\tilde{\mathbf{y}}_i = f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^i), \;\; i = 1, \ldots, m$$

where $\mathbf{x}^i = \arg\min_{\mathbf{x} \in \mathbb{R}^n} f_i(\tilde{\mathbf{a}}_i; \mathbf{x})$.

The problem is said to admit an ideal solution whenever the set of arguments $\{\mathbf{x}^i,\ i = 1, \ldots, m\}$, possesses a single element. Because the multi-objective framework is most often

ISBN: 978-989-95079-6-8

employed in problems with conflicting objectives, a typical multi-objective problem is unlikely to admit such a solution. However, due the existence of an ideal solution is very rare, such a possibility will not be considered in the present analysis.

Conceptually, an efficient solution is one which is not dominated by any other feasible solution. Hence, the domination concept of a fuzzy multi-objective problem should reflect the decision maker's preferences. In this work, a fuzzy dominance concept is proposed which can be adjusted to the decision maker's preferences. This renders the proposed approach flexible and customizable, and possibly applicable to a wide range of problems. For any point $\mathbf{x}^0 \in \mathbb{R}^n$, consider the following subsets

$$\Omega_<(\mathbf{x}^0;\alpha) \triangleq \{\mathbf{x} \in \mathbb{R}^n : Poss[F(\tilde{\mathbf{a}};\mathbf{x}) \leq F(\tilde{\mathbf{a}};\mathbf{x}^0)] \geq \alpha \text{ and } Poss[F(\tilde{\mathbf{a}};\mathbf{x}) = F(\tilde{\mathbf{a}};\mathbf{x}^0)] < 1\}$$

$$\Omega_\geq(\mathbf{x}^0;\alpha) \triangleq \{\mathbf{x} \in \mathbb{R}^n : Poss[F(\tilde{\mathbf{a}};\mathbf{x}) \geq F(\tilde{\mathbf{a}};\mathbf{x}^0)] \geq \alpha\}$$

$$\Omega_\sim(\mathbf{x}^0;\alpha) \triangleq \{\mathbf{x} \in \mathbb{R}^n : \max\{Poss[F(\tilde{\mathbf{a}};\mathbf{x}) \leq F(\tilde{\mathbf{a}};\mathbf{x}^0)], Poss[F(\tilde{\mathbf{a}};\mathbf{x}) \geq F(\tilde{\mathbf{a}};\mathbf{x}^0)]\} \leq \alpha\}$$

The subset $\Omega_<(\mathbf{x}^0;\alpha)$ comprises the points in $\mathbb{R}^n$ that dominate $\mathbf{x}^0$, whereas $\Omega_\geq(\mathbf{x}^0;\alpha)$ encompasses the points in $\mathbb{R}^n$ that are dominated by $\mathbf{x}^0$. The set of points that neither dominate nor are dominated by $\mathbf{x}^0$ is denoted by $\Omega_\sim(\mathbf{x}^0;\alpha)$. The parameter α is a vector where each one of the terms, α_i with $i = 1, 2, \ldots, m$, belong to the interval $[0, 1]$. Those sets being defined, one can denote the set of fuzzy Pareto-optimal solutions as below:

Definition 8 (Fuzzy Pareto-optimal solution) *$\mathbf{x}^* \in \Omega$ is said be a fuzzy Pareto-optimal solution if there exists no other $x \in \Omega$ such that $Poss[f_i(\tilde{\mathbf{a}}_i;\mathbf{x}) \leq f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*)] \geq \alpha_i$, $\forall i$ and $Poss[f_j(\tilde{\mathbf{a}}_j;\mathbf{x}) = f_j(\tilde{\mathbf{a}}_j;\mathbf{x}^*)] < 1$ for at least one j, where $\alpha_i \in [0, 1]$, $\forall i$.*

For difficult optimization problems it is often the case that a local optimal solution is acceptable. A local efficient solution for the proposed problem is defined below:

Definition 9 (Fuzzy local Pareto-optimal solution) *$\mathbf{x}^* \in \Omega$ is said to be a fuzzy local Pareto-optimal solution if there is a real number $\delta \geq 0$ such that there exists no other $x \in \Omega \cap \mathcal{N}(x^*, \delta)$ such that $Poss[f_i(\tilde{\mathbf{a}}_i;\mathbf{x}) \leq f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*)] \geq \alpha_i$, $\forall i$ and $Poss[f_j(\tilde{\mathbf{a}}_j;\mathbf{x}) = f_j(\tilde{\mathbf{a}}_j;\mathbf{x}^*)] < 1$ in at least one j, where $\alpha_i \in [0, 1]$, $\forall i$.*

Note that the definition above implies that a candidate solution to the proposed fuzzy problem is (locally) non-dominated or efficient, if one cannot find (in a certain vicinity) another solution that simultaneously improves all the objective functions. This interpretation matches the classical counterpart of multi-objective optimization.

The convexity hyphotesis determine that the neighbourhood of each one local solution involves whole the feasible region.

Theorem 1 *Let $f_i : \Omega \subset \mathcal{X} \to \mathbb{F}(\mathcal{Y})$, $i = 1, \ldots, m$ a convex fuzzy functions about a convex subset Ω of a linear space $\mathcal{X}$. Then whole locally efficient solution is globaly efficient solution.*

Proof: Let $\mathbf{x}^* \in \Omega$ is a locally efficient solution. By definition of convex subset, we obtain $\lambda\mathbf{x}^* + (1-\lambda)\mathbf{x} \in \Omega$, $\forall \mathbf{x} \in \Omega - \mathcal{N}(\mathbf{x}^*, \epsilon)$, with $\epsilon > 0$ e $\lambda \in [0, 1]$. Suppose $\lambda\mathbf{x}^* + (1-\lambda)\mathbf{x} \in \Omega \cap \mathcal{N}(\mathbf{x}^*, \epsilon)$ then by the fuzzy Pareto-optimal solution definition, we obtain $Poss[f_i(\tilde{a}_i;\mathbf{x}^*) \leq f_i(\tilde{a}_i;\lambda\mathbf{x}^* + (1-\lambda)\mathbf{x})] \geq \alpha_i^1$, $i \in \mathcal{I} = \{1, 2, \ldots, m\}$, and $Poss[f_j(\tilde{a}_j;\mathbf{x}^*) = f_j(\tilde{a}_j;\lambda\mathbf{x}^* + (1-\lambda)\mathbf{x})] < 1$ for at least one $j \in \mathcal{I}$, where $\alpha_i^1 \in (0, 1]$, $\forall i \in \mathcal{I}$. By the convex fuzzy function definition, we obtain $f_i(\tilde{a}_i;\lambda\mathbf{x}^* + (1-\lambda)\mathbf{x}) \lesssim \lambda f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*) + (1-\lambda) f_i(\tilde{\mathbf{a}}_i;\mathbf{x})$, $\forall i \in \mathcal{I}$, which it can be rewritten by using Possibility Theory as $Poss[f_i(\tilde{a}_i;\lambda\mathbf{x}^* + (1-\lambda)\mathbf{x}) \leq \lambda f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*) + (1-\lambda) f_i(\tilde{\mathbf{a}}_i;\mathbf{x})\}] \geq \alpha_i^2$, where $\alpha_i^2 \in (0, 1]$, $\forall i \in \mathcal{I}$. Thus, by using the ordered fuzzily subset definition, we obtain $Poss[f_i(\tilde{a}_i;\mathbf{x}^*) \leq \lambda f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*) + (1-\lambda) f_i(\tilde{\mathbf{a}}_i;\mathbf{x})\}] \geq \min\{\alpha_i^1, \alpha_i^2\} \Rightarrow Poss[f_i(\tilde{a}_i;\mathbf{x}^*) \leq f_i(\tilde{a}_i;\mathbf{x})] \geq \min\{\alpha_i^1, \alpha_i^2\}$, $\forall i \in \mathcal{I}$. By selecting a determined objective function $k \in \mathcal{I}$ and $k \neq i$, by the Theorem 2, we guarantee that $Poss[f_k(\tilde{a}_k;\mathbf{x}^*) = f_k(\tilde{a}_k;\mathbf{x})] < 1$ for at least one $k \in \mathcal{I}$. ■

3.2 Characterization of fuzzy efficient solutions

The characterization of efficient solutions, $efi(\Omega)$, by means of well defined scalar problems is a recurrent approach in fuzzy multi-objective problems. The following theorem relates efficient solutions and scalar problems.

Theorem 2 *$\mathbf{x}^* \in efi(\Omega)$ if and only if $\mathbf{x}^*$ solves the m scalar problems*

$$P_k: \quad \min_{\mathbf{x}\in\Omega} \quad f_k(\tilde{\mathbf{a}}_k;\mathbf{x}) \qquad s.t. \quad f_l(\tilde{\mathbf{a}}_l;\mathbf{x}) \lesssim f_l(\tilde{\mathbf{a}}_l;\mathbf{x}^*), \quad l = 1, 2, \ldots, m, \quad \forall\, l \neq k. \tag{6}$$

Proof: ($\Rightarrow$) If $\mathbf{x}^* \in efi(\Omega)$, then there exist no other $x \in \Omega$ such that $Poss[f_i(\tilde{\mathbf{a}}_i;\mathbf{x}) \leq f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*)] \geq \alpha_i$, $i = 1, 2, \ldots, m$, and $Poss[f_j(\tilde{\mathbf{a}}_j;\mathbf{x}) = f_j(\tilde{\mathbf{a}}_j;\mathbf{x}^*)] < 1$, for any j. In this case $\mathbf{x}^*$ solves (6) for all k.
($\Leftarrow$) Suppose $\mathbf{x}^*$ solves (6), but $\mathbf{x}^* \notin efi(\Omega)$, then there exists another $\mathbf{x} \in \Omega$ such that $Poss[f_i(\tilde{\mathbf{a}}_i;\mathbf{x}) \leq f_i(\tilde{\mathbf{a}}_i;\mathbf{x}^*)] \geq \alpha_i$, $\forall i$, and for some j, $Poss[f_j(\tilde{\mathbf{a}}_j;\mathbf{x}) \leq f_j(\tilde{\mathbf{a}}_j;\mathbf{x}^*)] < 1$. Therefore, $\mathbf{x}^*$ does not solve Problem (6). This contradiction concludes the proof. ■

The development of analytical conditions to efficient solutions, based on the characterization of non-dominated solutions to problems P_k, $k = 1, 2, \ldots, m$, is an important tool in the theoretical analysis. However, such an analysis yields only m non-dominated solutions, one to each scalar problem and is therefore, unable to generate the whole Pareto-optimal set.

Employing a similar analysis to the one presented above, we now establish the relationship between non-dominated solutions of a fuzzy multi-objective problem and solutions to the weighting problem. An alternative characterization based on the linear combination of the objectives can be expressed as

Theorem 3 *Let $\mathbf{x}^* \in \Omega$ solve the problem*

$$P_w: \quad \min_{\mathbf{x}\in\Omega} \quad \langle \mathbf{w}, F(\tilde{\mathbf{a}};\mathbf{x})\rangle = \textstyle\sum_{i=1}^m \omega_i f_i(\tilde{\mathbf{a}}_i;\mathbf{x}) \tag{7}$$

for some $\mathbf{w} \in \mathbb{R}^m$, $\mathbf{w} \geq \mathbf{0}$ and $\sum_{i=1}^m w_i = 1$. Then $\mathbf{x}^* \in efi(\Omega)$ if

ISBN: 978-989-95079-6-8

(i) $\mathbf{x}^*$ *is the unique solution(7), or*

(ii) $w_i > 0,\ i = 1, \ldots, m.$

Proof: *(i)* If $\mathbf{x}^* \in \Omega$ is a unique solution of (7), then $\forall \mathbf{x} \in \Omega$ and by definition, we obtain $Poss\left[\sum_{i=1}^{m} w_i \left(f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^*) - f_i(\tilde{\mathbf{a}}_i; \mathbf{x})\right) < 0\right] \geq \min_i\{\alpha_i\}$. Suppose $\mathbf{x}^* \notin efi(\Omega)$, i.e., there exists at least one $\mathbf{x}^0 \in \Omega$ such that $Poss[f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^0) \leq f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^*)] \geq \alpha_i,\ i = 1, 2, \ldots, m$ and $Poss[f_j(\tilde{\mathbf{a}}_j; \mathbf{x}^0) = f_j(\tilde{\mathbf{a}}_j; \mathbf{x}^*)] < 1$, for some j. This contradicts the uniqueness hypothesis, because $\mathbf{w} \geq \mathbf{0}$. Thus, $\mathbf{x}^* \in efi(\Omega)$.
(ii) Suppose $\mathbf{x}^* \notin efi(\Omega)$, but $\mathbf{x}^*$ is a solution of (7). Then there exists a $\mathbf{x}^0 \in \Omega$ such that $Poss[f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^0) \leq f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^*)] \geq \alpha_i,\ i = 1, 2, \ldots, m$ and $Poss[f_j(\tilde{\mathbf{a}}_j; \mathbf{x}^0) = f_j(\tilde{\mathbf{a}}_j; \mathbf{x}^*)] < 1$, for any j. Hence,

$$Poss\left[\sum_{i=1}^{m} w_i \left(f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^*) \leq f_i(\tilde{\mathbf{a}}_i; \mathbf{x}^0)\right) > 0\right] \geq \min_i\{\alpha_i\},\ \forall i.$$

A contradiction and therefore $\mathbf{x}^* \in efi(\Omega)$. ■

4 Results and analysis

The problems we use to evaluate this method are two hypothetic mathematical formulations, which are described in [5], with the fuzzy approach described in Section 3. Nevertheless, they are efficiency in validating the realized study. They were resolved using an modified implementation of **NSGA-II** that solves multi-objective programming problems with constraints or not. This modification was made in the comparison of the objective functions with fuzzy parameters between two feasible solutions which uses the concepts of fuzzy Pareto optimal solutions described in this work.

The vagueness was inserted into the costs of the objective function and fuzzy numbers are interpreted in the form $(a, \underline{a}, \overline{a})_{LR}$ where a is the modal value, $\underline{a}$ is the scattering left and $\overline{a}$ is the scattering right of each fuzzy number.

Example 1 (Schaffer's problem)

$$\begin{aligned} \min \quad & f_1(\tilde{\mathbf{a}}_1; \mathbf{x}) = (x + \tilde{a}_1)^2 \\ \min \quad & f_2(\tilde{\mathbf{a}}_2; \mathbf{x}) = (x - \tilde{a}_2)^2 \\ s.t \quad & -5 \leq \mathbf{x} \leq 5 \end{aligned} \tag{8}$$

where $\tilde{a}_1 = (0, 0, 2)_{LR}$ *and* $\tilde{a}_2 = (2, 1, 1)_{LR}$.

The figures below present the fuzzy solution and fuzzy front.

In Figure 2, each star represents one solution of this multi-objective problem by using the fuzzy Pareto optimal concept defined by Sakawa to $\alpha = 0.8$*, while each square represents one solution by using the fuzzy Pareto optimal concept described in this work to* $\alpha = 0.8$*, too. It can be observed that a range of possible Pareto optimal solutions is formed when the squares are merged. We can also see that many stars are inside some squares, i.e., this solutions have a degree of possibility great or equal to 0.8 and belong to the range of Pareto optimal solutions obtained by the definition that uses possibility theory.*

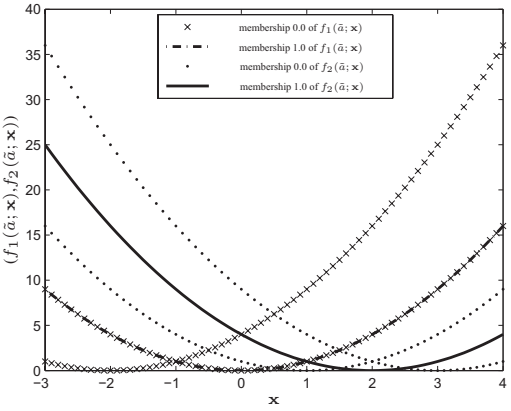

Figure 1: Objective functions

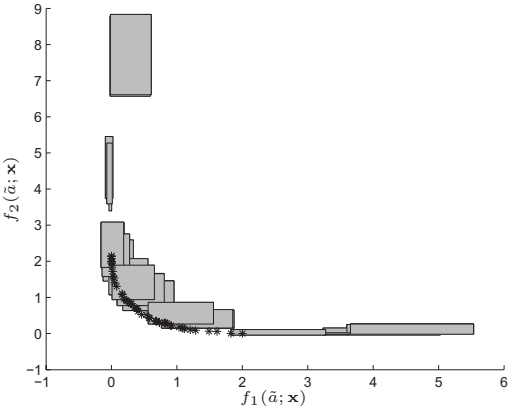

Figure 2: Pareto front

Example 2 (Binh and Kern's problem)

$$\begin{aligned} \min \quad & f_1(\tilde{\mathbf{a}}_1; \mathbf{x}) = \tilde{a}_{11} x_1^2 + \tilde{a}_{12} x_2^2 \\ \min \quad & f_2(\tilde{\mathbf{a}}_2; \mathbf{x}) = (x_1 - \tilde{a}_{21})^2 + (x_2 - \tilde{a}_{22})^2 \\ s.t. \quad & (x_1 - 5)^2 + x_2^2 \leq 25 \\ & (x_1 - 8)^2 + (x_2 + 3)^2 \geq 7.7 \\ & 0 \leq x_1 \leq 5,\ \ 0 \leq x_2 \leq 3 \end{aligned} \tag{9}$$

where $\tilde{a}_{11} = \tilde{a}_{12} = (4, 1, 1)_{LR}$, $\tilde{a}_{21} = \tilde{a}_{22} = (5, 1, 1)_{LR}$.

The figures below present the fuzzy solution and fuzzy front.

In Figure 3 are shown the function objectives of Problem (2) where the superior drawing represents the function $f_1(\tilde{\mathbf{a}}_1; \mathbf{x})$ *and the inferior one represents the function* $f_2(\tilde{\mathbf{a}}_2; \mathbf{x})$*. The drawings with solid line represent the value of the objective functions with* $\alpha = 1$ *while the ones with dotted line represent the value of the objective functions with* $\alpha = 0$*.*

Again, each star represents one solution by using the concept defined by Sakawa to $\alpha = 0.8$*, while each square represents one solution by using the concept described here to* $\alpha = 0.8$*, too. In this case, the stars are in the imaginary bound of the Pareto front range formed by possible Pareto solutions, i.e., the solutions obtained by Sakawa's definition have a satisfaction level closed in* $\alpha = 0.8$*.*

5 Conclusion

The use of defuzzification methods to solve fuzzy mathematical programming problems is very common. These methods transform a fuzzy number into a classical one, but some data are always lost in each case. The Pareto-optimality presented in this work makes use of different defuzzification methods in various stages of the definitions.

Multi-objective Programming problems are very important in a variety of both theoretical and practical areas. As ambiguity and vagueness are natural and ever-present in real-life situations that require precise solutions, it makes perfect sense to attempt to address these problems using Fuzzy Multi-objective Programming problems. In this context, this paper presented a novel theory to determine Pareto-optimality conditions which provide the user with a fuzzy solution. This theory is an expansion of the classical Pareto-optimality theory and demonstrates the necessary conditions for fuzzy Pareto-optimality. Some numerical examples are presented to validate the theory outlined.

The authors aim firstly to extend the line of investigation regarding Fuzzy Quadratic Programming problems in order to try to solve practical real-life problems by facilitating the building of Decision Support Systems. This requires the involvement of fuzzy costs as well as fuzzy coefficients, as a must.

Terrain Morphology Classification over Fuzzy Digital Elevation Models

Jorge M. F. Santos[1]
Departamento de Matemática da Universidade de Coimbra and INESC Coimbra, Portugal 1
Email: jmfs@mat.uc.pt

Abstract— *One way to incorporate uncertainty associated to the data and to the interpolation method in a digital elevation model (DEM) is to use Fuzzy Sets Theory. A fuzzy DEM can be generated from fuzzy data, where elevations are represented by fuzzy numbers. To use that type of terrain models in further applications, a generalization of known methods is needed. An example about the generalization of terrain morphology classification methods is proposed in this work. Given a fuzzy DEM, a procedure to find ridges and other morphological features will be analyzed. Two examples of this approach will be presented to illustrate the proposed methods.*

Keywords— Fuzzy DEM, fuzzy morphological feature, signal of a fuzzy number.

1 Introduction

Automated identification of objects representing terrain features (such as peaks, channels and ridges) from a digital elevation model is a well known procedure in Geomorphology. The development of those methods has important implications in terms of spatial analysis and for the generalization of spatial databases, for example. Another important application is the study of water flow over the terrain surface that represents a fundamental geomorphological process and it is closely related to its shape: it constraints the water route over the surface and it is mainly shaped by this flow.

The topographic surface is usually defined through a gridded DEM constructed by interpolation from a finite set of samples and it is a well-known problem in geographic modeling. The uncertainty associated to this process generates uncertain elevation values which can be modeled using fuzzy numbers [1, 2, 3]. Therefore, methods to identify morphological terrain features have to be generalized to fuzzy DEMs in order to express the impact of elevation uncertainty in terrain classification. In this work we will study one approach to this problems, generalizing known methods over fuzzy DEMs.

2 Morphology classification

To identify morphological objects over the terrain surface it is adopted here the strategy developed by Wood [4]. This problem can be seen as an image processing problem to classify each *pixel* (grid cell) in one class of *geomorphological feature* (usually, *peak*, *ridge*, *pass*, *plane*, *channel* or *pit*). The feature classification is based on table 1, where the signals [1] of the four morphological parameters: *slope* (S), *cross sectional curvature* ($crosc$), *maximum profile convexity* ($maxic$) and *minimum profile convexity* ($minic$), are given by

$$sign(S) = sign(\arctan\sqrt{d^2+e^2}), \quad (1)$$

$$sign(crosc) = sign(cde - bd^2 - ae^2), \quad (2)$$

$$sign(maxic) = -sign(a+b-\sqrt{(a-b)^2-c^2}), \quad (3)$$

$$sign(minic) = -sign(a+b+\sqrt{(a-b)^2-c^2}). \quad (4)$$

The values of a, b, c, d and e are evaluated from the first and second order derivatives of the quadric surface

$$z = ax^2 + by^2 + cxy + dx + ey + f, \quad (5)$$

usually fitted to a 3x3 data window [4].

Table 1: Feature classification criteria [4].

Feature	$slope$	$crosc$	$maxic$	$minic$
Peak	0	all	+	+
Ridge	0	all	+	0
	+	+	all	all
Pass	0	all	+	-
Plane	0	all	0	0
	+	0	all	all
Channel	0	all	0	-
	+	-	all	all
Pit	0	all	-	-

3 Fuzzy morphology classification

The above procedures are based on a regular elevation grid. Considering that the elevations have some degree of uncertainty which is expressed by fuzzy numbers, we will study the generalization of those procedures to a fuzzy DEM. The first step is to evaluate the first and second order fuzzy derivatives. This is done using interval arithmetic over the fuzzy numbers $\alpha - levels$. Those fuzzy derivatives will be used in equations (1 to 4) to obtain fuzzy morphological parameters using again interval arithmetic [5].

3.1 Signal of a fuzzy number

To use the fuzzy version of the above *slope*, *cross sectional curvature*, *maximum profile curvature* and *minimum profile curvature* it is need now a generalization of the $signal$ function. It is proposed here to adapt the concept of *overtaking between fuzzy numbers* in [3] to decide how much a fuzzy value is negative, positive or zero. This concept is based on the notion of *overtaking between intervals* defined by

[1] We assume that $sign$ is a three-valued function in $\{-1, 0, 1\}$.

ISBN: 978-989-95079-6-8

$$\sigma(X,Y) = \begin{cases} 0, & X_u \leq Y_l \\ \frac{X_u - Y_l}{X_u - X_l}, & X_u > Y_l \wedge X_l \leq Y_l \\ 1, & X_l < Y_l \end{cases}, \quad (6)$$

where X and Y are intervals defined by $X = [X_l, X_u]$ and $Y = [Y_l, Y_u]$.

Following, the *overtaking between fuzzy numbers* is

$$\sigma(\tilde{X}, \tilde{Y}) = \int_0^1 \sigma([\tilde{X}]_\alpha, [\tilde{Y}]_\alpha) w(\alpha) d\alpha, \quad (7)$$

where $[\tilde{X}]_\alpha$ and $[\tilde{Y}]_\alpha$ are the $\alpha - levels$ of fuzzy numbers $\tilde{X}$ and $\tilde{Y}$ and $w(\alpha)$ is a weight function $w : [0,1] \rightarrow \Re$ such that

$$\begin{aligned} & w(\alpha) \geq 0 \\ & \alpha < \alpha' \Rightarrow w(\alpha) < w(\alpha') \\ & \int_0^1 w(\alpha) d\alpha = 1. \end{aligned} \quad (8)$$

.

To apply this strategy, it is needed to define a fuzzy zero value. When fuzzy numbers like the fuzzy morphological parameters have very different support widths, ranging from 10 to 0.01, approximately, scaling problems may arise if comparison is needed. To prevent those problems, the zero value will depend on the fuzzy value to be evaluated. The fuzzy zero will have the same membership of the respective fuzzy value but there will be a shift over the real line such that the $\alpha - level$ of maximum membership will be centered in the zero of real line. For triangular fuzzy numbers it will be $\tilde{0} = (X_l - X_m/0/X_u - X_m)$ for fuzzy number $\tilde{X} = (X_l/X_m/X_u)$, see figure 1. This type of fuzzy zero value will be called here *twin zero* of $\tilde{X}$.

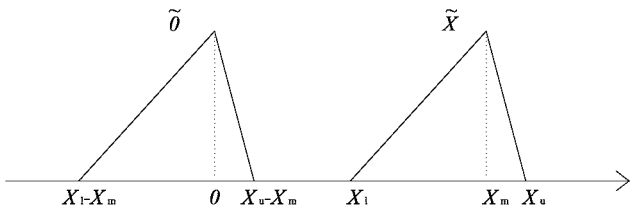

Figure 1: Twin zero of a triangular fuzzy number $\tilde{X}$.

First, to evaluate how much an interval X is positive, it is used a named $positive$ function defined by

$$pos(X) = \begin{cases} 0, & X_l \leq 0_l \\ \frac{X_u - 0_u}{X_u - X_l}, & 0_l < X_l < 0_u \\ 1, & X_l \geq 0_u \end{cases}, \quad (9)$$

where $[0_l, 0_u]$ is the twin zero of $X = [X_l, X_u]$, that is, it has the same width and it is centered in the real zero value. In the same way, $negative$ and $zero$ functions for intervals can be defined by

$$neg(X) = \begin{cases} 0, & X_u \geq 0_u \\ \frac{0_l - X_l}{X_u - X_l}, & 0_l < X_u < 0_u \\ 1, & X_u \leq 0_l \end{cases}, \quad (10)$$

and

$$zer(X) = \begin{cases} 0, & X_l \geq 0_u \\ \frac{0_u - X_l}{X_u - X_l}, & 0_l < X_l < 0_u \\ 1, & X_l = 0_l \\ \frac{X_u - 0_l}{X_u - X_l}, & 0_l < X_u < 0_u \\ 0, & X_u \leq 0_l \end{cases}. \quad (11)$$

Since the width of the zero interval and of X are the same, it is easy to see that[2]: $pos(X) + neg(X) + zer(X) = 1$ and $zer(X) = 1 - pos(X) \dot{\vee} zer(X) = 1 - neg(X)$. To extend those functions to fuzzy numbers it is used the same approach of (7):

$$pos(\tilde{X}) = \int_0^1 pos([\tilde{X}]_\alpha) w(\alpha) d\alpha, \quad (12)$$

where $w(\alpha)$ is the weight function in (8). The same can be done for $negative$ and $zero$ functions.

3.2 Fuzzy morphological features

From table 1, we can evaluate how much a grid cell belongs to a feature class using the above functions to evaluate the signals of the fuzzy morphological parameters and the standard fuzzy conjunction and disjunction defined by min and max operators [6]. This procedure will generate the fuzzy morphological classification, providing a method to quantify the membership of every terrain grid cell to the *fuzzy peak*, *fuzzy ridge*, *fuzzy pass*, *fuzzy plane*, *fuzzy channel* or *fuzzy pit* classes.

4 Examples

Two examples will be presented in this section to illustrate the methods discussed above. In the first case it will be used a digital elevation model of Coimbra region, crossed by Mondego river with narrow valleys and steep slopes (see figure 2). The second example is Kilimanjaro region, where a big volcanic cone lies down on the middle of a plain (see figure 5). In the following figures, all distance units are in meters and angles in degrees.

4.1 Coimbra region

The study region is a 2.0 by 2.1 kilometers rectangle, with elevations ranging from 20 do almost 300 meters. The elevation uncertainty model here is just the root mean square error (RMSE) provided by the map producer. It was introduced a small random gaussian variation added to that RMSE to define the support of symmetrical triangular fuzzy number to express elevation uncertainty. The modal values are taken from the elevations of the crisp DEM. Some results can be seen in figures 3 and 4.

4.2 Kilimanjaro mountain

It was used a rectangle with about 85 by 80 kilometers to enclose Kilimanjaro mountain, with elevations going from 800 to almost 6000 meters. The DEM for this region was taken from SRTM mission, version 4, with original gaps filled by interpolation and with other elevation data available available for that region. To quantify the distribution of DEM elevation uncertainty, about 100 GPS control points were measured around the mountain and in the top. The difference between the elevations of those points and the DEM were calculated

[2]The symbol $\dot{\vee}$ represents xor operator

ISBN: 978-989-95079-6-8

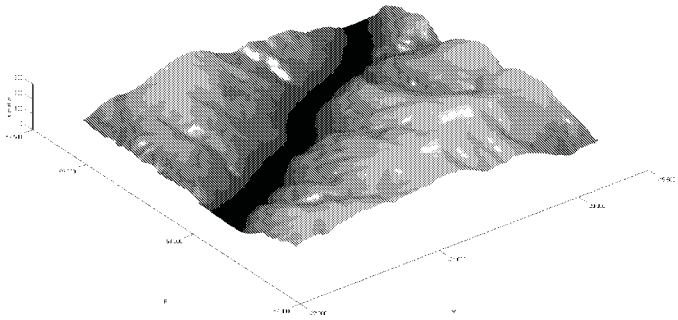

Figure 2: Coimbra digital elevation model.

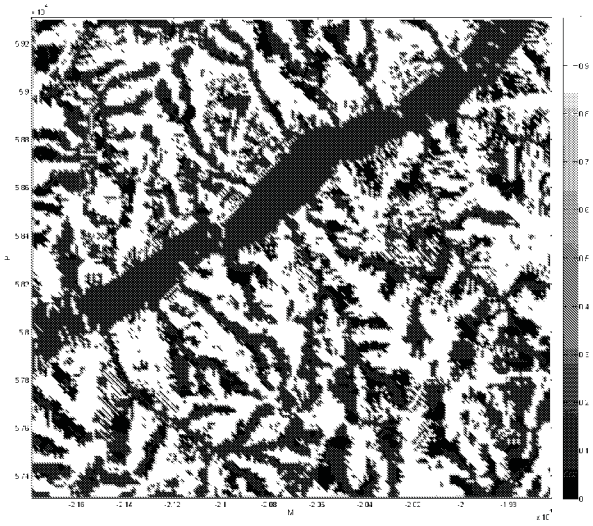

Figure 3: Fuzzy ridge membership for Coimbra study area.

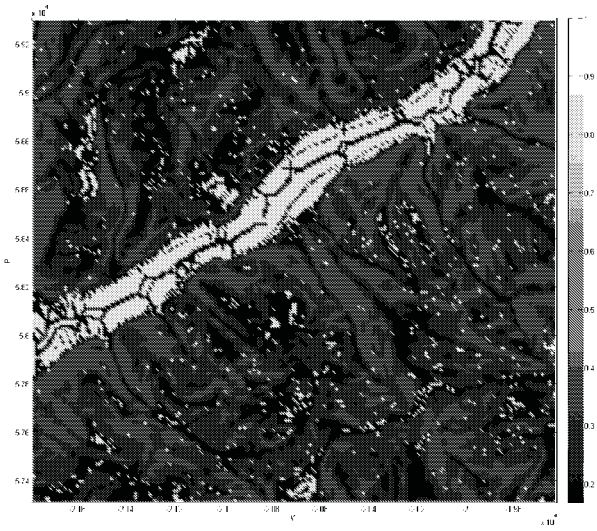

Figure 4: Fuzzy plane membership for Coimbra.

and an error surface were interpolated from those error samples. The error surface in figure 6 was used to estimate the support of symmetric triangular fuzzy numbers that will express the fuzzy elevations. The modal values of those fuzzy numbers are given by the crisp DEM. Some results can be seen in figures 7 and 8. Instead of crisp 0 or 1 membership values, now there are partial membership values to the fuzzy morphological objects, reflecting the uncertainty of the terrain model. Comparing figures 7 and 8, it is possible to detect visually some correlation between the error surface and the fuzzy membership values.

5 Conclusions

This work gave an example that methods applicable to crisp digital elevation models can be generalized to be also applicable to fuzzy DEMs or to similar gridded data expressed by fuzzy numbers. This approach has the advantage to allow the inclusion of uncertainty modeled by Fuzzy Set Theory in geographic analysis. The examples applications presented here are just a first step to develop more robust and advanced terrain classification methods to apply over fuzzy DEMs. Fuzzy values of morphological parameters, like slope and curvatures, have sometimes support intervals too wide. Therefore, those numerical operations are very sensitive to the input values and maybe more robust algorithms are needed here. These methods can also be combined with multi-scale classification methods used in [7, 8, 9, 10] or others approaches like in [11], for example, in order to improve the automated identification of morphological objects.

Abstract*—The aim of this study is to apply and compare statistical regression and an evolutionary fuzzy system to model color yield in the polyester high temperature (HT) dyeing as a function of disperse dyes concentration, temperature and time. The predictive power of the obtained models was evaluated by means of MSE value. It seems that for modeling cases such as the one considered in this study, the evolutionary fuzzy system with a minimum MSE showed a better predictive capability than the model based on statistical regression.*

Keywords— Evolutionary Algorithm, Fuzzy Inference System, Polyester Dyeing, Modelling.

1 Introduction

After introducing and developing soft computing methods many attempts have been made to use and apply them in textile research. In this work, we describe two modeling methodologies, namely; statistical regression and evolutionary-fuzzy systems and compare their capability for modeling of color yield in polyester dyeing. So, a summary of the evolutionary fuzzy approach and a brief note on polyester dyeing are described followed by literature review in use of soft computing in textile engineering.

1.1 Evolutionary Fuzzy System

Many real world problems are so complex that classical computing methods fail to deal with them efficiently. An alternative approach to deal with these problems is soft-computing. The Term soft computing refers to a family of computing techniques comprising four different partners: fuzzy logic, evolutionary computation, neural network and probabilistic reasoning. The term soft computing distinguishes these techniques from hard computing that is considered less flexible and computationally demanding. From this set of techniques, Fuzzy Inference System (FIS) are a powerful tool for modeling real control systems [1,2].
After the initial fuzzy inference system has been set up, the parameters of its fuzzy sets have been optimized in a subsequent step using the covariance matrix adaptation evolution strategy (CMA-ES) [3,4]. CMA-ES is an advanced evolution strategy that relies on an enhanced update mechanism for the mutation distribution's covariance matrix. A survey about genetic-fuzzy systems and its application can be found in [2].

1.2 Polyester Dyeing

Polyester is the most important man made fiber, which is produced by melt spinning process [5]. The dyeing of polyester is limited to only disperse dyes [6] and requires special conditions such as high temperature (≈ 130°C), dry heat (190-220°C), or using carrier in the dye bath [7]. The chemical structure of disperse dyes contains polar groups but there are no ionic groups present which leads to their very low solubility in water. The three main chemical structures of disperse dyes are azo, anthraquinone, and nitro diphenylamine [8]. Temperature, time and disperse dye concentration are the primary factors affecting the color yield in dyeing polyester. The relative importance of these factors can be seen in models representing the color yield as a function of them. These models may also have application in processing and cost minimization. The color yield is shown by K/S. K/S shows the ratio of the absorbed light by an opaque substrate relative to the scattered light from it. This ratio is calculated by Kubelka-Munk theory as [1,9]:

$$(K/S)_\lambda = \frac{(1-R_\lambda)^2}{2R_\lambda} \quad (1)$$

1.3 Literature Review

The research related to the subject of this work can be summarized as follows:
Kim et al. studied Fuzzy modeling, control and optimization of textile processes [10]. Soft computing methods in textile sciences has been reviewed by Sztandera and Pastore [11]. Zarandi et al. presented a fuzzy expert system for textile manufacturing system using fuzzy cluster analysis [12]. FIS has been applied by Hung and to control continuous dyeing [13]. Rautenberg et al. used fuzzy sets for color recipe specification in the textile print shop [14]. Jahmeerbacusa et al. studied fuzzy dye bath pH control in exhaust dyeing [15]. Fuzzy- based simulation model for declorization of industrial waste water has been presented by Abdou et al. [16] Marjoniemi and Mantysalo applied Adaptive Neuro Fuzzy Inference Systems (ANFIS) in modeling dye solution and concentration [17,18]. Active Tension Control of High Speed Splitting Machines using Fuzzy PID has been studied by Chung et al. [19]. Tavanai et al. used fuzzy regression method to model the color yield in dyeing [20]. Smith et al.

ISBN: 978-989-95079-6-8

studied improving computer control of batch dyeing operations [21]. Kim et al. proposed an emotion-based textile indexing system using colors, texture and patterns. Their system utilizes both fuzzy rules and neural networks [22]. A genetic-fuzzy approach has been applied by Nasiri et al. to model polyester dyeing [1]. Callhof and Wulfhort applied ANFIS [23], Veit et al. employed Neural Networks [24], and Nasiri used fuzzy regression in texturing [25]. Guifen et al. predicted the warp breakage rate in weaving using neural network techniques [26]. Predicting the properties of melt spun fibers using neural network has been studied by Chung-Feng [27]. Jeng-Jong applied an evolutionary algorithm to obtain the best combination of weaving parameters for woven fabric designs [28]. Sette et al. used soft computing techniques to Fiber-to-Yarn production process [29]. Peeva et al. examined fuzzy relational calculus theory with applications in various engineering subjects such as textile [30].Blaga studied the application of evolutionary algorithms in knitting technology [31]. An automatic textile sales forecast using fuzzy treatment of explanatory variables was used by Thomassey et al. [32]. Wong et al. studied genetic optimization of JIT operation schedules for fabric-cutting process in apparel manufacture [33]. Siddaiah applied automation in cotton ginning [34]. Aggregation as similarity in a morphological framework for the processing of textile images has been studied by Soria-Frisch [35].

2 Modeling of Polyester Dyeing

The aim of this study is to model variations of color yield of C.I. Disperse Blue 266 versus time, temperature, and disperse dye concentration in the high temperature (HT) polyester dyeing process using an evolutionary fuzzy system and the statistical regression method. A total number of 120 polyester samples were dyed according to the conditions in Table 1. The models based on statistical regression and the evolutionary fuzzy system was developed and compared [1].

Table 1: Dyeing conditions [1]

Dye Concentration (%owf)	0.75 1.5 3 4.5 6
Temperature (°C)	100 110 115 120 125 130
Time (min)	12 24 36 48

2.1 Modeling by Statistical Regression

Modeling of a dependent variable as a function of one or more independent variable(s) can be carried out by means of regression. A general multiple regression for modeling the color yield can be considered to take the following form:

$$Y = A_0 + A_1 x_1 + A_2 x_2 + A_3 x_3 \qquad (2)$$

After using the least squares method to obtain the coefficients in the above equation, the statistical regression model is obtained as fallows:

K/S=-79.4+1.54Conc.+0.11Time+0.71Temp.

To verify the necessary statistical regression conditions, the following four conditions can be used [1,36]:

1) Linear form for the normal plot of the residuals.
2) I chart of residuals should lie between the upper and lower control limits without any specific pattern.
3) The residuals histogram should be of an approximately normal form.
4) Residuals versus fitted values should show no specific pattern.

Fig. 1 shows the information related to the statistical regression model obtained for C.I. Disperse Blue 266 [1]. Regarding the above mentioned four conditions for the validity of the models, it can be said that the linear statistical model cannot be accepted [1,36].

Obviously, the model discussed above with its just four degrees of freedom is of limited capability and there are more powerful e.g. nonlinear regression models. However, these tend to be quite complicated and that is why in the following an evolutionary fuzzy approach will be considered.

2.2 Modeling by Evolutionary Fuzzy System

Variation of K/S function versus two variables of temperature, time and concentration for dyed samples in C.I. Disperse Blue 266 as curves and surfs in some figures like Fig. 2 are shown to study the effect and behaviour of each variable. In view of this figure, for example, it is clearly observed that temperature has a greater effect on K/S value than time has.

In the same way, the FIS model has been investigated along the following lines to model the colour yield of C.I. Disperse Blue 266 in polyester high temperature dyeing [1,37,38].

First, membership functions for input and output variables according to Table 2 and Table 3 have been determined. The Gaussian membership function, and Mamdani max-min Inference was used for all input and output variables [1].

Table 2: Parameters of fuzzy set for input variables [1].

Fuzzy set	Concentration		Time		Temperature	
	Mean	Std	Mean	Std	Mean	Std
Low	1.28	0.848	13.1	14.2	100	9.61
Medium	3.38	0.891	-	-	119	1.64
High	5.87	1.33	44.4	11.7	129	3.97

Table 3: Parameters of fuzzy set for output variable [1].

Fuzzy set	Color yield (K/S)	
	Mean	Std
Very low	3.29	0.62
Low	4.11	1.42
Medium	12.8	1.69
High	19.3	1.86
Very high	29.8	2.23

Secondly, the following nine rules were defined according to the physical and chemical structure of polyester fiber, HT dyeing of polyester, and the behavior of 120 samples dyed in C.I. Disperse Blue 266 [1].

1) If (temperature is low) and (time is low) and (concentration is low), then (K/S is very low).
2) If (temperature is medium) and (concentration is high), then (K/S is high).

ISBN: 978-989-95079-6-8

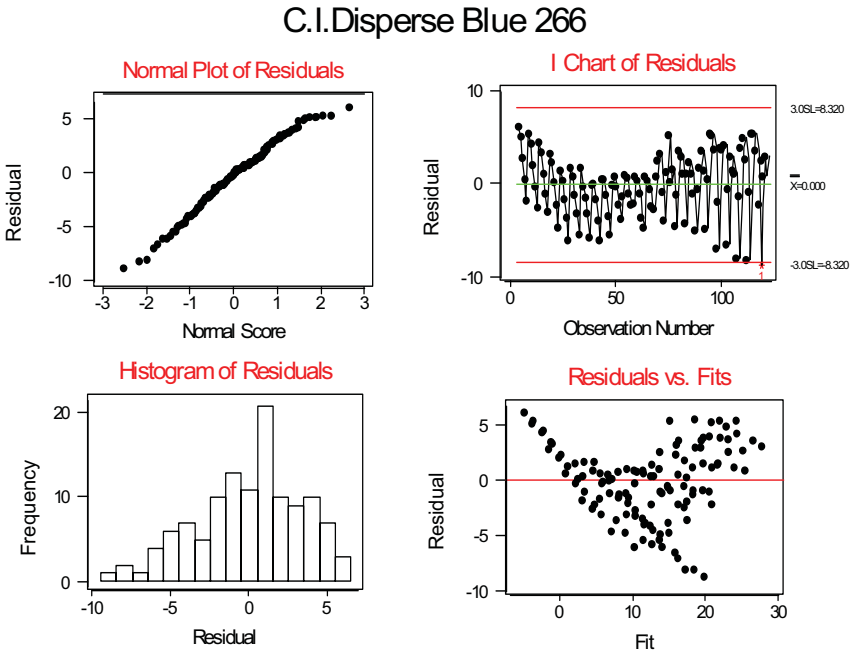

Figure 1: Plot of Residuals for K/S of C.I. Disperse Blue 266 [1].

3) If (temperature is high) and (concentration is low), then (K/S is medium).
4) If (temperature is high) and (concentration is medium), then (K/S is high).
5) If (temperature is low) and (time is high) and (concentration is low), then (K/S is very low).
6) If (temperature is high) and (concentration is high), then (K/S is very high)
7) If (temperature is medium) and (time is low) and (concentration is high), then (K/S is medium).
8) If (temperature is medium) and (time is high) and (concentration is high), then (K/S is high).
9) If (temperature is low) and (time is low) and (concentration is high), then K/S is low.

Then, after a centroid defuzzification of predicted K/S by FIS a Mean Square Errors (MSE) of 3.307 for the FIS model has been obtained [1].

2.3 Optimization of the Initial Fuzzy System

In a final step the fuzzy sets were tuned using the evolutionary algorithm. Hence, input of the CMA-ES algorithm is a vector of parameters of the predefined fuzzy inference system, in this setting the 16 values as given in Table 2. The CMA-ES was used without any modification, i.e. according to the 16 dimensions of the problem, 6 parents breeding 12 offspring were used as recommended. Also the build-in recombination and mutation operators have been applied. The initial step size of the optimization algorithm, also known as mutation strength, was set to 0.1. During the evolutionary loop the fuzzy sets' parameters are successively modified by the CMA-ES and in turn the squared error of the resulting fuzzy inference system is computed for the sample set. The optimization ends after 1000 generations.

3 Results and Interpretation

The FIS model has been improved along the following lines to model the colour yield of C.I. Disperse Blue 266 in polyester high temperature dyeing using an evolutionary algorithm. Table 4 shows parameters of improved fuzzy sets for input variables. As it can be seen in Table 4, concentration has two fuzzy sets in this new model. In the same way, the effect of rule 4 has been tested. Because of its low influence on the results, this rule can be neglected.

Table 4: Parameters of fuzzy sets for input variables.

Fuzzy set	Concentration		Time		Temperature	
	Mean	Std	Mean	Std	Mean	Std
Low	0.53	0.60	12.3	14.21	104.5	9.76
Medium	-	-	-	-	119.2	1.69
High	5.05	1.64	44.1	12.1	129.5	6.10

Regarding the remaining eight rules and changed input parameters according to Table 4, a Mean Square Error (MSE) of 2.333 for evolutionary fuzzy system has been obtained.

Fig. 3 shows the results of the FIS system applied to dyed samples in C.I. Disperse Blue 266.

ISBN: 978-989-95079-6-8

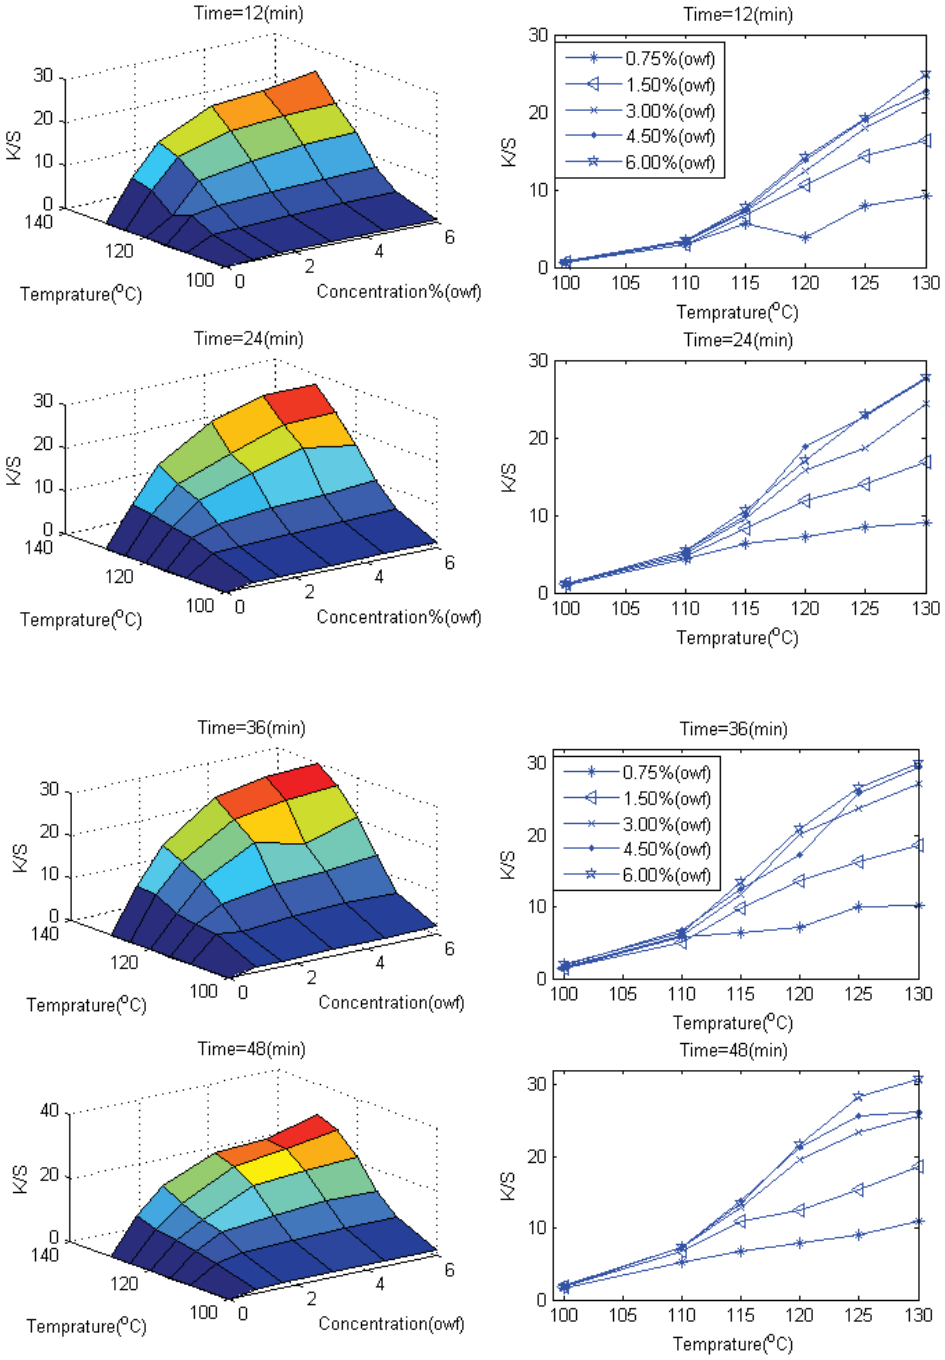

Figure 2: K/S in terms of temperature and concentration [1].

ISBN: 978-989-95079-6-8

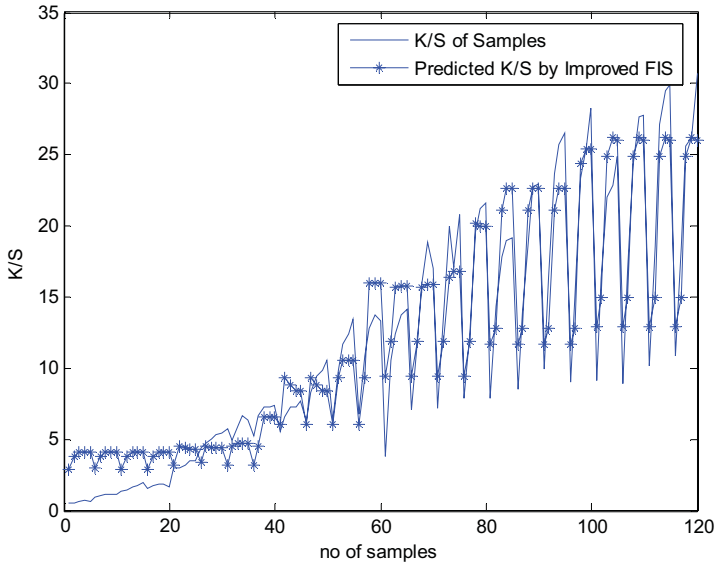

Figure 3: K/S of dyed polyester and predicted K/S by improved FIS.

3.1 Comparison of Statistical Regression and Evolutionary Fuzzy System

Table 5 shows a comparison of the predictive powers by statistical regression, the fuzzy inference system and the evolutionary fuzzy system using MSE. According to this table, the evolutionary fuzzy with minimal MSE and simpler structure showed the best predictive capability in comparison to statistical regression and the fuzzy inference system.

Table 5: Parameters of fuzzy set for output variables.

Method	MSE
Statistical Regression	3.382
Fuzzy Inference System	3.307
Evolutionary Fuzzy System	2.333

On the basis of the above considerations, it can be said that the evolutionary fuzzy system provides an appropriate method to predict the color yield.

4 Conclusions

This research employed statistical regression and an evolutionary fuzzy system to model the (HT) polyester dyeing process. Color yield has been predicted in terms of time, temperature, and disperse dye concentration. We improved the fuzzy sets and rules of the FIS model using an evolutionary algorithm. The results show that the prediction performance is best for the evolutionary fuzzy system.

Acknowledgment

The authors thanks Prof. Hossein Tavanai for his supervision during the first author's work on her MS dissertation when he lent his full support and knowledge to obtain the data used here and to study the behavior of the dyes and also Dr. S. Mahmoud Taheri for his helpful suggestions and assistance.

Abstract *— An L-fuzzy context is a triple consisting of a set of objects, a set of attributes and an L-fuzzy binary relation between them. An l-cut is a classical context over the same sets with relation as a set of all object attribute pairs, which fuzzy relation assigns truth degree geater or equal than l. Proto-fuzzy concept is a triple made of a set of objects and a set of attributes, which form a concept in some cut of L-fuzzy context and a supremum of all degrees in which cuts this concept exists. Aim of the paper is to show the connection of the structure of proto-fuzzy concepts and fuzzy concept lattice constructed in the way of [1][5]. This connection can help to generate of all fuzzy concepts.*

Keywords — formal concept analysis, fuzzy concept lattice, fuzzy Galois connection

1 Preliminaries

Basic notions of Formal Concept Analysis(FCA) are *formal context* and *formal concept*.

Definition 1 *A formal context $\langle B, A, R\rangle$ consists of a set of objects B, a set of attributes A and a relation R between B and A.*

Definition 2 *Define the mappings $\uparrow\colon {}^B2 \to {}^A2$ and $\downarrow\colon {}^A2 \to {}^B2$. The first assigns to the set $X \subseteq B$ the set of all attributes common to all objects of the set X*

$$\uparrow(X) = \big\{a \in A : \big(\forall o \in X\big)(o,a) \in R\big\}$$

and the second assigns to the set $Y \subseteq A$ the set of all objects common to all attributes of the set Y

$$\downarrow(Y) = \big\{o \in B : \big(\forall a \in Y\big)(o,a) \in R\big\}.$$

Definition 3 *A formal concept of the context $\langle B, A, R\rangle$ is a pair $\langle X, Y\rangle$ such that $X \subseteq B$, $Y \subseteq A$, $\uparrow(X) = Y$ and $\downarrow(Y) = X$.*

Ganter and Wille in [3] showed that the pair of mappings $\big(\uparrow, \downarrow\big)$ is a Galois connection and the composite mappings $\uparrow\downarrow\colon {}^B2 \to {}^B2$ and $\downarrow\uparrow\colon {}^A2 \to {}^A2$ are closure operators. Authors prooved an important theorem in FCA well known as The Basic Theorem On Concept Lattices.

Theorem 1 *(The Basic Theorem on Concept Lattices)The Concept Lattice (lattice of concepts with ordering $\langle X_1, Y_1\rangle \leq \langle X_2, Y_2\rangle$ iff $X_1 \subseteq X_2$ iff $Y_1 \supseteq Y_2$) is a complete lattice in which infimum and supremum are given by*

$$\bigwedge_{i\in I}\langle X_i, Y_i\rangle = \Big\langle \bigcap_{i\in I} X_i, \uparrow\downarrow\Big(\bigcup_{i\in I} Y_i\Big)\Big\rangle$$

$$\bigvee_{i\in I}\langle X_i, Y_i\rangle = \Big\langle \downarrow\uparrow\Big(\bigcup_{i\in I} X_i\Big), \bigcap_{i\in I} Y_i\Big\rangle.$$

A complete lattice V is isomorphic to the concept lattice of some context $\langle B, A, R\rangle$ if and only if there are mappings $\beta : B \to V$ and $\alpha : A \to V$, such that $\beta(B)$ is supremum-dense in V and $\alpha(A)$ is infimum-dense in V and $(o, a) \in R$ is equivalent to $\beta(o) \leq \alpha(a)$ for all $o \in B$ and $a \in A$. In particular V is isomorphic to the concept lattice of context $\langle V, V, \leq\rangle$.

Bělohlávek and Krajči in [1, 2, 5, 6] showed that above mentioned basic notions may be generalized by applying the fuzzy logic.

Everybody knows that reality provides situations where many of attributes are rather fuzzy than crisp. Answer of question "Does the object has the attribute?" is rather somewhere in the middle of false (0) and true (1).

Definition 4 An L-fuzzy formal context *is a triple $\langle B, A, r\rangle$ consists of a set of objects B, a set of attributes A and an L-fuzzy binary relation r, i.e. the L-fuzzy subset of $B \times A$ or mapping from $B \times A$ to L, where L is a complete residuated lattice.*

The class of all L-fuzzy sets in X will be denoted by ${}^XL$. If L is complete then the relation $\subseteq$ (defined by $f \subseteq g$ iff $f(x) \leq g(x)$ for all $x \in X$) makes ${}^XL$ into a complete lattice.

Definition 5 *A* complete residuated lattice *is an algebra $\boldsymbol{L} = \langle L, \wedge, \vee, \otimes, \to, 0, 1\rangle$ where*

(a) *$\langle L, \wedge, \vee, 0, 1\rangle$ is a complete lattice with the least element 0 and the greatest element 1,*

(b) *$\langle L, \otimes, 1\rangle$ is a commutative monoid,*

(c) *$\otimes$ and $\to$ satisfy adjointness, i.e.*

$$a \otimes b \leq c \iff a \leq b \to c$$

for each $a, b, c \in L$ ($\leq$ is the lattice ordering).

Definition 6 (Bělohlávek) *A triple $\langle B, A, r\rangle$ is an L-fuzzy context where $r : B \times A \to L$ and L is a complete residuated lattice. Define mappings $\uparrow\colon {}^BL \to {}^AL$ and $\downarrow\colon {}^AL \to {}^BL$ such that for every $f \in {}^BL$ and $g \in {}^AL$*

$$\uparrow(f)(a) = \bigwedge_{o\in B}\big(f(o) \to r(o,a)\big)$$

$$\downarrow(g)(o) = \bigwedge_{a\in A}\big(g(a) \to r(o,a)\big).$$

The aim of this paper is to give a new equivalent definition of Belohlavek's mappings, but using so-called protto-fuzzy concepts as basic building units for constructing the fuzzy concepts. In the next section an l-cuts of L-fuzzy contexts will be defined for any truth degree $l \in L$, main properties of their concepts and a relationship of concepts of different cuts will be showed. Finally Proto-fuzzy concepts will be defined. Then an equality of new mappings with Bělohlávek ones will be showed.

2 Cuts of L-fuzzy context

Lets have an example of L-fuzzy context (Table 1). In our example is the lattice of truth degrees is $\langle\{1;0,8;0,6;0,4;0,2;0,\};\leq\rangle$.

Definition 7 *Let $l \in L$ be an arbitrary truth degree. An l-*cut *of some L-fuzzy set $f \in {}^X L$ is a classical set denoted by*

$$f_l = \{x \in X : f(x) \geq l\}.$$

Definition 8 *An l-*cut *of the L-fuzzy formal context $\langle B, A, r\rangle$ for $l \in L$ is the classical context $\langle B, A, r_l\rangle$ where $r_l = \{(o,a) \in B \times A : r(o,a) \geq l\}$.*

Some of cuts of our example are in the tables.

Definition 9 *For every truth value $l \in L$ lets define mappings $\uparrow_l$: ${}^B2 \to {}^A2$ and $\downarrow_l$: ${}^A2 \to {}^B2$. For every object or attribute subset $X \subseteq B$ and $Y \subseteq A$ put*

$$\uparrow_l (X) = \{a \in A : (\forall o \in X) r(o,a) \geq l\}$$

$$\downarrow_l (Y) = \{o \in B : (\forall a \in Y) r(o,a) \geq l\}.$$

Lemma 1 *Let $K \subseteq L$ be an arbitrary subset of truth degrees. Then for every set of objects $X \subseteq B$ and attributes $Y \subseteq A$ holds that*

$$\uparrow_{(\bigvee K)} (X) = \bigcap_{l \in K} \uparrow_l (X)$$

$$\downarrow_{(\bigvee K)} (Y) = \bigcap_{l \in K} \downarrow_l (Y).$$

Proof:

$\boxed{\subseteq}$ Cuts of the L-fuzzy context were defined such that for every $l_1, l_2 \in L$ if $l_1 \leq l_2$ then $r_{l_1} \supseteq r_{l_2}$. Hence for every subset of objects X or subset of attributes Y, $\uparrow_{l_1} (X) \supseteq \uparrow_{l_2} (X)$ and $\downarrow_{l_1} (Y) \supseteq \downarrow_{l_2} (Y)$, which for every $l \in K$ implies $\uparrow_{\bigvee K} (X) \subseteq \uparrow_l (X)$ and $\downarrow_{\bigvee K} (Y) \subseteq \downarrow_l (Y)$. And from above we have $\uparrow_{(\bigvee K)} (X) \subseteq \bigcap_{l \in K} \uparrow_l (X)$ and $\downarrow_{(\bigvee K)} (Y) \subseteq \bigcap_{l \in K} \downarrow_l (Y)$.

$\boxed{\supseteq}$ Let a be an arbitrary attribute from $\bigcap_{l \in K} \uparrow_l (X)$. For all $l \in K$ and for every object $o \in X$, $r(o,a) \geq l$. From the properties of supremum is $r(o,a) \geq \bigvee K$ for all objects $o \in X$. It means that $a \in \uparrow_{(\bigvee K)} (X)$. Hence $\bigcap_{l \in K} \uparrow_l (X) \subseteq \uparrow_{(\bigvee K)} (X)$.

The second part can be prooved dually. □

Lemma 2 *For all $l \in L$ the pair $(\uparrow_l, \downarrow_l)$ forms a Galois connection between the power-set lattices ${}^B2$ and ${}^A2$.*

Now lets define the concept on the l-cut for some truth degree $l \in L$.

Definition 10 *Let $\langle B, A, r\rangle$ be the L-fuzzy context. A pair $\langle X, Y\rangle$ is called an l-*concept *iff*

$$\uparrow_l (X) = Y, \text{ and } \downarrow_l (Y) = X,$$

hence the pair is a concept in a classical context $\langle B, A, r_l\rangle$. The set of all l-concepts will be assigned $\mathrm{C}_l(B, A, r)$, shortly C_l.

2.1 *Relationship of concepts in different cuts*

Lemma 3 *Let $l_1, l_2 \in L$ be an arbitrary truth values, such that $l_2 \leq l_1$. Let $\langle X, Y\rangle \in \mathrm{C}_{l_1}$. Then there exists an interval $\mathcal{I}$ in concept lattice C_{l_2}, such that for every l_2-concept $\langle Z, W\rangle \in \mathcal{I}$ holds that $X \subseteq Z$ and $Y \subseteq W$.*

Proof: From $\langle X, Y\rangle \in \mathrm{C}_{l_1}$ we know that $\uparrow_{l_1} (X) = Y$ and $\downarrow_{l_1} (Y) = X$. So as the greatest element of wanted interval we can use the $\langle \downarrow_{l_2}\uparrow_{l_2} (X), \uparrow_{l_2} (X)\rangle$ and the least one $\langle \downarrow_{l_2} (Y), \uparrow_{l_2}\downarrow_{l_2} (Y)\rangle$. From the fact $r_{l_1} \subseteq r_{l_2}$ we have inclusions

$$Y = \uparrow_{l_1} (X) \subseteq \uparrow_{l_2} (X)$$

$$X = \downarrow_{l_1} (Y) \subseteq \downarrow_{l_2} (Y).$$

From closure property of conclusion of mappings we have

$$\downarrow_{l_2}\uparrow_{l_2} (X) \supseteq X \text{ and } \uparrow_{l_2}\downarrow_{l_2} (Y) \supseteq Y.$$

From $Y = \uparrow_{l_1} (X) \subseteq \uparrow_{l_2} (X)$ we have

$$\downarrow_{l_2} (Y) \supseteq \downarrow_{l_2}\uparrow_{l_2} (X)$$

and from properties of concepts from [3] we know that it is equivalent to

$$\uparrow_{l_2}\downarrow_{l_2} (Y) \subseteq \uparrow_{l_2} (X).$$

□

ISBN: 978-989-95079-6-8

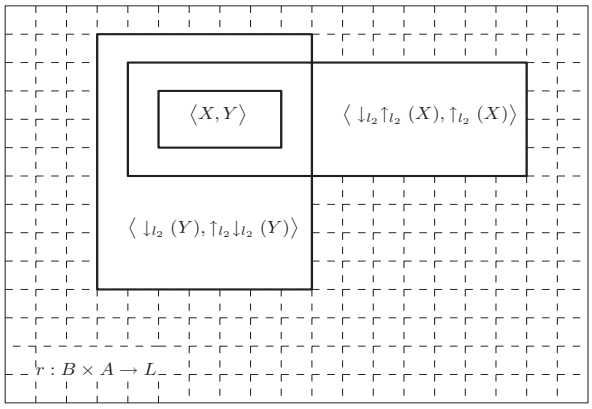

Figure 1: l_1-concept and its l_2-superconcepts

Definition 11 *Define an ordering "$\preceq$" on the set of all l-concepts of all cuts of L-fuzzy context. Lets have two concepts of two different cuts $\langle X, Y\rangle \in \mathrm{C}_{l_1}$ and $\langle Z, W\rangle \in \mathrm{C}_{l_2}$ (because of these pairs are concepts in two different cuts so we can assign them $\langle X, Y\rangle_{l_1}$ and $\langle Z, W\rangle_{l_2}$) then $\langle X, Y\rangle_{l_1} \preceq \langle Z, W\rangle_{l_2}$ iff $X \subseteq Z$ and $Y \subseteq W$ and $l_2 \leq l_1$.*

The lattice in the picture 3 isn't the concept lattice. It is the lattice of all l-concepts for all $l \in L$ and lines is assigning new ordering from definition.

Lemma 4 *Let $l_1, l_2 \in L$ are arbitrary truth values such that $l_2 \leq l_1$. Let $\langle X_1, Y_1\rangle, \langle X_2, Y_2\rangle \in \mathrm{C}_{l_1}$, such that $\langle X_1, Y_1\rangle \preceq \langle X_2, Y_2\rangle$. Than the geatest and least elements of corresponding intervals of l_2-concepts are ordered same as corresponding l_1-concepts.*

Proof: If $X_1 \subseteq X_2$ from properties of closure operator we have $\downarrow_{l_2}\uparrow_{l_2}(X_1) \subseteq \downarrow_{l_2}\uparrow_{l_2}(X_2)$ And from $Y_2 \subseteq Y_1$ we have $\downarrow_{l_2}(Y_1) \subseteq \downarrow_{l_2}(Y_2)$. □

3 Proto-fuzzy concepts

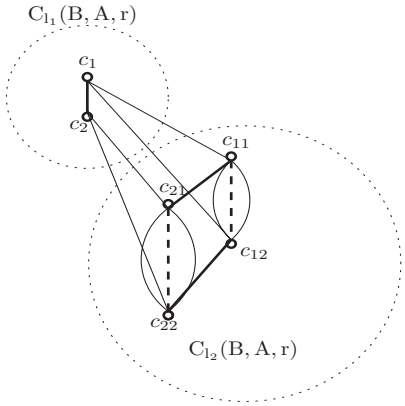

Figure 2: The relationship of concepts of different cuts

As we can see in the figure 3, some of l-concepts are equal, but in different cuts. If we fix some l-concept and look on the set of truth degrees in which cuts the conceot exists, we can see two important properties described in next theorems.

Theorem 2 is sayng that for every concept of some cut, a set of all truth degrees in which cut the concept exists is closed under its supremum.

Theorem 2 *Let $K \subseteq L$ be an arbitrary set of truth degrees, $\langle X, Y\rangle \in \mathrm{C}_l$ for all $l \in K$. Then $\langle X, Y\rangle \in \mathrm{C}_{\bigvee K}$.*

Proof: The lemma 1 implies

$$\uparrow_{\bigvee K}(X) = \bigcap_{l\in K} \uparrow_l (X) = \bigcap_{l\in K} Y = Y,$$

$$\downarrow_{\bigvee K}(Y) = \bigcap_{l\in K} \downarrow_l (Y) = \bigcap_{l\in K} X = X.$$

Hence $\langle X, Y\rangle \in \mathrm{C}_{\bigvee K}$. □

Next theorem 3 is saying that if some concept exist in two different cuts, then exists in every cut between them.

Theorem 3 (Convexity) *Let $l_1, l_2 \in L$ be an arbitrary truth degrees, and let $\langle X, Y\rangle \in \mathrm{C}_{l_1} \cap \mathrm{C}_{l_2}$. Then for all $l \in L$, such that $l_1 \leq l \leq l_2$, $\langle X, Y\rangle \in \mathrm{C}_l$.*

Proof: The lemma 1 implies, that for every set of object X and any two arbitrary truth degrees $k, m \in L$, such that $k \leq m$ holds

$$\uparrow_k (X) \subseteq \uparrow_k (X) \cap \uparrow_m (X) = \uparrow_{\bigvee\{k,m\}} (X) = \uparrow_m (X)$$

and

$$\downarrow_k (Y) \subseteq \downarrow_k (Y) \cap \downarrow_m (Y) = \downarrow_{\bigvee\{k,m\}} (Y) = \downarrow_m (Y).$$

So

$$Y = \uparrow_{l_1} (X) \supseteq \uparrow_l (X) \supseteq \uparrow_{l_2} (X) = Y,$$

$$X = \downarrow_{l_1} (Y) \supseteq \downarrow_l (Y) \supseteq \downarrow_{l_2} (Y) = X.$$

Hence $\uparrow_l (X) = Y$ and $\downarrow_l (Y) = X$, which implies $\langle X, Y\rangle \in \mathrm{C}_l$. □

Definition 12 *Let $\langle X, Y\rangle \in \bigcup_{k\in L} \mathrm{C}_k(B, A, r)$ be the concept of some cut of the fuzzy context $\langle B, A, r\rangle$. Triple $\langle X, Y, l\rangle$ such that $l = \bigvee\{k \in L : \langle X, Y\rangle \in \mathrm{C}_k(B, A, R)\}$ will be called a* proto-fuzzy concept. *The set of all proto-fuzzy concepts will be denoted by* $\mathrm{PFC}(B, A, r)$.

Definition 13 *Define a mapping* $\mathrm{pd} : {}^B2 \times {}^A2 \to L$ *such that for every set of objects $Z \subseteq B$ and set of attributes $W \subseteq A$ is*

$$\mathrm{pd}(Z, W) = \bigvee\{l \in L : (\exists X \subseteq B)(\exists Y \subseteq A)$$

$$\langle X, Y, l\rangle \in \mathrm{PFC}(B, A, r) Z \subseteq XW \subseteq Y\}.$$

This mapping assigns to every pair of sets of objects and attributes the truth degree of highest proto-fuzzy concept which owns them. Notation pd means proto-degree of input sets.

4 Alternative definition of Bělohlávek's mappings

Lets go back to introduction.

Definition 14 *A triple $\langle B, A, r\rangle$ is L-fuzzy context where $r : B \times A \to L$ and L is the complete residuated lattice. Define mappings $\uparrow: {}^BL \to {}^AL$ and $\downarrow: {}^AL \to {}^BL$ such that for every $f \in {}^BL$ and $g \in {}^AL$*

$$\uparrow (f)(a) = \bigwedge_{o\in B} \big(f(o) \to r(o, a)\big)$$

$$\downarrow (g)(o) = \bigwedge_{a\in A} \big(g(a) \to r(o, a)\big).$$

ISBN: 978-989-95079-6-8

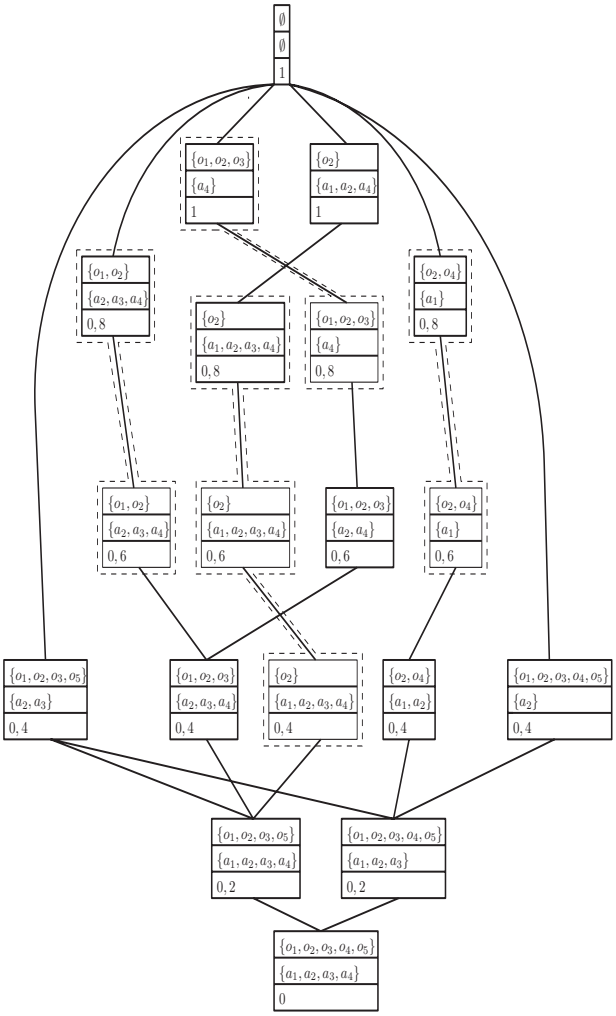

Figure 3: Lattice of all l-concepts of example for all $l \in L$, $\left\langle \cup_{l\in L} \mathbf{C}_l(B, A, r), \preceq \right\rangle$

Lets define new mappings and show that they are equivalent to the mappings above.

Definition 15 *A triple $\langle B, A, r\rangle$ is L-fuzzy context where $r : B \times A \to L$ and L is the complete residuated lattice. Define mappings $\Uparrow$: ${}^B L \to {}^A L$ and $\Downarrow$: ${}^A L \to {}^B L$ such that for every $f \in {}^B L$ and $g \in {}^A L$*

$$\Uparrow(f)(a) = \bigwedge_{l\in rng(f)} \big(l \to \mathrm{pd}(f_l, \{a\})\big)$$

$$\Downarrow(g)(o) = \bigwedge_{l\in rng(g)} \big(l \to \mathrm{pd}(\{o\}, g_l)\big).$$

Theorem 4 *For every set Z of objects, an every set W of attributes,*

$$\bigwedge_{(o,a)\in Z\times W} r(o, a) = \mathrm{pd}(Z, W).$$

Proof:

$\boxed{\leq}$ Let $l = \bigwedge_{(o,a)\in Z\times W} r(o, a)$. If $a \in W$ then $(\forall o \in Z) r(o, a) \geq l$, i.e. $a \in{\uparrow_l}(Z)$, so $W \subseteq{\uparrow_l}(Z)$. Take $Y = {\uparrow_l}(Z)$ and $X = {\downarrow_l}(Y)$ clearly $\langle X, Y\rangle \in \mathbf{C}_l(B, A, r)$. Hence $\langle X, Y, m\rangle \in \mathrm{PFC}(B, A, r)$ where $m = \bigvee\{k \in L : \langle X, Y\rangle \in \mathbf{C}_k(B, A, r)\}$.

Because $W \subseteq{\uparrow_l}(Y)$ and $Z \subseteq{\downarrow_l}{\uparrow_l}(Z) = {\downarrow_l}(Y) = X$, we have

$$\mathrm{pd}(Z, W) \geq m \geq l = \bigwedge_{(o,a)\in Z\times W} r(o, a).$$

$\boxed{\geq}$ Let $\langle X, Y, l\rangle \in \mathrm{PFC}(B, A, r)$, $Z \subseteq X$ and $W \subseteq Y$. Then $l = \bigvee\{k \in L : \langle X, Y\rangle \in \mathbf{C}_k(B, A, r)\}$ and it follows from Theorem 2 that $\langle X, Y\rangle \in \mathbf{C}_l(B, A, r)$. It means that, for all $o \in X$ and $a \in Y$ is $r(o, a) \geq l$
Hence $\bigwedge_{(o,a)\in Z\times W} r(o, a) \geq \bigwedge_{(o,a)\in X\times Y} \geq l$. It follows that $\bigwedge_{(o,a)\in Z\times W} r(o, a) \geq \bigvee\{l \in L : (\exists X \subseteq B)(\exists Y \subseteq A)\langle X, Y, l\rangle \in \mathrm{PFC}(B, A, r), Z \subseteq X, W \subseteq Y\} = \mathrm{pd}(Z, W)$. □

Theorem 5 *For above defined mappings holds*

$$\uparrow = \Uparrow \text{ and } \downarrow = \Downarrow.$$

Proof: Note these three facts:

- Because $\to$ is antitone in the first argument, $f(o) \geq l$ implies
$$f(o) \to r(o, a) \leq l \to r(o, a)$$
- Because $\{o \in B : f(o) \geq l\} \supseteq \{o \in B : f(o) = l\}$, we have
$$\bigwedge_{o\in B: f(o)\geq l} (l \to r(o, a)) \leq \bigwedge_{o\in B: f(o)=l} (l \to r(o, a))$$
- $$\bigcup_{l\in \mathrm{rng}(f)} \{o \in B : f(o) \geq l\} =$$
$$= \bigcup_{l\in \mathrm{rng}(f)} \bigcup_{m\in \mathrm{rng}(f): m\geq l} \{o \in B : f(o) = m\} =$$
$$= \bigcup_{l\in \mathrm{rng}(f)} \{o \in B : f(o) = l\}$$

Using the previous facts we obtain

$$\bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)=l} (f(o) \to r(o, a)) =$$
$$= \bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)\geq l} (f(o) \to r(o, a)) \leq$$
$$\leq \bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)\geq l} (l \to r(o, a)) \leq$$
$$\leq \bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)=l} (l \to r(o, a)) =$$
$$= \bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)=l} (f(o) \to r(o, a))$$

It follows that both inequalities are in fact equalities, hence (using Theorem 4)

$$\uparrow(f)(a) = \bigwedge_{o\in B} (f(o) \to r(o, a)) =$$

ISBN: 978-989-95079-6-8

$$= \bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)=l} (f(o) \to r(o,a)) =$$

$$= \bigwedge_{l\in \mathrm{rng}(f)} \bigwedge_{o\in B: f(o)\geq l} (l \to r(o,a)) =$$

$$= \bigwedge_{l\in \mathrm{rng}(f)} (l \to \bigwedge_{o\in B: f(o)\geq l} r(o,a)) =$$

$$= \bigwedge_{l\in \mathrm{rng}(f)} (l \to \bigwedge_{o\in f_l} r(o,a)) =$$

$$= \bigwedge_{l\in \mathrm{rng}(f)} (l \to \mathrm{pd}(f_l, \{a\})) = \Uparrow (f)(a)$$

The second part can be proved dually. □

4.1 *One-sided fuzzy concepts*

In [8] we defined so-called one-sided fuzzy concepts, the pairs consisting of one classical set of objects and fuzzy set of attributes and defined mappings which are creating them.

Definition 16 *For L-context* $\langle B, A, r\rangle$ *define mappings* $\uparrow\uparrow$: ${}^B2 \to {}^AL$ *and* $\downarrow\downarrow$: ${}^AL \to {}^B2$. *For an arbitrary set of objects* $X \in {}^B2$ *and an L-fuzzy set of attributes* $g \in {}^AL$ *put*

$$\uparrow\uparrow (X)(a) = \bigwedge_{o\in X} r(o,a)$$

$$\downarrow\downarrow (g) = \{o \in B : (\forall a \in A) g(a) \leq r(o,a)\}.$$

By the theorem 4 we can write $\uparrow\uparrow (X)(a) = \mathrm{pd}(X, \{a\})$. Bělohlávek's theorem ([2]) say:

Theorem 6 *For* $X \in {}^B2$ *and* $g \in {}^AL$ *and mappings* $\uparrow, \downarrow, \uparrow\uparrow, \downarrow\downarrow$ *we have*

$$\uparrow\uparrow (X) = \uparrow (X') \text{ and } \downarrow\downarrow (g) = (\downarrow (g))_1$$

and X' *means L-fuzzy set of objects corresponding to* X, *and* $(\downarrow (g))_1$ *means* 1*-cut of* $\downarrow (g)$.

With the theorem 5 we can in previous theorem change the mappings $\uparrow, \downarrow$ by $\Uparrow, \Downarrow$.

A Preliminary Analysis for Improving Model Structure of Fuzzy Habitat Preference Model for Japanese Medaka (*Oryzias latipes*)

Shinji Fukuda[1]

1. Institute of Tropical Agriculture, Kyushu University
Fukuoka, Japan
Email: shinji-fkd@agr.kyushu-u.ac.jp

Abstract—*The present study examined a preliminary analysis for improving model structure of fuzzy habitat preference model for Japanese medaka (Oryzias latipes) dwelling in agricultural canals in Japan. The present model employed a simplified fuzzy reasoning method for evaluating habitat preference of the fish based on the relationship with physical habitat characteristics observed in the field survey. The model parameter was optimized by using a simple genetic algorithm, in which number of fuzzy membership function was fixed. In the present analysis, number of fuzzy membership function was changed while the other methods were fixed as the original model. The model performance was evaluated based on mean square error between observed and predicted fish population density, and by using two different data sets. As a result, there was no clear tradeoff between number of fuzzy membership functions and prediction accuracy. By contrast, calibration and validation results showed a slight tendency of tradeoff. Further studies on clarifying the tradeoffs would be necessary for improving the model structure in an effective way.*

Keywords— fish habitat, genetic algorithm, habitat modelling, simplified fuzzy reasoning

1 Introduction

Since anthropogenic impacts largely affect and degrade aquatic environments, assessment based on geomorphologic and ecological data is the basis for evaluating the state of the environment and its management planning [1]. In the evaluation, a habitat preference approach, such as habitat evaluation procedure (HEP) [2, 3] and Instream Flow Incremental Methodology (IFIM) [4], is often applied for its simplicity and intuitiveness. Habitat suitability index (HSI), which was originally proposed for HEP and IFIM, is usually classified into three categories: Category I—professional judgements; Category II—habitat use indices; Category III—habitat preference indices [5]. Despite its generality, some studies concluded that HSI cannot describe habitat uses [6, 7, 8, 9]. This failure would be ascribed to non-linear and complex interactions between environmental factors affecting the habitat use and to uncertainty in ecology.

The uncertainty is increasingly recognized and gaining public interests in natural ecosystem research. In ecological modelling, the uncertainty of the model is caused by both the lack of knowledge (i.e. data imperfection) and the variability of models and parameters (models' sensitivity) [10]. For coping with the data imperfection, an approach using fuzzy logic was proposed and widely applied to expressing expert knowledge and dealing with incomplete and/or subjective information [11, 12, 13, 14, 15, 16]. This approach enables qualitative information consisting of linguistic terms to be used for quantitative evaluation of target systems that are required for decision-making at an ecosystem level. By contrast, [17] introduced fuzziness as a reliability bound so as to consider the subjective uncertainty in habitat evaluation by different interpretation. The author also applied fuzzy set theory to habitat evaluation for considering the vagueness of fish behaviour, measurement errors and dispersions of physical environment, in which models showed high ability to represent habitat use of the target fish by integrating fuzzy rule-based model with model optimization techniques of genetic algorithm (GA) [18, 19, 20, 21, 22, 23, 24] or artificial neural network [25, 26]. By applying GA, all the model parameters can be simultaneously optimized, which enables us to assess the nonlinearity in fish habitat preference [23]. This emerging property clarified from the modelling would make an appeal to researchers for applying artificial intelligence techniques. However, as reported in [22], the fuzzy habitat preference model showed weakness in terms of transferability which might be ascribed to the complexity of the models. Therefore, to assess the relationship between models' complexity and accuracy would be necessary for the model improvement without losing its accuracy. This could also promote the application of genetic fuzzy systems in ecological research.

The present study aims to examine a preliminary analysis for improving model structure of fuzzy habitat preference model (FHPM) for Japanese medaka (*Oryzias latipes*) dwelling in agricultural canals in Japan. Field surveys were conducted in the agricultural canals to establish a relationship between fish habitat preference and physical environments of water depth, current velocity, lateral cover ratio and percent vegetation coverage. All the FHPMs of different model structure were compared focusing on the tradeoffs between complexity of the model and accuracy of habitat prediction.

2 Methods

In this section, the author first gives a brief review on the application of fuzzy systems to ecological research. Second, an overview of the study site and target fish is described. And then, the author explains the field surveys and the modelling procedure of habitat prediction models together with the explanation on assessment and comparison of the models.

2.1 Fuzzy Modelling in Ecological Research

The pioneer work of fuzzy logic application to ecological study would be [27] in which fuzzy set theory was introduced to habitat quality evaluation, classification of wetlands, and formation of compartments of ecosystem components. Since

ISBN: 978-989-95079-6-8

then, many researchers have employed fuzzy logic-based approaches in ecological research (e.g., population dynamics [28, 29, 30, 31], cluster analysis [32], elicitation of expert knowledge [33], human decision behaviour [34]). Reference [35] reviewed applications of fuzzy logic for decision support in ecosystem management with focus on the identification, optimization, validation, interpretability and uncertainty aspects of rule-based models. As mentioned earlier, fuzzy modelling has also been applied to habitat assessment. This can be classified into two categories of knowledge-based modelling [12, 13, 14, 15] and data-driven modelling [16, 18, 19, 20, 21, 22, 23, 24, 25, 26, 36]. The former cannot optimize model parameters, while the latter can do it. Several approaches were employed for data-driven optimization of model parameters. For instance, [16] employed a nearest ascent hill climbing algorithm, [22, 25, 26] incorporated fuzzy membership function into artificial neural network, and the others employed GA [18, 19, 20, 21, 22, 23, 24, 36]. According to [37], the latter two approaches can be classified into genetic fuzzy systems. The genetic fuzzy systems would gain more attentions in ecological research because of its interpretability and learning ability.

2.2 Study Site and Target Fish

The survey was carried out in an agricultural canal located in Kurume City, Fukuoka, Japan (33˚20’ N, 130˚42’ E; Fig. 1). The spring-fed canal runs through paddy fields, and is used for both irrigation and drainage purposes. It flows into the Kose River, which is a tributary of the Chikugo River.

The target fish, Japanese medaka (*Oryzias latipes*), is one of the most common freshwater fish in Japan. This fish has been considered as one of the symbols of rural environmental conservation and restoration because of the vulnerability to alterations of physical environment such as concrete lining of the earthen canal. For instance, Japanese medaka generally grows up to approximately 2 cm in length and thus is vulnerable to fast flowing water.

2.3 Field Survey

The field surveys were conducted on 14 October, and 5 and 9 November 2004. The surveys were conducted during a non-irrigation period, thus the discharge in the study reaches remained stable. Therefore, the habitat uses of Japanese medaka were not affected by any agricultural activities or agricultural chemicals. The water temperature remained stable (16.1–20.3˚C) during the surveys.

The habitat uses of Japanese medaka and the physical habitat characteristics of water depth (henceforth referred to as depth), current velocity (velocity), lateral cover ratio (cover), and percent vegetation coverage (vegetation) in the study reach were surveyed on sunny days. The four physical environments are found to be the primary factors affecting spatial distribution, i.e., habitat use, of the fish [20]. After mapping the reach, habitat use of the fish was first observed (11:00–14:30) and then the physical habitat characteristics within the reach were surveyed.

The habitat use of Japanese medaka was observed visually from the bank; the observer moved slowly and carefully to avoid disturbing the fish. The number of the fish was counted in units of five to take into consideration the habit of school formation, i.e., fish in a small school (less than five) were not counted. Observations were repeated eight times and the results were averaged to reduce observational error.

Immediately after completing the fish observation, the four physical habitat characteristics of depth, velocity, cover, and vegetation were surveyed to establish a relationship between physical environment and habitat preferences of Japanese medaka. First, depth and velocity were measured to divide the study reach into small water bodies having similar condition with regard to these two physical parameters. Depth was measured with a stainless steel ruler, and velocity with a portable propeller current meter (KENEK, V-303) at three lateral points comprising a midpoint and two near-shore points at longitudinal intervals of 1 m. By using the measurements of depth and velocity, the reach was divided into water bodies. Next, the other two factors of cover and vegetation were calculated from the schematic diagrams of the water bodies. The lateral cover ratio is defined as a function of the presence of lateral cover, which comprises the water’s edge, a dike, or anything that emerges from the water surface and surrounds the water body. The cover thus consists of four components (four lateral sides). The maximum cover ratio is 100%, and each of the cover components is assigned a score of 25%. In the definition of the cover, objects attached to more than 90% of the boundary between water bodies were regarded as cover components. That is, only instream and undersurface cover structures were considered as cover component because they may have had the same effects as the margin of the stream. Percent vegetation coverage is defined as the percentage of the area covered with aquatic vegetation in each water body. Both submerged and emergent vegetation were pooled because of their same roles in providing food and shelter from predators and fast-flowing currents.

Figure 1: Study reach

The habitat use data used in the following analyses were the observed fish population density obtained for the i^{th} water body $\rho_{o,i}$ (individuals per square metre), where i (i=1, 2, …, n) denotes the index of the water body and n the total number of water bodies.

2.4 Fuzzy Habitat Preference Model

In fuzzy habitat preference model (FHPM), a simplified fuzzy reasoning was introduced to relate physical habitat characteristic to habitat preference with the consideration of the uncertainties (Fig. 2), and a simple GA to optimize the

ISBN: 978-989-95079-6-8

model structure. GA was employed because it enables us to simultaneously optimize all the parameters in FHPM even under the nonlinear, complex interactions between physical environment and fish habitat preference. The premise part of FHPM (Fig. 2(i)), i.e. fuzzy membership functions, is defined for the purpose of reflecting the ecology of Japanese medaka. For instance, because the body length of an adult medaka is approximately 2 cm, the critical requirements for Japanese medaka with regard to depth and velocity thus would be relatively shallower and slowly flowing water. The habitat preference is calculated by taking the weighted mean of singletons in the consequent part (Fig. 2(ii)) by the membership value μ_i. That is,

$$P_j = \frac{\sum_{i=1}^{n_m} \mu_{j,i} \cdot c_{j,i}}{\sum_{i=1}^{n_m} \mu_{j,i}} \quad (1)$$

where P_j denotes the habitat preference to the environmental factor j (=depth, velocity, cover, and vegetation), c_i is the value assigned to each singleton (i.e., degree of habitat preference assigned to the corresponding membership function in the premise part), μ_i is the membership value (i.e., degree of fitness to the membership functions in the premise part), i is the index of the membership functions, and n_m is the number of membership functions (Fig. 2). By taking the weighted mean (1), the results are given in a simple linear form. The singletons in the consequence part are determined by using GA so as to minimize mean square error (MSE) between predicted and observed fish population density. The optimization procedure is summarized as follows.

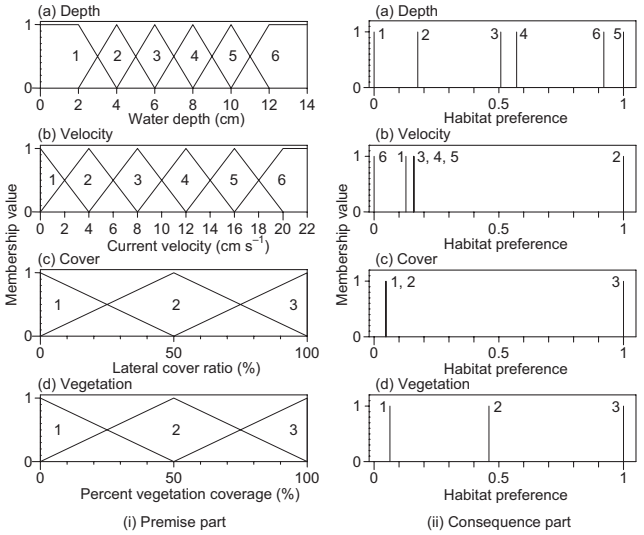

Figure 2: Membership functions of FHPM

First, GA proposed a set of initial model structures (i.e., consequence part) of FHPM. Second, the environmental measurements were given as input values. The input values, i.e., four physical environmental variables, are represented by symmetric triangular fuzzy numbers for considering the uncertainty originated from measurement errors and spatial dispersions. The fuzzy inputs are expressed by its centre a^c_j and spread a^s_j as (a^c_j, a^s_j), where j denotes the environmental factors of depth, velocity, cover, and vegetation. The spread a^s_j is determined from allowable variance when dividing the reach into water bodies: 1 cm is given for the spread of depth a^s_d, 2 cm s^{-1} for velocity a^s_v, 10% each for cover a^s_c and vegetation a^s_{veg}. Of these, the abbreviations of d, v, c, and veg indicate depth, velocity, cover, and vegetation, respectively. Third, habitat preferences for each environmental factor were calculated. Fourth, the habitat preferences to the four environmental factors were combined using (2).

$$P_i = P_{d,i} \times P_{v,i} \times P_{c,i} \times P_{veg,i} \quad (2)$$

Fifth, the habitat use of Japanese medaka was predicted by using (3).

$$\rho_{c,i} = \left(P_i \Big/ \sum_{i=1}^{n} P_i \right) \cdot \sum_{i=1}^{n} \rho_{o,i} \quad (3)$$

Table 1: Condition of GA optimization

Operation	Condition & Remarks

Number*	1	1	1	1	2	2	2	2	2	2	3	3	3	3	4

*Number of membership functions modified.

Next, MSE between the predicted and observed fish population density was calculated, and then GA repeatedly modified the singletons so as to minimize MSE. Finally, the optimized FHPM was obtained. The basic condition of GA optimization is summarised in Table 1. In the original setting, totalled 17 parameters were optimised (5 for depth, 6 for velocity, and 3 each for cover and vegetation). The number of parameters to be modified differed by the condition of model structure modification (see Table 2).

2.5 Model Development and Analysis

In the present study, a data set collected on 14 October and 5 November 2004 was used for calibration while the other data set collected on 9 November was used for validation. The condition given for comparing the results of model structure modification is summarised in Table 2. Totalled 31 sets of the condition were given in which one is given for original model, and 15 each for reducing and adding membership functions to the original model. Since model structures of the models vary in accordance with their initial conditions in the optimization, 20 different initial conditions

ISBN: 978-989-95079-6-8

were thus given to each model so as to evaluate the variance of model structure developed. For the comparison, MSE between predicted and observed fish population densities was calculated. Average and standard deviation of MSE on all the models were then used for the comparison. The relationship between MSE and number of fuzzy membership functions was compared in order to clarify the accuracy-complexity tradeoffs in FHPM.

3 Results

The results of field surveys on 14 October and 5 November 2004 were pooled and used for model calibration (Fig. 3(i)), while the result of survey on 9 November was used for model validation (Fig. 3(ii)). All the models were developed by using raw data shown in Fig. 3.

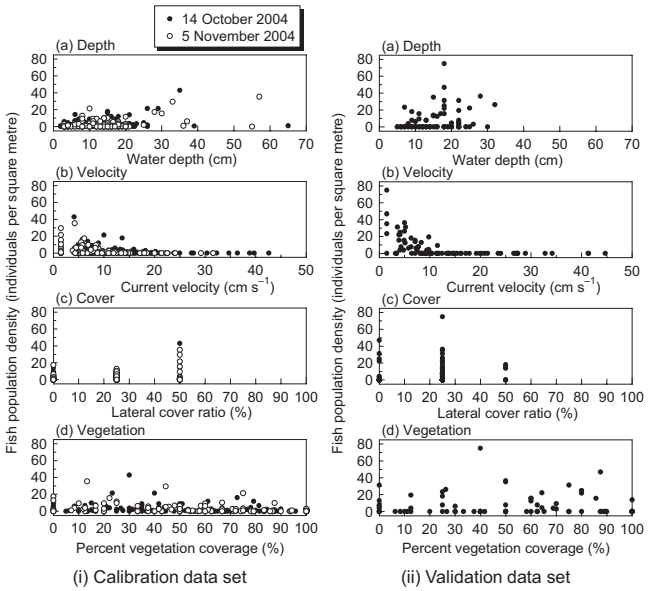

Figure 3: Result of field survey

Habitat preferences evaluated by all the models reflected their model structure, in which the variance in habitat preference curves would be ascribed to the difference in model structure among 20 different initial conditions. Of these, three habitat preference curves evaluated by the models of no modification (original), four-factor reduced and four-factor added are shown as an example (Fig. 4). Despite of the similar tendency in habitat preference, the larger variance in model structure was found in the case of four-factor added model.

By using the habitat preference models together with (2) and (3), habitat uses of Japanese medaka were predicted, of which MSE between predicted and observed fish population density (i.e., habitat use) were used for the comparison. Because some calibration turned out to be failure (especially in the case of adding fuzzy membership function), the best result (i.e., model) achieved at each condition was used in the following analysis. Fig. 5 shows the scatter diagrams of the averaged MSE and number of fuzzy membership functions in both calibration and validation, in which the number of 17 indicates the original model. The model structure could not be improved by modifying the number of fuzzy membership functions in calibration. By contrast, reducing number of fuzzy membership functions resulted in deterioration of prediction ability of the models. The degree of deterioration differed by factors that was modified. As a result, no tradeoff was found between prediction ability of the models (i.e., MSE) and number of fuzzy membership function (i.e., model complexity).

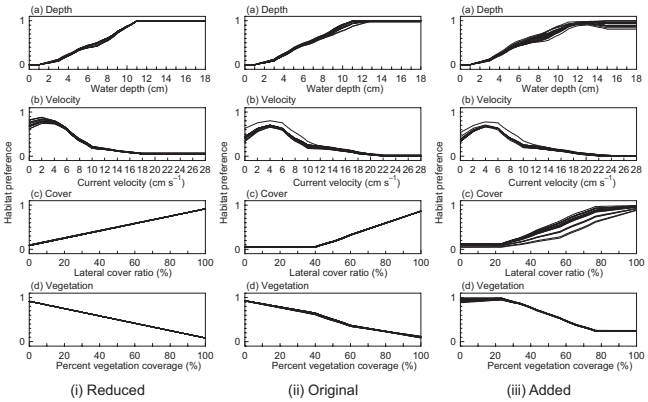

Figure 4: Habitat preference curves evaluated by three models of four-factor reduced (i), no modification (original) (ii), and four-factor added (iii).

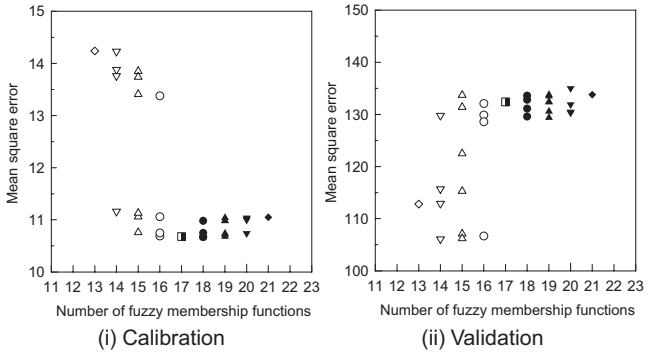

Figure 5: Scatter diagram between minimum mean square error and number of fuzzy membership functions in calibration (i) and validation (ii), in which open marks represent the case of reduced number of fuzzy membership function while filled marks represent that of added.

The MSEs of calibration and validation were compared for the deeper understandings of the relationship between prediction ability and model structure of FHPM. In Fig. 6, there were slight tradeoffs between calibration and validation results. For instance, models with smaller MSE in calibration resulted in larger MSE in validation. Fig. 6 also indicated that no improvement was achieved by adding fuzzy membership functions to the original one.

4 Discussion

The complex interactions between physical environment and habitat preference of the fish made it difficult to clarify the tradeoffs in FHPM. All the habitat preference curves of 31 different conditions showed similar trend of larger water depth, slower velocity, larger cover and smaller vegetation (Fig. 4). However, the prediction result differed between models (Figs. 5 & 6). In Fig. 5, reducing fuzzy membership

ISBN: 978-989-95079-6-8

function resulted in better prediction in the validation data set while prediction in the calibration data set resulted in deterioration. On one hand, this clearly indicates the effect of over-fitting to the data used in model calibration. This could be improved by modifying the conditions of GA optimization such as number of iteration and number of data used in model development. On the other hand, this would be ascribed to the different distribution of the physical environment and habitat use of the fish (Fig. 3). This is one of the major problems in habitat modelling and is often discussed as "transferability" of the habitat models [8, 9]. Adding fuzzy membership function thus could not improve prediction ability of the model. To achieve the model transferability, it is necessary to develop habitat models by using sufficient data which satisfy generality of the habitat use of the fish. In the present case, an approach to achieve generality would be the use of different sub-sets of data in model optimization. For instance, [38] employed different subsets of data to cope with the problems of overtraining and high sensitivity to outliers in the application of artificial neural network model. Reference [16] also applied similar approach in the optimization of fuzzy rule-based habitat model. Another approach would be to modify the fuzzy membership function into less precise definition as often applied in habitat modelling of riverine fish [12, 13, 14, 15, 16]. In this case, the advantage of consideration of critical requirement into model structure would however be lost at the same time. Besides the discussion on complexity and improvement of the model, the present result may suggest the significance of cover in the habitat use of the fish. In [20], the significance of cover was also supported by an approach using Akaike Information Criterion (AIC).

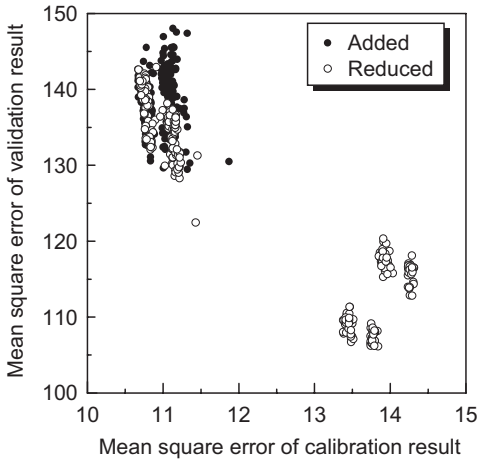

Figure 6: Scatter diagram between mean square errors of calibration and validation results, in which open circles represent the case of reduced number of fuzzy membership function while filled circles represent that of added.

As a concept, adding fuzzy membership function would improve model performance by precisely describing habitat preference of the fish. By contrast, increasing number of parameters to be optimised would put searching loads on GA. Although no clear trend was found between accuracy of the habitat prediction and model structure (i.e., number of fuzzy membership functions), further analyses should be carried out to assess the complex combination such as reducing and adding fuzzy membership functions at the same time. The use of AIC would be appropriate for the quantification of the complex relationship between model structure and prediction ability. In addition, different performance measures such as correctly fuzzy classified instances (%CCFI) and average deviation (AD), and interpretability-preserving optimization of the fuzzy models as presented in [36], can be a pathway for the accuracy improvement of the present model. Further studies would be needed to quantitatively understand the complexity-accuracy tradeoff of FHPM .

Abstract— *One of the most efficient techniques for processing interval and fuzzy data is a Monte-Carlo type technique of Cauchy deviates that uses Cauchy distributions. This technique is mathematically valid, but somewhat counterintuitive. In this paper, following the ideas of Paul Werbos, we provide a natural neural network explanation for this technique.*

Keywords— Cauchy deviate method, fuzzy uncertainty, interval uncertainty, Monte-Carlo simulations, neural networks

1 Formulation of the Problem: Cauchy Deviate Method and Need for Intuitive Explanation

1.1 Practical Need for Uncertainty Propagation

In many practical situations, we are interested in the value of a quantity y which is difficult or even impossible to measure directly. To estimate this difficult-to-measure quantity y, we measure or estimate related easier-to-measure quantities $x_1, \ldots, x_n$ which are related to the desired quantity y by a known relation $y = f(x_1, \ldots, x_n)$. Then, we apply the relation f to the estimates $\widetilde{x}_1, \ldots, \widetilde{x}_n$ for x_i and produce an estimate $\widetilde{y} = f(\widetilde{x}_1, \ldots, \widetilde{x}_n)$ for the desired quantity y.

In the simplest cases, the relation $f(x_1, \ldots, x_n)$ may be an explicit expression: e.g., if we know the current x_1 and the resistance x_2, then we can measure the voltage y by using Ohm's law $y = x_1 \cdot x_2$. In many practical situations, the relation between x_i and y is much more complicated: the corresponding algorithm $f(x_1, \ldots, x_n)$ is not an explicit expression, but a complex algorithm for solving an appropriate non-linear equation (or system of equations).

Estimates are never absolutely accurate:

- measurements are never absolutely precise, and
- expert estimates can only provide approximate values of the directly measured quantities $x_1, \ldots, x_n$.

In both cases, the resulting estimates $\widetilde{x}_i$ are, in general, different from the actual (unknown) values x_i. Due to these estimation errors $\Delta x_i \stackrel{\text{def}}{=} \widetilde{x}_i - x_i$, even if the relation $f(x_1, \ldots, x_n)$ is exact, the estimate $\widetilde{y} = f(\widetilde{x}_1, \ldots, \widetilde{x}_n)$ is different from the actual value $y = f(x_1, \ldots, x_n)$: $\Delta y \stackrel{\text{def}}{=} \widetilde{y} - y \neq 0$.

(In many situations, when the relation $f(x_1, \ldots, x_n)$ is only known approximately, there is an additional source of the approximation error in y caused by the uncertainty in knowing this relation.)

It is therefore desirable to find out how the uncertainty Δx_i in estimating x_i affects the uncertainty Δy in the desired quantity, i.e., how the uncertainties Δx_i *propagate* via the algorithm $f(x_1, \ldots, x_n)$.

1.2 Propagation of Probabilistic Uncertainty

Often, we know the probabilities of different values of Δx_i. For example, in many cases, we know that the approximation errors Δx_i are independent normally distributed with zero mean and known standard deviations σ_i; see, e.g., [16].

In this case, we can use known statistical techniques to estimate the resulting uncertainty Δy in y. For example, since we know the probability distributions, we can simulate them in the computer, i.e., use the Monte-Carlo simulation techniques to get a sample population $\Delta y^{(1)}, \ldots, \Delta y^{(N)}$ of the corresponding errors Δy. Based on this sample, we can then estimate the desired statistical characteristics of the desired approximation error Δy.

1.3 Propagation of Interval Uncertainty

In many other practical situations, we do not know these probabilities, we only know the upper bounds Δ_i on the (absolute values of) the corresponding measurement errors Δx_i: $|\Delta x_i| \leq \Delta$.

In this case, based on the known approximation $\widetilde{x}_i$, we can conclude that the actual (unknown) value of i-th auxiliary quantity x_i can take any value from the interval

$$\mathbf{x}_i = [\widetilde{x}_i - \Delta_i, \widetilde{x}_i + \Delta_i]. \tag{1}$$

To find the resulting uncertainty in y, we must therefore find the range $\mathbf{y} = [\underline{y}, \overline{y}]$ of possible values of y when $x_i \in \mathbf{x}_i$:

$$\mathbf{y} = f(\mathbf{x}_1, \ldots, \mathbf{x}_n) \stackrel{\text{def}}{=}$$

$$\{f(x_1, \ldots, x_n) \,|\, x_1 \in \mathbf{x}_1, \ldots, x_n \in \mathbf{x}_n\}. \tag{2}$$

Computations of this range under interval uncertainty is called *interval computations*; see, e.g., [4, 5].

The corresponding computational problems are, in general, NP-hard [9]. Crudely speaking, this means that, in general, such problems require a large amount of computation time – and that therefore faster methods are needed.

1.4 Propagation of Fuzzy Uncertainty

In many practical situations, the estimates $\widetilde{x}_i$ come from experts. Experts often describe the inaccuracy of their estimates

ISBN: 978-989-95079-6-8

in terms of imprecise words from natural language, such as "approximately 0.1", etc. A natural way to formalize such words is to use special techniques developed for formalizing this type of estimates – specifically, the technique of fuzzy logic; see, e.g., [6, 15].

In this technique, for each possible value of $x_i \in \mathbf{x}_i$, we describe the degree $\mu_i(x_i)$ to which this value is possible. For each degree of certainty α, we can determine the set of values of x_i that are possible with at least this degree of certainty – the *α-cut* $\mathbf{x}_i(\alpha) = \{x \,|\, \mu(x) \geq \alpha\}$ of the original fuzzy set. Vice versa, if we know α-cuts for every α, then, for each object x, we can determine the degree of possibility that x belongs to the original fuzzy set [3, 6, 12, 13, 15]. A fuzzy set can be thus viewed as a nested family of its (interval) α-cuts.

We already know how to propagate interval uncertainty. Thus, to propagate this fuzzy uncertainty, we can therefore consider, for each α, the fuzzy set y with the α-cuts

$$\mathbf{y}(\alpha) = f(\mathbf{x}_1(\alpha), \ldots, \mathbf{x}_1(\alpha)); \tag{3}$$

see, e.g., [3, 6, 12, 13, 15]. So, from the computational viewpoint, the problem of propagating fuzzy uncertainty can be reduced to several interval propagation problems.

1.5 Need for Faster Algorithms for Uncertainty Propagation

Summarizing the above analysis, we can conclude that in principle, we need to consider three basic types of uncertainty propagation: situations when we propagate probabilistic, interval, and fuzzy uncertainty. It is also possible that some quantities are represented by fuzzy sets, while others may be represented by probabilities.

For probabilistic uncertainty, there exist reasonable efficient uncertainty propagation algorithms such as Monte-Carlo simulations. In contrast, the problems of propagating interval and fuzzy uncertainty are, in general, computationally difficult. It is therefore desirable to design faster algorithms for propagating interval and fuzzy uncertainty.

Once such methods are developed, we can then use these methods to propagate interval and fuzzy uncertainty components, and Monte-Carlo simulations to propagate the probabilistic uncertainty.

The computational problem of propagating fuzzy uncertainty can be naturally reduced to the problem of propagating interval uncertainty. Because of this reduction, in the following text, we will mainly concentrate on faster algorithms for propagating interval uncertainty.

1.6 Linearization Situations: Description

Due to the approximation errors $\Delta x_i = \widetilde{x}_i - x_i$, the unknown (actual) values $x_i = \widetilde{x}_i - \Delta x_i$ of the input quantities x_i are, in general, different from the approximate estimates $\widetilde{x}_i$. In many practical situations, the approximation errors Δx_i are small – e.g., when the approximations are obtained by reasonably accurate measurements. In such situations, we can ignore terms which are quadratic (and of higher order) in Δx_i.

1.7 Linearization Situations: Analysis

In the above situations, we can expand the expression for

$$\Delta y = \widetilde{y} - y = f(\widetilde{x}_1, \ldots, \widetilde{x}_n) - f(x_1, \ldots, x_n) =$$

$$f(\widetilde{x}_1, \ldots, \widetilde{x}_n) - f(\widetilde{x}_1 - \Delta x_1, \ldots, \widetilde{x}_n - \Delta x_n) \tag{4}$$

in Taylor series in Δx_i and keep only the linear terms in this expansion. In this case, we get

$$\Delta y = c_1 \cdot \Delta x_1 + \ldots + c_n \cdot \Delta x_n, \tag{5}$$

where we denoted

$$c_i \stackrel{\text{def}}{=} \frac{\partial f}{\partial x_i}(\widetilde{x}_1, \ldots, \widetilde{x}_n).$$

For a linear function, the largest possible value of Δy is obtained when each of the variables $\Delta x_i \in [-\Delta_i, \Delta_i]$ attains:

- either its largest value Δ_i (when $c_i \geq 0$)
- or its smallest value $-\Delta_i$ (when $c_i < 0$).

In both cases, the largest possible value of the corresponding term in Δy is equal to $|c_i| \cdot \Delta_i$. Thus, the largest possible value of Δy is equal to

$$\Delta = |c_1| \cdot \Delta_1 + \ldots + |c_n| \cdot \Delta_n. \tag{6}$$

Similarly, the smallest possible value of Δy is obtained when each of the variables $\Delta x_i \in [-\Delta_i, \Delta_i]$ attains

- either its smallest value $-\Delta_i$ (when $c_i \geq 0$)
- or its largest value Δ_i (when $c_i < 0$).

In both cases, the smallest possible value of the corresponding term in Δy is equal to $-|c_i| \cdot \Delta_i$. Thus, the smallest possible value of Δy is equal to

$$-\Delta = -|c_1| \cdot \Delta_1 - \ldots - |c_n| \cdot \Delta_n. \tag{7}$$

Can we transform these natural formulas into an algorithm? Due to the linearization assumption, we can estimate each partial derivative c_i as

$$c_i \approx \frac{f(\widetilde{x}_1, \ldots, \widetilde{x}_{i-1}, \widetilde{x}_i + h_i, \widetilde{x}_{i+1}, \ldots, \widetilde{x}_n) - \widetilde{y}}{h_i} \tag{8}$$

for some small values h_i. So, we arrive at the following algorithm.

1.8 Linearization Situations: Algorithm

To compute the range $\mathbf{y}$ of y, we do the following.

- First, we apply the algorithm f to the original estimates $\widetilde{x}_1, \ldots, \widetilde{x}_n$, resulting in the value $\widetilde{y} = f(\widetilde{x}_1, \ldots, \widetilde{x}_n)$.
- Second, for all i from 1 to n, we compute $f(\widetilde{x}_1, \ldots, \widetilde{x}_{i-1}, \widetilde{x}_i + h_i, \widetilde{x}_{i+1}, \ldots, \widetilde{x}_n)$ for some small h_i and then compute

$$c_i = \frac{f(\widetilde{x}_1, \ldots, \widetilde{x}_{i-1}, \widetilde{x}_i + h_i, \widetilde{x}_{i+1}, \ldots, \widetilde{x}_n) - \widetilde{y}}{h_i}. \tag{9}$$

- Finally, we compute

$$\Delta = |c_1| \cdot \Delta_1 + \ldots + |c_n| \cdot \Delta_n$$

and the desired range $\mathbf{y} = [\widetilde{y} - \Delta, \widetilde{y} + \Delta]$.

ISBN: 978-989-95079-6-8

1.9 Linearization Situations: Computational Complexity

The main computation time is spent on calling the time-consuming algorithm f. In the above uncertainty propagation algorithm, after one call to f to compute $\widetilde{y}$, we need n calls to f to compute the corresponding partial derivatives c_i and then, we can estimate the desired uncertainty Δ in y by using the above simple formula.

Overall, we thus need $n+1$ calls to the algorithm f.

1.10 Cauchy Deviate Method

For large n, we can further reduce the number of calls to f if we use a special technique of Cauchy-based Monte-Carlo simulations, which enables us to use a fixed number of calls to f (≈ 200) for all possible values n; see, e.g., [7, 8].

1.11 Mathematics Behind the Cauchy Method

In our simulations, we use *Cauchy distribution* – i.e., probability distributions with the probability density

$$\rho(z) = \frac{\Delta}{\pi \cdot (z^2 + \Delta^2)}; \tag{10}$$

the value Δ is called the *(scale) parameter* of this distribution.

Cauchy distribution has the following property that we will use: if $z_1, \ldots, z_n$ are independent random variables, and each of z_i is distributed according to the Cauchy law with parameter Δ_i, then their linear combination

$$z = c_1 \cdot z_1 + \ldots + c_n \cdot z_n \tag{11}$$

is also distributed according to a Cauchy law, with a scale parameter $\Delta = |c_1| \cdot \Delta_1 + \ldots + |c_n| \cdot \Delta_n$.

Therefore, if we take random variables δ_i which are Cauchy distributed with parameters Δ_i, then the value

$$\delta \stackrel{\text{def}}{=} f(\widetilde{x}_1, \ldots, \widetilde{x}_n) - f(\widetilde{x}_1 - \delta_1, \ldots, \widetilde{x}_n - \delta_n) =$$

$$c_1 \cdot \delta_1 + \ldots + c_n \cdot \delta_n \tag{12}$$

is Cauchy distributed with the desired parameter

$$\Delta = \sum_{i=1}^{n} |c_i| \cdot \Delta_i. \tag{13}$$

So, repeating this experiment N times, we get N values $\delta^{(1)}, \ldots, \delta^{(N)}$ which are Cauchy distributed with the unknown parameter, and from them we can estimate Δ.

The bigger N, the better estimates we get.

1.12 Cauchy Method: Towards Implementation

To implement this idea, we must answer the following two questions:

- how to simulate the Cauchy distribution; and
- how to estimate the parameter Δ of this distribution from a finite sample.

Simulation can be based on the functional transformation of uniformly distributed sample values:

$$\delta_i = \Delta_i \cdot \tan(\pi \cdot (r_i - 0.5)), \tag{14}$$

where r_i is uniformly distributed on the interval $[0, 1]$.

In order to estimate Δ, we can apply the Maximum Likelihood Method

$$\rho(\delta^{(1)}) \cdot \rho(\delta^{(2)}) \cdot \ldots \cdot \rho(\delta^{(N)}) \to \max, \tag{15}$$

where $\rho(z)$ is a Cauchy distribution density with the unknown Δ. When we substitute the above-given formula for $\rho(z)$ and equate the derivative of the product with respect to Δ to 0 (since it is a maximum), we get an equation

$$\frac{1}{1 + \left(\dfrac{\delta^{(1)}}{\Delta}\right)^2} + \ldots + \frac{1}{1 + \left(\dfrac{\delta^{(N)}}{\Delta}\right)^2} = \frac{N}{2}. \tag{16}$$

The left-hand side of (16) is an increasing function that is equal to $0 (< N/2)$ for $\Delta = 0$ and $> N/2$ for $\Delta = \max\left|\delta^{(k)}\right|$; therefore the solution to the equation (16) can be found by applying a bisection method to the interval $\left[0, \max\left|\delta^{(k)}\right|\right]$.

It is important to mention that we assumed that the function f is reasonably linear within the box

$$[\widetilde{x}_1 - \Delta_1, \widetilde{x}_1 + \Delta_1] \times \ldots \times [\widetilde{x}_n - \Delta_n, \widetilde{x}_n + \Delta_n]. \tag{17}$$

However, the simulated values δ_i may be outside the box. When we get such values, we do not use the function f for them, we use a normalized function that is equal to f within the box, and that is extended linearly for all other values (we will see, in the description of an algorithm, how this is done).

As a result, we arrive at the following algorithm.

1.13 Cauchy Deviates Method: Algorithm

- Apply f to the results of direct measurements:

$$\widetilde{y} := f(\widetilde{x}_1, \ldots, \widetilde{x}_n); \tag{18}$$

- For $k = 1, 2, \ldots, N$, repeat the following:
  - use the standard random number generator to compute n numbers $r_i^{(k)}$, $i = 1, 2, \ldots, n$, that are uniformly distributed on the interval $[0, 1]$;
  - compute Cauchy distributed values

$$c_i^{(k)} := \tan(\pi \cdot (r_i^{(k)} - 0.5)); \tag{19}$$

  - compute the largest value of $|c_i^{(k)}|$ so that we will be able to normalize the simulated measurement errors and apply f to the values that are within the box of possible values: $K := \max_i |c_i^{(k)}|$;
  - compute the simulated measurement errors

$$\delta_i^{(k)} := \Delta_i \cdot c_i^{(k)} / K; \tag{20}$$

  - compute the simulated "actual values"

$$x_i^{(k)} := \widetilde{x}_i - \delta_i^{(k)}; \tag{21}$$

  - apply the program f to the simulated "actual values" and compute the simulated error of the indirect measurement:

$$\delta^{(k)} := K \cdot \left(\widetilde{y} - f\left(x_1^{(k)}, \ldots, x_n^{(k)}\right)\right); \tag{22}$$

ISBN: 978-989-95079-6-8

- Compute Δ by applying the bisection method to solve the equation (16).

Comment. To avoid confusion, we should emphasize that, in contrast to the Monte-Carlo solution for the probabilistic case, the use of Cauchy distribution in the interval case is a computational trick and *not* a truthful simulation of the actual measurement error Δx_i: indeed, we know that the actual value of Δx_i is always inside the interval $[-\Delta_i, \Delta_i]$, but a Cauchy distributed random attains values outside this interval as well.

1.14 Cauchy Deviate Method: Need for Intuitive Explanation

The above Cauchy deviate method is one of the most efficient techniques for processing interval and fuzzy data. However, this method has a serious drawback: while the corresponding technique is mathematically valid, it is somewhat counterintuitive – we want to analyze errors which are located *instead* a given interval $[-\Delta, \Delta]$, but this analysis use Cauchy simulated errors which are located, with a high probability, *outside* this interval.

It is therefore desirable to come up with an intuitive explanation for this technique. In this paper, we show that such an explanation can be obtained from neural networks. (For a general introduction to neural networks, see, e.g., [2, 11].)

2 Solution: Neural Explanation

2.1 Werbos's Idea: Use Neurons

Our explanation comes from the idea promoted by Paul Werbos, the author of the backpropagation algorithm for training neural networks. Traditionally, neural networks are used to simulate a deterministic dependence; Paul Werbos suggested that the same neural networks can be used to describe stochastic dependencies as well – if as one of the inputs, we take a standard random number r uniformly distributed on the interval $[0, 1]$; see, e.g., [18] and references therein.

In view of this idea, as a natural probability distribution, we can take the result of applying a neural network to this random number. The simplest case is when we have a single neuron. In this case, we apply the activation (input-output) function $f(y)$ corresponding to this neuron to the random number r.

So, let us see what will happen if we apply a neuron to the standard random number and get a value $f(r)$.

2.2 What is the Activation Function of a Neuron: Reminder

To answer the above question, let us recall what are the optimal choices of an activation function of a neuron. This problem was analyzed in detail in [14]; see also [10].

2.3 We Must Choose a Family of Functions, Not a Single Function

We talk about choosing f, but the expression for $f(y)$ will change if we change the units in which we measure all the signals (input, output and intermediate), so in mathematical terms, it is better to speak about choosing a *family* of functions f.

It is reasonable to suggest that if an f belongs to this family, then this family must contain $k \cdot f$ for positive real numbers k. This corresponds to changing units.

Also, it must contain $f + c$, where c is a constant. This is equivalent to adding a constant bias and therefore does not change the abilities of the resulting network.

Since we are talking about non-linear phenomena, we can also assume that some non-linear "rescaling" transformations $x \to g(x)$ are also applicable, i.e., the family must include the composition $g(f(y))$ for each of functions f.

This family must not be too big, therefore, it must be determined by finitely many parameters and should ideally be obtained from one function $f(y)$ by applying all these transformations. Without loss of generality, we can assume that this set of transformations is closed under composition and under inverse, i.e., if $z \to g_1(z)$ and $z \to g_2(z)$ are possible transformations, then $z \to g_1(g_2(z))$ and $z \to g_1^{-1}(z)$ are possible transformations, where by g_1^{-1} we denoted an inverse function $g_1^{-1}(z) = w$ if and only if $g_1(w) = z$. In mathematical terms this means that these transformations form a *group*, and therefore a family is obtained by applying to some function $f(y)$ all transformations from some finite-dimensional transformation group G that includes all linear transformations (and maybe some non-linear ones).

All these transformations correspond to appropriate "rescalings". Rescaling is something that is smoothly changing the initial scale. This means that if we have two different transformations, there must be a smooth transition between them. In mathematical terms, the existence of this continuous transition is expressed by saying that the group is *connected*, and the fact that both the transformations and the transitions are smooth is expressed by saying that this is a *Lie group*).

2.4 Which Family is the Best?

Among all such families, we want to choose the best one. In formalizing what "the best" means we follow the general idea described in [14].

The criteria to choose may be computational simplicity, efficiency of training, or something else. In mathematical optimization problems, numeric criteria are most frequently used, when to every family we assign some value expressing its performance, and choose a family for which this value is maximal. However, it is not necessary to restrict ourselves to such numeric criteria only. For example, if we have several different families that have the same training ability A, we can choose between them the one that has the minimal computational complexity C. In this case, the actual criterion that we use to compare two families is not numeric, but more complicated: *a family F_1 is better than the family F_2 if and only if either $A(F_1) > A(F_2)$ or $A(F_1) = A(F_2)$ and $C(F_1) < C(F_2)$*. A criterion can be even more complicated. What a criterion *must* do is to allow us for every pair of families to tell whether the first family is better with respect to this criterion (we'll denote it by $F_1 > F_2$), or the second is better ($F_1 < F_2$) or these families have the same quality in the sense of this criterion (we'll denote it by $F_1 \sim F_2$). Of course, it is necessary to demand that these choices be consistent, e.g., if $F_1 > F_2$ and $F_2 > F_3$ then $F_1 > F_3$.

Another natural demand is that this criterion must choose a *unique* optimal family (i.e., a family that is better with respect to this criterion than any other family). The reason for this demand is very simple. If a criterion does not choose any family at all, then it is of no use. If several different families are "the

ISBN: 978-989-95079-6-8

best" according to this criterion, then we still have a problem to choose among those "best". Therefore, we need some additional criterion for that choice. For example, if several families turn out to have the same training ability, we can choose among them a family with minimal computational complexity. So what we actually do in this case is abandon that criterion for which there were several "best" families, and consider a new "composite" criterion instead: F_1 is better than F_2 according to this new criterion if either it was better according to the old criterion or according to the old criterion they had the same quality and F_1 is better than F_2 according to the additional criterion. In other words, if a criterion does not allow us to choose a unique best family it means that this criterion is not ultimate; we have to modify it until we come to a final criterion that will have that property.

The next natural condition that the criterion must satisfy is connected with the following. Suppose that instead of a neuron with the transformation function $f(y)$ we consider a neuron with a function $\bar{f}(y) = f(y + a)$, where a is a constant. This new neuron can be easily simulated by the old ones: namely, the output of this new neuron is $\bar{f}(y) = f(y + a)$, so it is equivalent to an old neuron with an additional constant input a. Likewise, the old neuron is equivalent to the new neuron with an additional constant input $-a$. Therefore, the networks that are formed by these new neurons have precisely the same abilities as those that are built from the old ones.

We cannot claim that the new neurons have the same quality as the old ones, because adding a can increase computational complexity and thus slightly worsen the overall quality. But it is natural to demand that adding a does not change the *relative* quality of the neurons, i.e., if a family $\{f(y)\}$ is better that a family of $\{g(y)\}$, then for every a the family $\{f(y+a)\}$ must be still better than the family $\{g(y + a)\}$.

Now, we are ready for the formal definitions.

2.5 Definitions

By a *transformation* we mean a smooth (differentiable) function from real numbers into real numbers. By an *appropriate transformation group* G we mean a finite-dimensional connected Lie group of transformations. By a *family* of functions we mean the set of functions that is obtained from a smooth (everywhere defined) non-constant function $f(y)$ by applying all the transformations from some appropriate transformation group G. Let us denote the set of all the families by F.

A pair of relations $(>, \sim)$ is called *consistent* if it satisfies the following conditions: (1) if $a > b$ and $b > c$ then $a > c$; (2) $a \sim a$; (3) if $a \sim b$ then $b \sim a$; (4) if $a \sim b$ and $b \sim c$ then $a \sim c$; (5) if $a > b$ and $b \sim c$ then $a > c$; (6) if $a \sim b$ and $b > c$ then $a > c$; (7) if $a > b$ then $b > a$ or $a \sim b$ are impossible.

Assume a set A is given. Its elements will be called *alternatives*. By an *optimality criterion* we mean a consistent pair $(>, \sim)$ of relations on the set A of all alternatives. If $a > b$, we say that a is *better* than b; if $a \sim b$, we say that the alternatives a and b are *equivalent* with respect to this criterion. We say that an alternative a is *optimal* (or *best*) with respect to a criterion $(>, \sim)$ if for every other alternative b either $a > b$ or $a \sim b$.

We say that a criterion is *final* if there exists an optimal alternative, and this optimal alternative is unique.

In the present section we consider optimality criteria on the set F of all families.

By the *result of adding* a to a function $f(y)$ we mean a function $\bar{f}(y) = f(y + a)$. By the *result of adding* a to a family F we mean the set of the functions that are obtained from $f \in F$ by adding a. This result will be denoted by $F+a$. We say that an optimality criterion on F is *shift-invariant* if for every two families F and G and for every number a, the following two conditions are true:

i) if F is better than G in the sense of this criterion (i.e., $F > G$), then $F + a > G + a$;

ii) if F is equivalent to G in the sense of this criterion (i.e., $F \sim G$), then $F + a \sim G + a$.

2.6 Main Result

As we have already remarked, the demands that the optimality criterion is final and shift-invariant are quite reasonable. The only problem with them is that at first glance they may seem rather weak. However, they are not, as the following theorem shows:

Theorem. *If a family F is optimal in the sense of some optimality criterion that is final and shift-invariant, then every function f from F has the form $a + b \cdot s_0(K \cdot y + l)$ for some a, b, K and l, where $s_0(y)$ is either a linear function, or a fractional-linear function, or $s_0(y) = \exp(y)$, or the logistic (sigmoid) function $s_0(y) = 1/(1 + \exp(-y))$, or $s_0(y) = \tan(y)$.*

Comment. The logistic function is indeed the most popular activation function for actual neural networks, but others are also used. For our purpose, we will use the tangent function. As we have mentioned earlier, the application of the tangent function to the standard random number r indeed leads to the desired Cauchy distribution.

2.7 Proof: Main Idea

The idea of this proof is as follows: first we prove that the appropriate transformation group consists of fractionally-linear functions (in Part 1), then we prove that the optimal family is shift-invariant (in Part 2), and from that in Part 3 we conclude that any function f from F satisfies some functional equations, whose solutions are known.

2.8 Proof: Part 1

By an *appropriate group* we meant a connected finite-dimensional Lie group of transformations of the set of real numbers R onto itself that contains all linear transformations. Norbert Wiener asked [19] to classify such groups for an n-dimensional space with arbitrary n, and this classification was obtained in [17]. In our case (when $n = 1$) the only possible groups are the group of all linear transformations and the group of all fractionally-linear transformations $x \to (a \cdot x + b)/(c \cdot x + d)$. In both cases the group consists only of fractionally linear transformations.

2.9 Proof: Part 2

Let us now prove that the optimal family F_{opt} exists and is *shift-invariant* in the sense that $F_{opt} = F_{opt} + a$ for all real numbers a. Indeed, we assumed that the optimality criterion

ISBN: 978-989-95079-6-8

is final, therefore there exists a unique optimal family F_{opt}. Let's now prove that this optimal family is shift-invariant.

The fact that F_{opt} is optimal means that for every other F, either $F_{opt} > F$ or $F_{opt} \sim F$. If $F_{opt} \sim F$ for some $F \neq F_{opt}$, then from the definition of the optimality criterion we can easily deduce that F is also optimal, which contradicts the fact that there is only one optimal family. So for every F either $F_{opt} > F$ or $F_{opt} = F$.

Take an arbitrary a and let $F = F_{opt} + a$. If $F_{opt} > F = F_{opt} + a$, then from the invariance of the optimality criterion (condition ii) we conclude that $F_{opt} - a > F_{opt}$, and that conclusion contradicts the choice of F_{opt} as the optimal family. So $F_{opt} > F = F_{opt} + a$ is impossible, and therefore $F_{opt} = F = F_{opt} + a$, i.e., the optimal family is really shift-invariant.

2.10 Proof: Part 3

Let us now deduce the actual form of the functions f from the optimal family. If $f(y)$ is such a function, then the result $f(y + a)$ of adding a to this function f belongs to $F + a$, and so, due to 2., it belongs to F. But all the functions from f can be obtained from each other by fractionally linear transformations, so $f(y + a) = (A + B \cdot f(y))/(C + D \cdot f(y))$ for some A, B, C and D. So we arrive at a functional equation for f. Let us reduce this equation to a one with a known solution. For that purpose, let us use the fact that fractionally linear transformations are projective transformations of a line, and for such transformations the cross ratio is preserved ([1], Section 2.3), i.e., if $g(y) = (A + B \cdot f(y))/(C + D \cdot f(y))$, then

$$\frac{g(y_1) - g(y_3)}{g(y_2) - g(y_3)} \cdot \frac{g(y_2) - g(y_4)}{g(y_1) - g(y_4)} = \frac{f(y_1) - f(y_3)}{f(y_2) - f(y_3)} \cdot \frac{f(y_2) - f(y_4)}{f(y_1) - f(y_4)} \tag{23}$$

for all y_i. In our case this is true for $g(y) = f(y+a)$, therefore for all a the following equality is true:

$$\frac{f(y_1 + a) - f(y_3 + a)}{f(y_2 + a) - f(y_3 + a)} \cdot \frac{f(y_2 + a) - f(y_4 + a)}{f(y_1 + a) - f(y_4 + a)} = \frac{f(y_1) - f(y_3)}{f(y_2) - f(y_3)} \cdot \frac{f(y_2) - f(y_4)}{f(y_1) - f(y_4)}. \tag{24}$$

The most general continuous solutions of this functional equation are given by Theorem 2.3.2 from [1]: either f is fractionally linear, or $f(y) = (a+b\cdot\tan(k\cdot y))/(c+d\cdot\tan(k\cdot y))$ for some a, b, c, d, or $f(y) = (a+b\cdot\tanh(k\cdot y))(c+d\cdot\tanh(k\cdot y))$, where

$$\tanh(z) \stackrel{\text{def}}{=} \frac{\sinh(z)}{\cosh(z)}, \quad \sinh(z) \stackrel{\text{def}}{=} \frac{\exp(z) - \exp(-z))}{2},$$

$$\cosh(z) \stackrel{\text{def}}{=} \frac{\exp(z) + \exp(-z)}{2}. \tag{25}$$

The $\tanh(z)$ expression is equivalent to the logistic function.

The theorem is proven.

Abstract— *The study of human behavior during driving is of primary importance for the improvement of drivers' security. This study is complex because of numerous situations in which the driver may be involved. In this paper, we propose a hierarchical fuzzy system for human in a driver-vehicle-environment system to model takeover by different drivers. The driver's behavior is affected by the environment. We include climate, road and car conditions in a fuzzy mode. For obtaining fuzzy rules, we have provided three separate questionnaires on the effects of climate; road and car condition on driver's performance. The number of fuzzy rules is optimized by Particle Swarm Optimization algorithm. Also the precision, age and driving individuality are used to model the driver's behavior under difference environments. We investigate the behavior of different drivers when a driver intends to pass the leading car. The comparative study showed that the simulation result is in good agreement with the real situations.*

Keywords— Fuzzy, PSO, Driver's behaviour.

1 Introduction

In recent years, by using new control ideas, safety in driving has been improved. MacAdam (1980) developed an optimal preview control algorithm; however, this algorithm could only be applied to single input single output systems. Fenton applied Linear Quadratic algorithm (1988) to design a controller for steering. Ackermann and Sienel (1990) used parameter space robust control to design the automatic steering controller. These models did not take the driver's preview behavior into consideration. Lee (1989) developed a discrete time preview control algorithm for four-wheel steering passenger vehicles and found that the control accuracy was improved substantially by taking the preview behavior into account. The fuzzy logic has proven to be a very effective tool for handling imprecision and uncertainty, which are both very important characteristics of driving environments. This makes fuzzy logic a powerful candidate tool in most traffic engineering studies [1]. In [2] Kamada et al. proposed a fuzzy logic lateral controller. Hessburg and Tomizuka [6] developed a fuzzy logic controller for vehicle lateral guidance which consisted of three sub-controllers: preview, feedback and gain scheduling. Cai, Lin and Mourant investigated the influence of driver emotion on performance through platoon driving simulated with multiple simulators [4]. They induced two kinds of emotion states (anger and excitation) through realistic driver-driver interaction by using networked driving simulators. Drivers' psycho physiological parameters changes were the indicators of emotions. In the anger and excitation states, drivers showed poorer lane control capability. In [4] the author investigated emotional behavior (anger, neutral, and excitation) of drivers by collecting driving performance data. The results demonstrated the feasibility and efficiency of using multiple networked driving simulators to study driver emotional behavior, e.g., road rage.

In this paper, we use new parameters to identify uniqueness of driving maneuver of each driver under different environment, the precision, age and driving individuality. In modeling, the decision making process is based on three positions, one position in equal lane and two positions in opposite lane. By considering three positions, the speed, direction of car and the steering angle, a fuzzy model is presented for steering angle and speed control. We used two levels for modeling. The low level control model is responsible for modeling the steering angle and the speed variations enforced by the driver. The high level control model, models the decision making process of the driver. For this purpose, first the fuzzified low level control models are illustrated in section 2. The high level decision making model is designed in section 3 and the simulation results are presented in section 4. Finally section 5 describes conclusions.

2 Low level control

In order to implement the low-level control model, a simple car's model is required [5]. The car states include the Cartesian position (x,y) centered mid-way between the rear wheels and the car's orientation denoted by equations 1 to 3, where φ is the steering angle, V is the car's speed and θ is the angle of the car with respect to the X axis and L is the distance between center of rear and front wheels.

$$x_{n+1} = x_n + V_n \times \cos(\theta_n) \times \Delta t \quad (1)$$

$$y_{n+1} = y_n + V_n \times \sin(\theta_n) \times \Delta t \quad (2)$$

$$\theta_{n+1} = \theta_n + \frac{V_n \times \tan(\varphi_n) \times \Delta t}{L} \quad (3)$$

The driver controls V and φ. In order to model the complete low level control procedure, we have assumed that apart from the information from the environment that the driver perceives, other information such as age and driver's individuality are influential in the driver's control procedure. This can be formulated as:

$$\Delta V = f(x_n, y_n, \varphi_n, \theta_n, Environment_n, Driver_n) \quad (4)$$

ISBN: 978-989-95079-6-8

$$\Delta\varphi = f(x_n, y_n, \varphi_n, \theta_n, Environment_n, Driver_n) \quad (5)$$

Where $(x_n, y_n, \theta_n, \varphi_n)$ determine car's state, *Environment* is the information of the condition of *Climate*, *Road* and *Car* and *Driver* is the individual driver influence.

2-1) Environmental condition

The *Climate* condition is the information of luminosity, field of view, rain, temperature and humidity. The *Road* condition is about the traffic surrounding the driver, road safety, quality of road materials, moving obstacle and having enough signs and finally the *Car* condition is the information of car's ergonomic, safety equipments performance and agent of distraction in car. The information is considered as the input variables of fuzzy system (Figure 1).

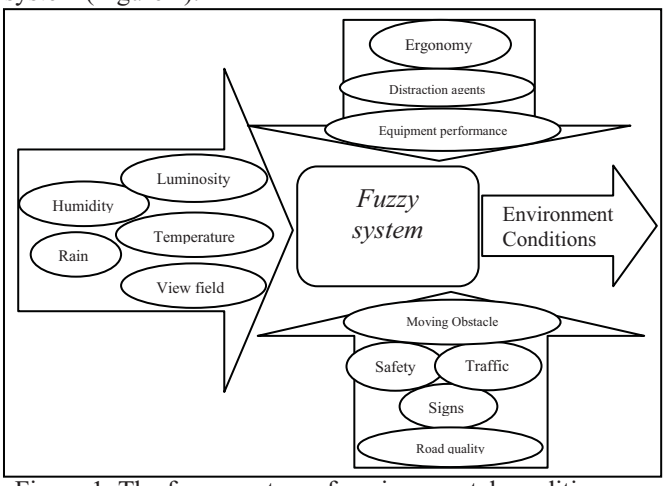

Figure 1. The fuzzy system of environmental condition

2-1-1) *Fuzzy rule base and membership functions*

Questionnaires have been provided to obtain the fuzzy rules, where the effects of climate, road and car condition in driving have been questioned separately. Each expert driver answered each question in three manners, percent value, graphic representation and linguistic term. We allocated a weight for each of them. For percent value $w_{per} = 1$, graphic representation $w_{gr} = 2$ and finally for linguistic term $w_{ling} = 0.5$ have been considered.

The membership functions of fuzzy values are supposed to be bell shape as follows:

$$\mu(x) = \frac{1}{1 + \frac{(x-c)^2}{d}} \quad (6)$$

where x is the member of universe, c is the median and d represents the shape factor.

By using collected data, the median value and shape factor for each expert driver is calculated as follows:

$$c_{ij} = \frac{w_{per} \times val_{per,j} + w_{gr} \times val_{gr,j} + w_{ling} \times val_{ling,j}}{w_{per} + w_{gr} + w_{ling}} \quad (7)$$

$$d_{ij} = \frac{\left(\left|val_{per,j} - val_{gr,j}\right|\right) + \left(\left|val_{per,j} - val_{ling,j}\right|\right) + \left(\left|val_{gr,j} - val_{ling,j}\right|\right)}{3} \quad (8)$$

where c_{ij} is median and d_{ij} is the shape factor suggested by i^{th} driver for the j^{th} parameter. So we have n values of c_{ij} and d_{ij} for n drivers.

Now we can obtain the overall membership function for each of environmental parameters by:

$$\mu_{P_j}(x) = \frac{1}{1 + \frac{(x - c_{P_j})^2}{d_{P_j}}} \quad (9)$$

where c_{P_j} and d_{P_j} are the proposed median and shape factor for the j^{th} parameter. c_{P_j} is obtained based on the number of linguistic terms which are optimized by PSO algorithm (section 2-1-2). For example, suppose the number of linguistic terms and range of universe for a variable are 5 and [0 1] respectively. Then values of medians for five verbal are: 0, 0.25, 0.5, 0.75 and 1 for *very bad*, *bad*, *medium*, *good* and *very good* respectively.

Also d_{P_j} is defined as:

$$d_{Pj} = \frac{1}{2} \times \frac{W_{univ_j} \times d_{ref_j}}{W_{ref\_univ_j} \times (N_{ling\_term_j} - 1)} \quad (10)$$

where W_{univ_j} is the width of universes for j^{th} parameter, $N_{ling\_term_j}$ is the number of linguistic terms for j^{th} parameter (obtained from PSO algorithm), $W_{ref\_univ_j}$ and d_{ref_j} are the width and the shape factor of reference universe for j^{th} parameter. The average of n value of the shape factors (obtained from eq. 8) is considered as d_{ref}. For all of parameters, $W_{ref\_univ_j}$ is fixed to 10.

The importance of the parameters of climate, road and car condition varies for different people. So we use a pair wise comparison table for determining the weights of different parameters. Table1 shows part of pair wise comparison table.

Table1. A part of compared table

Parameter	A	B	C	D
A		√	√	-

The above table shows that parameter A is more important than parameters B and C. But parameter D is more important than parameter A. The proposed method for determining weights of parameters in fuzzy rules is as follows:

First arrange the parameters. First parameter is the least important. Then a_i is assigned to i^{th} parameter such that $a_i = i \times w$. where i is the priority index of parameter and w is the priority weight which is considered as 2 in this paper. When k parameters have equal importance, $a = w \times \frac{\sum i}{k}$ for all of k parameters. After that, we form the priority table as follows:

- If i^{th} parameter is more important than the j^{th} parameter, value of i^{th} row and j^{th} column in table is equal to $T_{ij} = a_i - a_j$.

ISBN: 978-989-95079-6-8

- If the *jth* parameter is more important than the i^{th} one then $T_{ij} = \frac{1}{a_j - a_i}$
- For diagonal elements $T_{ii} = 1$

Finally the weight of each parameter is obtained as follow:

$$M_i = (\prod_{j=1}^{m} T_{ij})^{\frac{1}{m}} \quad , \quad W_i = \frac{M_i}{\sum_{j=1}^{m} M_j} \qquad (11)$$

where *m* is the number of parameters. The obtained weights for parameters are used to generate valid fuzzy rules in section 2-1-2.

The general form of fuzzy rules for climate condition is as follows:

If field of View is … *and* Luminosity is … *and* *Rain* is … *and* Temperature is … *and* Humidity is … *Then* climate condition is …

For road condition:

If Traffic is … *and* Road quality is … *and* Sign is … *and* Moving obstacle is … *and* Safety is … *Then* Road condition is …

Finally for car condition, we have:

If Safety equipment operation is … *and* Ergonomic is … *and* Distract agent is … *Then* Car condition is …

2-1-2) *Particle Swarm Optimization*

Particle Swarm Optimization (PSO) is an optimization algorithm which uses properties of a swarm to find an optimal solution [4]. In this work, the swarm is represented by 100 individuals (or *particles*) whose values change at each iteration. The performance of each particle is measured at each position using a "fitness" function. This function increases as the optimality of the solution increases; in this way, a particle with a higher fitness is considered to fit better than the one with a lower fitness. Also, a record of the best position (*pbest*) for each particle, as well as the best overall position (*gbest*) for all particles, is kept in memory. The entire swarm then searches around the gbest solution and each of the pbest solutions, all the while trying to find even better solutions.

a) particle representation

The number of fuzzy rules depends on the number of linguistic terms of input variables. So, in order to optimize number of fuzzy rules, the number of linguistic terms of each parameter of climate, road and car condition is optimized using PSO. The number of linguistic terms for each input parameter is randomly selected 3, 5 or 7, so maximum number of fuzzy rules will be 7^m (*m* is the number of input variables). The number of linguistic terms of output fuzzy variable is set to 5.

To optimize the number of fuzzy rules and linguistic terms, the following particle is considered for PSO:

Particle=[*par_set par_rules*]

In the presented particle, the first part *par*_set is related to number of linguistic terms and is defined as follows:

$par\_set = (N_{in1}, N_{in2}, \ldots, N_{in_j}, \ldots, N_{in_m})$

Where *m* is the number of input variables and N_{in_j} shows the number of linguistic terms of j^{th} input variable. The number of linguistic terms of output variable is always equal to 5. So the *par_set* has *m* elements.

The second part of particle *par_rules* is:

$par\_rules = (O_{R1}, O_{R2}, \ldots, O_{Ri}, \ldots, O_{R7^m})$

The allele value at each location in the second part of particle contains either zero or the label of an output linguistic value to be used for a given rule. In other words, if O_{Ri} represents the allele at position *i*, its nonzero value gives the consequent part (i.e., the label of the corresponding fuzzy set on the output variable) of the rule which corresponds to the i^{th} location of the rules particle. A particle containing a zero allele value at the i^{th} position (i.e., R_i=0) indicates that the rule set represented by the rule particle has not selected any rule with the i^{th} antecedent clause.

As mentioned before, maximum number of fuzzy rules is 7^m. So in each rule_par, when the number of fuzzy rules is less than 7^m, other elements are considered to be zero. A simple example is considered which has 2 input variables. Both of variables have 3 linguistic terms (named Lt1, Lt, Lt3). So the maximum of fuzzy rules is nine.

All fuzzy rules are as follows:

Rule1: *If* $input_1$ is Lt_1 *and* $input_2$ is Lt_1 *Then* output is O_{R1}
Rule2: *If* $input_1$ is Lt_1 *and* $input_2$ is Lt_2 *Then* output is O_{R2}
Rule3: *If* $input_1$ is Lt_1 *and* $input_2$ is Lt_3 *Then* output is O_{R3}
Rule4: *If* $input_1$ is Lt_2 *and* $input_2$ is Lt_1 *Then* output is O_{R4}
Rule5: *If* $input_1$ is Lt_2 *and* $input_2$ is Lt_2 *Then* output is O_{R5}
Rule6: *If* $input_1$ is Lt_2 *and* $input_2$ is Lt_3 *Then* output is O_{R6}
Rule7: *If* $input_1$ is Lt_3 *and* $input_2$ is Lt_1 *Then* output is O_{R7}
Rule8: *If* $input_1$ is Lt_3 *and* $input_2$ is Lt_2 *Then* output is O_{R8}
Rule9: *If* $input_1$ is Lt_3 *and* $input_2$ is Lt_3 *Then* output is O_{R9}

Since the number of linguistic terms of output variable is 5, then $O_{Ri} \in \{0, 1, 2, 3, 4, 5\}$. Suppose linguistic terms of output variable are {*very bad*, *bad*, *medium*, *good* and *very good*}, therefore, the allele value is 0 when the corresponding rule hasn't been selected as a fuzzy rule, 1 when output variable is *very bad*, 2 when it is *bad*, and so on.

The optimized *par_rules* is obtained by PSO algorithm as follows:

par_rules =(0, 1, 2, 0, 3, 0, 0, 3, 5, 0, … , 0)

where first nine values are related to fuzzy rules. By considering the optimized *par_rules* , We have five rules: Rule2, Rule3, Rule5, Rule8 and Rule9. So optimized fuzzy rules are:

If $input_1$ is Lt_1 *and* $input_2$ is Lt_2 *Then* output is *very bad*
If $input_1$ is Lt_1 *and* $input_2$ is Lt_3 *Then* output is *bad*
If $input_1$ is Lt_2 *and* $input_2$ is Lt_2 *Then* output is *medium*
If $input_1$ is Lt_3 *and* $input_2$ is Lt_2 *Then* output is *medium*
If $input_1$ is Lt_3 *and* $input_2$ is Lt_3 *Then* output is *very good*

b) The fitness function

In the fitness function, we need to use some valid fuzzy rules. In order to generate valid fuzzy rules, we select the worse (value=0) and the best (value=1) state (verbal value) of each input variable. The linguistic terms of them are *very bad* and *very good* respectively. For the middle state (*medium*), value of 0.5 is assigned. If the input variable is defined by 5 linguistic terms, the state between the worse

ISBN: 978-989-95079-6-8

and middle state (*bad*) is set to 0.25 and the state between the best and middle (*good*) is set to 0.75. Also the center of gravity defuzzifier is applied as follows:

$$z^* = \frac{\sum_{i=1}^{m} z_i \times w_i}{\sum_{i=1}^{m} w_i} \quad (12)$$

where z_i *and* w_i are the value and weight (section 2-1-1, eq.11) of i^{th} input variable respectively. All of the rules where z^* gets one of values 0, 0.25, 0.5, 0.75 and 1, corresponding to linguistic terms of input variables, are considered as valid rules.

For example if linguistic term of traffic, road quality, sign, moving obstacle and safety are considered to be medium, then values of all of them is 0.5. Then by considering appropriate weight for each input variable (section 2-1-1, eq.11), z^* will be obtained as follows:

$$z^* = \frac{0.5\times0.21+0.5\times0.13+0.5\times0.11+0.5\times0.21+0.5\times0.34}{0.21+0.13+0.11+0.21+0.34} = 0.5$$

The obtained value is corresponding to *medium* linguistic term for z^*. By this way the following valid rule is obtained:

Rule: If Traffic is medium *and* Road quality is medium *and* Sign is medium *and* Moving obstacle is medium *and* Safety is medium *Then* Road condition is medium

Finally the fitness function used for the optimization of the membership functions is defined by:

$$\text{Fitness} = W_b \times n_c + \frac{W_r}{n_R} \quad (13)$$

Where n_R is the number of rules and W_r is its weighting factor, n_c is the number of input data set which have same output for valid fuzzy rules and the rules generated by PSO and W_r is its weighting factor.

2-2) Driver behavior

The personality (individuality) of each person is very important in the task performance. Because it affects on driver's decisions and acts. We consider drivers personality into three groups, risky person, normal person and attentive person. Also, the people have different reactions in different ages. So we include age of driver in modeling of driver's behavior. In addition, the precision of each person affect on calculating of distance. So we include it by considering graduating diploma and the measure of necessary precision in his work. Figure 2 shows the hierarchical fuzzy system which models driver behavior in decision making. For obtaining fuzzy rules in hierarchical fuzzy system, we use the applied method to generating valid rules in PSO algorithm. In proposed model, only by applying one coefficient in the universes of speed change and steering angle change also the ideal low and high speed for each person, we can easily model the different behavior under take over conditions.

3 High Level Control

3-1) Structure of road and existence cars

Two lanes road is considered as the movement trajectory of cars. In the simulation, four cars are considered (Figure 3). The *A* car is the car which we intend to control it by fuzzy rules, it is called *Controlled car*. The *B* car is the back car which intends to pass *Controlled car* and it is called *BEDOL*. The *C* car is the front car which moves in opposite lane. If *C* car moves in the same direction as *Controlled car,* then it is called *FEDOL* and if direction of movement is in opposite direction then it is called *FODOL*. The *D* car is the front car which moves in the same lane of *Controlled car*. If *D* car moves in the same direction as controlled car then it is called *FEDEL* and if it is in opposite direction then it is called *FODEL*.

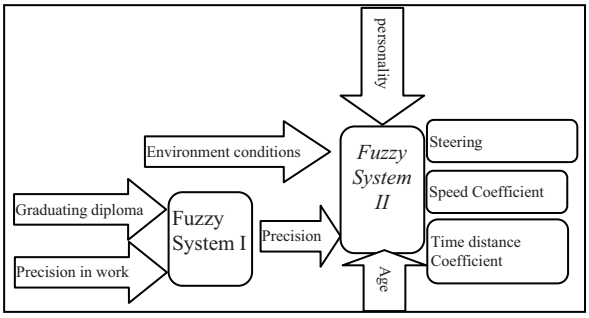

Figure 2. The driver's behavior hierarchy fuzzy system

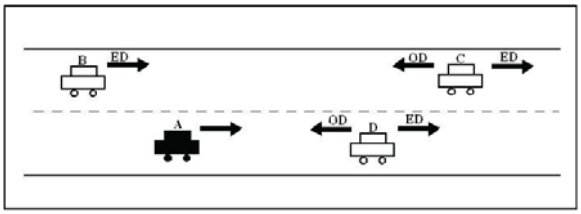

Figure 3. The movement trajectory of cars

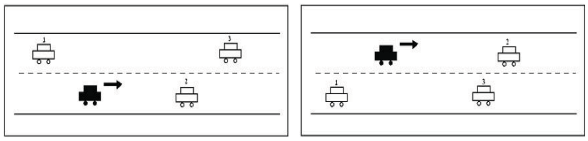
3-2) Effective cars in the decision making of driver

When a person drives a car on the road, movements of other cars affect his/her decision making. For example, *FODEL* car is more important than *FEDEL* car and *FODOL* is more important than *FEDOL* car. When driver decides to pass *FEDEL* car, location of *BEDOL* and *FODOL* is very important. The three important cars in decision making of driver are shown in Figure 4.



(a) Controlled car is on the right lane

(b) Controlled car is on the left lane

Figure 4. The situations of important cars

3-3) Decision making process

By considering three positions, the speed and direction of car and the steering angle, the fuzzy variables for steering angle and speed control are presented as follows:

Td_{BOL}: (input variable) time distance of *Controlled car* with the back car in other lane, moving in the same direction.

Td_{FEL}: (input variable) Time distance with the front car, moving in the same lane

ISBN: 978-989-95079-6-8

Td_{FOL} : (input variable) Time distance with the car moving in opposite lane
V: (input variable) Speed of *Controlled car*
Dir: (input variable) *Controlled car*'s direction
Δv : (output variable) Change of speed
$\Delta\varphi$: (output variable) Direction change of steering.

Each of the input variables, Td_{BOL} , Td_{FEL} and Td_{FOL} has four linguistic values or fuzzy sets: The speed has three fuzzy sets. The car direction and the steering angle direction have seven fuzzy sets. Each of output variables is defined by using seven linguistic variables. We define a vector for Td_{BOL} , Td_{FEL} and Td_{FOL} separately. First element of each time distance vector represents the minimum time distance for collision with corresponding car. It is called very low. The second element is the lowest value of the middle time with corresponding car. We call it medium time. The last element is the lowest value as the highest time with corresponding car which is called high time. The above time distance vectors are defined for a *normal driver* who drives according to driving laws. But for modeling different behaviors of driver, we use the time distance coefficient which is obtained by hierarchical fuzzy system. The time distance coefficient is called *K_TD*. The purposed time distance vectors for different drivers are shown in table 2.
In table 2 we have

$$b=\begin{cases}(\sqrt{k\_TD})^{-1}, & K\_TD\geq 1\\ \sqrt{k\_TD}, & K\_TD<1\end{cases}$$

$$Td_{FEL}=\begin{cases}Td_{FEDEL}, & \text{if } FEDEL \text{ exict}\\ Td_{FODEL}, & \text{oherwise}\end{cases}$$

$$Td_{FOL}=\begin{cases}Td_{FEDOL}, & \text{if } FEDOL \text{ exict}\\ Td_{FODOL}, & \text{oherwise}\end{cases}$$

Table 2: Time distance vector for different drivers

Left Lane:	Right Lane:
Td_{BOL}=*K_TD**[0.5/b 2/b 7]	Td_{BOL}=*K_TD**[3 10 15]
Td_{FEDEL}=*K_TD**[1 3 5]	Td_{FEDEL}=*K_TD**[4/b 8/b 12]
Td_{FEDOL}=*K_TD**[3 5 8]	Td_{FEDOL}=*K_TD**[1 3 7]
Td_{FODEL}=*K_TD**[2 4 6]	Td_{FODEL}=*K_TD**[4 7 20]
Td_{FODOL}=*K_TD**[3 7 20]	Td_{FODOL}=*K_TD**[3 7 15]

3-3-1) Road partitions in decision making of driver
Drivers drive in different positions of road. When a driver intends to pass the leading car, he/she moves toward the middle of road while in low speed and dangerous conditions, the car moves toward the shoulder of road. So in decision making, we divide the road to four divisions: Left lane, Middle Lane, Right lane and Shoulder of lane. Among four decision lanes, the middle of lane and the shoulder of road lane are the transient lanes. A driver is driving in the right lane and only when he/she is passing the leading car, he/she drives in the left lane.

3-3-2) Fuzzy rule base for decision making of driver
The decision making process is categorized into four scenarios:
1. Right lane
- Staying in the same lane and continuing the path

a) No car is in front. The car continues its path.
b) A car is in front and the time distance with it is low, the driver starts to make a decision based on his/her desired speed, safety priorities but *FODOL* car is near or there is *BEDOL* car, then the driver decreases the car's speed and continues the path.

- Going to the shoulder of road

A car is in front and the time distance with it is very low; but *FODOL* car is near and *BEDOL* car is near. So the takeover from the left lane is impossible. In order to avoid collision, the driver must move the car to the shoulder of road.

- Going to the middle lane to passing

When the driver decides to change lane and perform a takeover from the left lane. So he/she moves the car to the middle lane.
2. Middle lane
As mentioned before, this lane is a transient lane. If the takeover conditions are satisfied, the driver increases the speed and continues with the same direction to enter the left lane. Otherwise he/she decides to stay in middle lane or to return to right lane.
After taking over, driver with the same speed from this lane enters to right lane
3. Left lane
- Before taking over

If the takeover conditions are satisfied, the driver continues the path with high speed. Otherwise he/she goes to middle lane and decides to stay there until the takeover conditions are provided or he/she returns to right lane.

- After taking over

The driver with the same speed from this lane goes to middle lane in order to go to the right lane.
4. Shoulder of road lane
As mentioned before, a driver in order to avoid collision goes to this lane. So he/she must stay in this lane until he/she could return.

4 Results

The obtained weights of each of environmental parameters from eq. (11) are summarized in Table 3. This table shows that among climate parameters, view field is the most important parameter. Safety is the most important among the road parameters and safety equipment operation is the most important among the car parameters.

Table 3: The weights of environmental parameters in fuzzy rules

Climate parameter	*W*	Road parameter	*W*	Car parameter	*W*
View	0.37	Traff.	0.21	Eq.o.	0.47
Lum.	0.297	R.q.	0.13		
Rain	0.178	Sign	0.11	Er.	0.25
Temp.	0.098	M.obs	0.21	Dis.a.	0.28
Hum.	0.057	Safety	0.34		

ISBN: 978-989-95079-6-8

The obtained optimum number of fuzzy sets for environmental parameters input variables by PSO algorithm is shown in Table 4. The number of fuzzy sets of output variables (climate, road and car condition) is fixed and is equal to 5 sets.

Table 4. The optimum number of fuzzy sets for environmental parameters

Climate parameter	number	Road parameter	number	Car parameter	number
View	5	Traff.	3	Eq.o.	5
Lum.	3	R.q.	5		
Rain	5	Sign	3	Er.	5
Temp.	3	M.obs.	5	Dis.a.	5

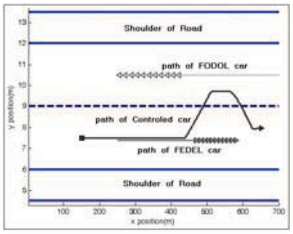
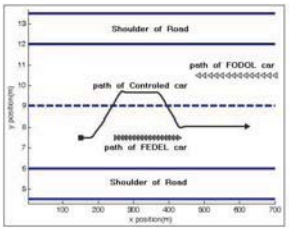
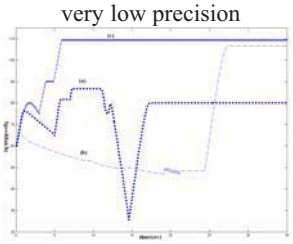
(a) Normal driver



(b) Attentive old driver with very low precision



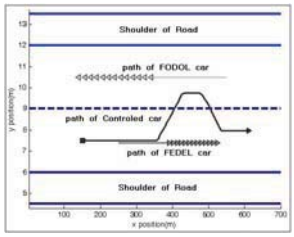
(c) Attentive old driver with very high precision



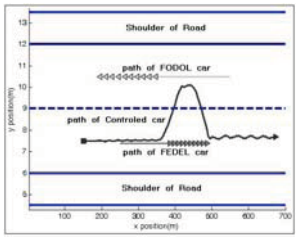
(d) Car's speed by (a), (b), (c) drivers

Figure 5: Comparison of different drivers in the same conditions

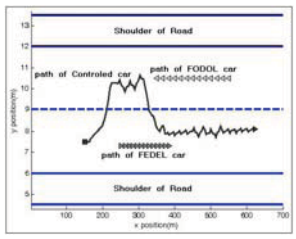
We investigate the behavior of different drivers under take over condition. The comparison of behavior of three drivers under equal passing conditions and the best environmental conditions is shown in Figures 5 and 6. As it is seen in Figure 5, *normal driver* and attentive old driver with very high precision pass the leading car. But attentive old driver with very low precision waits until the *FODOL* passes and then he/she passes the leading car. The paths of cars before passing are shown by solid lines. The very low precision person's error is higher than the very high precision person in calculating distance with other car. Because of being attentive, the driver waits for passing the leading car to collision avoidance. The car's speed of each driver shows the driver's behavior and decision under equal conditions. The *normal driver* is decided to passing and increases the speed. The movement of car is smooth. The old person with very high precision has more steering direction change because he/she is attentive and old and needs more time of passing than normal driver. The old person with very low precision is late in decision making and waits. After that he/she is passing the leading car and returns the right lane as soon as because of being attentive. Figure 6 compares a *normal driver* with a young driver. In equal conditions, the risky young driver passes the leading car. But the attentive young driver and normal driver waits until the *FODOL* car is passed. The speeds of cars are shown in figure (11- d). The results are obtained in good mental status.



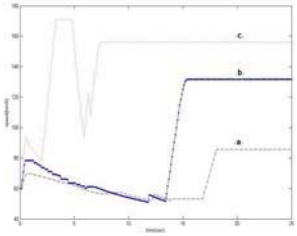
(a) Normal driver



(b) Attentive young driver with very low precision



(c) Risky young driver with very low precision



(d) Car's speed by (a), (b), (c) drivers

Figure 6: The comparison of different driving behavior in equal conditions

5 Conclusion

In this paper a fuzzy three positions model has been presented for the low-level control model and a fuzzy hierarchical system have been proposed for the high-level Control Model. The obtained results show that in equal conditions an attentive old driver with very high precision passes the leading car, but attentive old driver with very low precision waits until *FODOL* car passes and then he/she passes the leading car. The very low precision person's error is higher than that of the very high precision person in calculating distance with other car. This method also provides a basis for modeling individual driver behavior characteristics that may be tuned and used in automatically guided vehicles. It also provides a reference of natural driver behavior of each individual.

Abstract—This paper uses a Fuzzy Expert System (FES) in order to evaluate firms in terms of Gender Equity (GE). The scope for using FES is connected not only to the multidimensional nature of GE and to the need of providing a synthetic indicator of firm's GE without losing the its complexity, but even with the composite group of experts involved. The presence of sociologists, economists trade unions members, not used to a mathematics language, carried us to propose an instrument more user friendly like a FES.

Keywords— Fuzzy logic, Fuzzy expert system, gender equity, equal opportunity, discrimination.

1 Introduction

The Italian labour market shows remarkable gender inequalities notwithstanding the advanced labour market regulation in terms of Equal Opportunities. Italian women still experience many inequalities at their workplaces such as: wage differences, lower career paths, higher percentages of fixed-term and short-term contracts, etc. Women's employment rate on average in Italy was 46.6% in year 2007 (Istat, Labour Force Survey data) far below the 60% Lisbon target and far below men's employment rate (70.7%) Inequalities at the workplace are reinforced by and interact with the unequal distribution of unpaid work at home (care and domestic work). Italian women bear a higher share of unpaid work than their partners and when they enter the labour market this is going to produce an unequal share of total (paid and unpaid) work. [3],[10]. Though the Italian situation in terms of gender equity and access to paid labour is particularly weak gender segregation in employment is a feature that characterizes EU27 on average as the results by Burchell, Fagan, O'Brien and Smith [6], based on the European Foundation for the Improvement of living and working conditions 2005 Survey shows. The problem of firms' evaluation with regards to gender equity has been differently tackled across Europe in connection also to the different level of enforcement of equal opportunity laws and a different level of integration of gender equality policies in employment policies [5]. In order to improve women employment rates and to reduce the existing gender gaps in the workplaces the former Italian Ministry of Labour promoted the project "Bollino Rosa" together with Isfol (Istituto per la Formazione Professionale dei Lavoratori). The project started in June 2007 in the framework of the European Year of Equal Opportunities for All and has been co-financed by the European Commission. The test was carried out from November 2007 until February 2008. This study presents the fuzzy expert system (Section 2.1-3) proposed within the Bollino Rosa project and applied to a sample (section 2.4) of firms. Section 3 comments on the results of the application of the system to firms involved in the project while section 4 contains concluding remarks and proposals for the extension of the project.

2 A fuzzy expert system for evaluation

2.1 Why a fuzzy expert system

To face this complex problem and to reach an aggregated value of the certification level, we propose a Fuzzy Expert System (FES), which utilizes fuzzy sets and fuzzy logic to overcome some of the problems that occur when the data provided by the user are vague or incomplete.

This is not the natural framework of a FES, in fact engineering problems are more typical for FES, but recently economic and management researches have found in this instrument interesting applications, [2], [4], [7], [8], [9], [15]. In a multidisciplinary research, like the one we present, the power of FES shows its ability to describe linguistically a particular phenomenon or process, and then to represent that description with a small number of very flexible rules. In a FES, the knowledge is contained both in its rules and in fuzzy sets, which hold general description of the properties of the phenomenon under consideration. FES provides all possible solutions whose truth is above a certain threshold, and the user or the application program can then choose the appropriate solution depending on the particular situation. This fact adds flexibility to the system and makes it more powerful. FES uses fuzzy data, fuzzy rules, and fuzzy inference, in addition to the standard ones implemented in the ordinary Expert Systems. From the mathematical point of view a fuzzy system can be described as a function approximator. [16] More specifically it aims at performing an approximate implementation of an unknown mapping $f : A \subseteq R^n \to R^m$ where A is a compact of R^n. By means of

ISBN: 978-989-95079-6-8

variable knowledge relevant to the unknown mapping, it is possible to prove that that fuzzy systems are dense in the space of continuous functions on a compact domain and so can approximate arbitrarily well any continuous function on a compact domain. The following are the main phases of a FES design ([11], [17]):

- Identification of the problem and choice of the type of FES, which best suits the problem requirement. A modular system can be designed. It consists of several fuzzy modules linked together. A modular approach may greatly simplify the design of the whole system, dramatically reducing its complexity and making it more comprehensible. Fixed input and output variables, it is necessary to describe their linguistic attributes (fuzzy values) and their membership function (fuzzification of input and output);
- definition of the set of heuristic fuzzy rules. (IF-THEN rules);
- choice of the fuzzy inference method (selection of aggregation operators for precondition and conclusion);
- translation of the fuzzy output in a crisp value (defuzzification methods);
- test of the fuzzy system prototype, drawing of the goal function between input and output fuzzy variables, change of membership functions and fuzzy rules if necessary, tuning of the fuzzy system, validation of results.

2.2 System structure

The structure of the Fuzzy Expert System (FES) we present is very complex and contains sixty initial inputs. We try in the space we have to explain how it is born. Preparing the questionnaire, the economics and sociology experts fix the macro-indicators that produce the final evaluation called "certification". The two are "Gender Equity"(GE) and "Gender SusTainability" (GT). The two are macro-aggregations may be split in other sub macro-indicators: GE sums up two: Equity in the Firm (EF) and Equal Opportunity (EO). They include information on what firm makes to treat woman at the same level of man in the policy of entrance, haw firm respects welfare laws and so on. The EF intermediate variable, we present in detail, contains information on the firm's gender fairness in terms of wages and career opportunities. Firms are assessed with respect to employment equity (measured by horizontal segregation in terms of area or type of job), equity in earnings (measured by the gender wage gap and the share of women and men in top positions as a gross index of vertical segregation) and the participation of women as trade unions representatives. The other macro-indicator GT contains several types of information: how firm takes into account work life balance policy (WLB) that is how the way working time is scheduled and its balance with other use of time related to the family. The Human Resource Management (HRM) variables contain information on firm's recruitment methods for entrance into work and on employees leaving or being fired by the firm. The third Safety (S) produces information on security policies that the firm adopts and on the awareness of gender specific health risks at work. Due to limits of space we are going to present more in depth the "Equity in the Firm (EF)". Women tend to be severely underrepresented in Italy in apical positions [13], [14] and their low presence in apical positions in the firm is considered in this system as a negative element in firm's assessment with regards to gender equity both because:

1) it can lead to a higher wage gap at the disadvantage of women;

2) it can be a sign of employment discrimination by gender; 3) it can be a signal of an environment not favourable to women progression of career;

4) it can be a sign of a human resources evaluation system that rewards less women's competences than men's.

The wage gap has been computed by the ratio of women total cost of labour to men's. This is a gross measure of wage gap that, in further research, can be computed as a net wage gap by taking into account employee's characteristics (like work experience, tenure, education, hours of work). We have then considered the bargaining power of women inside the firm by computing how many women are representatives in trade unions with respect to women employed in the firm. An underrepresentation of women in unions representatives contributes to decrease the value of the final outcome since we deem that their voice cannot be enough listened in bargaining on job conditions if they are underrepresented amongst employees representatives. Equal opportunity, EO, takes into account the existence of agreements with unions and public institutions in terms of equal opportunities (the highest mark has been given to enacted agreements and the lowest if there are no agreements and the firm does not

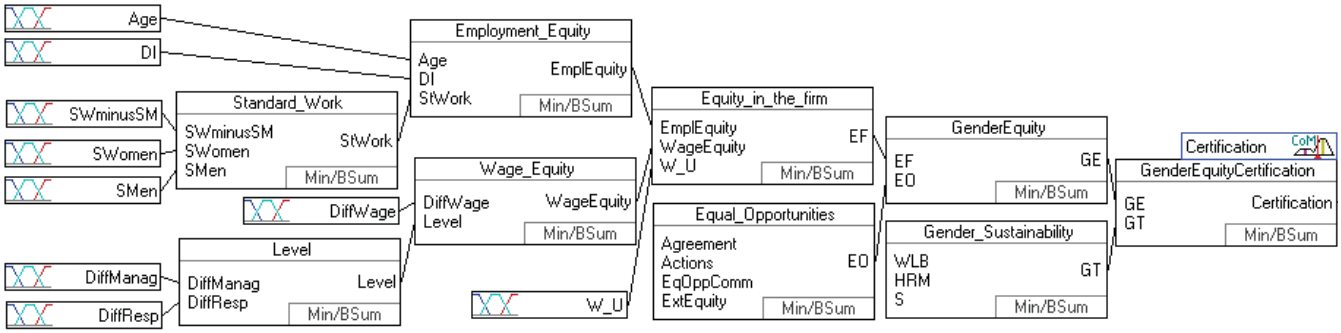

Figure 1: Reduced system layout

ISBN: 978-989-95079-6-8

intend to sign any in the future), of affirmative actions, of incentives to hire women,of the use of Italian Law 53/2000- that contains measures to increase work life balance in the firm - and equal opportunities and the presence of an Equal Opportunity Commission in the firm. We aim at improving the measurement of this last variable by collecting information on the type of activities performed by the Commission. This dimension contains also all strategies enacted by the firm to inform and make aware personnel about gender differences and all the actions that lead to an increase (in qualitative and quantitative terms) of women's participation in the firm. The equal opportunity dimension is also extended to include firm's awareness of the other firms of the network in which it operates.

2.3 Reduced system layout

We present the inputs involved in EF macro-indicator and the sub-system in which the variable GE is split in the original inputs.

Age. Age

SWminusSM. Gender gap in standard employment inside the firm

DI. Dissimilarity index defined as $\frac{1}{2}\sum_i \left|\frac{w_i}{w} - \frac{m_i}{m}\right|$ where m_i and w_i are the numbers of men and women in the i-th area.

SWomen. Women in standard jobs

SMen. Men in standard jobs

DiffMang. Gender gap in managerial position

DiffResp. Gender gap in high responsibility white-collar positions

DiffWage. Gender wage gap

W_U. Women share in union's representatives

Intermediate variables:

EmplEquity. Employment equity

EF. Equity in the firm

EO. Equal opportunities

GE. Gender equity

GT. Gender Sustainability

HRM. Human resources management

Level. Level in the job ladder as percentage of women in apical positions

S. Safety

StWork. Standard work

WageEquity. Wage equity

WLB. Work Life Balance

Now we present the fuzzyfied input variable DiffWage and a rule block in which this variable is involved. DiffWage measures the gross wage gap in the firm as the ratio of women's average labour cost with respect to men's. As it is possible to see, this variable enters directly at the second step and is aggregated with the intermediate variable Level. Level measures the share of women in apical positions with respect to men and can be considered as a measure of vertical segregation against women. Wage equity is then evaluated with respect to both variables to evaluate current wage gap and a cause of wage gap at disadvantage of women. All the cut points that define the fuzzifcation and the rules have been discussed in depth inside the research group where also the researchers who interviewed firm's representatives were involved.

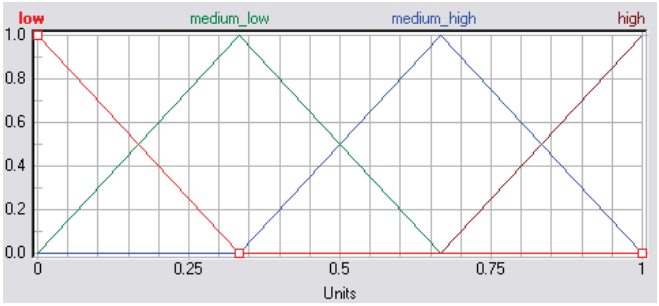

Figure 2: **DiffWage** variable layout

This research step can be deemed very important both in order to state the rules that are at the basis of evaluation in FES and in order to detect problems in the evaluation process and in the tools that have been used.

The following Rule Table is referred to Wage Equity: this intermediate variable is built with the input DiffWage and the intermediate variable Level.

Table 1: rule table of **WageEquity**

#	DiffRetrib	Level	WageEquity
1	low v medium_low	low	very_low
2	low	medium_low	very_low
3	low	medium	low
4	low	medium_high	medium_low
5	low	high	medium_high
6	medium_low	medium_low	low
7	medium_low	medium	medium_low
8	medium_low	medium_high	medium_high
9	medium_low v medium_high	high	high
10	medium_high	low	low
11	medium_high	medium_low	medium_low
12	medium_high	medium	medium_high
13	medium_high	medium_high	high
14	high	low	medium_low
15	high	medium_low	medium_high
16	high	medium	high
17	high	medium_high	very_high

The experts decided that if women's wage cost with respect to men's is low or medium and women's share in managerial and high responsibility white-collar positions are low the wage equity dimension assumes value 'very low'. The experts have suggested this rule that combines wage differentials and gender inequalities in access to apical positions since though the existence of a wage gap at the disadvantage of women can be related to vertical employment segregation one can observe wage differentials also in the same job position. Moreover the measure of the wage gap obtained from the sample of firms, given the structure of the questionnaire, is a gross wage gap (not corrected for employee's level of education or work experience). Inequalities in the access to apical positions can be considered as a proxy of vertical employment segregation by gender to which the experts' group assigns a high weigh in affecting firms' gender equity. This rule block shows that there is a function $f(DiffWage, Level): R^2 \rightarrow R$ increasing

ISBN: 978-989-95079-6-8

in all the two variables but they are weighted in a different way. Looking at rules 5 and 14 we have that: 5) *f(Low, High)→ medium_high;14) f(High, Low)→ medium_low* . This table translates in a simple way what the experts consider correct. This way to translate the experts' position is simpler than asking them numerical weights for the single variables and what type of function better represents their idea.

2.4 The sample of firms to which the system has been applied

The system introduced in this Section has been applied to the gender evaluation of 34 private firms of different size belonging to the different productive sectors that have been selected by the Italian Ministry of Labour through a public call. The sample was formed by: 14 joint-stock companies, 2 Ltds, 3 cooperatives Ltd, 10 social cooperatives and 5 others form of enterprise. According to the number of employees those firms can be classified as follows: 1 micro-enterprise (<10 employees), 12 small and medium enterprises (>10 employees <250), 21 big enterprises of which 4 employ more than 30.000 employees. 21 firms have got a turnover of max 50 millions euro (SMEs) while 5 companies exceed a turnover of 1 billion euro per year. Concerning the economic sectors, 17 firms belong to the service industry (research and training, welfare services, company services), 5 are utility companies (telecommunications and public transports), 3 of them belong to the pharmaceuticals industry, 3 to the retail trade, 1 is an energy producing industry and 1 is a bank. The last 4 firms of the sample belong to other sectors like: edutainment, food production and airport management. The selected firms filled in the self-assessment questionnaires and the sociologists conducted in-depth interviews to the relevant union representatives. The system has been presented and discussed inside a group of experts to whom the results of evaluation has also been submitted to validate the fuzzy outcome.

3 Results

We can start by observing that none of the 34 firms that applied to be evaluated and were selected in the Bollino Rosa project obtained a high result in terms of "Certification value", the final output of the FES presented in the previous section. The firm at the top position in terms reached a final evaluation of 0.68 against the maximum of 1 (Table 2) and the firm at the bottom has a value of 0.25, with 9 firms out of 34 with a value for the final outcome of the system lower than 0.40 (Table 3).At this stage of the project we cannot analyse in depth the situation of each firm in the sample and, for privacy reasons, we cannot provide more details about the firms involved in this experimental phase of the project. In the two tables we call them Ai and Ci if the firm is "not corporate" or "corporate" respectively. Table 2 shows the value of the intermediate and input variables of the first ten firms (in terms of the value of the final output of the system that we call certification) and Table 3 shows the last 10 firms. The tables show how similar output values can be derived by different situation in terms of the dimensions of gendered equity condensed in our intermediate variables. For instance the corporate firm C08 that performs as the not corporate firm A01 In terms of the final value of the FES output (0.62) shows a higher evaluation in terms of gender equity (GE=0.57) than in terms of gender sustainability (GT=0.65), whereas firm A01 performs better in terms of gender sustainability (GT=0.71) than in terms of gender equity (GE=0.53). The same result in terms of certification can therefore mean different outcomes in terms of policies suggestions to the firm in order to improve its 'Bollino Rosa' outcome. A further investigation on the reasons of a lower evaluation of firm A01 in terms of gender equity with respect to firm C08 reveals that this is connected to the high degree of vertical segregation in the firm (with no woman in apical positions) whereas the presence of women in apical position in firm C08 though lower (0.32) is higher than in firm A01. On the other hand both perform rather well in terms of gross wage gap.

Turning to the last ten firms in terms of the final assessment of gender certification, we can see that the bottom one performs very poorly both in terms of wage equity (0.00) and in terms of the equal opportunities (0.20) and gender sustainability (0.33) dimensions while it scores better (0.575) in terms of employment equity denoting a more equal presence of women and men in the areas of the firm and with regards to the type of contract. This firm is very far from a sufficient level and has to work a lot in all the dimensions to

ISBN: 978-989-95079-6-8

be certified as a 'Bollino Rosa' Firm.
The results shown in the previous section can be considered as a step in the whole process of certification that can use FES tools for assessing firms and addressing specific policies for each firm to reach a final assessment. The results of Fuzzy evaluation will be transmitted to the firms and commented upon by the relevant expert/auditor. According to the results obtained each firm will introduce the needed changes for correcting the gender discriminations. At the end of the evaluation path and only when the organizational situation within the firm will be improved, it will receive a Label that will identify it as a "Bollino Rosa firm", i.e. a gender friendly workplace in terms of equity and sustainability. The process towards certification of gender equity and sustainability involves also an assessment of the steps towards a higher values in the critical dimensions by means of the FES application to evaluate the changes occurred over time. Firms can therefore assess their level of 'Bollino Rosa' connected to the strategies enacted to improve its value.

4 Pursuing in the process of certification

The results shown in the previous section can be considered as a step in the whole process of certification that can use FES tools for assessing firms and addressing specific policies for each firm to reach a final assessment. The results of Fuzzy evaluation will be transmitted to the firms and commented upon by the relevant expert/auditor. According to the results obtained each firm will introduce the needed changes for correcting the gender discriminations. At the end of the evaluation path and only when the organizational situation within the firm will be improved, it will receive a Label that will identify it as a "Bollino Rosa firm", i.e. a gender friendly workplace in terms of equity and sustainability. The process towards certification of gender equity and sustainability involves also an assessment of the steps towards a higher values in the critical dimensions by means of the FES application to evaluate the changes occurred over time. Firms can therefore assess their level of 'Bollino Rosa' connected to the strategies enacted to improve its value. Further research involve considering how the level of gender equity and sustainability in the firm relates to the socioeconomic environment the firm is inserted in. As shown in the following chart the firm operates in connection to local, national government and European Commission that can set rules or adopt policies that are going to affect the firm's situation with regard to Gender Equity or Gender Sustainability. For instance the National Law 53/00 introduces the possibility for firms to receive funds dedicated to the implementation of family friendly policies that can improve gender sustainability in the firm. On the other hand the firm can supply childcare services for their employees but open to other families that can improve gender sustainability of employment in the area. Equal Opportunity Counsellor can take an action to remove discrimination in the firm. The firms that are suppliers or clients can be characterized by a different degree of gender equity and the workers in the firm are going to be affected by the equality or gender sustainability policies of the firm. Trade unions at local or at national level can bargain over working hours schedule to obtain a working time more that balances more with private and family life. The network of relations amongst private and public agents leading to the obtained results can itself be evaluated calling for an extension of the evaluation process to subcontractors, suppliers, clients. The system now includes firms' evaluation on the situation of clients and suppliers with regards to gender equity and this awareness is accounted for as a part of the gender equity dimension. However to have a more precise information on the interactions amongst firms in a gender perspective the whole network of firms should be reconstructed and subject to the evaluation process. Italy is characterized by a highly segmented labour market (by area and type of occupation) and by a different level of diffusion of public care services that can have an impact on gender equity and sustainability of work. Local labour market and institutional variables can be inserted to provide a comparative analysis upon different areas in Italy producing a more complex indicator of gender equity that can be inserted in the evaluation of gender human development.

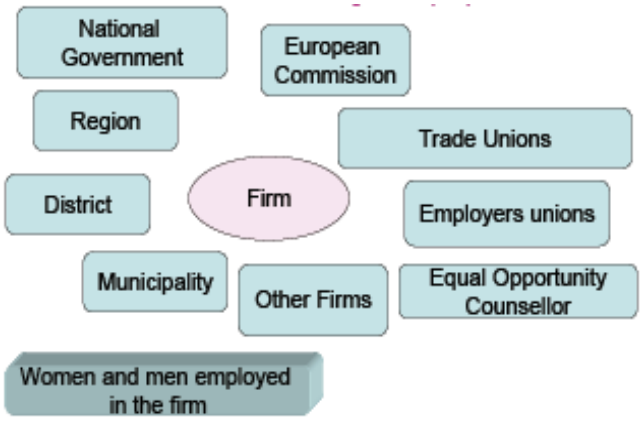

Figure 3: Toward firm's evaluation in a gendered perspective

5 Conclusions

The process of firm's evaluation in terms of gender equity pursued by the project 'Bollino Rosa' promoted by the Italian Ministry of Labour in year 2007 requires collecting and analysing indicators on different dimensions of gender equity. To provide a synthetic indicator on the firm's situation without loosing the complexity of the different dimensions of gender equity we have modelled and applied a Fuzzy Expert System. To our knowledge this is the first attempt of using Fuzzy Expert System to assess firms with respect to gender equity and gender sustainability, though broader issue of the gender perspective in the evaluation of quality of work using fuzzy expert system has been considered in [8]. Other experiences carried out in European countries implies self-evaluation like Total Equity Prize in Germany) or evaluation on the basis of the policies enacted by the firms in terms of equal opportunities, on their human resources management and on the presence of work life balance policies (like Label Egalité in France) however they do not use a system of evaluation structured as the one used

ISBN: 978-989-95079-6-8

in this application [5]. The micro data used have been collected through a structured questionnaire submitted to a sample of firms in the Private Sector that have proposed themselves by answering to a public competition on participation to the experiment, further extension to the public sector and a calibration of the questionnaire should follow its experimental phase. In this line we plan to let firms construct measures of net gender wage gap (by connecting wages to employees' individual characteristics on their work experience and education) that can improve the system of gender equity evaluation (currently based on gross wage gap). With respect to other systems of evaluation the proposed method entails an analytical model of evaluation that confers numerical indicators useful for the firm to assess its position as far as gender equity and sustainability are concerned allowing a backward process to detect causes of poor grades in terms of gender certification. Another advantage of the system is the transparency of the evaluation system reached by a clear statement of input variables and the rules used by the experts. Sometimes the transparency is not an advantage especially in situations in which politics is involved, but we think that a clear and transparent method is better than others in which the choices are expressed in "obscure" words in order to hide real choices from people involved. Public institutions and government can use the results of this model in terms of gender certification of firms to take policy decisions. They can also infer by comparative analyses on different areas how different policies and agreement carried out also at local level may interact with the gender assessment of firms in that area. Policies to consider firms' gender certification in gender equity and sustainability can also be used as an indicator for the assessment of firms when public institutions or firms contract out part of their production. This approach, more typical of engineering problems, finds here an interesting multi-disciplinary application. A very heterogeneous research unit containing mathematics, economics, sociology, political and trade union experts have faced this application. The fuzzy approach has given us all the possibility to work together, to have a common language. This language is due to the linguistic attributes of the variables, the rules given in a verbal way and the final interpretation of the results

Abstract— *Morphisms of some categories of sets with similarity relations (Ω-sets) are investigated, where Ω is a complete residuated lattice. Namely a category $\mathbf{SetF}(\Omega)$ with morphisms $(A,\delta)\to(B,\gamma)$ defined as special maps $A\to B$ and a category $\mathbf{SetR}(\Omega)$ with morphisms defined as a special relations $A\times B\to\Omega$. It is proved that arbitrary maps $A\to\Omega$ and $A\times B\to\Omega$ can be extended onto morphisms $(A,\delta)\to(\Omega,\leftrightarrow)$ in $\mathbf{SetF}(\Omega)$ and morphisms $(A,\delta)\to(B,\gamma)$ in $\mathbf{SetR}(\Omega)$, respectively and that these extension processes are from categorical point of view special reflections. Moreover, if Ω is a complete Heyting algebra we also investigate morphisms in another category $\mathbf{Set}(\Omega)$ which consists of classical fuzzy sets $f:A\to\Omega$.*

Keywords— residuated lattice, Heyting algebra, similarity relations, fuzzy sets.

1 Introduction

In fuzzy set theory the category $\mathbf{SetF}(\Omega)$ of sets with similarity relations defined over a complete residuated lattice $\Omega=(\Omega,\to,\otimes,\vee,\wedge)$ is of principal importance ([5]-[10]). This category consists of objects (A,δ) (called Ω-sets), where A is a set and δ is a similarity relation, i.e. a map $\delta:A\times A\to\Omega$ such that

(a) $\delta(x,x)=1$,

(b) $\delta(x,y)=\delta(y,x)$,

(c) $\delta(x,y)\otimes(\delta(y,y)\to\delta(y,z))\le\delta(x,z)$.

A morphism $f:(A,\delta)\to(B,\gamma)$ in $\mathbf{SetF}(\Omega)$ is a map $f:A\to B$ such that $\gamma(f(x),f(y))\ge\delta(x,y)$ for all $x,y\in A$.

From historical point of view there is another category consisting of sets with similarity relations defined. This category $\mathbf{SetR}(\Omega)$ is an analogy of a category of sets with relations between sets as morphisms. Objects of this category $\mathbf{SetR}(\Omega)$ are the same as in the category $\mathbf{SetF}(\Omega)$ and morphism $f:(A,\delta)\to(B,\gamma)$ are maps $f:A\times B\to\Omega$ such that

(a) $(\forall x,z\in A)(\forall y\in B)\quad\delta(z,x)\otimes f(x,y)\le f(z,y)$,

(b) $(\forall x\in A)(\forall y,z\in B)\quad f(x,y)\otimes\gamma(y,z)\le f(x,z)$,

If $f:(A,\delta)\to(B,\gamma)$ and $g:(B,\gamma)\to(C,\omega)$ are two morphisms then their composition is a relation $g\circ f:A\times C\to\Omega$ such that

$$g\circ f(x,z)=\bigvee_{y\in B}(f(x,y)\otimes g(y,z)).$$

Finally we can consider a classical category $\mathbf{Set}(\Omega)$ of fuzzy sets over Ω with objects couples (A,f), where A is a set and f is a map $A\to\Omega$ and with morphisms $u:(A,f)\to(B,g)$ such that $u:A\to B$ is map and $f(a)\le g\circ u(a)$ for all $a\in A$.

With categories $\mathbf{SetF}(\Omega)$ and $\mathbf{SetR}(\Omega)$ we can consider new sets of objects:

(a) the set $\mathbf{Mor}(\mathbf{SetR}(\Omega))$ of all morphisms in $\mathbf{SetR}(\Omega)$,

(b) the set $\mathbf{Rel}(\mathbf{SetR}(\Omega))$ of all *weak morphisms* in $\mathbf{SetR}(\Omega)$, where $f:(A,\delta)\to(B,\gamma)$ is a weak morphism in $\mathbf{SetR}(\Omega)$ if $f:A\times B\to\Omega$ is an Ω-valued relation,

(c) the set $\mathbf{Map}(\mathbf{SetF}(\Omega))$ of all *weak fuzzy sets* in $\mathbf{SetF}(\Omega)$, where $f:(A,\delta)\to(\Omega,\leftrightarrow)$ is a weak fuzzy set in $\mathbf{SetF}(\Omega)$ if $f:A\to\Omega$ is a map and where $\leftrightarrow$ is a biresiduation in a lattice Ω.

(d) the set $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$ of all *fuzzy sets* in $\mathbf{SetF}(\Omega)$, i.e. morphisms $(A,\delta)\to(\Omega,\leftrightarrow)$ in the category $\mathbf{SetF}(\Omega)$, where (A,δ) is an Ω-set.

It is clear that we have

$$\mathbf{Mor}(\mathbf{SetR}(\Omega))\hookrightarrow\mathbf{Rel}(\mathbf{SetR}(\Omega)),$$
$$\mathbf{Fuz}(\mathbf{SetF}(\Omega))\hookrightarrow\mathbf{Map}(\mathbf{SetF}(\Omega)).$$

In this paper we want to consider some relationships between these sets. We show that new categories (denoted by the same symbols as the above sets) can be defined with the above sets as object sets. Then we will receive the following functor commutative diagram:

$$\begin{array}{ccc}\mathbf{Fuz}(\mathbf{SetF}(\Omega)) & \xrightarrow{\ \hookrightarrow\ } & \mathbf{Map}(\mathbf{SetF}(\Omega))\\ {\scriptstyle F}\downarrow & & \downarrow{\scriptstyle F}\\ \mathbf{Mor}(\mathbf{SetR}(\Omega)) & \xrightarrow{\ \hookrightarrow\ } & \mathbf{Rel}(\mathbf{SetR}(\Omega))\end{array}$$

Finally, we show that

(a) the category $\mathbf{Mor}(\mathbf{SetR}(\Omega))$ is a full reflective subcategory in the category $\mathbf{Rel}(\mathbf{SetR}(\Omega))$,

(b) the category $\mathbf{Map}(\mathbf{SetF}(\Omega))$ is a full reflective subcategory in the category $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$.

The reflections $f\to\tilde{f}$ and $g\to\widehat{g}$ of a weak morphism $f:(A,\delta)\to(B,\gamma)$ and a weak fuzzy set $g:(A,\delta)\to(\Omega,\leftrightarrow)$ can be then used for construction of a fuzzy logic formulas interpretation in corresponding categories $\mathbf{SetF}(\Omega)$ and $\mathbf{SetR}(\Omega)$.

ISBN: 978-989-95079-6-8

2 Categories of maps and relations

Let us firstly define two categories $\mathbf{Rel}(\mathbf{SetR}(\Omega))$ and $\mathbf{Mor}(\mathbf{SetR}(\Omega))$. Objects of the category $\mathbf{Rel}(\mathbf{SetR}(\Omega))$ are all weak morphisms from $\mathbf{SetR}(\Omega)$. A morphism from a weak morphism $f : (A,\delta) \to (B,\gamma)$ to a weak morphism $g : (C,\rho) \to (D,\omega)$ is a couple (u,v) of morphisms from the category $\mathbf{SetR}(\Omega)$ such that

(i) $u : (A,\delta) \to (C,\rho)$ is a morphism in $\mathbf{SetR}(\Omega)$,

(ii) $v : (B,\gamma) \to (D,\omega)$ is a morphism in $\mathbf{SetR}(\Omega)$,

(iii) $(v \circ f)(a,d) \le (g \circ u)(a,d)$ for all $a \in A, d \in D$, where the composition of a morphism and a weak morphism is formally the same as for morphisms in the category $\mathbf{SetR}(\Omega)$.

In that case we say that the diagram

$$\begin{array}{ccc} (A,\delta) & \xrightarrow{f} & (B,\gamma) \\ {\scriptstyle u}\downarrow & & \downarrow{\scriptstyle v} \\ (C,\rho) & \xrightarrow{g} & (D,\omega) \end{array}$$

fuzzy commutes. If $(u,v) : f \to g$ and $(u_1,v_1) : g \to h$ are two morphisms in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$ such that $f : (A,\delta) \to (B,\gamma)$, $g : (C,\rho) \to (D,\omega)$, $h : (E,\sigma) \to (F,\tau)$ are weak morphisms then a composition $(u_1,v_1) \circ (u,v)$ is defined as $(u_1 \circ u, v_1 \circ v)$. Using a composition of weak morphisms we can easily prove that the following diagram fuzzy commutes

$$\begin{array}{ccc} (A,\delta) & \xrightarrow{f} & (B,\gamma) \\ {\scriptstyle u_1\circ u}\downarrow & & \downarrow{\scriptstyle v_1\circ v} \\ (E,\sigma) & \xrightarrow{h} & (F,\tau), \end{array}$$

i.e. the definition is correct.

Objects of the category $\mathbf{Mor}(\mathbf{SetR}(\Omega))$ are all morphisms $f : (A,\delta) \to (B,\gamma)$ in the category $\mathbf{SetR}(\Omega)$ and morphisms between such objects are defined formally in the same way as for the category $\mathbf{Rel}(\mathbf{SetR}(\Omega))$. It is clear that $\mathbf{Mor}(\mathbf{SetR}(\Omega))$ is a full subcategory of the category $\mathbf{Rel}(\mathbf{SetR}(\Omega))$.

Now, objects of the category $\mathbf{Map}(\mathbf{SetF}(\Omega))$ are all weak fuzzy sets $(A,\delta) \to (\Omega,\leftrightarrow)$ in the category $\mathbf{SetF}(\Omega)$, where (A,δ) are Ω-sets. If $f : (A,\delta) \to (\Omega,\leftrightarrow)$ and $g : (B,\gamma) \to (\Omega,\leftrightarrow)$ are objects in $\mathbf{Map}(\mathbf{SetF}(\Omega))$ then $u : f \to g$ is a morphism in $\mathbf{Map}(\mathbf{SetF}(\Omega))$ if $u : (A,\delta) \to (B,\gamma)$ is a morphism in $\mathbf{SetF}(\Omega)$ and $g \circ u(a) \ge f(a)$ for all $a \in A$. A composition of such morphisms is defined as a composition of corresponding morphisms in the category $\mathbf{SetF}(\Omega)$.

Finally objects of the category $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$ are all fuzzy sets in the category $\mathbf{SetF}(\Omega)$, i.e. morphisms $(A,\delta) \to (\Omega,\leftrightarrow)$ in the category $\mathbf{SetF}(\Omega)$. Morphisms in the category $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$ are defines similarly as in the category $\mathbf{Map}(\mathbf{SetF}(\Omega))$.

It is well known that there exists a functor $F : \mathbf{SetF}(\Omega) \to \mathbf{SetR}(\Omega)$ such that F is an identity on objects and if $f : (A,\delta) \to (B,\gamma)$ is a morphism in $\mathbf{SetF}(\Omega)$ then $F(f) : A \times B \to \Omega$ is such that $F(f)(a,b) = \gamma(f(a),b)$.

Lemma 1
Let $g : (A,\delta) \to (B,\gamma)$ be a weak morphism in $\mathbf{SetR}(\Omega)$. Let $\tilde{g} : A \times B \to \Omega$ be defined by the formula

$$\tilde{g}(a,b) = \bigvee_{x\in A}\bigvee_{y\in B} g(x,y) \otimes \delta(a,x) \otimes \gamma(b,y).$$

Then

(a) $\tilde{g}$ is a morphism in $\mathbf{SetR}(\Omega)$,

(b) $\tilde{g} = \bigwedge\{h : h$ is a morphism $(A,\delta) \to (B,\gamma)$ in $\mathbf{SetR}(\Omega), h \ge g\}$,

(c) If g is a morphism in $\mathbf{SetR}(\Omega)$, then $\tilde{g} = g$.

Lemma 2
Let $s : (A,\delta) \to (\Omega,\leftrightarrow)$ be a weak fuzzy set in $\mathbf{SetF}(\Omega)$. Let a map $\widehat{s} : A \to \Omega$ be defined such that $\widehat{s}(a) = \bigvee_{x\in A} \delta(a,x) \otimes s(x)$ for all $a \in A$. Then

(a) $\widehat{s} : (A,\delta) \to (\Omega,\leftrightarrow)$ is a morphism in $\mathbf{SetF}(\Omega)$,

(b) $\widehat{s} = \bigwedge\{t : t$ is a morphism $(A,\delta) \to (\Omega,\leftrightarrow)$ in $\mathbf{SetF}(\Omega), t \ge s\}$.

(c) If $s : (A,\delta) \to (\Omega,\leftrightarrow)$ is a fuzzy set in $\mathbf{SetF}(\Omega)$ then $\widehat{s} = s$,

Now
we define functors $G : \mathbf{Rel}(\mathbf{SetR}(\Omega)) \to \mathbf{Mor}(\mathbf{SetR}(\Omega))$ and $H : \mathbf{Map}(\mathbf{SetF}(\Omega)) \to \mathbf{Fuz}(\mathbf{SetF}(\Omega))$ which will be reflections.

Proposition 1
(a) Let a weak morphism f be an object from $\mathbf{Rel}(\mathbf{SetR}(\Omega))$ and let $(u,v) : f \to g$ be a morphism in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$. Let $G(f) = \tilde{f}$ and $G(u,v) = (u,v)$. Then

$$G : \mathbf{Rel}(\mathbf{SetR}(\Omega)) \to \mathbf{Mor}(\mathbf{SetR}(\Omega))$$

is a functor.

(b) Let a weak fuzzy set f be an object in $\mathbf{Map}(\mathbf{SetF}(\Omega))$ and let $u : f \to g$ be a morphism in $\mathbf{Map}(\mathbf{SetF}(\Omega))$. Let $H(f) = \widehat{f}$ and $H(u) = u$. Then

$$H : \mathbf{Map}(\mathbf{SetF}(\Omega)) \to \mathbf{Fuz}(\mathbf{SetF}(\Omega))$$

is a functor.

Proof. (a) Let $f : (A,\delta) \to (B,\gamma)$ and $g : (C,\rho) \to (D,\tau)$ be weak morphisms. We show that (u,v) is a morphism $\tilde{f} \to \tilde{g}$. Since $(u,v) : f \to g$ is a morphism in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$, we have $v \circ f \le g \circ u$. Then since v and u are morphisms in $\mathbf{SetR}(\Omega)$, we have

$$\begin{aligned} v \circ \tilde{f}(a,d) = \\ \bigvee_{b,b',a'} f(a',b') \otimes \delta(a,a') \otimes \gamma(b,b') \otimes v(b,d) \le \\ \bigvee_{b',a'} f(a',b') \otimes \delta(a,a') \otimes v(b',d) = \\ \bigvee_{a'} v \circ f(a',d) \otimes \delta(a,a') \le \\ \bigvee_{a'} g \circ u(a',d) \otimes \delta(a,a') \le \bigvee_{c} u(a,c) \otimes g(c,d) \le \\ \tilde{g} \circ u(a,d). \end{aligned}$$

ISBN: 978-989-95079-6-8

(b) Let $f : (A,\delta) \to (\Omega,\leftrightarrow)$ and $g : (B,\gamma) \to (\Omega,\leftrightarrow)$ be weak fuzzy sets. We need to show that $\widehat{g} \circ u \geq \widehat{f}$. Since u is a morphism in $\mathbf{SetF}(\Omega)$, we have

$$\widehat{g} \circ u(a) = \bigvee_{b\in B} g(b) \otimes \gamma(b,u(a)) \geq \bigvee_{x\in A} g(u(x)) \otimes \gamma(u(x),u(a)) \geq \bigvee_{x\in A} g \circ u(x) \otimes \delta(x,a) \geq \bigvee_{x\in A} f(x) \otimes \delta(x,a) = \widehat{f}(a).$$

We now introduce a notion of a fuzzy reflective subcategory.

Theorem 1

(a) $\mathbf{Mor}(\mathbf{SetR}(\Omega))$ *is a full reflective subcategory in the category* $\mathbf{Rel}(\mathbf{SetR}(\Omega))$ *and* G *is a reflection.*

(b) $\mathbf{Map}(\mathbf{SetF}(\Omega))$ *is a full reflective subcategory in the category* $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$ *and* H *is a reflection.*

Proof. (a) Let $f : (A,\delta) \to (B,\gamma)$ be an object in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$. It is clear that $(id_A, id_B) : f \to \tilde{f}$ is a morphism in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$, where for an object (X,σ) from $\mathbf{SetR}(\Omega)$ the identity morphism $id_X : (X,\sigma) \to (X,\sigma)$ is defined such that $id_X : X \times X \to \Omega$ is such that $id_X(x,y) = 1_\Omega$ if $x = y$ and 0_Ω, otherwise. Let $g : (C,\rho) \to (D,\tau)$ be an object in $\mathbf{Mor}(\mathbf{SetR}(\Omega))$ and let $(u,v) : f \to g$ be a morphism in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$. Then we show that (u,v) is the unique morphism such that the diagram commutes:

$$\begin{array}{ccc} f & \xrightarrow{(id_A,id_B)} & \tilde{f} \\ \| & & \downarrow{\scriptstyle (u,v)} \\ f & \xrightarrow{(u,v)} & g \end{array}$$

In fact, it suffices to prove that $(u,v) : \widetilde{f} \to g$ is a morphism in $\mathbf{Rel}(\mathbf{SetR}(\Omega))$, i.e. that the diagram

$$\begin{array}{ccc} (A,\delta) & \xrightarrow{\widetilde{f}} & (B,\gamma) \\ {\scriptstyle u}\downarrow & & \downarrow{\scriptstyle v} \\ (C,\rho) & \xrightarrow{g} & (D,\tau) \end{array}$$

fuzzy commutes. We have $v \circ f(a,d) \leq g \circ u(a,d)$ for all $a \in A, d \in D$. Since u and v are morphisms in a category $\mathbf{SetR}(\Omega)$, we have

$$v \circ \tilde{f}(a,d) = \bigvee_{b,b'\in B, a'\in A} f(a',b') \otimes \delta(a,a') \otimes \gamma(b,b') \otimes v(b,d) \leq \bigvee_{b,b'\in B a'\in A} f(a',b') \otimes \delta(a,a') \otimes v(b',d) = \bigvee_{a'\in A} \delta(a,a') \otimes v \circ f(a',d) \leq \bigvee_{a'\in A} \delta(a,a') \otimes g \circ u(a',d) \leq g \circ u(a,d).$$

It is clear that (u,v) is the unique morphism with such property and that the diagram commutes.

(b) Let $f : (A,\delta) \to (\Omega,\leftrightarrow)$ be an object of $\mathbf{Map}(\mathbf{SetF}(\Omega))$. It is clear that $id_A : f \to \widehat{f}$ is a morphism in $\mathbf{Map}(\mathbf{SetF}(\Omega))$. Let $g : (B,\gamma) \to (\Omega,\leftrightarrow)$ be an object in $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$ and let $u : f \to g$ be a morphism in $\mathbf{Map}(\mathbf{SetF}(\Omega))$. Then u is the unique morphism in $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$ such that the diagram commutes:

$$\begin{array}{ccc} f & \xrightarrow{id_A} & \widehat{f} \\ {\scriptstyle u}\downarrow & & \downarrow{\scriptstyle u} \\ g & = & g. \end{array}$$

In fact, since $g \circ u(a) \geq f(a)$ and $g \circ u$ is an object in $\mathbf{Fuz}(\mathbf{SetF}(\Omega))$, we have

$$\widehat{f}(a) = \bigvee_{x\in A} \delta(a,x) \otimes f(x) \leq \bigvee_{x\in A} \delta(a,x) \otimes g \circ u(x) \leq g \circ u(a).$$

3 Reflections and fuzzy logic models

The reflections G, H can be used for a definition of fuzzy logic formulas interpretation in categories $\mathbf{SetR}(\Omega)$ and $\mathbf{SetF}(\Omega)$, respectively (see [10]). Let J be a first order language of a fuzzy logic which consists (as classically) of a set of predicate symbols $P \in \mathscr{P}$, a set of functional symbols $f \in \mathscr{F}$ and a set of classical logical connectives $\{\wedge, \vee, \Rightarrow, \neg, \otimes\}$. Moreover J contains also a set Ω of logical constants.

Definition 1

Let $\mathbf{K}$ *be a category with products and with* Ω*-sets as objects. Then a model of a language* J *in a category* $\mathbf{K}$ *is*

$$\mathscr{D} = ((A,\delta), \{P_{\mathscr{D}} : P \in \mathscr{P}\}, \{f_{\mathscr{D}} : f \in \mathscr{F}\}),$$

where

(a) (A,δ) *is an* Ω*-set from a category* $\mathbf{K}$*,*

(b) $P_{\mathscr{D}} : (A,\delta) \times \cdots \times (A,\delta) \to (\Omega,\leftrightarrow)$ *is a morphism in* $\mathbf{K}$*,*

(c) $f_{\mathscr{D}} : (A,\delta) \times \cdots \times (A,\delta) \to (A,\delta)$ *is a morphism in a category* $\mathbf{K}$*.*

Further, let ψ (t, respectively) be a formula (term, respectively) with free variables contained in a set X of variables. Then an interpretation $\|\psi\|_{\mathscr{D},X}$ ($\|t\|_{\mathscr{D},X}$, respectively) of ψ (t, respectively) in a model $\mathscr{D}$ in a category $\mathbf{K}$ should be defined such that

(a) $\|\psi\|_{\mathscr{D},X} : (A,\delta)^X \to (\Omega,\leftrightarrow)$ is a morphism in $\mathbf{K}$,

(b) $\|t\|_{\mathscr{D},X} : (A,\delta)^X \to (A,\delta)$ is a morphism in $\mathbf{K}$,

where $(A,\delta)^X$ is a product $(A,\delta)^{|X|} = (A^{|X|}, \delta_X)$ in a category $\mathbf{K}$. We show shortly how by using reflections H and G the definition of a formula interpretation can be done in models $\mathscr{D}$ in categories $\mathbf{K} = \mathbf{SetF}(\Omega), \mathbf{SetR}(\Omega)$.

Let $\mathscr{D} = ((A,\delta), \{P_{\mathscr{D}} : P \in \mathscr{P}\}, \{f_{\mathscr{D}} : f \in \mathscr{F}\})$ be a model of a language J in a category $\mathbf{K}$, where $\mathbf{K} = \mathbf{SetF}(\Omega)$ or $\mathbf{K} = \mathbf{SetR}(\Omega)$, i.e.

ISBN: 978-989-95079-6-8

(i) (A,δ) is a Ω-set from $\mathbf{K}$,

(ii) $P_{\mathscr{D}} : (A,\delta)\times\cdots\times(A,\delta)\to(\Omega,\leftrightarrow)$ is a morphism in a category $\mathbf{K}$,

(iii) $f_{\mathscr{D}} : (A,\delta)\times\cdots\times(A,\delta)\to(A,\delta)$ is a morphism in a category $\mathbf{K}$.

Let t be a term with a set of variables contained in a set X. Then $\|t\|_{\mathscr{D},X} = \|t\|_X : (A,\delta)^X \to (A,\delta)$ is a morphism in $\mathbf{K}$ defined as follows.

(i) Let $t = x$, where $x \in X$. Then $\|t\|_X := pr_x : (A,\delta)^X \to (A,\delta)$ is a projection morphism in a category $\mathbf{K}$.

(ii) Let $t = f(t_1,\dots,t_n)$. Then $\|t\|_X$ is a composition (in $\mathbf{K}$) of morphisms

$$(A,\delta)^X \xrightarrow{\prod_i \|t_i\|_X} (A,\delta)^n \xrightarrow{f_{\mathscr{D}}} (A,\delta)\cdot$$

Hence, for $\mathbf{K} = \mathbf{SetR}(\Omega)$ we have $\|t\|_X(\mathbf{a},b) = \bigvee_{\mathbf{x}\in A^n}(\prod_i \|t_i\|_X(\mathbf{a},\mathbf{x})\otimes f_{\mathscr{D}}(\mathbf{x},b)$, where $\mathbf{a}\in A^X$.

Now let ψ be a formula with free variables contained in a set X. In a category $\mathbf{K}$ we will define firstly a weak morphisms (i.e. *weak fuzzy set* for $\mathbf{K} = \mathbf{SetF}(\Omega)$ or a *weak morphism* for $\mathbf{K} = \mathbf{SetR}(\Omega)$) $|\psi|_{\mathscr{D},X} = |\psi|_X : (A,\delta)^X \to (\Omega,\leftrightarrow)$. A definition will be done by induction principle on a structure of ψ.

(a) Let $\psi \equiv P(t_1,\dots,t_n)$. Then (according to induction assumption) $\|t_i\|_X, P_{\mathscr{D}}$ are defined and we define $|\psi|_X$ as a composition of the following morphisms in $\mathbf{K}$:

$$(A,\delta)^X \xrightarrow{\prod_i \|t_i\|_X} (A,\delta)^n \xrightarrow{P_{\mathscr{D}}} (\Omega,\leftrightarrow).$$

(b) Let $\psi \equiv t_1 = t_2$. Then $|\psi|_X$ is a composition of the following weak morphisms:

$$(A,\delta)^X \xrightarrow{\|t_1\|_X\times\|t_2\|_X} (A,\delta)^2 \xrightarrow{\Delta_{\mathbf{K},A}} (\Omega,\leftrightarrow).$$

(c) Let $\psi \equiv \psi_1\wedge\psi_2$. Then $|\psi|_X$ is a composition of the following weak morphisms:

$$(A,\delta)^X \xrightarrow{\|\psi\|_X\times\|\psi_2\|_X} (\Omega,\leftrightarrow)^2 \xrightarrow{\sqcap_{\mathbf{K}}} (\Omega,\leftrightarrow).$$

(d) Let $\psi \equiv \psi_1\vee\psi_2$. Then $|\psi|_X$ is a composition of the following weak morphisms:

$$(A,\delta)^X \xrightarrow{\|\psi\|_X\times\|\psi_2\|_X} (\Omega,\leftrightarrow)^2 \xrightarrow{\sqcup_{\mathbf{K}}} (\Omega,\leftrightarrow).$$

(e) Let $\psi \equiv \sigma\Rightarrow\tau$. Then $|\psi|_X$ is a composition of the following weak morphisms:

$$(A,\delta)^X \xrightarrow{\|\sigma\|_X\times\|\tau\|_X} (\Omega,\leftrightarrow)^2 \xrightarrow{\Rrightarrow_{\mathbf{K}}} (\Omega,\leftrightarrow).$$

(f) Let $\psi \equiv \neg\sigma$. Then $|\psi|_X$ is a composition of the following weak morphisms:

$$(A,\delta)^X \xrightarrow{\|\sigma\|_X} (\Omega,\leftrightarrow) \xrightarrow{\neg_{\mathbf{K}}} (\Omega,\leftrightarrow).$$

(g) Let $\psi \equiv (\exists x)\sigma$. Then $\|\sigma\|_{X\cup\{x\}}$ is already defined as a morphism $(A,\delta)^{X\cup\{x\}} = (A,\delta)^X\times(A,\delta)\to(\Omega,\leftrightarrow)$ in $\mathbf{K}$. Then we set

$$|\psi|_X(\mathbf{a},\alpha) = \bigvee_{x\in A}\|\sigma\|_{X\cup\{x\}}((\mathbf{a},x),\alpha), \quad \text{if } \mathbf{K} = \mathbf{SetR}(\Omega),$$
$$|\psi|_X(\mathbf{a}) = \bigvee_{x\in A}\|\sigma\|_{X\cup\{x\}}(\mathbf{a},x), \quad \text{if } \mathbf{K} = \mathbf{SetR}(\Omega).$$

The maps $\Rrightarrow_{\mathbf{K}}, \neg_{\mathbf{K}}, \sqcup_{\mathbf{K}}, \sqcap_{\mathbf{K}}, \Delta_{\mathbf{K},A}$ are defined as follows: For $\mathbf{K} = \mathbf{SetR}(\Omega)$, we have

(i) $\Delta_{\mathbf{SetR}(\Omega),A}((a,b),\alpha) = \alpha \leftrightarrow \delta(a,b)$ for all $a,b\in A, \alpha\in\Omega$.

(ii) $\sqcap_{\mathbf{SetR}(\Omega)}((\beta,\gamma),\alpha) = \alpha\leftrightarrow(\beta\wedge\gamma)$.

(iii) $\sqcup_{\mathbf{SetR}(\Omega)}((\beta,\gamma),\alpha) = \alpha\leftrightarrow(\beta\vee\gamma)$.

(iv) $\Rrightarrow_{\mathbf{SetR}(\Omega)}((\beta,\gamma),\alpha) = (\beta\otimes\alpha)\to\gamma$.

(v) $\neg_{\mathbf{SetR}(\Omega)}(\alpha,\beta) = \beta\leftrightarrow(\alpha\to 0)$.

For $\mathbf{K} = \mathbf{SetF}(\Omega)$, we have

(a) $\Delta_{\mathbf{SetF}(\Omega),A}(a,b) = \delta(a,b)$ for all $a,b\in A$.

(b) $\sqcap_{\mathbf{SetF}(\Omega)}(\beta,\gamma) = \beta\wedge\gamma$.

(c) $\sqcup_{\mathbf{SetF}(\Omega)}(\beta,\gamma) = \beta\vee\gamma$.

(d) $\Rrightarrow_{\mathbf{SetF}(\Omega)}(\beta,\gamma) = \beta\to\gamma$.

(e) $\neg_{\mathbf{SetF}(\Omega)}(\beta) = \neg\beta$.

Definition 2
Let ψ be a formula in J and let X be a set of variables containing all free variables of ψ. Let $\mathscr{D}$ be a model of J in a category $\mathbf{K} = \mathbf{SetF}(\Omega), \mathbf{SetR}(\Omega)$. Then we set

$$\|\psi\|_{\mathscr{D},X} = G(|\psi|_{\mathscr{D},X}) \quad \textit{if} \quad \mathbf{K} = \mathbf{SetR}(\Omega),$$
$$\|\psi\|_{\mathscr{D},X} = H(|\psi|_{\mathscr{D},X}) \quad \textit{if} \quad \mathbf{K} = \mathbf{SetF}(\Omega).$$

Theorem 2
For any formula ψ, $\|\psi\|_{\mathscr{D},X} : (A,\delta)^X \to (\Omega,\leftrightarrow)$ is a morphism in a category $\mathbf{K} = \mathbf{SetR}(\Omega), \mathbf{SetF}(\Omega)$.

4 Category $\mathbf{Set}(\Omega)$

To investigate a relationship between classical fuzzy sets (A,f), where $f : A\to\Omega$ is a map and Ω-sets (A,δ) it will be necessary to modify a definition of a similarity relation δ. There are several natural ways how to transform a classical fuzzy set into a similarity relation. For example, for a fuzzy set f we can define a similarity relation σ_f such that $\sigma_f(x,y) = f(x)\leftrightarrow f(y)$. We can also introduce another relation, namely $\Delta_f(x,y) = f(x)$ iff $x = y$ and $\Delta_f(x,y) = 0$, otherwise. It is clear that in that case Δ_f does not satisfies the condition $\Delta_f(x,x) = 1$ from the definition of similarity relations. Nevertheless to investigate a relationship between fuzzy sets and such similarity relations, we will introduce in this section a generalization of Ω-sets, namely we will define a new category $\mathbf{SetR}(\Omega)_*$ with objects (A,δ), where A is a set and δ satisfies only the conditions (b) and (c) from definition of a

ISBN: 978-989-95079-6-8

similarity relation. Moreover, we will require that morphisms of $\mathbf{SetR}(\Omega)_*$ are those of morphisms $f : (A,\delta) \to (B,\gamma)$ from $\mathbf{SetR}(\Omega)$ that satisfy the following additional conditions:

(a) $\gamma(x,x) = \bigvee_{y\in B} f(x,y)$, for all $x \in A$,

(b) $f(x,y) \otimes f(x,z) \le \gamma(y,z)$.

In this section we show a deeper relationship between morphisms in $\mathbf{Set}(\Omega)$ and $\mathbf{SetR}(\Omega)_*$ but only for a very special Ω, namely for a totally ordered Heyting algebra Ω.

Proposition 2
Let Ω be a totally ordered complete Heyting algebra and let $(A,\alpha),(B,\beta)$ be objects from a category $\mathbf{Set}(\Omega)$. Let $f : A \times B \to \Omega$ be a map. Then the following statement are equivalent.

(a) $f : (A,\Delta_\alpha) \to (B,\Delta_\beta)$ is a morphism in the category $\mathbf{SetR}(\Omega)_*$.

(b) There exist a morphism $g : (A,\alpha) \to (B,\beta)$ in a category $\mathbf{Set}(\Omega)$ such that

(i) $(\forall a \in A, b \in B) \quad f(a,b) \le \Delta_\beta(g(a),b)$,

(ii) $(\forall a \in A, b \in B) \quad f(a,g(a)) = \alpha(a)$.

(c) There exists a morphism $g : (A,\alpha) \to (B,\beta)$ in a category $\mathbf{Set}(\Omega)$ such that

$$(\forall a \in A, b \in B) \quad f(a,b) = \alpha(a) \wedge \Delta_\beta(g(a),b).$$

Proof. Recall that a *singleton* in $(X,\delta) \in \mathbf{SetR}(\Omega)_*$ is a map $s : X \to \Omega$ such that

$$(\forall x,y \in X) \quad s(x) \wedge \delta(x,y) \le s(y),$$
$$(\forall x,y \in X) \quad s(x) \wedge s(y) \le \delta(x,y).$$

The set $\mathrm{singl}\,(X,\delta)$ of all singletons of (X,δ) with a function $\tau_{(X,\delta)}$ is then an object of $\mathbf{SetR}(\Omega)_*$ if we set

$$(\forall s,t \in \mathrm{singl}\,) \quad \tau_{(X,\delta)}(s,t) = \bigvee_{a\in X} s(a) \wedge t(a).$$

(a)⇒ (b). We construct a map $h : A \to \mathrm{singl}\,(B,\Delta_\beta)$ such that

$$(\forall a \in A)(\forall y \in B) \quad h(a)(y) = \bigvee_{x\in A} (f(x,y) \wedge \Delta_\alpha(a,x)).$$

We have to show that $h(a) \in \mathrm{singl}\,(B,\Delta_\beta)$ for any $a \in A$. In fact, for $y \ne y' \in B$ we have

$$h(a)(y) \wedge h(a)(y') \le f(a,y) \wedge f(a,y') \le \Delta_\beta(y,y') = 0,$$
$$h(a)(y) \le f(a,y) \le \Delta_\alpha(a,a) = \alpha(a).$$

Moreover, $h : (A,\Delta_\alpha) \to (\mathrm{singl}\,(B,\Delta_\beta),\tau)$ is a morphism in a category $\mathbf{SetR}(\Omega)_*$. In fact, for any $a,a' \in A$ we have

$$\tau(h(a),h(a')) = \bigvee_{y\in B}\bigvee_{x,x'\in A} (f(x,y) \wedge \Delta_\alpha(a,x) \wedge f(x',y) \wedge \Delta_\alpha(a',x')) \ge$$
$$\ge \bigvee_{y\in B} (f(a,y) \wedge \Delta_\alpha(a,a) \wedge \Delta_\alpha(a',a)) = \Delta_\alpha(a',a),$$
$$\tau(h(a),h(a)) = \bigvee_{y\in B}\bigvee_{x\in A} f(x,y) \wedge \Delta_\alpha(a,x) \le \bigvee_{y\in B} f(a,y) = \Delta_\alpha(a,a).$$

Since $h(a)(y) \wedge h(a)(y') = 0$ for all $y \ne y' \in B$ and Ω is totally ordered, for any $a \in A$ there exists at most one element $g(a) \in B$ such that $h(a)(g(a)) > 0$. If $h(a)(y) = 0$ for all $y \in B$, let $g(a) \in B$ be an arbitrary element. Then $g : (A,\alpha) \to (B,\beta)$ is a morphism in $\mathbf{Set}(\Omega)$. In fact, if $h(a)(g(a)) > 0$, then we have

$$\alpha(a) = \Delta_\alpha(a,a) = \tau(h(a),h(a)) = \bigvee_{y\in B} h(a)(y)$$
$$= h(a)(g(a)) = \bigvee_{x\in A} f(x,g(a)) \wedge \Delta_\alpha(a,x) \le$$
$$f(a,g(a)) \le \Delta_\beta(g(a),g(a)) = \beta(g(a)).$$

If $h(a)(y) = 0$ for all $y \in B$, then $\alpha(a) = \Delta_\alpha(a,a) = 0 \le \Delta_\beta(g(a),g(a))$. We show that the function g satisfies the conditions (i) and (ii). Let $h(a)(g(a)) > 0$. Then we have

$$0 < h(a)(g(a)) = \bigvee_{x\in A} f(x,g(a)) \wedge \Delta_\alpha(a,x) \le f(a,g(a)).$$

Moreover, since f is a morphism in $\mathbf{SetR}(\Omega)_*$, we have

$$(\forall a,b) \quad f(a,b) \wedge f(a,g(a)) \le \Delta_\beta(b,g(a)),$$

and it follows that $f(a,b) = 0$ for all $b \in B$ such that $b \ne g(a)$. Hence, the condition (i) holds. Since $\alpha(a) = \Delta_\alpha(a,a) = \bigvee_{y\in B} f(a,y) = f(a,g(a))$, the condition (ii) holds. Now, if $h(a)(y) = 0$ for all $y \in B$, it follows that $f(a,y) = 0$ for all $y \in B$ and the conditions (i),(ii) hold as well.

(b)⇒(c). This is a trivial computation only.

(c)⇒(a). Let $g : (A,\alpha) \to (B,\beta)$ be a morphism in $\mathbf{Set}(\Omega)$ and let $f : A \times B \to \Omega$ be a function from the statement (c). Then for any $a \in A$ we have

$$\bigvee_{b\in B} f(a,b) = \bigvee_{b\in B} (\alpha(a) \wedge \Delta_\beta(g(a),b)) =$$
$$= \alpha(a) \wedge \Delta_\beta(g(a),g(a)) = \alpha(a) \wedge \beta(g(a)) = \alpha(a).$$

and $f : (A,\Delta_\alpha) \to (B,\Delta_\beta)$ is a morphism in $\mathbf{SetR}(\Omega)_*$. ■

It is clear that Proposition 2 introduces a map

$$\varphi : \mathbf{Hom}_{\mathbf{Set}(\Omega)}((A,\alpha),(B,\beta)) \to$$
$$\mathbf{Hom}_{\mathbf{SetR}(\Omega)_*}((A,\Delta_\alpha),(B,\Delta_\beta))$$

such that for any morphism $f : (A,\alpha) \to (B,\beta)$ in $\mathbf{Set}(\Omega)$, $\varphi(f) : (A,\Delta_\alpha) \to (B,\Delta_\beta)$ is a morphism in $\mathbf{SetR}(\Omega)_*$ such

ISBN: 978-989-95079-6-8

that $\varphi(f)(a,b) = \alpha(a) \wedge \Delta_\beta(f(a),b)$ for all $a \in A, b \in B$. On the other hand, there exists a relation

$$\psi \subseteq \mathbf{Hom}_{\mathbf{SetR}(\Omega)_*}((A,\Delta_\alpha),(B,\Delta_\beta)) \times \mathbf{Hom}_{\mathbf{Set}(\Omega)}((A,\alpha),(B,\beta))$$

such that $(f,g) \in \psi$ if g is a morphism from (c) (Proposition 2) for a morphism f. It should be observed that (on the contrary to φ) ψ is not a map, in general. In fact, let (A,α) be an object in $\mathbf{Set}(\Omega)$ such that $\alpha(a) = 0$ for some $a \in A$. Let $f : (A,\Delta_\alpha) \to (B,\Delta_\beta)$ be a morphism in $\mathbf{SetR}(\Omega)_*$ and let $g : (A,\alpha) \to (B,\beta)$ be a morphism in $\mathbf{Set}(\Omega)$ satisfying the condition (c) from Proposition 2. Let us define a map $g' : A \to B$ such that $g'(x) = g(x)$ for all $x \in A, x \neq a$ and $g'(a) \neq g(a)$. Then $g' : (A,\alpha) \to (B,\beta)$ is a morphism, $(f,g),(f,g') \in \psi$ and $g' \neq g$. Hence, ψ is not a map.

Abstract *— The concept of a bipolar query is studied in the framework of the flexible fuzzy querying of databases. The focus is on the aggregation of the negative and positive conditions forming a bipolar query. Three formal logical representations of such an aggregation are proposed and analyzed taking into account various possible interpretations of fuzzy logical connectives. The relation to other approaches known in the literature is shown.*

Keywords— aggregation operators, bipolar queries, flexible queries, fuzzy logic, logical connectives modeling.

1 Introduction

A query to a (relational) database may be identified, in a slightly simplified view, with a condition expressing what the user is looking for. A database management system returns in the response to a query a list of tuples satisfying this condition. Such a condition is usually composed of a few, simple, atomic conditions putting some constraints on the values of the attributes characterizing given relation (table). We will adopt such a simplified view, assuming moreover that the user is concerned with just one relation, i.e., using SQL's terminology, joins, subqueries etc. are excluded for the sake of clarity of the presentation of the main idea.

Atomic conditions are connected using the classical logical connectives of the conjunction, disjunction and negation. In many standard application scenarios this is exactly what is needed to retrieve required data from a database. However in some other scenarios more sophisticated forms of the queries seem to be useful. Thus, in the literature further extensions of this basic setting are proposed. Firstly, many authors advocate the convenience of using *linguistic terms* in queries (cf., e.g., [1, 2]). For example, it is more natural and comfortable for a user of a real-estate agency to state that she or he is looking for a "not very expensive house" rather than to use a precise interval of acceptable prices. The benefits of using fuzzy logic to model linguistic terms in queries are widely advocated and there is a large number of of both theoretical and practical results obtained by the researchers in this area (cf., e.g., [3, 1, 2]). Secondly, some (atomic) conditions may be for the user more important than the others. For example, a customer of a real-estate agency may be looking for a "not very expensive house located in a nice city district" and to treat the former condition as a much more important than the latter. Thus in the overall matching degree of a tuple against such a query the satisfaction of the former condition is crucial, while of the latter is to some extent secondary. Proper modeling of importance weights is a subject of many papers (cf., e.g., [4]).

The essence of the concept of a *bipolar query* is in a new way of differentiating the conditions than by assigning them with some *fixed* importance weights. Namely, a bipolar query is defined by two conditions: one – *negative (required)* – expresses the constraints that *have to be* satisfied while the second – *positive (preferred)* – expresses only what is *desired* and its violation does not necessarily lead to the rejection of given tuple. This combination of conditions may be meant and studied in a few different ways. Here we are interested in the ways the satisfaction of both types of conditions should be combined to obtain an overall matching degree of the whole query. From this point of view the most important is the question if there is a conflict between the conditions or they can be satisfied simultaneously. If there is a total conflict, i.e., satisfying one condition means totally failing to satisfy another, the bipolar query reduces itself to the required condition. On the other hand, if both conditions may be totally satisfied simultaneously then the bipolar query reduces to a simple conjunction. Thus, the most interesting are intermediate cases which may be characterized by a degree of conflict between the conditions.

In this paper we study three logical formulas which may be used as a representation of a bipolar query. They are equivalent in case of the classical predicate logic but as soon as we adopt the fuzzy (multivalued) logic context they become distinct and exhibit different properties depending on the assumed set of fuzzy operators used to model logical connectives. Our study may be seen as an attempt at justifying particular choices in this respect.

The structure of this paper is as follows. In Section 2 we briefly remind the concept of the bipolar query and introduce the notation used later on. We also discuss the concept of the *winnow* operator which is used to derive logical representations of bipolar queries. In Section 3 we compare particular representations under different choices of logical operators, i.e., operators used to model particular logical connectives.

2 The concept of a bipolar query

The very concept of bipolar queries has been introduced by Dubois and Prade [5]. Its basic idea is to distinguish two types of query conditions, which are related to the *negative* and *positive* preferences of a user. The former coincide with the traditional understanding of a condition as a constraint, which defines a set of *feasible* tuples or, equivalently, excludes all tuples that do not satisfy it. The latter, on the other hand, characterizes those tuples which are really desired, with such an un-

ISBN: 978-989-95079-6-8

derstanding that violating such a condition by a tuple does not necessarily exclude it from the consideration. Bipolar queries may be exemplified by the following one:

"Find a *non-expensive* house *and possibly* located *near* a railway station (1)

where the condition referring to the price is a negative one, excluding expensive houses, and the condition referring to the location is a positive one, expressing just a desire to get a house conveniently located, *if possible*.

Now there is a crucial question of the interplay between these two types of conditions which distinguishes different lines of research in this area. Namely, Dubois and Prade basically assume that these conditions should be consistent in such a sense that the set of desired tuples should be a subset of the set of feasible tuples. Then the main question is how to take into account the sets of negative and positive conditions. These are aggregated separately and if the resulting overall negative and positive conditions are not consistent some measures are undertaken to make them so. The answer to such a bipolar query is generated according to the strategy "first select (with respect to the negative condition) and then order (with respect to the positive condition)". This strategy requires a precisiation in case the first condition is fuzzy, i.e., is satisfied by tuples to a degree – what is, of course, the most interesting case, anyway. Then it is not that clear what does it mean to select tuples satisfying a fuzzy condition as they form, in fact, a fuzzy set. Dubois and Prade [6] propose to employ here a lexicographic order of the tuples represented by vectors of the degrees of matching of particular conditions. They propose also a comprehensive representation of bipolar preferences in the framework of the possibility theory [7].

Another line of research explicitly takes into account the conflict between the constraints and the desires and looks for the aggregation of both conditions directly referring to the degree of this conflict. This interpretation is emphasized by the use of the "and possibly" operator in (1). Thus, in general describing a bipolar query we will use the following notation:

$$C \textit{ and possibly } P \tag{2}$$

or, equivalently, an answer to a bipolar query may be defined as the set of tuples: $\{t : C(t) \textit{ and possibly } P(t)\}$. The above form puts emphasis on the question of a proper modeling of the aggregation of both types of conditions, which is expressed here with the use of the "and possibly" operator.

The interest of the database community in this type of queries dates back to the paper by Lacroix and Lavency [8]. They were the first to propose the use of a query comprising two categories of conditions: one which is mandatory (C) and another which expresses just mere preferences (desires) (P). The bipolarity of these conditions becomes evident as soon as one adopts the following interpretation. The former condition C may be seen as expressing the *negative* preferences: the tuples which do not satisfy it are definitely not matching the whole query. The latter condition P, on the other hand, has a *positive* character: a tuple satisfying it is preferred over another tuple not satisfying it, provided both tuples satisfy the mandatory condition C.

For the purposes of a further discussion we will use the following notation. We assume the queries are addressed against a set of tuples $T = \{t_j\}$ comprising a relation. We will identify the negative and positive conditions of a bipolar query with the predicates that represent them and denote them as C and P, respectively. For a tuple $t \in T$, $C(t)$ and $P(t)$ will denote that the tuple t satisfies respective condition (in crisp case) or the degrees of satisfaction, if the conditions are fuzzy. We will also denote the whole bipolar query as (C, P).

According to the original (crisp) approach by Lacroix and Lavency if there are no tuples meeting both conditions then the result of the aggregation is determined by the negative condition C alone. Otherwise the aggregation becomes a regular conjunction of both conditions. Thus the answer to such a query depends not only on the explicit arguments, i.e., $C(t)$ and $P(t)$, but also on the content of the database. This dependence is best expressed by the following logical formula [8]:

$$C(t) \textit{ and possibly } P(t) \equiv C(t) \wedge \exists s(C(s) \wedge P(s)) \Rightarrow P(t) \tag{3}$$

The characteristic feature of such an interpretation of bipolar queries is that if there is no conflict between the conditions P and C, i.e., there are tuples satisfying both of them, then the query turns into a conjunction of the conditions. On the other hand if there are no tuples satisfying both conditions then only condition C is used to select tuples.

Such an aggregation operator has been later proposed independently by Dubois and Prade [9] in the context of default reasoning and by Yager [10, 11] in the context of the multicriteria decision making for the case of so-called *possibilistically qualified criteria*. Yager [11] intuitively characterizes a possibilistically quantified criterion as such which should be satisfied unless it interferes with satisfaction of other criteria. This is in fact the essence of bipolar queries in the sense advocated in this paper. This concept was also applied by Bordogna and Pasi [12] for the textual information retrieval task.

Lacroix and Lavency [8] consider only the case of crisp conditions C and P. Then a bipolar query may be, in fact, processed using the "first select using C then order using P" strategy, i.e., the answer to the bipolar query (C, P) is obtained by, first, finding tuples satisfying C and, second, choosing from among them those satisfying the condition P, if any. If C is crisp and P is fuzzy then the second step consists in non-increasingly *ordering* the tuples satisfying C according to their degree of satisfaction of P. This understanding is predominant in the literature dealing with fuzzy extensions of the original concept of Lacroix and Lavency. Both, direct extensions proposed by Bosc and Pivert [13, 14] as well as sophisticated possibility theory-based interpretation of this concept by Dubois and Prade [6] focus, in fact, on the proper treatment of *multiple* required and preferred conditions, basically assuming the above strategy as the way of combining the negative and positive conditions.

In [15, 16] we propose a "fuzzification" of the formula (3) and study its basic properties. Here we focus on the question of combining fuzzy conditions C and P and will treat them in what follows as atomic. From this point of view it is worth mentioning some other approaches which are of relevance here. Dujmović [17] introduced the concept of the *partial absorption function* which may be used to combine the values of two variables in such a way that one variable controls the influence of the other on the result of their combina-

ISBN: 978-989-95079-6-8

tion. It makes it possible to express the requirement that for a high value of the result a high value of the first variable is mandatory while the high value of the second is desired but not mandatory. When applied to the aggregation of the values of $C(t)$ and $P(t)$ this is somehow similar to the idea of bipolar query expressed by (3), but lacks its dependence on the content of the whole database. This approach may be seen as based on a sophisticated, *dynamic* weighting of the importance of the combined values, where the weights itself depend on the combined values. A similar approach has been proposed by Dubois and Prade; cf., e.g., [4].

The operator "among", very close to the discussed here operator "and possibly", has been proposed by Tudorie [18]. She considers queries of the type "find tuples satisfying a condition P among those satisfying a condition C", which are in fact equivalent to the bipolar queries understood as in (2). The evaluation of a query with the "among" operator is very similar to the one adopted by us for the bipolar query, but is expressed in terms of the rescaling of the linguistic terms used in the condition P. Namely, first the set of tuples satisfying the condition C to a non-zero degree is selected. Then the membership functions of the fuzzy sets representing the linguistic terms appearing in P (such as "near" in (1)) are rescaled taking into account the actual range of the corresponding attributes in the set of tuples selected in the first step. For example, if originally the distance of 2 kilometers from the station has the membership value to the fuzzy set representing the term "near" equals 0.5, and it turns out that it is the shortest distance among the houses selected in the first step (i.e., among non-expensive houses, in case of the query (1)), then this membership degree may be changed to 1 (the actual algorithm of rescaling may, of course, take different forms). Finally, the overall matching degree is computed as a conjunction of the matching degrees against the condition C and the "modified" condition P, i.e., the one for which the rescaled membership function of the linguistic terms is used. Please note that if there is no interference between both conditions (in the sense discussed earlier) then there is no need for rescaling the membership functions and the query turns into a conjunction of both conditions, like in the case of the bipolar query.

Bipolar queries may be also seen a special case of *queries with preferences* proposed recently, for the crisp case, by Chomicki [19]. In the framework of this approach a new relational algebra operator called *winnow* is introduced. This unary operator selects from a set of tuples T those which are *non-dominated* with respect to a given *preference relation* R, $R \subseteq T \times T$. If two tuples $t, s \in T$ are in relation R, i.e., $R(t, s)$, then it is said that the tuple t *dominates* the tuple s with respect to the relation R. Then the *winnow* operator ω_R is defined as follows

$$\omega_R(T) = \{t \in T : \neg\exists_{s \in T}\ R(s, t)\} \tag{4}$$

Thus, for a given set of tuples it yields a subset of the *non-dominated* tuples with respect to R.

The concept of the *winnow* operator may be illustrated with the following example. Let us consider a database of a real-estate agency with a table `HOUSES` describing the details of particular real-estate properties offered by an agency. The schema of the relation `HOUSES` contains, among other, the attributes `city` and `price`. Let us assume that we are interested in the list of the *cheapest* houses in each city. Then the preference relation should be defined as follows

$$R(t, s) \Leftrightarrow (t.\texttt{city} = s.\texttt{city}) \wedge (t.\texttt{price} < s.\texttt{price})$$

where $t.A$ denotes the value of attribute A (e.g., `price`) at a tuple t. Then the *winnow* operator $\omega_R(\texttt{HOUSES})$ will select the houses that are sought. Indeed, according to the definition of the *winnow* operator, we will get as an answer a set of houses, which are non-dominated with respect to R, i.e., for which there is no other house in the same city which has a lower price.

In [16] we proposed a fuzzy counterpart of the *winnow* operator taking into account the fuzziness of the preference relation R and of the related concept of non-dominance as well as the fact that the set of tuples T is also a fuzzy set. It may be expressed as follows:

$$\mu_{\omega_R(T)}(t) = \text{truth}(T(t) \wedge \forall_s\ (T(s) \rightarrow \neg R(s, t))) \tag{5}$$

where $\mu_{\omega_R(T)}(t)$ denotes the value of the membership degree of the tuple t to the fuzzy set of tuples defined by $\omega_R(T)$.

A bipolar query (C, P) may be expressed using the concept of the fuzzy *winnow* operator as follows [19, 16]. Let R be a fuzzy preference relation of the following form (symbols R and P denote both the fuzzy predicates and the membership functions of corresponding fuzzy sets, depending on the context):

$$R(t, s) \Leftrightarrow P(t) \wedge \neg P(s) \tag{6}$$

Then the bipolar query may be expressed as the combination of the selection and fuzzy *winnow* operators $\omega_R(\sigma_C(T))$, i.e.,

$$\mu_{\omega_R(\sigma_C(T))} = \text{truth}(C(t) \wedge \forall_s\ (C(s) \rightarrow (\neg P(s) \vee P(t)))) \tag{7}$$

(where $\sigma_C(T)$ is a usual "fuzzy" extension of the standard relational algebra selection operator, i.e., $\mu_{\sigma_C(T)}(t) = C(t)$).

The definition of the fuzzy *winnow* operator (5) as well as the "fuzzification" of the formula defining a bipolar query (3) leave open the question of a choice of the logical operators which should be used to model particular logical connectives occurring in both formulas. In [16] we show that for a specific choice of them the fuzzy set of tuples obtained using (7) is identical with the fuzzy set defined by (3). In [20] we analyze the properties of the "fuzzified" version of (3) for the broader class of the logical operators. In the next section we further advance this study.

3 Various interpretations of bipolar queries and their properties

In our previous work [15, 16, 20] we studied a specific fuzzy version of the Lacroix and Lavency formula (3) representing an interpretation of the concept of bipolar queries. We have also shown its basic relation with a fuzzy version of the *winnow* operator we proposed. Here we extend this study comparing three formulas that may be used to represent the bipolar query and their properties under different interpretations of the logical connectives occurring in them.

We derive the logical formulas expressing the matching degree of a bipolar query in three different ways (we repeat here some formulas introduced in the previous section for the convenience of the reader):

ISBN: 978-989-95079-6-8

- making a direct "fuzzification" of the formula (3) proposed for the crisp case by Lacroix and Lavency [8]:

$$C(t) \textit{ and possibly } P(t) \equiv C(t) \wedge (\exists s\ (C(s) \wedge P(s)) \Rightarrow P(t)) \quad (8)$$

- making a direct "fuzzification" of the crisp *winnow* operator (4) and applying it with a specific preference relation (6) to obtain a bipolar query representation:

$$C(t) \textit{ and possibly } P(t) \equiv C(t) \wedge \neg\exists s\ ((C(s) \wedge P(s) \wedge \neg P(t))) \quad (9)$$

- using our fuzzy version of the *winnow* operator (5) and applying it as above:

$$C(t) \textit{ and possibly } P(t) \equiv C(t) \wedge \forall s\ (C(s) \Rightarrow (\neg P(s) \vee P(t))) \quad (10)$$

It may be easily seen that in the framework of the classical logic all three above formulas are equivalent. Here we study their properties in case of fuzzy (multivalued) interpretation, in particular taking into account various operators which may be used to model logical connectives. We follow usual approach of modeling conjunction and disjunction by the t-norm and t-conorm operators, respectively [21].

In order to carry out the analysis we consider so-called De Morgan Triples $(\wedge, \vee, \neg)$ that comprise a t-norm operator $\wedge$, a t-conorm operator $\vee$ and a negation operator $\neg$, where $\neg(x \vee y) = \neg x \wedge \neg y$ holds. Three following De Morgan Triples play the most important role in fuzzy logic (cf., e.g., [21] for a justification) $(\wedge_{min}, \vee_{max}, \neg)$, $(\wedge_{\Pi}, \vee_{\Pi}, \neg)$, $(\wedge_{W}, \vee_{W}, \neg)$, where particular t-norms and t-conorms are defined as follows:

$t-$ *norms*		
$x\ \wedge_{min}\ y$	$= \min(x, y)$	*minimum*
$x\ \wedge_{\Pi}\ y$	$= x \cdot y$	*product*
$x\ \wedge_{W}\ y$	$= \max(0, x + y - 1)$	*Łukasiewicz*

$t-$ *conorms*		
$x\ \vee_{max}\ y$	$= \max(x, y)$	*maximum*
$x\ \vee_{\Pi}\ y$	$= x + y - x \cdot y$	*probabilistic sum*
$x\ \vee_{W}\ y$	$= \min(1, x + y)$	*Łukasiewicz*

We will refer to these De Morgan Triples in what follows as, respectively, MinMax, Π and W triples. The negation operator $\neg$ in case of all the above De Morgan Triples is defined as: $\neg x = 1 - x$. Both t-norms and t-conorms are by definition associative and thus may be treated as m-ary operators, i.e., expressions like $x \wedge y \wedge \ldots$ and $x \vee y \vee \ldots$ are well defined.

Basically, the general and existential quantifiers are identified in fuzzy logic, for the case of a finite universe, with the maximum and minimum operators, respectively. They may be generalized via the use of other t-norms and t-conorms what leads to the concept of *t-quantifiers* and *s-quantifiers*; cf., e.g., [22]. The truth of a statement involving such a quantifier is computed as follows ($\{a_1, \ldots, a_m\}$ is a finite universe under consideration):

$$\text{truth}(\forall x A(x)) = \mu_A(a_1) \wedge \mu_A(a_2) \wedge \ldots \wedge \mu_A(a_m) \quad (11)$$

$$\text{truth}(\exists x A(x)) = \mu_A(a_1) \vee \mu_A(a_2) \vee \ldots \vee \mu_A(a_m) \quad (12)$$

We use generalized quantifiers while interpreting formulas (8)-(10) and particular t- and s-quantifiers will be denoted in what follows by the $\forall$ and $\exists$ symbol with a subscript indicating underlying t-norm or s-norm, e.g., $\exists_{max}$ denotes a fuzzy existential quantifier which obtains when the t-conorm "maximum" is used.

We consider two implication operators related to a given De Morgan Triple $(\wedge, \vee, \neg)$, so-called S-implications:

$$x \rightarrow_{S-\vee} y = \neg x \vee y \quad (13)$$

and R-implications:

$$x \rightarrow_{R-\wedge} y = \sup\{z : x \wedge z \leq y\} \quad (14)$$

Thus, for particular De Morgan Triples one obtains the following R-implication operators:

$$x\ \rightarrow_{R-min}\ y = \begin{cases} 1 & \text{for } x \leq y \\ y & \text{for } x > y \end{cases}$$

$$x\ \rightarrow_{R-\Pi}\ y = \begin{cases} 1 & \text{for } x = 0 \\ \min\{1, \frac{y}{x}\} & \text{for } x \neq 0 \end{cases}$$

$$x\ \rightarrow_{R-W}\ y = \min(1 - x + y, 1)$$

and the following S-implication operators:

$$x\ \rightarrow_{S-max}\ y = \max(1 - x, y)$$

$$x\ \rightarrow_{S-\Pi}\ y = 1 - x + x \cdot y$$

$$x\ \rightarrow_{S-W}\ y = \min(1 - x + y, 1)$$

Now let us consider the question of the choice of one of the formulas (8)-(10) to represent bipolar queries and an appropriate modeling of the logical connectives occurring therein, i.e., the choice of one of the De Morgan Triples.

In [20] we have shown certain basic properties of the fuzzified version of the original formula (8). Some of them are valid for any choice of logical operators, some are limited to some special cases. We study some of them here again, checking if they are valid also for the formulas (9) and (10). However, first we start with a property identifying the equivalence between formulas (8)-(10) for a certain choice of the logical operators.

Property 1 For a distributive De Morgan triple, i.e., when $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$, and a related S-implication all formulas (8)-(10) are equivalent.

We will show the equivalence between (8) and (9) and the remaining equivalences may be shown in a similar way (the equivalence of (8) and (10) was shown by us in [16] for the specific case of the MinMax De Morgan Triple). Formula (9) may be rewritten as follows:

$$C(t) \wedge \forall s\ (\neg C(s) \vee \neg P(s) \vee P(t))$$

what, due to the assumed distributivity of the triple is equivalent to:

$$C(t) \wedge ((\forall s\ (\neg C(s) \vee \neg P(s))) \vee P(t))$$

and via the following series of transformations leads to (8):

$$C(t) \wedge ((\forall s\ \neg(C(s) \wedge P(s))) \vee P(t)) \equiv$$
$$C(t) \wedge ((\neg\exists s\ (C(s) \wedge P(s))) \vee P(t)) \equiv$$
$$C(t) \wedge (\exists s\ (C(s) \wedge P(s)) \Rightarrow P(t))$$

ISBN: 978-989-95079-6-8

The last equivalence holds for "⇒" being an S-implication.

Among three De Morgan Triples that we consider in this paper only the MinMax triple is distributive. Thus for it and related S-implication we get equivalence of all three formulas (8)-(9). Property 1 shows only a sufficient condition for this equivalence, but for the other two triples some counterexamples for such an equivalence may be easily shown.

In [20] we have shown a property which is worth reminding as it best characterizes the understanding of the bipolar queries adopted here. Namely, if there is no conflict between the required (C) and preferred (P) conditions at all, i.e., there is a tuple fully (to a degree equal 1) satisfying both of them then the formula (8) turns into a regular conjunction of both conditions. This may be formally expressed as follows.

Property 2 If there exists a tuple t such that $C(t) = P(t) = 1$ then a bipolar query (C, P) turns into the conjunction $C \wedge P$.

In [20] we have shown that for any combination of a t-norm, t-conorm and S-implication or R-implication such that $(1 \Rightarrow x) = x$, Property 2 holds in case of the formula (8). Note that the conjunction mentioned in the Property is modeled then via assumed t-norm.

Here, in view of the Property 1, it is clear that in case of the MinMax De Morgan Triple and the S-implication, Property 2 holds also for the formulas (9) and (10). Moreover, it may be easily proved that this property also holds for the MinMax De Morgan Triple and the R-implication in case of the formula (10). Namely, we will show that:

$$\text{truth}(\forall s\ (C(s) \Rightarrow_{R-min} (\neg P(s) \vee_{max} P(t))) = \min_s \begin{cases} 1 & \text{if } C(s) \leq \neg P(s) \vee_{max} P(t) \\ \neg P(s) \vee_{max} P(t) & \text{otherwise} \end{cases} \tag{15}$$

is equal $P(t)$ for any tuple t, under the assumptions of the Property 2. If $P(t) = 1$ then for all tuples s the value of $C(s)$ is lower or equal $\max(1 - P(s), P(t))$ and thus (15) is equal 1, i.e., is equal to $P(t)$. Now let us assume that $P(t) < 1$ and let us denote with u a tuple for which $C(u) = P(u) = 1$ (the existence of such a tuple is assumed in the Property 2). Then, for any tuple t, the minimum over s in (15) is realized for $s = u$ and thus is equal $\max(1 - 1, P(t))$, i.e., $P(t)$, what completes our proof of the Property 2 also for the formula (10) and the R-implication operator.

Some examples may be easily found showing that Property 2 fails for the W and Π De Morgan triples.

Another property of the formula (8), shown in [20], is valid for two other formulas (9) and (10), and may be expressed as follows.

Property 3 If for a tuple t the value of $P(t)$ is equal to 1, then a bipolar query (C, P) turns into $C(x)$.

This property holds for all formulas (8)-(10), for any combination of a t-norm, t-conorm and S-implication or R-implication.

This property is a direct consequence of the general properties of the t-norm ($(x \wedge 0) = 0$), t-conorm ($(x \vee 1) = 1$ and $(0 \vee 0) = 0$) and implication operators ($(x \Rightarrow 1) = 1$).

Now we show some additional properties of the formulas (8)-(10).

Property 4 Let us assume that truth($\exists s\ (C(s) \wedge P(s))) > 0$. Then, for a De Morgan Triple with a t-norm without zero divisors, i.e., where $\forall x, y > 0\ (x \wedge y) \neq 0$, and the related R-implication, the matching degree computed using (8) for a tuple t fully satisfying the required condition and not satisfying the preferred condition at all (i.e., $C(t) = 1$ and $P(t) = 0$) is equal 0.

This is a property of the R-implication. Notice that this means that such a tuple t will get lower matching degree than a tuple s which satisfies both conditions to a degree ϵ, whatever small ϵ is. Thus it is surely a property we would like to avoid and which makes (8) under both MinMax and Π De Morgan Triples (whose t-norms do not have zero divisors) with related R-implications less appealing as models of the bipolar query.

A similar property, formulated below, is exhibited by (10).

Property 5 Let us assume that there is at least one tuple u such that $C(u) > 0$ and $P(u) = 1$. Then, for a De Morgan Triple with a t-norm without zero divisors and the related R-implication the matching degree computed using (10) for a tuple t fully satisfying the required condition and not satisfying the preferred condition at all (i.e., $C(t) = 1$ and $P(t) = 0$) is equal 0.

Thus also (10) under both MinMax and Π De Morgan Triples with related R-implications is not very appealing as a model of the bipolar query. This property seems to favor the W De Morgan Triple, at least in case of the R-implication and formulas (8) and (10).

Another negative property of (8) for a specific combination of logical operators may be expressed as follows.

Property 6 For the MinMax De Morgan Triple used with related S-implication, the aggregation scheme defined by (8) may lead to the same matching degree for two tuples t and u while t strongly Pareto dominates u, i.e., $C(t) > C(u)$ and $P(t) > P(u)$.

This may be demonstrated with the following example. Let us denote $\exists_s\ (C(s) \wedge P(s))$ with $\exists CP$. Let $\exists CP = 0.7$ and $C(t) = 1$, $P(t) = 0.3$, $C(u) = 0.3$ and $P(u) = 0$. Then the matching degree computed for both tuples is equal 0.3, while t strongly Pareto dominates u.

In fact this property may be supplemented by observing that all tuples t such that $P(t) \leq (1 - \exists CP)$ and $C(t) \geq (1 - \exists CP)$ obtain the same matching degree, equal $1 - \exists CP$. This fact has been observed by Dubois and Prade [5] for a formula similar to (8). However, it should be noted that even for the tuples not satisfying the above conditions, the Pareto domination may be not reflected by (8) used with the logical operators specified by Property 6. For example, for a tuple u, such that $C(u) = P(u) = 0.6$, still assuming $\exists CP = 0.7$, the matching degree is equal 0.6. The same matching degree obtains for t such that $C(t) = 1$ and $P(t) = 0.6$ as well as for t such that $C(t) = 0.6$ and $P(t) = 1.0$, while in both these cases the tuple t Pareto dominates u.

Note, that due to the Property 1, the Property 6 is also valid for two other formulas (9)-(10).

Certainly the list of properties discussed in the paper is not exhaustive and they should be seen as a first attempt at a more comprehensive analysis of the bipolar queries and their various representations proposed here. Such an analysis should provide some hints which representation should be used un-

ISBN: 978-989-95079-6-8

der which conditions and using which set of logical operators. However, already the properties discussed here provide some hints which may be summarized as follows.

We first list some general properties shared by all three formulas (8)-(10) under any combination of the logical operators. These properties may be expressed concisely as the properties of the "and possibly" operator, which is the essence of our understanding of bipolar queries (this operator is denoted below as $\wedge_{possibly}$, but it should be remembered that this operator is not truth-functional):

- monotonicity (but not strict) in both arguments,
- boundary properties: $1 \wedge_{possibly} 1 = 1$ and $x \wedge_{possibly} 1 = x$ (Property 3).

Now let us look at particular formulas (8)-(10) and summarize their properties in combinations with all considered logical operators.

Formula (8) exhibits Property 2 when used with any combination of logical operators. This is surely its advantage as this property is characteristic for our understanding of bipolar queries. Property 4 seems to suggest that the R-implication should be avoided in case of formula (8) (unless it is used in the framework of the W De Morgan Triple, but then both types of implication operators are identical, thus a general hint of avoiding R-implication may be still seen as valid). Property 6 suggests that the MinMax De Morgan Triple is generally not appropriate for the formula (8).

Formula (9) exhibits Property 2 only for the MinMax De Morgan Triple, but Property 6 makes this triple inappropriate to some extent.

Formula (10) also satisfies Property 2 only for the MinMax De Morgan Triple, which is on the other hand somehow inappropriate due to the Properties 5 and 6.

Concluding, if Property 2 is required, what seems to be a reasonable postulate, then the best choice of the representation of the bipolar queries and logical operators to model the logical connectives therein– according to studied properties– seems to be formula (8) with the Π De Morgan Triple and the S-implication operator. Such a choice saves the obtained representation from some negative properties discussed in this paper. Further studies are needed in order to identify a more comprehensive list of postulated properties.

***Abstract*— *In this paper, we introduce a fuzzy extension of the Rand index, a well-known measure for comparing two clustering structures. In contrast to an existing proposal, which is restricted to the comparison of a fuzzy partition with a non-fuzzy reference partition, our extension is able to compare two proper fuzzy partitions with each other. Elaborating on the formal properties of our fuzzy Rand index, we show that it exhibits desirable metrical properties.*

***Keywords*—** Clustering, Distance, Fuzzy Partition, Metric, Rand Index, Similarity

1 Introduction

The problem to compare two partitions of a set of objects occurs quite naturally in various domains, notably in data analysis and clustering. For example, one way to evaluate the result of a clustering algorithm is to compare the clustering structure produced by the algorithm with a correct partition of the data (which of course presumes that this information is available). In cluster analysis, so called *external evaluation measures* have been developed for this purpose [1, 2]. However, measures of that kind are not only of interest as evaluation criteria, i.e., for comparing a hypothetical partition with a true one. Instead, distance measures for partitions are interesting in their own right and can be used for different purposes.

In [3], for example, the authors consider the problem of clustering data in a very high-dimensional space. To increase efficiency, they propose to map the data into a low-dimensional space first and to cluster the transformed data thus obtained afterward. In this context, a distance measure for clustering structures (partitions) is useful to measure the loss of information incurred by the data transformation: If the transformation is (almost) lossless, the clustering structures in the two spaces should be highly similar, i.e., their distance should be small. On the other hand, a significant difference between the two partitions would indicate that the transformation does have a strong effect in the sense of distorting the structure of the data set.

Even though a large number of evaluation criteria and similarity indexes for clustering structures have been proposed in the literature, their extension to the case of fuzzy partitions has received much less attention so far. This is especially true for external evaluation criteria and measures comparing two clustering structures, whereas *internal criteria* for evaluating a single partition[1] have been studied more thoroughly (see, e.g., [4] and [5] for early proposals).

In a recent paper by Campello [6], the author has proposed an extension of the *Rand index* [7], a well-known measure of similarity between two partitions of a data set. Even though Campello's proposal is quite interesting, it also exhibits a number of disadvantages. Most notably, it is properly defined only for the comparison of a fuzzy partition with a non-fuzzy reference partition. It is true that this restriction can be tolerated if the index is used as an external evaluation criterion since, as correctly argued by the author, a reference partition provided by an external source is typically non-fuzzy. Yet, our example above has clearly shown that there is also a need for measures comparing two fuzzy partitions.

In this paper, we propose an alternative extension of the Rand index (which is, in principle, also applicable to related similarity measures for clustering structures). As opposed to Campello's proposal, our variant is able to compare two proper fuzzy partitions with each other. Moreover, we study our fuzzy Rand index from a formal point of view and show that it satisfies the desirable properties of a metric (when being used as a distance function).

The remainder of the paper is organized as follows. In the next section, we briefly review the proposal of Campello and discuss some of its properties in a critical way. In Section 3, we introduce our new measure and elaborate on its formal properties. The paper concludes with a short summary and an outlook on future work in Section 4.

2 Review of Campello's Proposal

Before reviewing Campello's proposal and discussing some of its properties, we briefly recall the original definition of the Rand index.

2.1 The Rand Index

Let $\mathbf{P} = \{P_1, \ldots, P_k\} \subset 2^X$ and $\mathbf{Q} = \{Q_1, \ldots, Q_\ell\} \subset 2^X$ be two (crisp) partitions of a finite set $X = \{x_1, x_2 \ldots x_n\}$ with n elements, which means that $P_i \neq \emptyset$, $P_i \cap P_j = \emptyset$ for all $1 \leq i \neq j \leq k$, and $P_1 \cup P_2 \cup \ldots \cup P_k = X$ (and analogously for $\mathbf{Q}$). Let

$$C = \{ (x_i, x_j) \in X \times X \mid 1 \leq i < j \leq n \}$$

denote the set of all tuples of elements in X.[2] We say that two elements $(x, x') \in C$ are *paired* in $\mathbf{P}$ if they belong to the same

[1] Typically, such criteria compare the intra-cluster variability, i.e., the variability among objects within the same cluster (which should be small) with the inter-cluster variability, i.e., the variability among objects from different clusters (which should be high).

[2] Since we consider unordered tuples, we should more correctly write $\{x_i, x_j\}$ instead of (x_i, x_j).

ISBN: 978-989-95079-6-8

cluster, i.e., if there is a cluster $P_i \in \mathbf{P}$ such that $x \in P_i$ and $x' \in P_i$. Moreover, we distinguish the following subsets of C:

- $C_1 \equiv$ the set of tuples $(x,x') \in C$ that are paired in $\mathbf{P}$ and paired in $\mathbf{Q}$;
- $C_2 \equiv$ the set of tuples $(x,x') \in C$ that are paired in $\mathbf{P}$ but not paired in $\mathbf{Q}$;
- $C_3 \equiv$ the set of tuples $(x,x') \in C$ that are not paired in $\mathbf{P}$ but paired in $\mathbf{Q}$;
- $C_4 \equiv$ the set of tuples $(x,x') \in C$ that are neither paired in $\mathbf{P}$ nor in $\mathbf{Q}$.

Obviously, $\{C_1,C_2,C_3,C_4\}$ is a partition of C, and $a+b+c+d = |C| = n(n-1)/2$, where

$$a = |C_1|,\ b = |C_2|,\ c = |C_3|,\ d = |C_4|. \tag{1}$$

The tuples $(x,x') \in C_1 \cup C_4$ are the *concordant* pairs, i.e., the pairs for which there is agreement between $\mathbf{P}$ and $\mathbf{Q}$, while the tuples $(x,x') \in C_2 \cup C_3$ are the *discordant* pairs for which the two partitions disagree. The Rand index is defined by the number of concordant pairs divided by the total number of pairs:

$$\mathrm{R}(\mathbf{P},\mathbf{Q}) = \frac{a+d}{a+b+c+d} \tag{2}$$

Thus defined, the Rand index is a similarity measure which assumes values between 0 and 1. It can easily be turned into a distance function by defining

$$\mathrm{D}_R(\mathbf{P},\mathbf{Q}) = 1 - \mathrm{R}(\mathbf{P},\mathbf{Q}) = \frac{b+c}{a+b+c+d}\ .$$

It is worth mentioning that D_R satisfies the classical properties of a distance (reflexivity, separation, symmetry, and triangular inequality).

2.2 Campello's Fuzzy Rand Index

The aim of Campello's paper is to extend the Rand index to the case of fuzzy partitions. To this end, he first reformulates it within a set-theoretic framework. An extension to the fuzzy case can then be accomplished in a straightforward way by using generalized set-theoretical operators. Recall that $k = |\mathbf{P}|$ and $\ell = |\mathbf{Q}|$, and consider the following sets:

- $V \equiv$ the set of pairs $(x,x') \in C$ that belong to the same cluster in $\mathbf{P}$; it can be expressed as $V = \bigcup_{i=1\ldots k} V_i$, where V_i is the set of pairs that both belong to the i-th cluster $P_i \in \mathbf{P}$.
- $W \equiv$ the set of pairs $(x,x') \in C$ that belong to different clusters in $\mathbf{P}$; it can be expressed as $W = \bigcup_{1\le i\ne j\le k} W_{ij}$, where W_{ij} is the set of pairs such that $x \in P_i$ and $x' \in P_j$.
- $Y \equiv$ the set of pairs $(x,x') \in C$ that belong to the same cluster in $\mathbf{Q}$; it can be expressed as $Y = \bigcup_{i=1\ldots \ell} Y_i$, where Y_i is the set of pairs that both belong to the i-th cluster $Q_i \in \mathbf{Q}$.
- $Z \equiv$ the set of pairs $(x,x') \in C$ that belong to different clusters in $\mathbf{Q}$; it can be expressed as $Z = \bigcup_{1\le i\ne j\le \ell} Z_{ij}$, where Z_{ij} is the set of pairs such that $x \in Q_i$ and $x' \in Q_j$.

The Rand index can directly be written in terms of the cardinalities of these sets, since the four quantities (1) are obviously given by

$$a = |V \cap W|, \qquad b = |V \cap Z|,$$
$$c = |W \cap Y|, \qquad d = |W \cap Z|.$$

In the fuzzy case, the above sets become fuzzy sets. Let $P_i(x) \in [0,1]$ denote the degree of membership of element $x \in X$ in the cluster $P_i \in \mathbf{P}$. The sets V, W, Y, and Z can then be defined through fuzzy-logical expressions involving a t-norm $\top$ and t-conorm $\bot$:

$$\begin{aligned} V(x,x') &= \bot_{i=1}^{k} \top(P_i(x),P_i(x')) \\ W(x,x') &= \bot_{1\le i\ne j\le k} \top(P_i(x),P_j(x')) \\ Y(x,x') &= \bot_{i=1}^{\ell} \top(Q_i(x),Q_i(x')) \\ Z(x,x') &= \bot_{1\le i\ne j\le \ell} \top(Q_i(x),Q_j(x')) \end{aligned} \tag{3}$$

Moreover, defining the intersection of sets by the t-norm combination of membership degrees and resorting to the commonly used sigma-count principle [8] for defining set cardinality, one obtains

$$\begin{array}{rcccl} a & = & |V \cap Y| & = & \sum_{(x,x')\in C} \top(V(x,x'),Y(x,x')) \\ b & = & |V \cap Z| & = & \sum_{(x,x')\in C} \top(V(x,x'),Z(x,x')) \\ c & = & |W \cap Y| & = & \sum_{(x,x')\in C} \top(W(x,x'),Y(x,x')) \\ d & = & |W \cap Z| & = & \sum_{(x,x')\in C} \top(W(x,x'),Z(x,x')) \end{array} \tag{4}$$

As before, the Rand index can then be defined as in (2), namely as the fraction

$$\frac{a+d}{a+b+c+d}\ .$$

2.3 Properties of Campello's Fuzzy Rand Index

Having defined a similarity or, equivalently, a distance function, it is natural to ask for desirable metrical properties of that function. In the case of the above fuzzy Rand index, however, this question has to be considered with caution, since Campello is actually only interested in comparing a fuzzy partition $\mathbf{P}$ with a non-fuzzy partition $\mathbf{Q}$. And indeed, formal properties of the measure are not investigated in his paper.

On the other hand, it is noted by Campello himself that, formally, the measure can in principle be applied to compare two fuzzy partitions. When doing so, however, it turns out quickly that it fails to be a proper metric. In fact, it does not even satisfy reflexivity, the perhaps most basic axiom: Even for two identical partitions $\mathbf{P}$ and $\mathbf{Q}$, the quantities b and c in (4) will generally not vanish, a necessary condition for having $\mathrm{R}(\mathbf{P},\mathbf{Q}) = 1$.

Consider, for example, the simple fuzzy partition $\mathbf{P}$ illustrated in Fig. 1, which consists of two clusters P_1 and P_2. Instead of a hard boundary, there is a "soft" transition between P_1 and P_2; the elements x_1, x_2, x_3, and x_4 partially belong to both clusters and have membership degrees, respectively, of $3/4$, $1/2$, $1/2$, $1/4$ in P_1 and $1/4$, $1/2$, $1/2$, $3/4$ in P_2. Comparing $\mathbf{P}$ to itself in terms of the fuzzy Rand index, we obtain $\mathrm{R}(\mathbf{P},\mathbf{P}) < 1$.

Upon closer examination, it seems that the core principle of Campello's extension is not suitable for comparing partitions in a fuzzy sense. In fact, despite being defined in terms

ISBN: 978-989-95079-6-8

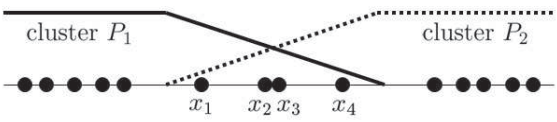

Figure 1: Illustration of a simple fuzzy partition of a subset of the reals (indicated by circles). The partition consists of two clusters, P_1 (left) and P_2 (right). While some elements definitely belong to only one of the clusters, some "critical" points in the middle have partial membership in both clusters.

of fuzzy logical formulas, the very idea of the approach has arguably a more "probabilistic flavor". This becomes especially obvious when using the product as a t-norm and the (bounded) sum as t-conorm. Then, if $P_i(x)$ is interpreted as the probability that x belongs to the i-th cluster, $V(x,x')$ is nothing else than the probability that x and x' are put in the same cluster, given that the two corresponding clusters are chosen *independently of each other* according to the distributions $(P_1(x),P_2(x)\dots P_k(x))$ and $(P_1(x'),P_2(x')\dots P_k(x'))$, respectively. Likewise, $W(x,x')$ is the probability that x and x' are put into different clusters.

Even if one accepts the probabilistic interpretation of a single membership degree, the additional assumption of independence is clearly not tenable. In fact, this property is obviously violated when comparing a partition with itself, since for each element $x \in X$, a cluster can then only be chosen once and not two times independently of each other. But even if $\mathbf{P}$ and $\mathbf{Q}$ are not identical, independence of cluster membership is in conflict with the topological relationships between the elements and clusters. In the example in Fig. 1, for instance, it is not reasonable to put x_1 and x_4 into cluster P_2 and x_2 and x_3 into cluster P_1. When putting elements independently of each other into clusters, however, this is a possible scenario. And indeed, this scenario contributes to Campello's fuzzy Rand index according to (3).

Seen from this point of view, one may even question the usefulness of the approach for its original purpose, namely the comparison of a fuzzy with a non-fuzzy partition. What the fuzzy partition in our example truly suggests is that we are uncertain about the boundary between the two clusters. More concretely, the fuzzy partition suggests four possible non-fuzzy partitions:

- $\mathbf{P}_1$ which puts the boundary left to x_1;
- $\mathbf{P}_2$ with boundary between x_1 and x_2;
- $\mathbf{P}_3$ with boundary between x_3 and x_4;
- $\mathbf{P}_4$ which puts the boundary right to x_4.

Thus, it seems reasonable to define an extension of the Rand index as an aggregation (e.g., weighted average) of the results of the non-fuzzy comparisons, namely

$$\mathrm{R}(\mathbf{P}_1,\mathbf{Q}), \mathrm{R}(\mathbf{P}_2,\mathbf{Q}), \mathrm{R}(\mathbf{P}_3,\mathbf{Q}), \mathrm{R}(\mathbf{P}_4,\mathbf{Q}).$$

In Campello's approach, there are not 4 but 16 scenarios which have an influence on the result, since each of the four cluster memberships is determined independently of each other. In general, the result will therefore be different. In fact, differences already occur for single pairs of elements. For example, since x_2 and x_3 are always in the same cluster in $\mathbf{P}_1,\dots,\mathbf{P}_4$, it is natural to say that they are paired with degree 1. According to Campello's approach, however, the degree to which x_2 and x_3 are in the same cluster in $\mathbf{P}$ is given by

$$V(x_2,x_3) = \bot(\top(1/2,1/2),\top(1/2,1/2)),$$

which corresponds to the truth degree of the proposition that "x_1 is put into P_1 AND x_2 is put into P_1 OR x_1 is put into P_2 AND x_2 is put into P_2". In general, this degree will be < 1 (except for special $(\top,\bot)$-combinations such as $\top = \min$ and $\bot =$ bounded sum).

3 A New Fuzzy Rand Index

In this section, we propose a new fuzzy variant of the Rand index which is able to compare any pair of fuzzy partitions and, moreover, has desirable metric properties. In the following, we focus on the view of the Rand index as a distance function. Thanks to the affine transformation $\mathrm{D}_R = 1 - \mathrm{R}$, all results can directly be transferred to the original conception as a measure of similarity.

3.1 Definition

Given a fuzzy partition $\mathbf{P} = \{P_1,P_2\dots P_k\}$ of X, each element $x \in X$ can be characterized by its membership vector

$$\mathbf{P}(x) = (P_1(x),P_2(x)\dots P_k(x)) \in [0,1]^k, \tag{5}$$

where $P_i(x)$ is the degree of membership of x in the i-th cluster P_i. We define a fuzzy equivalence relation on X in terms of a similarity measure on the associated membership vectors (5). Generally, this relation is of the form

$$E_{\mathbf{P}}(x,x') = 1 - \|\mathbf{P}(x) - \mathbf{P}(x')\|, \tag{6}$$

where $\|\cdot\|$ is a proper distance on $[0,1]^k$. The basic requirement on this distance is that it yields values in $[0,1]$. The relation (6) generalizes the equivalence relation induced by a conventional partition (where each cluster forms an equivalence class). In passing, we note that this definition is invariant toward a permutation (renumbering) of the clusters in $\mathbf{P}$, which is clearly a desirable property.

Now, given two fuzzy partitions $\mathbf{P}$ and $\mathbf{Q}$, the idea is to generalize the concept of concordance as follows. We consider a pair (x,x') as being concordant in so far as $\mathbf{P}$ and $\mathbf{Q}$ agree on their degree of equivalence. This suggest to define the *degree of concordance* as

$$1 - |E_{\mathbf{P}}(x,x') - E_{\mathbf{Q}}(x,x')| \in [0,1]. \tag{7}$$

Analogously, the *degree of discordance* is

$$|E_{\mathbf{P}}(x,x') - E_{\mathbf{Q}}(x,x')| \ .$$

Our distance measure on fuzzy partitions is then defined by the normalized sum of degrees of discordance:

$$d(\mathbf{P},\mathbf{Q}) = \frac{\sum_{(x,x')\in C} |E_{\mathbf{P}}(x,x') - E_{\mathbf{Q}}(x,x')|}{n(n-1)/2} \tag{8}$$

Likewise,

$$1 - d(\mathbf{P},\mathbf{Q}) \tag{9}$$

corresponds to the normalized degree of concordance and, therefore, is a direct generalization of the original Rand index.

ISBN: 978-989-95079-6-8

3.2 Formal Properties

In this section, we first show that our proposal is indeed a proper generalization of the Rand index. Afterward, we study the metrical properties of the measure.

Proposition: *In the case where* **P** *and* **Q** *are non-fuzzy partitions, the measure (9) reduces to the original Rand index.*

Proof: In the non-fuzzy case, the membership vectors (5) are 0/1-vectors. More specifically, each vector has a single entry $P_i(x) = 1$, while all other entries are 0. Consequently, the fuzzy equivalence (6) reduces to the conventional equivalence, that is, $E_{\mathbf{P}}(x,x') = 1$ if x and x' are in the same cluster and $E_{\mathbf{P}}(x,x') = 0$ otherwise. Likewise, (7) yields 1 if (x,x') is a concordant pair and 0 otherwise. Consequently, the measure (9) is the (normalized) sum of concordant pairs and, therefore, equals the original Rand index. □

Recall that a non-negative $U^2 \to \mathbb{R}$ mapping $d(\cdot)$ is called a metric on U if is satisfies the following properties for all $u,v,w \in U$:

- Reflexivity: $d(u,u) = 0$
- Separation: $d(u,v) = 0$ implies $u = v$
- Symmetry: $d(u,v) = d(v,u)$
- Triangle inequality: $d(u,w) \leq d(u,v) + d(v,w)$

The properties of reflexivity and symmetry are quite obviously valid for our measure (8). To show the triangle inequality, consider three fuzzy partitions **P**, **Q**, **R** and fix a single tuple $(x,x') \in C$. Let

$$a = E_{\mathbf{P}}(x,x'),\ b = E_{\mathbf{Q}}(x,x'),\ c = E_{\mathbf{R}}(x,x').$$

Since a, b, and c are real numbers (from the unit interval), and the simple difference on the reals satisfies the triangle inequality, we have $|a-c| \leq |a-b| + |b-c|$. Now, since this inequality holds for each pair $(x,x') \in C$, it remains valid when summing over all these pairs. In other words, it is also satisfied by (8), which means that

$$d(\mathbf{P},\mathbf{R}) \leq d(\mathbf{P},\mathbf{Q}) + d(\mathbf{Q},\mathbf{R}).$$

The separation property is not immediately valid for (8). Roughly speaking, this is due to the fact that, by mapping elements to their membership vectors (5), some information about the partition itself is lost. In particular, it is possible that two partitions, even though they are not identical, cannot be distinguished in terms of the distances between these vectors.

Nevertheless, we can guarantee the separation property by restricting to a reasonable subclass of fuzzy partitions. We call a fuzzy partition $\mathbf{P} = \{P_1, P_2 \ldots P_k\}$ *normal*, if it satisfies the following:

N1 For each $x \in X$: $P_1(x) + \ldots + P_k(x) = 1$.

N2 For each $P_i \in \mathbf{P}$, there exists an $x \in X$ such that $P_i(x) = 1$.

In other words, we consider Ruspini partitions [9] and assume that each cluster has a prototypical element. Moreover, we assume the following equivalence relation on X:

$$E_{\mathbf{P}}(x,x') = 1 - \frac{1}{2}\sum_{i=1}^{k} |P_i(x) - P_i(x')|. \tag{10}$$

Note that $0 \leq E_{\mathbf{P}}(x,x') \leq 1$ for all $(x,x') \in X^2$ under assumption N1.

Now, consider two normal fuzzy partitions **P** and **Q**, and suppose that $d(\mathbf{P},\mathbf{Q}) = 0$. According to our definition of $d(\cdot)$, this obviously means that

$$E_{\mathbf{P}}(x,x') = E_{\mathbf{Q}}(x,x') \tag{11}$$

for all $(x,x') \in C$. We call a set $\{p_1, p_2 \ldots p_k\} \subset X$ a prototype set for **P**, if $P_i(p_i) = 1$ for all $i = 1,\ldots,k$ (note that a prototype set is not necessarily unique). We distinguish two cases.

(a) There are no identical prototype sets for **P** and **Q** (note that this is necessarily the case if **P** and **Q** have a different number of clusters). Then, we can find elements $x,x' \in X$ such that x and x' are prototypes for **P** but not for **Q**. Note that N1 and N2 jointly imply that a prototype is represented by a 0/1 membership vector, and that $|\mathbf{P}(x) - \mathbf{P}(x')| = 1$ for two different prototypes x and x'. Moreover, these properties imply that the extreme distance of 1 can *only* be assumed for prototypes, whereas $|\mathbf{P}(x) - \mathbf{P}(x')| < 1$ if either x or x' is not a prototype. Thus, it follows that $E_{\mathbf{P}}(x,x') = 0$ and $E_{\mathbf{Q}}(x,x') > 0$, which means that condition (11) is violated. Hence, we have constructed a contradiction with the assumption that $d(\mathbf{P},\mathbf{Q}) = 0$.

(b) There are identical prototype sets $\{p_1,\ldots,p_k\} = \{q_1,\ldots,q_\ell\}$, respectively, for **P** and **Q** (which means that $k = \ell$, i.e., **P** and **Q** do have the same number of clusters). We can then establish a one-to-one correspondence between prototypes such that, without loss of generality, $p_i = q_i$ for $i = 1,\ldots,k$. From properties N1 and N2, it follows that the membership degree of any element x in the cluster P_i is a function of $E_{\mathbf{P}}(x,p_i)$. In fact, noting that $\mathbf{P}(p_i)$ is a 0/1 vector with a single 1 on position i, we get

$$\begin{aligned} E_{\mathbf{P}}(x,p_i) &= 1 - \frac{1}{2}\sum_{j=1}^{k} |P_j(x) - P_j(p_i)| \\ &= 1 - \frac{1}{2}\left((1-P_i(x)) - \sum_{j\neq i} P_j(x)\right) \\ &= 1 - \frac{1}{2}\left((1-P_i(x)) - (1-P_i(x))\right) \\ &= P_i(x). \end{aligned}$$

From (11), it thus follows that $P_i(x) = Q_i(x)$ for all $x \in X$, i.e., the i-th cluster in **P** and the i-th cluster in **Q** are identical. Since this holds for all $i \in \{1,2\ldots k\}$, we have shown that $\mathbf{P} = \mathbf{Q}$.

The above results can be summarized as follows.

Theorem: *The distance function (8) on fuzzy partitions is a pseudometric, i.e., it is reflexive, symmetric, and subadditive. Moreover, on the restricted class of normal fuzzy partitions or, more specifically, under the assumptions N1, N2, and (10), it also satisfies the separation property and, therefore, is a metric.*

4 Summary and Outlook

We have introduced a generalization of the Rand index for comparing two fuzzy clustering structures. Elaborating on the formal properties of our measure, we have shown that it is a

ISBN: 978-989-95079-6-8

pseudo-metric and, on a subclass of fuzzy partitions obeying certain normality assumptions, even a metric.

In future work, we plan to extent our approach to other similarity measures for (non-fuzzy) clustering structures which are related to the Rand index in the sense of being defined in terms of the same basic quantities, namely the numbers a, b, c, and d of concordant and discordant object pairs. An example of such a measure is the Jaccard coefficient, which is defined as $a/(a+b+c)$.

Fuzzy Modeling of Labeled Point Cloud Superposition for the Comparison of Protein Binding Sites

Thomas Fober and Eyke Hüllermeier

Email: {thomas,eyke}@mathematik.uni-marburg.de

Abstract— *Geometric objects are often represented approximately in terms of a finite set of points in three-dimensional Euclidean space. In this paper, we extend this representation to what we call labeled point clouds. A labeled point cloud is a finite set of points, where each point is not only associated with a position in three-dimensional space, but also with a discrete class label that represents a specific property. This type of model is especially suitable for modeling biomolecules such as proteins and protein binding sites, where a label may represent an atom type or a physico-chemical property. Proceeding from this representation, we address the question of how to compare two labeled points clouds in terms of similarity. Using fuzzy modeling techniques, we develop a suitable similarity measure as well as an efficient evolutionary algorithm to compute it. Finally, an application study is presented in which the approach is used to classify protein binding sites.*

Keywords— structural bioinformatics, proteins, similarity, classification

1 Introduction

Geometric objects are often represented in terms of a set of points in three-dimensional Euclidean space. This type of representation is finite and hence approximate (even though the number of points can become very large, as for example in laser range scanning), focusing on the most important characteristics of the object while ignoring less important details. A well-known example of a representation of this kind is the *Molfile* format [1], where molecules are described in terms of the spatial coordinates of all atoms. However, since not only the position but also the type of an atom is of interest, this representation is not a simple point cloud. Likewise, other biomolecular structures, such as proteins and protein binding sites, are not only characterized by their geometry but also by additional features, such as physico-chemical properties. In this paper, we therefore introduce the concept of a *labeled point cloud*. A labeled point cloud is a finite set of points, where each point is not only associated with a position in three-dimensional space, but also with a discrete class label that represents a specific property.

Since theory formation in the biological sciences is largely founded on similarity-based and analogical reasoning principles, the comparison of two (or more) objects with each other is a fundamental problem in bioinformatics. To compare two point clouds, the authors in [2] make use of a measure based on the *Gromov-Hausdorff distance* of sets. This approach is limited to unlabeled point clouds, however. Another possibility is to transform a labeled point cloud into a (labeled) graph first, capturing, in one way or the other, geometrical information in terms of edges, and to apply graph matching techniques afterward. This strategy was recently proposed in [3], where the use of *graph kernels* as similarity measures [4, 5, 6] has been especially advocated. At first sight, this idea looks appealing, especially since methods for comparing graphs abound in the literature. Nevertheless, it also comes with a number of disadvantages. For example, many techniques for matching and comparing graphs capture aspects of similarity which are reasonable for graphs but not necessarily for geometric objects. Besides, graph matching techniques are typically quite complex from a computational point of view.

Perhaps most importantly, however, a graph representation captures the geometrical information only in an *implicit* way, namely through the presence, absence, and possibly the labeling of edges. Moreover, the transformation is often not even lossless. Matching objects while obeying geometrical constraints can then become troublesome, since the geometrical information is not explicitly available. Instead, it must be reconstructed from the graph representation whenever needed.

As an alternative to an indirect approach of that kind, we therefore propose the method of *labeled point cloud superposition* (LPCS), which operates on labeled point clouds directly. Thus, it preserves as much geometrical information as possible and facilitates the exploitation thereof. Related to the concept of an LPCS, we introduce a similarity measure which makes use of modeling techniques from fuzzy set theory. This measure proceeds from the idea of equivalence (inclusion) of point clouds in a set-theoretic sense, but is tolerant toward exceptions (on the level of label information) and geometric deformations.

The remainder of the paper if organized as follows. Subsequent to a brief introduction to protein binding sites and their representation in Section 2, we introduce the concept of LPCS in Section 3. The problem of computing an LPCS is then addressed in Section 4, where an evolution strategy is proposed for this purpose. Section 5 is devoted to the experimental validation of the approach, and Section 6 concludes the paper.

2 Modeling Protein Binding Sites

In this paper, our special interest concerns the modeling of protein binding sites. More specifically, our work builds upon CavBase [7], a database for the automated detection, extraction, and storing of protein cavities (hypothetical binding sites) from experimentally determined protein structures (available through the PDB). In CavBase, a set of points is used as a first approximation to describe a binding pocket. The database currently contains 113,718 hypothetical binding sites that have been extracted from 23,780 publicly available protein structures using the LIGSITE algorithm [8].

ISBN: 978-989-95079-6-8

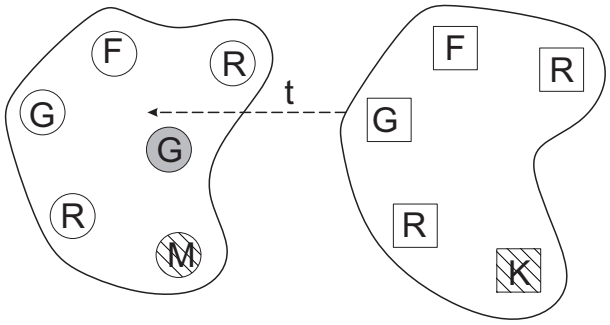

Figure 1: Two point clouds A (left, points as circle) and B (right, points as squares): The intra-point distances are the same in both point clouds, except for the additional gray point in A. Labels are depicted as letters within the circles and boxes, respectively.

The geometrical arrangement of the pocket and its physicochemical properties are first represented by predefined *pseudocenters* – spatial points that represent the center of a particular property. The type and the spatial position of the centers depend on the amino acids that border the binding pocket and expose their functional groups. They are derived from the protein structure using a set of predefined rules [7]. As possible types for pseudocenters, hydrogen-bond donor, acceptor, mixed donor/acceptor, hydrophobic aliphatic, metal ion, pi (accounts for the ability to form π–π interactions) and aromatic properties are considered.

Pseudocenters can be regarded as a compressed representation of areas on the cavity surface where certain protein-ligand interactions are experienced. Consequently, a set of pseudocenters is an approximate representation of a spatial distribution of physicochemical properties. Obviously, just like in the case of Molfile, this representation is already in the form of a labeled point cloud: pseudocenters are given with their coordinates and labels, so that no further transformation is needed.

3 Labeled Point Cloud Superposition

Intuitively, two labeled point clouds are similar if they can be spatially superimposed. That is, by fixing the first and "moving" the second one (as a whole, i.e., without changing the internal arrangement of points) in a proper way, an approximate superposition of the two structures is obtained. More specifically, we will say that two point clouds are well superimposed if, for each point in one of the structures, there exists a point in the other cloud which is spatially close and has the same label. As an illustration, the example in Fig. 1 shows two point clouds A and B, for simplicity only in two dimensions. By moving B to the left (or A to the right), a superposition can be found so that, except for the hatched and gray nodes, all points in A spatially coincide with a corresponding point in B having the same label, and vice versa. So, A and B can be considered as being similar, at least to some extent.

More formally, let

$$A = \{(x_1, \ell(x_1)), \ldots, (x_m, \ell(x_m))\}$$

be a point cloud consisting of m points $x_i = (x_{i1}, x_{i2}, x_{i3}) \in \mathbb{R}^3$ with associated label $\ell(x_i) \in \mathcal{L}$, where $\mathcal{L}$ is a discrete set of labels (in the context of modeling protein binding sites, as discussed in the previous section, $\mathcal{L}$ is given by the seven types of pseudocenters). Moreover, let

$$B = \{(y_1, \ell(y_1)), \ldots, (y_n, \ell(y_n))\}$$

be a second point cloud to be compared with A. In the following, we define a function $\mathrm{SIM}(\cdot,\cdot)$ that returns a degree of similarity between two such structures A and B.

Roughly speaking, we consider similarity as a generalized (fuzzy) equivalence, which we in turn reduce to two inclusion relations, namely the inclusion of A in B and, vice versa, of B in A. Thus, we are first of all interested in whether each point $y \in B$ is also present in A (and each point $x \in A$ also present in B). For a fixed $y \in B$, we define the membership degree of this point in A by

$$\mu_A(y) = \exp\left(-\gamma \cdot d(y, A)\right) \quad , \tag{1}$$

where

$$d(y, A) = \min_{\substack{x \in A \\ \ell(x) = \ell(y)}} \|y - x\|_1$$

is the distance between a point $y \in B$ and the closest point $x \in A$ having the same label ($d(y,A) = \infty$ and hence $\mu_A(y) = 0$ if no such point exists); for $x \in A$, $\mu_B(x)$ and $d(x,B)$ are defined analogously.

In its proper sense, the inclusion of a set B in a set A means that *each* point $y \in B$ is also contained in A or, stated differently, if a point y is in B, then it is also present in A. If membership is a matter of degree, i.e., if A and B are fuzzy sets, this condition is often formalized in terms of a fuzzy implication [9]:

$$\min_{y \in B} \left(\mu_B(y) \to \mu_A(y)\right) \quad .$$

Here, the minimum operator plays the role of a generalization of the universal quantifier. In our case, $\mu_B(y) \equiv 1$, so that the above expression can be simplified as follows:

$$inc(B, A) = \min_{y \in B} \mu_A(y) \quad . \tag{2}$$

However, a universal quantification (modeled by the min operator) is too strict in our biological context, where data is typically inexact and noisy. To relax this definition of fuzzy inclusion, we replace the minimum by a fuzzy quantifier Q, which is specified in the form of a non-decreasing $[0,1] \to [0,1]$ mapping [10, 11]. This leads to

$$inc(B, A) = \min_{i=1\ldots|B|} \max\{Q(i/|B|), m_i\} \quad ,$$

where m_i is the i-th largest membership degree in the fuzzy set $\{\mu_A(y) \,|\, y \in B\}$. (Note that we recover (2) for Q defined by $Q(1) = 1$ and $Q(t) = 0$ for $0 \leq t < 1$.) Here, we simply take Q as the identical mapping $t \mapsto t$. Roughly speaking, $inc(B,A)$ thus defined can be interpreted as the generalized truth degree of the proposition that A is *almost* contained in B. The degree of inclusion of A in B, $inc(A,B)$, is defined analogously.

As mentioned above, the idea of our approach is to define the similarity between two labeled point clouds in terms of the best superposition of these two clouds. Therefore, let $\mathrm{TF}(\cdot, t)$ be a function that moves a point cloud via rotation and translation, as specified by the six-dimensional vector $t = (\theta_1, \theta_2, \theta_3, \delta_1, \delta_2, \delta_3) \in [0, 2\pi]^3 \times \mathbb{R}^3$. Thus,

$$B^* = \mathrm{TF}(B, t) = \{(y_1^*, \ell(y_1^*)), \ldots, (y_n^*, \ell(y_n^*))\}$$

ISBN: 978-989-95079-6-8

is the point cloud obtained by translating the point cloud B by $\delta = (\delta_1, \delta_2, \delta_3)$ (which means adding δ to each point $y \in B$) and rotating the result thus obtained by the angles θ_1, θ_2, and θ_3. Note that this operation leaves the label information unchanged (i.e., $\ell(y_i) = \ell(y_i^*)$). The position-invariant degree of inclusion of B in A is then given by

$$\mathrm{INC}(B,A) = \max_{t \in [0,2\pi]^3 \times \mathbb{R}^3} inc(\mathrm{TF}(B,t),A) \ , \qquad (3)$$

and $\mathrm{INC}(A,B)$ is defined analogously.

Based on these degrees, the similarity between A and B, in the sense of a generalized equivalence, can be defined as

$$\mathrm{SIM}(A,B) = \min\{\,\mathrm{INC}(A,B), \mathrm{INC}(B,A)\,\} \ . \qquad (4)$$

It is worth mentioning, however, that (4) is not always appropriate, especially if A and B greatly differ in size. In some applications, it makes sense to have a high similarity degree even if A is only a substructure of B, for example if A is a subpocket of B containing the most important catalytic residues (while the rest of the binding site B is functionally less important). Obviously, this is not guaranteed by (4). An interesting generalization, therefore, is to let

$$\begin{aligned} \mathrm{SIM}(A,B) = & \alpha \cdot \min\{\mathrm{INC}(A,B), \mathrm{INC}(B,A)\} + \\ & + (1-\alpha) \cdot \max\{\mathrm{INC}(A,B), \mathrm{INC}(B,A)\} \ . \end{aligned} \qquad (5)$$

Formally, this similarity measure can be motivated from a fuzzy logical point of view as follows. Considering the min (max) operator as a generalized conjunction (disjunction), the first (second) combination of the two inclusion degrees is the truth degree of the proposition that A is contained in B AND (OR) B is contained in A. A conjunctive combination of the two degrees of inclusion is obviously more demanding than a disjunctive one, as the former requires equality between A and B while the latter only requires inclusion of A in B or B in A. The measure (5), which formally corresponds to an OWA (ordered weighted average) combination of the two degrees of inclusion [12], achieves a trade-off between these two extreme aggregation modes, which is controlled by the parameter $\alpha \in [0,1]$: The closer α is to 0, the closer the aggregation is to the maximum, i.e., the less demanding it becomes. The optimal α is application-specific and depends on the purpose of the similarity measure.

4 Solving the LPCS Problem

The computation of the similarity (5) involves the solution of a real-valued optimization problem, namely the problem of finding an optimal vector t in (3) and, thus, an optimal point cloud superposition. The objective function to be maximized here is highly non-linear and multimodal. As an illustration, Fig. 2 shows the objective function obtained for the superposition of a randomly generated two-dimensional point cloud A (in which all points have the same label) with itself. This function maps each two-dimensional translation vector $t = (x,y)$ to the corresponding similarity degree between $\mathrm{TF}(A)$ and A (where we used $\alpha = 0.5$ in (5) and did not consider rotation). As can be seen, there is a sharp peak at $t = (0,0)$, which corresponds to the optimal superposition. Surrounding this solution, however, there are also many local optima.

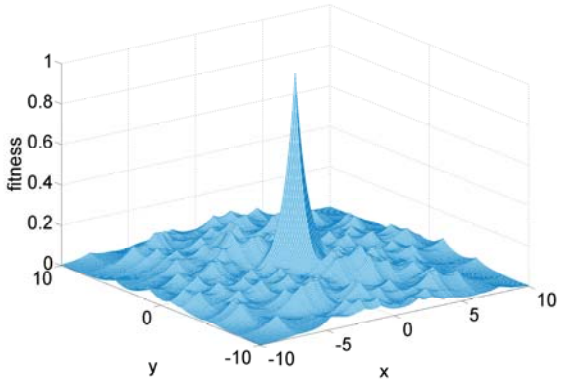

Figure 2: Example of an LPCS objective function.

The problem of local optima also becomes clear from the small example in Fig. 1. Moving the point cloud A from left to right, into the direction of B, has the following effect: First, a good superposition of two sub-clouds will be found, namely the right part of cloud A and the left part of cloud B. This results in a local maximum. Moving A further to the right leads to a larger local maximum (sub-clouds are growing), until the global maximum will eventually be reached.

4.1 Evolution Strategies

To solve the LPCS problem, we resort to *evolution strategies* (ES), a population-based, stochastic optimization method inspired by biological evolution and specifically developed for real-valued optimization problems [13]. An evolution strategy is based on a population, a set of μ (sub-optimal) candidate solutions that are initially spread randomly over the search space. In each generation, new solutions are generated by applying the genetic operators *recombination* and *mutation*. Recombination randomly selects ρ individuals from the current population and combines them to a new solution. Mutation takes this solution and shifts it randomly in the search space. An ES produces $\lambda = \lceil \mu \cdot \nu \rceil$ offsprings per iteration, so that this procedure has to be repeated λ times. A selection operator implements the "survival of the fittest" principle by picking the best individuals for the new population. There are two kinds of selection: The *plus*-selection chooses the best μ individuals among the offsprings plus the parents, while the *comma*-selection ignores the parent generation (this requires $\nu > 1$). A main advantage of the ES is its self-adaptation mechanism that controls the step sizes used in the mutation operator. One property of this mechanism (the advantage during optimization is obvious) is that step sizes decrease dramatically if the optimization reached a maximum. This property can be used as a qualitative termination criterion (stop when the largest step size falls below a given threshold).

Population-based optimization methods are especially advantageous for highly multimodal problems. Using a large population leads to an increased probability to generate a candidate solution in a region where the direction of descent points to the global maximum. Choosing the membership function (1) as a strictly monotone decreasing function which converges to zero ensures to have this direction in each point $t \in [0,2\pi]^3 \times \mathbb{R}^3$ and thus greatly simplifies the maximization problem. However, our experiments indicated that the solu-

ISBN: 978-989-95079-6-8

tion we found was most often only a local maximum. Therefore, we propose to use *fast restarts* of the ES. This means that the ES is started n times using comma-selection and weak termination criteria to achieve a large and quick but inexact exploration of our search space. We thus obtain n results in total. In a last step, we use the ES with plus-selection and strong termination criterion. Additionally, we include the best solution so far in the start population. The last run of the ES usually yields a globally optimal degree of similarity.

4.2 Complexity

Even though evolution strategies are generally known to be quite efficient solvers, the concrete complexity does of course depend on the application at hand. The application-specific part is the fitness function, i.e., the objective function to be optimized. This function has to be evaluated frequently and, therefore, is an important factor for the runtime. In our case, this function is given by the similarity measure (5), and its evaluation is strongly dominated by the nearest neighbor search which has to be conducted for each single point in both structures (recall that, according to (1), membership degrees are determined by the distance to closest points with the same label).

There exist a lot of data structures for supporting nearest neighbor search; see e.g. [14]. The most efficient among them need time $O(n\log^2 n)$ for construction and $O(\log^3 n)$ for answering a query. Unfortunately, we are not aware of an approach that allows for updating a data structure in an efficient and dynamic way. This would be desirable for our problem, in which the point clouds permanently change (the point cloud associated with an individual changes in each iteration). Instead, conventional approaches necessitate a construction from scratch in every iteration.

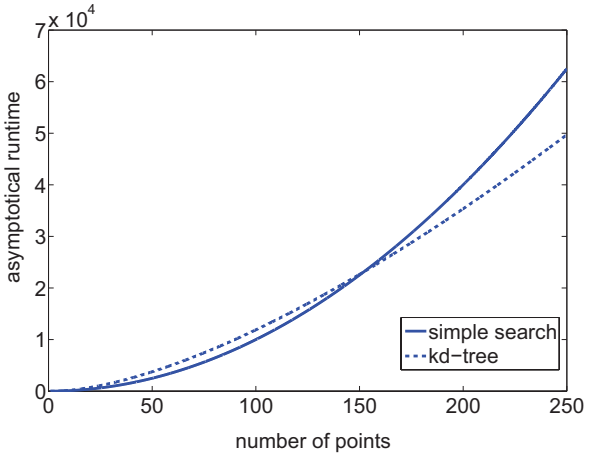

Figure 3: Runtime of a simple procedure and a more complex data structure as a function of the number of points.

Fig. 3 compares the runtimes, as a function of the number of points, for two approaches: (1) The use of a kd-tree data structure, which is reconstructed in each iteration and then used for query processing. (2) The use of a simple linear data structure, in which the points are stored in a fixed order. It needs linear instead of logarithmic time to answer a query but, on the other hand, does not cause additional costs for reconstruction. As can be seen, the use of a more complex approach pays off only for sufficiently large point clouds: The kd-tree reaches a break-even point at approximately 150 points.

In our application, we are mainly concerned with protein binding sites, which are characterized by around 180 points on average (even though much larger structures do of course exist). The use of a complex data structure did therefore not pay off. Nevertheless, we increased efficiency by hashing the points x_i of a point cloud, using the label $\ell(x_i) \in \mathcal{L}$ as a key. Since nearest neighbors are only searched among points having the same label, this obviously reduces runtime by a factor of approximately $|\mathcal{L}|$.

5 Experimental Results

5.1 Methods

In our experiments, we compared our novel method (LPCS) with existing graph-based approaches, namely the random walk (RW) kernel [6], the shortest path (SP) kernel [5], and the method of multiple graph alignment (MGA) recently introduced in [15]. Given two labeled points clouds as input, all these methods produce a degree of similarity as an output. Yet, for the graph-based approaches, it is of course necessary to transform a point cloud into a graph representation in a preprocessing step. This was done as as proposed in [15]:

1. each point is transformed into a node with corresponding node label
2. for each pair of nodes:
   (a) the Euclidean distance between both nodes is calculated
   (b) if the distance is below a certain threshold (here 11 Å to ensure connected graphs), an edge with weight equal to this distance is added

Our ES was restarted $n = 5$ times. The parameterization was optimized with the *sequential parameter optimization toolbox* [16] and was chosen as follows:

- inexact ES: $\mu = 30, \nu = 4, \rho = 2$, comma-selection, termination criteria: largest step size < 0.05, discrete recombination for strategy- and object-component.
- exact ES: $\mu = 30, \nu = 4, \rho = 6$, plus-selection, termination criteria: largest step size < 0.00001, intermediate recombination for object and discrete recombination for strategy-component.

A comprehensive explanation of the different ES parameters and operators can be found in [13].

For both variants we initialized the object-component in $[-150, 150]^3$ for translation and $[0, 2\pi]^3$ for rotation: The step sizes were initialized in $[5, 15]^3$ and $[1, \pi]^3$, respectively. The SP-kernel is parameter-free, the RW-kernel expects a parameter λ that is set to the largest degree of a node in the data set to ensure a geometric series during calculation, which results in a simpler evaluation [4]. Since the geometric information of real-world data is noisy, we also need a tolerance parameter ε to decide whether two edges have equal length (difference $\leq \varepsilon$) or not; in our experiments, we used $\varepsilon = 0.2$. For MGA, we chose the parameterization proposed in [15].

ISBN: 978-989-95079-6-8

The assessment of a similarity measure for biomolecular structures, such as protein binding sites, is clearly a non-trivial problem. In particular, since the concept of similarity by itself is rather vague and subjective, it is difficult to evaluate corresponding measures in an objective way. To circumvent this problem, we propose to evaluate similarity measures in an indirect way, namely by means of their performance in the context of nearest neighbor (NN) classification. The underlying idea is that, the better a similarity measure is, the better should be the predictive performance of an NN classifier using this measure for determining similar cases.

5.2 Data

One important problem in pharmaceutical chemistry is the identification of protein binding sites that bind a certain ligand. We selected two classes of binding sites that bind, respectively, to NADH or ATP. This gives rise to a binary classification problem: Given a protein binding site, predict whether it binds NADH or ATP.

More concretely, we compiled a set of 355 protein binding pockets representing two classes of proteins that share, respectively, ATP and NADH as a cofactor. To this end, we used CavBase to retrieve all known ATP and NADH binding pockets that were co-crystallized with the respective ligand. Subsequently, we reduced the set to one cavity per protein, thus representing the enzymes by a single binding pocket. As protein ligands adopt different conformations due to their structural flexibility, it is likely that the ligands in our data set are bound in completely different ways, hence the corresponding binding pocket does not necessarily share much structural similarity. We thus had to ensure the selection of binding pockets with ligands bound in similar conformation. To achieve this, we used the Kabsch algorithm [17] to calculate the root mean square deviation (RMSD) between pairs of ligand structures. Subsequently, we combined all proteins whose ligands yielded a RMSD value below a threshold of 0.2, thereby ensuring a certain degree of similarity. This value was chosen as a trade-off between data set size and similarity. Eventually, we thus obtained a two-class data set comprising 214 NADH-binding proteins and 141 ATP-binding proteins.

5.3 Results

The results of a leave-one-out cross validation, using the simple 1-NN classifier for prediction, are summarized in Table 1. As can be seen, the kernel-based methods (SP and RW) perform very poorly and are hardly better than random guessing. In terms of accuracy, MGA is much better, though still significantly worse than LPCS. In fact, LPCS performs clearly best on this problem.

Table 1: Accuracy and runtimes (in seconds with standard deviation, referring to a single comparison) of LPCS ($\alpha = 0.5$, with restarts like described above), MGA, RW, and SP on the NADH/APT data set.

Method	Accuracy	Runtime
MGA	0.7662	121.74 ± 418.02
SP	0.6056	$\mathbf{9.75 \pm 97.77}$
RW	0.5972	65.51 ± 89.07
LPCS	**0.9352**	20.04 ± 24.65

Table 2 furthermore shows how the performance of LPCS depends on the choice of the trade-off parameter α in (5). As can be seen, this parameter does indeed have an influence, even though the differences are not extreme. For this data set, α-values around 0.5 yield better results than extreme values close to 0 or 1; the optimal choice would be $\alpha = 0.7$. In practice, α can be considered as a tuning parameter to be adapted to the problem at hand (e.g., by means of a cross-validation on the training data).

Table 2: Accuracy of LPCS for different values of α in (5).

α	accuracy	α	accuracy
0	0.9042	0.6	0.9352
0.1	0.9183	0.7	0.9380
0.2	0.9126	0.8	0.9239
0.3	0.9154	0.9	0.9267
0.4	0.9267	1	0.9183
0.5	0.9352		

Regarding runtime, the experiment shows that LPCS is quite efficient, abandon restarts of the ES it would be the fastest of all alternatives, however with an increasing risk to get stuck in a local optimum. Using restarts, only SP is still a bit faster on average, however, it completely fails in terms of predictive accuracy. Even though we did not investigate this issue in a systematic way so far, our experience has shown that LPCS scales much better than typical graph-based approaches. This is hardly surprising, since the dimensionality of the LPCS optimization problem is constant (six parameters have to be optimized) and does not depend on the number of data points. It is true that the size of the point clouds does have an influence on the evaluation of the objective function, which involves a nearest neighbor search for each point. The increase in runtime is at most quadratic, however. As opposed to this, the complexity of graph-based methods such as MGA, in which graph matching is reduced to a combinatorial optimization problem, grows exponentially with the number of nodes.

6 Conclusions

In this paper, we have introduced labeled point cloud superposition (LPCS) as a novel tool for structural bioinformatics, namely as a method for comparing biomolecules on a structural level. Besides, using fuzzy modeling techniques, we have defined a related similarity measure. The concept of a labeled point cloud appears to be a quite natural representation for biological structures, especially since it is closely leaned on existing database formats. In comparison to other approaches, such as the prevalent graph-based methods, the modeling is hence simplified and does not involve any complex transformations. More importantly, a labeled point cloud preserves the full geometric information and makes it easily accessible to computational procedures.

A labeled point cloud superposition is a spatial "alignment" of two point clouds which is optimal in the sense of a given scoring (similarity) function. As for related problems in bioinformatics, such as sequence alignment, the computation of the similarity between two objects hence involves the solution of an optimization problem. To this end, we have proposed the

ISBN: 978-989-95079-6-8

use of an evolution strategy, an approach from the family of evolutionary algorithms, which appears to be especially suitable for this problem.

First experimental results with classification data are quite promising and suggest that our approach is able to compare protein binding sites in a reasonable way. In terms of classification accuracy, LPCS turned out to be significantly better than existing (graph-based) methods used for comparison. Moreover, even though it is computationally more complex than these methods for small data sets, it scales much better and becomes more efficient for larger data sets. This is due to the fact that, in contrast to graph-based methods, the search space does not depend on the size of the point clouds and remains low-dimensional.

Abstract *In this paper, a revisited approach for fuzzy regression linear model representation and identification is introduced. By adopting the commonly used principle of α-cuts, the fuzzy regression implementation is reduced to the handling of conventional intervals, for inputs, parameters and outputs. Using the Midpoint-Radius representation of intervals, the uncertainty attached to linear models becomes more interpretable. Actually, it is possible to determine the output uncertainty origin (model parameters and/or inputs). In this context, a possibilistic regression method is proposed to identify models of minimal global uncertainty, that is with respect to all possible inputs.*

Keywords Interval Regression, Fuzzy Regression, Uncertainty Representation, Fuzzy Inputs-Fuzzy Outputs.

1 Introduction

Fuzzy regression, a fuzzy type of conventional regression analysis, has been proposed to evaluate the functional relationship between input and output variables in a fuzzy environment. Indeed, unlike statistical regression modeling based on probability theory, fuzzy regression is based on possibility theory and fuzzy set theory [14].

In the fuzzy literature, the regression problem with fuzzy data has been previously treated from different points of view. According to [5], fuzzy regression techniques can be classified into two distinct areas. The first proposed by Tanaka ([10], [12]) which minimizes the total spread of the output is named possibilistic regression. In this case, the problem is viewed as finding fuzzy coefficients of a regression model according to a mathematical programming problem. The second approach developed by Diamond [4], which minimizes the total square error of the output is called the fuzzy least square method. In this paper a possibilistic approach is adopted.

In the chosen possibilistic context, different kinds of input/output data can be considered. Actually, the complete specification of regression problems highly depends on the nature of input-output data [5]. Some researches are thus devoted to Crisp-Input Crisp-Output (CICO) data [9] while others [6], [7], [8], [13] consider the regression problem using Fuzzy-Inputs and Fuzzy-Outputs (FIFO) data. Most commonly, a mixed approach with Crisp-Inputs and Fuzzy-Outputs (CIFO) is used [1], [2], [10], [11], [12].

In this framework, the fuzzy regression with CICO and CIFO data aroused a major interest. However, the FIFO model regression remains a little studied field. Indeed, only a few papers concerning this problem have been published ([6], [7], [8], [13]). For instance, in [6] and [13], different distances are proposed in order to extend the least square method to FIFO data. In [8], a multiobjective optimization technique for FIFO systems is proposed, whereas in [7] the optimization is based on the minimization of the deviation between observations and predictions.

All above mentioned methods lead to interesting results but present a lack of representativity and an awkward illustration of the uncertainties in the regression model. In order to overcome this problem, an extension of the regression methodology initially developed for CIFO systems in [1], [2] to FIFO ones is proposed. The key idea of the proposed approach resides in using a Midpoint-Radius regression model representation. By doing so, the regression problem can be viewed as a conventional linear optimization problem where a new criterion is proposed.

From a practical point of view and as commonly used in fuzzy regression literature ([5], [7], [8], [12]), the a-cut principle is adopted. In this case, for a specified a-cut, the fuzzy interval becomes a conventional interval, which states that a fuzzy interval representation is a generalization of a conventional one. In order to take into account the maximum of uncertainty in the system (the pessimistic case), an a-cut equal to 0 (0-cut) is considered. In this case, the fuzzy regression problem can be reduced to an interval regression one. That is the approach adopted in this paper where a new regression methodology is proposed.

The structure of this paper is as follows. In section 2, relevant concepts and notations are introduced. Section 3 is devoted to fuzzy regressive models representation. An identification method of such models based on a linear problem optimization is proposed in section 4. An application is shown in section 5. Finally, conclusion and perspectives are presented in section 6.

2 Relevant Concepts and Notations

For the sake of rigor and clarity, let us define the basic notions and notations used in this paper.
A fuzzy trapezoidal interval A is a particular case of a fuzzy number where a possibility distribution, represented by a membership function μ_A, is associated with the conventional intervals of the support and the kernel (see Figure 1).

ISBN: 978-989-95079-6-8

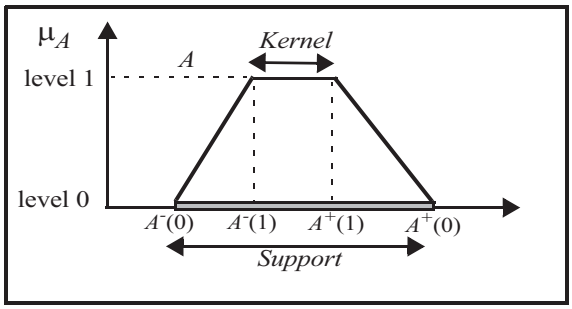

Figure 1: Trapezoidal fuzzy interval representation

In this case, for a given α-cut (α∈[0, 1]) on the fuzzy interval A, a conventional interval is obtained:

$$A(\alpha) = [A^{-}(\alpha), A^{+}(\alpha)] \tag{1}$$

Using the α-cut representation, a symmetrical fuzzy interval is viewed as a weighted family of nested intervals. In the sequel, in order to consider the maximum uncertainty, only α-cuts at level 0 will be considered. Consequently, all computations are performed with conventional intervals.

In this framework, an interval A is defined by the set of elements lying between its lower and upper limits (endpoints) as:

$$A = [A^{-},\ A^{+}] = \{x \mid A^{-} \le x \le A^{+}, x \in \Re\} \tag{2}$$

The interval A is called thick if $A^{-} < A^{+}$ and thin (or point) if $A^{-} = A^{+}$.

In order to manipulate and exhibit the uncertainty with intervals, an efficient representation is needed. Indeed, the latter should be able to represent arbitrary intervals and their sets in a single and uniform graphical way. In this framework, it is obvious that to uniquely define an interval, two parameters are necessary, hence the space of intervals is two-dimensional. There are many possible representations of an interval. The most used one is the endpoints representation given in equation (2). However, the main drawback of this representation resides in the fact that the uncertainty (the Radius) is awkward and not directly exhibited in the interval. In order to overcome this difficulty, another representation is adopted. Indeed, in order to facilitate the uncertainty representation, Midpoint (M) and Radius (R) coordinates are used (see Figure 2). In this case, an interval is represented as a point in the space (M, R).

For an interval A, its Midpoint and its Radius are defined by:

$$M_A = (A^{-} + A^{+})/2 \ \text{ and: } \ R_A = (A^{+} - A^{-})/2 \tag{3}$$

Moreover, the set of all the intervals contained in the interval A can be represented by a domain $C(A)$. As shown in Figure 2, the domain $C(A)$ is represented by the upper and lower bound lines of A, forming a triangle.

In the (M, R) representation, it is clear that the most imprecise element of $C(A)$ is the interval A itself which corresponds to the highest value of Radius, i.e. the top of the triangle. On the opposite, the triangle base represents all the crisp values between the lower and the upper bounds (the set of all the thin intervals).

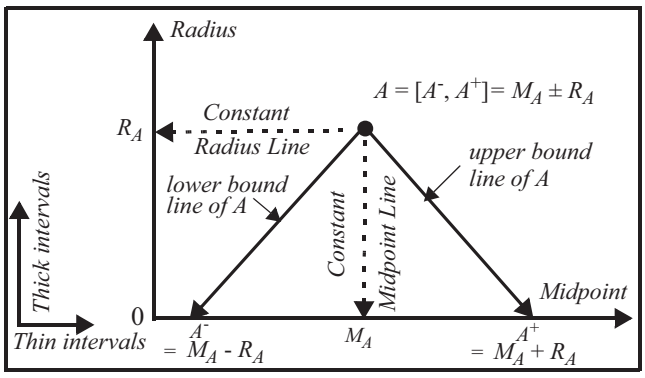

Figure 2: Midpoint-Radius representation of A and $C(A)$

For two intervals $A = [A^{-}, A^{+}]$ and $B = [B^{-}, B^{+}]$, the addition and multiplication operations are defined as follows:

$$\begin{cases} A \oplus B = [A^{-} + B^{-}, A^{+} + B^{+}] \\ A \otimes B = [min(Z), max(Z)] \end{cases} \tag{4}$$

where:

$$Z = \{A^{-}B^{-}, A^{-}B^{+}, A^{+}B^{-}, A^{+}B^{+}\} \tag{5}$$

In this case, it can be stated that the Midpoint and Radius of these operations are given by:

$$\begin{cases} M_{A \oplus B} = M_A \oplus M_B \\ R_{A \oplus B} = R_A \oplus R_B \end{cases} \tag{6}$$

and:

$$\begin{cases} M_{A \otimes B} = M_A M_B + \varphi_{A \otimes B} \cdot sign(M_A M_B) \\ R_{A \otimes B} = R_A R_B + |M_A| R_B + R_A |M_B| - \varphi_{A \otimes B} \end{cases} \tag{7}$$

where:

$$\varphi_{A \otimes B} = min\{|M_A| R_B, R_A |M_B|, R_A R_B\} \tag{8}$$

For two intervals [3] A and B, an inclusion relation of A in B (see Figure 3) is defined as follows:

$$A \subseteq B \Leftrightarrow \begin{cases} B^{-} \le A^{-} \\ A^{+} \le B^{+} \end{cases} \Leftrightarrow \begin{cases} M_B - R_B \le M_A - R_A \\ M_A + R_A \le M_B + R_B \end{cases} \tag{9}$$

$$\Leftrightarrow \begin{cases} M_B - M_A \le R_B - R_A \\ M_A - M_B \le R_B - R_A \end{cases} \tag{10}$$

From equation (10) it follows:

$$A \subseteq B \Leftrightarrow |M_B - M_A| \le R_B - R_A \tag{11}$$

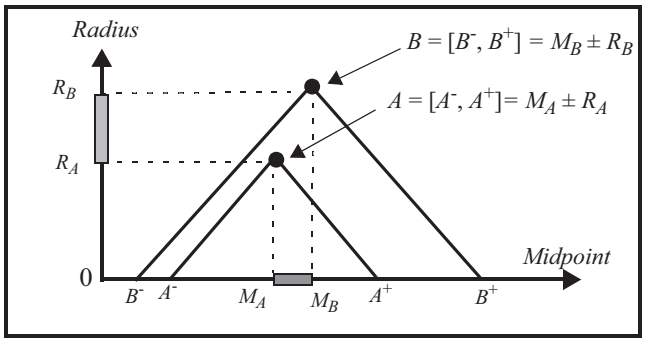

Figure 3: Inclusion of two intervals ($A \subseteq B$)

3 Fuzzy Regressive Model Representation

ISBN: 978-989-95079-6-8

The fuzzy linear regression model is the most frequently used form in regression analysis for expressing the relationship between one or more explanatory variables and response. For the sake of simplicity and as commonly assumed in the fuzzy regression literature, the case of simple linear regression model involving a single independent variable is considered. The case of multiple inputs is a straightforward generalization of this methodology but more complex in a computational point of view.

An interval regression model is mathematically expressed in the following form:

$$Y(X) = A_0 \oplus A_1 \otimes X \tag{12}$$

where Y is the interval output (dependant variable), A_0 and A_1 the interval parameters, i.e. unknowns to be estimated from observed data. According to (3), the parameters A_0 and A_1 are denoted as follows:

$$\begin{aligned} A_0 &= [A_0^-, A_0^+] = [M_{A_0} - R_{A_0}, M_{A_0} + R_{A_0}] \\ A_1 &= [A_1^-, A_1^+] = [M_{A_1} - R_{A_1}, M_{A_1} + R_{A_1}] \end{aligned} \tag{13}$$

The input X can take any value in a definition domain to be chosen.

As mentioned in the introduction, the regression problem has been previously treated from different points of view and by considering different kinds of input/output data. Indeed, according to the nature of X (crisp or imprecise) two regression problems can been distinguished. The first one deals with Crisp-Input Imprecise-Output data ([12], [10], [1], [2]). In this case, as the model is linear and the inputs are considered as crisp values, the model output (12) will also be an interval. So, for a crisp input $X = X_*$, equation (12) becomes:

$$Y(X_*) = [Y_*^-, Y_*^+] = A_0 \oplus A_1 \cdot X_* \tag{14}$$

In this case, the definition domain is the interval $D = [inf(D), sup(D)]$, which means that the input X can take any crisp value in D.

For the sake of illustration simplicity, in the sequel, the particular case when the parameter A_1 and the input are positive is considered. The other cases are a straightforward generalization of this particular case. The evolution of the model output (14) is illustrated in Figure 4. Actually, as the input X is a crisp value of D, the model output uncertainty is only due to the uncertainty of the two parameters A_0 and A_1.

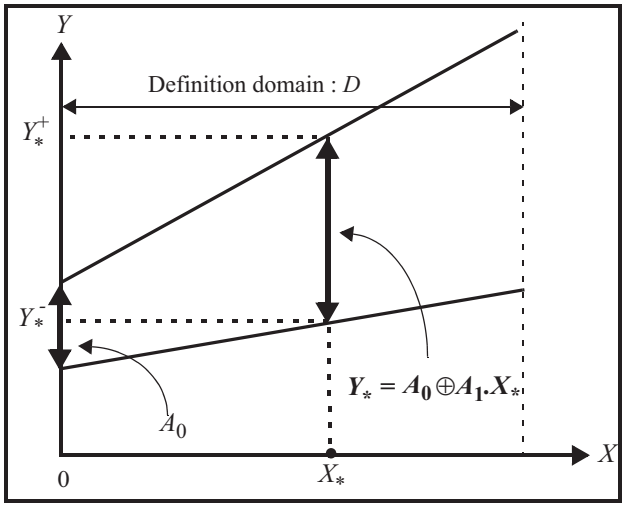

Figure 4: Interval model representation with a crisp input

The second regression problem is devoted to systems with Imprecise-Inputs and Imprecise-Outputs. For an interval input $X = X_* = [X_*^-, X_*^+]$, the interval model output is given by the following equation with Z defined according to (5):

$$\begin{aligned} Y(X_*) = [Y_*^-, Y_*^+] &= [A_0^- + min(Z), A_0^+ + max(Z)] \\ &= [A_0^- + A_1^- \cdot X_*^-, A_0^+ + A_1^+ \cdot X_*^+] \end{aligned} \tag{15}$$

In this case, the input X can be any interval included in the interval D previously defined for crisp inputs. Consequently, the model definition domain is now $\Delta = C(D)$ (see Figure 2). The model output evolution is presented in Figure 5.

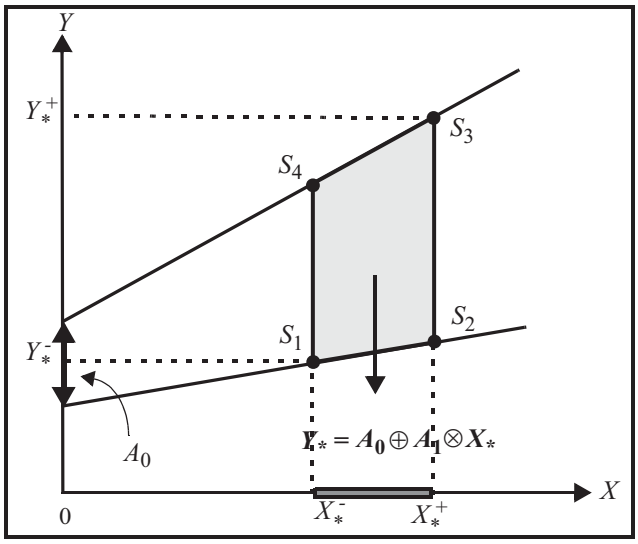

Figure 5: Conventional interval model representation

Several main drawbacks can be underlined:

- The interval input X_* is represented by its endpoints coordinates on a real line with only one dimension. It leads to a lack of information about the input uncertainty (Radius). In this case, neither the definition domain Δ nor the output uncertainty on it can be exhibited in a conventional 2D space.
- According to Figure 5, the model output is defined by the 4-sided area delimited by the four vertices (S_1, S_2, S_3, S_4). If the vertices S_1 and S_3 exhibit the model output bounds, the others (S_2 and S_4) have no interpretability in the model output. In this situation, two intervals are defined to represent the model output, which limits the interpretability of this kind of representation ([7], [8]).

In order to deal with these drawbacks, the Midpoint-Radius representation is used to define all handled intervals. In this context, the output Y is expressed by:

$$\begin{aligned} Y(X_*) &= [Y_*^-, Y_*^+] \\ &= [M_{Y(X_*)} - R_{Y(X_*)}, M_{Y(X_*)} + R_{Y(X_*)}] \end{aligned} \tag{16}$$

where:

$$\begin{cases} M_{Y(X_*)} = M_{A_0} + M_{A_1} \otimes X_* \\ R_{Y(X_*)} = R_{A_0} + R_{A_1} \otimes X_* \end{cases} \tag{17}$$

For positive parameter A_1 and input X_*, we have:

$$M_{A_1 \otimes X_*} = M_{A_1} M_{X_*} + \varphi_{A_1 \otimes X_*} \cdot sign(M_{A_1} M_{X_*}) \tag{18}$$

As:

ISBN: 978-989-95079-6-8

$$\varphi_{A_1 \otimes X_*} = min\{M_{A_1}R_{X_*}, R_{A_1}M_{X_*}, R_{A_1}R_{X_*}\} = R_{A_1}R_{X_*}, \quad (19)$$

the equation (18) becomes:

$$M_{A_1 \otimes X_*} = M_{A_1}M_{X_*} + R_{A_1}R_{X_*} \quad (20)$$

By adopting the same principle, the following Radius expression is determined:

$$R_{A_1 \otimes X_*} = R_{A_1}R_{X_*} + M_{A_1}R_{X_*} + R_{A_1}M_{X_*} - R_{A_1}R_{X_*} = M_{A_1}R_{X_*} + R_{A_1}M_{X_*} \quad (21)$$

By substitution of equations (20) and (21) in (17), it follows:

$$\begin{cases} M_{Y(X_*)} = M_{A_0} + M_{A_1}M_{X_*} + R_{A_1}R_{X_*} \\ R_{Y(X_*)} = R_{A_0} + M_{A_1}R_{X_*} + R_{A_1}M_{X_*} \end{cases} \quad (22)$$

The Midpoint and Radius output evolutions on the domain Δ are illustrated in Figure 6 and Figure 7.

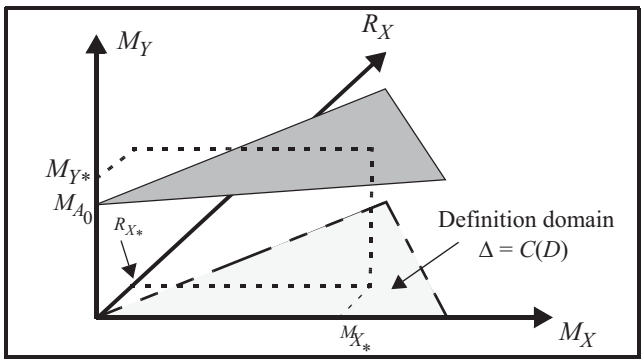

Figure 6: The midpoint output evolution

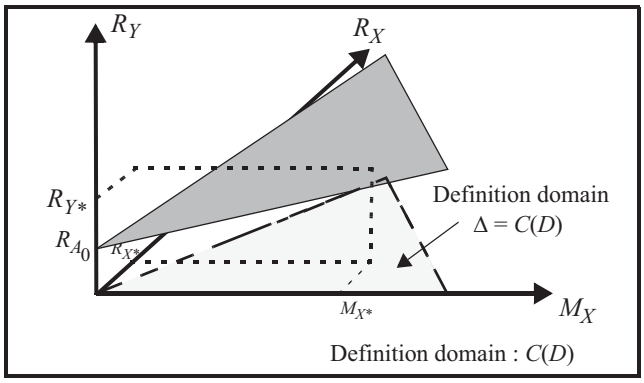

Figure 7: The radius output evolution.

From equations (16) and (22), it is obvious that:

$$\begin{cases} Y_*^- = M_{A_0} - R_{A_0} + (M_{A_1} - R_{A_1})(M_{X_*} - R_{X_*}) \\ Y_*^+ = M_{A_0} + R_{A_0} + (M_{A_1} + R_{A_1})(M_{X_*} + R_{X_*}) \end{cases} \quad (23)$$

A global representation of the model output evolution on the domain Δ is illustrated in Figure 8.

This Midpoint-Radius representation presents several advantages:

- In this representation, only one interval output is defined for a considered input. Indeed, the output expression represents as well the contribution of the input Midpoint and Radius.
- According to this representation, the origin of uncertainty in the output can be precisely determined. In other words, the contributions of the parameters A_0, A_1 and the input X are well defined in the model output (22).

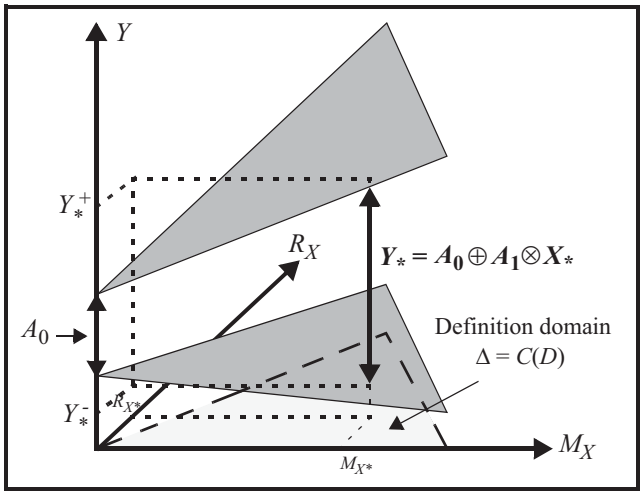

Figure 8: The model output evolution

4 Interval Regressive Model Identification

In the context of regression model identification, two main problems come up, namely, the model structure specification and the estimation of the given model. The first problem is focused on the choice of a suitable model structure for a data set. This problem is traditionally addressed *a priori.* In this paper, as commonly used, the model structure is assumed to be linear. In this case, the regression problem is reduced to an estimation problem of the model parameters.

Let us consider a set of N observed data samples. Let the j^{th} sample be represented by the couple $(X_j, Y_j), j = 1,..., N$ where X_j are interval inputs and the Y_j are the corresponding interval output.

All the observed input intervals are assumed to be included in the interval $D = [D^-, D^+]$ given by:

$$D^- = min(X_j^-) \text{ and } D^+ = max(X_j^+) \quad (24)$$

Like any regression technique, the fuzzy regression objective is to determine a predicted functional relationship between inputs X and outputs Y:

$$\hat{Y}(X) = A_0 \oplus A_1 \otimes X \quad (25)$$

In this case, the definition domain of the identified model is the set of all the intervals included in D, i.e. $\Delta = C(D)$.

As discussed in the paper introduction, a possibilistic regression approach is adopted where the objective is to determine the model parameters such that the observed data are included in the predicted ones (possibility model). In this framework, another kind of model (necessity one) could be identified [11].

In the proposed identification methodology, two points have to be considered for its implementation:

- the interval inclusion constraints to be introduced in the optimization problem,
- the identification criterion to be optimized.

4.1 The optimization constraints

In this case, the inclusion constraints are given by:

ISBN: 978-989-95079-6-8

$$Y_j \subseteq \hat{Y}_j \Leftrightarrow \left|M_{\hat{Y}_j} - M_{Y_j}\right| \leq R_{\hat{Y}_j} - R_{Y_j} \quad (26)$$

with:

$$M_{\hat{Y}_j} = M_{A_0} + M_{A_1} \otimes X_j \text{ and: } R_{\hat{Y}_j} = R_{A_0} + R_{A_1} \otimes X_j \quad (27)$$

By substitution of (27) in (26), the constraints inclusion can be written as:

$$\begin{aligned} &\left|M_{A_0} + M_{A_1} M_{X_j} + R_{A_1} R_{X_j} - M_{Y_j}\right| \leq \\ &R_{A_0} + M_{A_1} R_{X_j} + R_{A_1} M_{X_j} - R_{Y_j} \end{aligned} \quad (28)$$

Moreover, the optimization constraints must ensure the identification of intervals, whose bounds are ordered. Moreover, the sign of the parameter A_1 must be constrained as well. In the case of a model whose parameter A_1 is identified as positive, it follows:

$$R_{A_0} \geq 0, \text{ and } : M_{A_1} \geq R_{A_1} \geq 0 \quad (29)$$

It is important to note that all the considered constraints in the identification problem are linear according to the identification variables (Midpoint and Radius of A_0 and A_1).

4.2 The used criterion

The objective is to identify the less imprecise model on its definition domain, as it has been proposed in our previous works [1]. The computation of the global uncertainty on the whole domain D proposed in [1] is here extended to the whole domain Δ, whose elements are intervals. It follows that the criterion J to be optimized, i.e. the global uncertainty on Δ, is expressed as::

$$\begin{aligned} J &= \iint_{\Delta} (\hat{Y}^{+} - \hat{Y}^{-}) dM_X dR_X = 2 \iint_{\Delta} R_{\hat{Y}} dM_X dR_X \\ &= 2 \iint_{\Delta} R_{A_0} + M_{A_1} R_X + R_{A_1} M_X) dM_X dR_X \end{aligned} \quad (30)$$

The substitution of equation (23) in (30) yields to:

$$J = 2R_{A_0} \cdot R_D^2 + 2R_{A_1} \cdot R_D^2 \cdot M_D + \frac{2}{3} M_{A_1} \cdot R_D^3 \quad (31)$$

To sum up, the identification method is performed by minimizing the criterion (31) under the constraints (28) and (29).

At this stage, several points can be discussed about the proposed approach:

- As the interval D is defined with the observed inputs, its Radius and Midpoint are known numerical values. So, the criterion J is linear according to the optimization variables. Moreover, J is independent of the observed inputs, i.e. the optimization is made on the whole domain Δ of the model, not only on the observed data. This point contributes to improve the model robustness.
- It is obvious that the criterion must be optimized under constraints in order to ensure inclusion property. If the constraints are released, the identified model corresponds to the minimal possible uncertainty, achieved with null parameters, and has no sense.
- As the minimization of the model uncertainty is performed on Δ, the input uncertainty is considered in the model output expression in the identification process.

5 Illustrative example

In this part, the proposed identification method is applied on the illustrative example given in [8], [7]. Given the data set [8], [7] illustrated in Table 1, corresponding of α-cuts of level 0 of proposed fuzzy data set, the objective is to identify the model parameters A_0 and A_1.

Table 1: Observed data set and predicted one

[3 ; 4]	[5 ; 6]	[4.16 ; 7.25]
[4.5 ; 6.5]	[6.5 ; 8.5]	[4.82 ; 8.5]
[6.5 ; 7.5]	[6 ; 7]	[5.69 ; 9]
[8 ; 9]	[8 ; 9]	[6.35 ; 9.75]
[9.5 ; 11.5]	[7 ; 9]	[7 ; 11]
[10.5 ; 11.5]	[10 ; 11]	[7.45 ; 11]
[12 ; 13]	[9 ; 10]	[8.1 ; 11.75]

The considered definition domain is D = [1.5, 13] and represented in Figure 9. This domain corresponds to a set of positive inputs, and, as discussed previously, the parameter A_1 is assumed to be positive too.

The identified parameters corresponding to the less imprecise model according to the criterion J defined in (31) are:

$$A_0 = [2.844 ; 5.25] \text{ and } A_1 = [0.438 ; 0.5] \quad (32)$$

In this case, the optimal value of uncertainty obtained is $J = 153.95$.

The identified model output representation is given in Figure 9, whereas the predicted outputs are presented in Table 1.

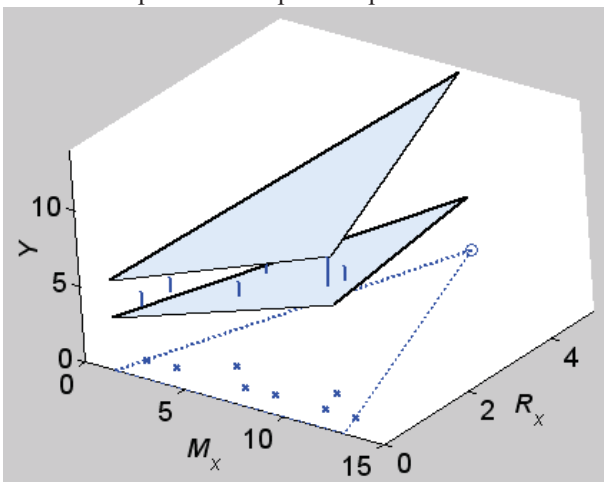

Figure 9: Identified model representation.

As presented in Table 1, the main advantage of the proposed approach compared to those presented in [7] and [8] is that only one interval output corresponds to a considered input. In Figure 9, it can be stated that the desired inclusion is respected.

Another advantage of the representation using the (Midpoint, Radius) space for the interval inputs concerns the exploitation

ISBN: 978-989-95079-6-8

of the model characteristics. According to (22), the output Radius evolution on Δ can be represented (see Figure 10). On the axe (M_X, $R_X = 0$), i.e. the triangle basis, only the parameter uncertainty is exhibited, whereas at the top of the triangle, the output uncertainty is maximum, corresponding to the most uncertain input in Δ, i.e. D. In this example (Figure 10), the output radius is nearly constant on the basis of the triangle, corresponding to the case of a nearly crisp parameter A_1. The output radius increasing on Δ is essentially due to the input uncertainty.

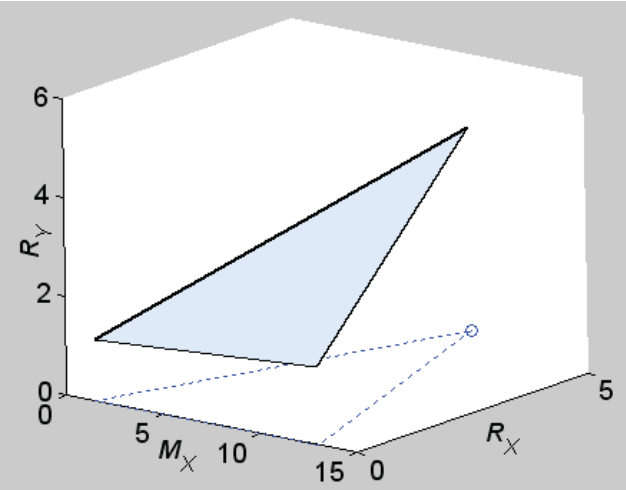

Figure 10: Identified model output Radius evolution.

The same analysis can be performed on the output Midpoint evolution on Δ, corresponding to the global tendency of the output on the domain.

In [8], the identified model, whose output respects the inclusion statement, corresponds to a criterion value $J = 281.03$, according to (31). Its parameters are the following:

$$A_0 = [1.25 ; 6.75] \text{and } A_1 = [0.4 ; 0.56] \quad (33)$$

In fact, the vertical dimension α is introduced into the proposed multiobjective optimization problem. It is known that the higher the α value is set for optimization, the more uncertain the identified model is and inclusion is respected for any lower α levels. So, this compromise between higher level of inclusion and lower uncertainty leads to the identification of a model whose uncertainty is not minimal on the domain.

On the other hand, the proposed method in [7], which minimizes deviations between observations and predictions without constraining inclusion, leads to the identification of a model which corresponds to a criterion value $J = 102.6$, and whose parameters are:

$$A_0 = [3 ; 3.82] \text{and } A_1 = [0.5 ; 0.54] \quad (34)$$

It is obvious that guaranteeing the inclusion increase the model uncertainty.

6 Conclusion

In this paper, a revisited representation of interval regressive model is proposed and used in an identification problem.

By adopting the Midpoint-Radius formalism for intervals, uncertainty representation is improved. Applied to regressive interval models, this formalism allows a better handling of the input uncertainty in the definition domain establishment and in the model output definition. In an identification problem, based on the optimization of a linear expression of the model output global uncertainty on its definition domain, the desired inclusion is ensured.

Further work will focus on the extension of this approach to fuzzy linear systems, by considering the vertical dimension α. In the proposed space, a symmetrical trapezoidal fuzzy interval can be interpreted by a zooming operation as illustrated in the following Figure 11:

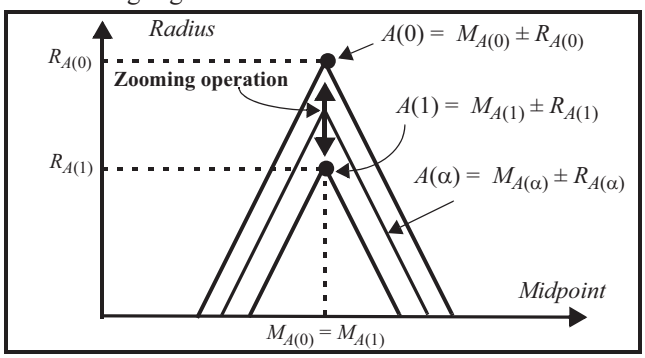

Figure 11: Midpoint-Radius representation of symmetrical trapezoidal fuzzy interval α-cuts.

A particular attention should be paid to the loss of linearity of the membership function of the model output, due to the fuzzy product between the input X and the parameter A_1.

Abstract— *The aim of this paper is to study a predator-prey population model which takes into account the uncertainty that arises when determining the initial populations of predator and prey . This model is solved numerically by means of a 4^{th}-order Runge-Kutta method. Simulations are made and a graphical representation is also provided to show the evolution of both populations over time. In addition to that, a new phase-plane in this fuzzy setting, referred to as fuzzy phase-plane, is introduced. The stability of the equilibrium points is also described. Finally, this paper points out a new research direction on fuzzy dynamical systems, especially in non-linear cases.*

Keywords— Equilibrium points, Fuzzy predator-prey population model, Fuzzy phase-plane, Fuzzy stability, Uncertainty.

1 Introduction

Nowadays, differential equations have proved a successful modelling paradigm. In a wide range of disciplines, the behaviour of an idealised version of a problem under study has been adequately described by one or more ordinary differential equations. Real-world problems, however, are pervaded with uncertainty. According to Diniz *et al.* [1], the uncertainty can arise in the experimental part, the data collection, the measurement process, as well as when determining the initial conditions. These are patently obvious when dealing with "living" material, such as soil, water, microbial populations, etc. In order to handle these problems, the use of fuzzy sets may be seen as an effective tool for a better understanding of the studied phenomena. It is therefore not surprising that there is a vast literature dealing with fuzzy differential equations (FDEs) for modelling this kind of perception. In the study of differential equations in a fuzzy environment, the term fuzzy differential equations is used for referring to differential equations with fuzzy coefficients, differential equations with fuzzy initial values or fuzzy boundary values, or even differential equations dealing with functions on the space of fuzzy intervals (see [2, 3, 4, 5, 6, 7, 8]).

In population dynamics, Bassanezi *et al.* [9] have started using FDEs to study the stability of fuzzy dynamical systems. The variables and/or the parameters in the systems under consideration were supposed to be uncertain and modelled by fuzzy sets. The authors have suggested a new definition of fixed point: if f is a continuous function, then u is a fixed point if $f([u]^\alpha) = [u]^\alpha$ for $\alpha \in [0,1]$, where $[u]^\alpha = [u_1^\alpha, u_2^\alpha] = [\min_{x\in[u_1^\alpha,u_2^\alpha]} f(x), \max_{x\in[u_1^\alpha,u_2^\alpha]} f(x)]$ (see [9] for more details). According to Ortega *et al.* [10], the proposed idea is not easy to implement in practice because several details should be treated carefully. Guo *et al.* [11] have adopted Hüllermeier's approach [7] to establish fuzzy impulsive functional differential equations and some results were applied in the logistic model and the Gompertz model. In [12], the author has established existence and uniqueness results for fuzzy functional differential equations. These results were applied in population models whose solutions define fuzzy intervals. Recently, Peixoto *et al.* [13] have studied the fuzzy predator-prey population model. The authors have elaborated the classical deterministic model by means of a fuzzy rule-based system. The fuzzy rule-based system considered in their work consists of two inputs and two outputs. The fuzzy rule base is given by 30 rules of the type: "If the number of preys is large AND the potential of predation is very small, THEN the variation of preys increase a little AND the variation of the potential of predation increase a lot". The words such as "large", "very small", "increase a little" and "increase a lot" are modelled by fuzzy sets. This might be a possible way to treat the model in a fuzzy setting. In this paper, we propose a new way of studying the fuzzy predator-prey population model. For this purpose, we only consider the initial populations of predator and prey to be fuzzy intervals.

2 Preliminary Concepts

In this section, let us first introduce the notations and some theoretical background we will be using throughout this paper. Denote $\mathcal{F}(\mathbb{R}) = \{U \mid U : \mathbb{R} \to [0,1]\}$, where U satisfies the following conditions:

1. U is normal: there exists $x_0 \in \mathbb{R}$ such that $U(x_0) = 1$;
2. U is convex: for $x, y \in \mathbb{R}$ and $0 \leq \lambda \leq 1$, one has
$$U(\lambda x + (1-\lambda)y) \geq \min\left(U(x), U(y)\right);$$
3. U is upper semi-continuous: for any $x_0 \in \mathbb{R}$, one has
$$U(x_0) \geq \lim_{x \to x_0^{\pm}} U(x);$$
4. $[U]^0 = \overline{\{x \in \mathbb{R} \mid U(x) > 0\}}$ is a compact subset of $\mathbb{R}$.

If U satisfies (1)–(4), then it is called a fuzzy interval. We can define its α-cuts as follows:

$$[U]^\alpha = \{x \in \mathbb{R} \mid U(x) \geq \alpha\}, \;\; 0 < \alpha \leq 1$$

For a fuzzy interval U, its α-cuts are closed intervals in $\mathbb{R}$. Let us denote them by $[U]^\alpha = [u_1^\alpha, u_2^\alpha]$.

In what follows, we introduce some results we adopt from [14] concerning the notion of interactivity of fuzzy intervals.

ISBN: 978-989-95079-6-8

Definition 1 *Two fuzzy intervals A and B are said to be interactive fuzzy intervals if there exist $q, r \in \mathbb{R}$, $q \neq 0$, such that their joint possibility distribution is given by*

$$\begin{aligned} C(x_1, x_2) &= A(x_1) \cdot \chi_{\{qx_1+r=x_2\}}(x_1, x_2) \\ &= B(x_2) \cdot \chi_{\{qx_1+r=x_2\}}(x_1, x_2) \end{aligned} \tag{1}$$

where $\chi_{\{qx_1+r=x_2\}}(x_1, x_2)$ stands for the characteristic function of the line

$$\left\{(x_1, x_2) \in \mathbb{R}^2 \mid qx_1 + r = x_2\right\}.$$

In this case we have

$$[C]^\alpha = \left\{(x, qx + r) \in \mathbb{R}^2 \mid x = (1-t)a_1^\alpha + ta_2^\alpha, t \in [0,1]\right\}$$

where $[A]^\alpha = [a_1^\alpha, a_2^\alpha]$ and $[B]^\alpha = q[A]^\alpha + r$ for any $\alpha \in [0,1]$, and, finally

$$B(x) = A\left(\frac{x-r}{q}\right)$$

for all $x \in \mathbb{R}$.

Definition 2 *Two fuzzy intervals A and B are said to be completely positively interactive if q is positive in (1).*

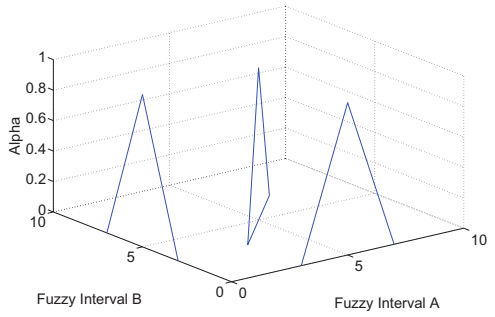

Figure 1: Completely positively interactive fuzzy intervals.

Definition 3 *Let C be a joint possibility distribution with marginal possibility distributions A and B, and let $f : \mathbb{R}^2 \to \mathbb{R}$ be a continuous function. If A and B are interactive fuzzy intervals, then the extension of f via C is defined as*

$$f(A, B)(y) = \sup_{y=f(x_1,x_2)} C(x_1, x_2), \quad \forall y \in \mathbb{R}. \tag{2}$$

Remark 1 *If A and B are non-interactive fuzzy intervals, that is, their joint possibility distribution is defined by*

$$C(x_1, x_2) = \min\left(A(x_1), B(x_2)\right),$$

then (2) turns into the extension principle introduced by Zadeh [15].

Definition 4 *If A and B are two fuzzy intervals, then the distance D between A and B is defined as*

$$D(A, B) = \sup_{\alpha \in [0,1]} d_H([A]^\alpha, [B]^\alpha)$$

where

$$d_H([A]^\alpha, [B]^\alpha) =$$

$$\max\left\{\sup_{a \in [A]^\alpha} \inf_{b \in [B]^\alpha} d(a,b), \sup_{b \in [B]^\alpha} \inf_{a \in [A]^\alpha} d(a,b)\right\}$$

3 Two-Dimensional Autonomous Systems

In this section, we first consider a general two-dimensional autonomous system with crisp initial values:

$$\begin{cases} x'(t) = f(x,y), & x(t_0) = x_0 \\ y'(t) = g(x,y), & y(t_0) = y_0 \end{cases} \tag{3}$$

where $f, g : \mathbb{R}^2 \to \mathbb{R}$ are continuous functions and $x_0, y_0 \in \mathbb{R}$. This model is called an autonomous system because the functions appearing on the right-hand side of (3) do not depend on the independent variable t. Suppose that the initial values in (3) are uncertain and modelled by fuzzy intervals, then we have the following fuzzy autonomous system [16]:

$$\begin{cases} x'(t) = f(x,y), & x(t_0) = X_0 \\ y'(t) = g(x,y), & y(t_0) = Y_0 \end{cases} \tag{4}$$

where $f, g : \mathbb{R}^2 \to \mathbb{R}$ are continuous functions and $X_0, Y_0 \in \mathcal{F}(\mathbb{R})$ with $[X_0]^\alpha = [x_{01}^\alpha, x_{02}^\alpha]$ and $[Y_0]^\alpha = [qx_{01}^\alpha + r, qx_{02}^\alpha + r]$ for $\alpha \in [0,1]$, $q \in \mathbb{R}^+$ and $r \in \mathbb{R}$. Here we assume that X_0 and Y_0 are completely positively interactive fuzzy intervals.

A solution to (4) can be approximated by any numerical method existing in the literature. For any fixed value of t, the solution is represented as a joint possibility distribution in the xy-plane. As t varies, the solution traces out the joint possibility distributions in the plane. By plotting a collection of such joint possibility distributions, we gain graphical insight into the behaviour of solutions. In this paper, the set of joint possibility distributions and the xy-plane are called fuzzy trajectories and the fuzzy phase-plane, respectively.

4 Numerical Methods

In many cases, model (4) presented in Section 3 cannot be solved analytically and therefore we need a numerical scheme to approximate the exact solution. We consider the following 4^{th}-order Runge-Kutta method:

$$x_{i+1} = x_i + \frac{h}{6}\left[K_1 + 2K_2 + 2K_3 + K_4\right] \tag{5}$$

$$y_{i+1} = y_i + \frac{h}{6}\left[L_1 + 2L_2 + 2L_3 + L_4\right] \tag{6}$$

where

$$\begin{aligned} K_1 &= f\left(x_i, y_i\right) \\ L_1 &= g\left(x_i, y_i\right) \\ K_2 &= f\left(x_i + \frac{h}{2}K_1, y_i + \frac{h}{2}L_1\right) \\ L_2 &= g\left(x_i + \frac{h}{2}K_1, y_i + \frac{h}{2}L_1\right) \\ K_3 &= f\left(x_i + \frac{h}{2}K_2, y_i + \frac{h}{2}L_2\right) \\ L_3 &= g\left(x_i + \frac{h}{2}K_2, y_i + \frac{h}{2}L_2\right) \\ K_4 &= f\left(x_i + hK_3, y_i + hL_3\right) \\ L_4 &= g\left(x_i + hK_3, y_i + hL_3\right) \end{aligned}$$

ISBN: 978-989-95079-6-8

Since the arguments x_i and y_i on the right-hand side of (5) and (6) are interactive, we can define new functions as follows:

$$F_h(x_i, y_i) = x_i + \frac{h}{6}\left[K_1 + 2K_2 + 2K_3 + K_4\right] \quad (7)$$

$$G_h(x_i, y_i) = y_i + \frac{h}{6}\left[L_1 + 2L_2 + 2L_3 + L_4\right] \quad (8)$$

By using the concept of interactivity of fuzzy intervals proposed by Majlender [14], we have the following generalised 4^{th}-order Runge-Kutta method for solving (4), where X_0 and Y_0 are interactive fuzzy intervals.

$$X_{i+1} = F_h(X_i, Y_i) \quad (9)$$

$$Y_{i+1} = G_h(X_i, Y_i). \quad (10)$$

The idea is that if $X_i(u) \geq \alpha$ for some $u \in \mathbb{R}$, then there exists a unique $v \in \mathbb{R}$ that Y_i can take. Furthermore, if u is moved to the left (right), then the corresponding value (that Y_i can take) will also move to the left (right). Vice versa, if u is moved to the left (right), then the corresponding value (that Y_i can take) will move to the right (left) [14]. From this explanation, we can compute the numerical approximations as follows:

$$x^{\alpha}_{1,i+1} = F_h(x^{\alpha}_{1,i}, y^{\alpha}_{1,i}) \quad (11)$$

$$x^{\alpha}_{2,i+1} = F_h(x^{\alpha}_{2,i}, y^{\alpha}_{2,i}) \quad (12)$$

$$y^{\alpha}_{1,i+1} = G_h(x^{\alpha}_{1,i}, y^{\alpha}_{1,i}) \quad (13)$$

$$y^{\alpha}_{2,i+1} = G_h(x^{\alpha}_{2,i}, y^{\alpha}_{2,i}) \quad (14)$$

Our purpose here is to generate accurate approximations at each α-cut. We begin by making a partition of the form $t_0 < t_1 < t_2 < ... < t_{N-1} < t_N = T$ on the interval $[t_0, T]$. This partition is uniformly spaced, that is the partition points are $t_i = t_0 + ih$, $i = 0, 1, 2, ..., N$ and the partition spacing $h = \frac{T - t_0}{N} > 0$ is sufficiently small and we called it the step-size or step-length.

5 Stability

In this section, we consider the following fuzzy autonomous system in vector form [16]:

$$\mathbf{z}'(t) = \mathbf{f}(\mathbf{z}), \quad \mathbf{z}(t_0) = \mathbf{Z}_0 \quad (15)$$

where $\mathbf{f} : \mathbb{R}^2 \to \mathbb{R}^2$ and $\mathbf{Z}_0 \in \mathcal{F}(\mathbb{R}^2)$ is a joint possibility distribution of which the marginal possibility distributions are interactive fuzzy intervals.

Next, we give several definitions and sufficient conditions for stability of the model studied.

Definition 5 *A point $\mathbf{z}_e$ is called an equilibrium point of (15) at time t_0, if for all $t \geq t_0$, it holds that $\mathbf{f}(\mathbf{z}_e) = 0$.*

This definition asserts that an equilibrium point $\mathbf{z}_e$ is a constant solution of (15), since $\mathbf{f}(\mathbf{z}_e) = 0$ and thus $\mathbf{z}'(t) = 0$ at such a point.

Lemma 1 *If $\mathbf{Z}$ is joint possibility distribution and $\mathbf{z}_e$ is an equilibrium point, then*

$$D(\mathbf{Z}, \mathbf{z}_e) = \sup_{\mathbf{s} \in [\mathbf{Z}]^0} d(\mathbf{s}, \mathbf{z}_e)$$

Definition 6 *An equilibrium point $\mathbf{z}_e$ of (15) is defined to be fuzzy stable if for all $\epsilon > 0$, there exists $\delta > 0$ such that if $D(\mathbf{Z}(t_0), \mathbf{z}_e) < \delta$ then $D(\mathbf{Z}(t), \mathbf{z}_e) < \epsilon$ for all $t \geq t_0$.*

This definition states that all solutions of (15) that start "sufficiently close" to an equilibrium point $\mathbf{z}_e$ stay "close" to $\mathbf{z}_e$. Note that this definition of fuzzy stability does not require the solution to approach the equilibrium point.

Proposition 1 *If an equilibrium point $\mathbf{z}_e$ is stable, then it is also fuzzy stable.*

Definition 7 *An equilibrium point $\mathbf{z}_e$ of (15) is defined to be asymptotically fuzzy stable if it is fuzzy stable and there exists $\delta > 0$ such that if $D(\mathbf{Z}(t_0), \mathbf{z}_e) < \delta$ then $\lim_{t \to \infty} D(\mathbf{Z}(t), \mathbf{z}_e) = 0$ for all $t \geq t_0$.*

This definition asserts that solutions of (15) that start "sufficiently close" to an equilibrium point $\mathbf{z}_e$ not only stay "close" to $\mathbf{z}_e$, but must eventually approach the equilibrium point $\mathbf{z}_e$ as t approaches infinity. Note that this is a stronger requirement than fuzzy stability, since the equilibrium point $\mathbf{z}_e$ must be stable before one can talk about whether or not it is asymptotically fuzzy stable.

Proposition 2 *If an equilibrium point $\mathbf{z}_e$ is asymptotically stable, then it is also asymptotically fuzzy stable.*

Definition 8 *An equilibrium point $\mathbf{z}_e$ of (15) is defined to be fuzzy unstable if it is not fuzzy stable. Hence, there exists an $\epsilon > 0$ such that for any choice of $\delta > 0$, there exists $\mathbf{Z}(t)$ satisfying $D(\mathbf{Z}(t_0), \mathbf{z}_e) < \delta$ such that $D(\mathbf{Z}(t), \mathbf{z}_e) \geq \epsilon$ for some t.*

This definition states that all solutions of (15) that start "sufficiently close" to an equilibrium point $\mathbf{z}_e$ move away from $\mathbf{z}_e$ when t increases.

Proposition 3 *If an equilibrium point $\mathbf{z}_e$ is unstable, then it is also fuzzy unstable.*

6 Fuzzy Predator-Prey Population Model

Consider the following fuzzy predator-prey population model

$$\begin{cases} x'(t) = x - 0.1xy \\ y'(t) = -0.5y + 0.02xy \end{cases}$$

where the initial populations of prey and predator are interactive fuzzy intervals with $q = 1$ and $r = -5$, and they are defined as follows, respectively:

$$X_0 = \begin{cases} 0, & \text{if } x < 14, \\ x - 14, & \text{if } 14 \leq x < 15, \\ -x + 16, & \text{if } 15 \leq x < 16, \\ 0, & \text{if } x > 16 \end{cases}$$

and

$$Y_0 = \begin{cases} 0, & \text{if } y < 9, \\ y - 9, & \text{if } 9 \leq y < 10, \\ -y + 11, & \text{if } 10 \leq y < 11, \\ 0, & \text{if } y > 11 \end{cases}$$

ISBN: 978-989-95079-6-8

First we find the equilibrium points of the model by setting the derivatives equal to zero. One can note that the model has two equilibrium points: $(0, 0)$ and $(25, 10)$. The equilibrium point $(0, 0)$ is uninteresting because there are no populations to observe in the model. However, the second equilibrium point is of interest. From the numerical approximation, we can see that the point $(25, 10)$ is fuzzy stable since the supports of the joint possibility distributions move around the equilibrium point when t increases (see Fig. 4). This is true since the prey population increases when the predator population is minimum, and the prey population decreases when the predator population is maximal (see Figs. 2 and 3).

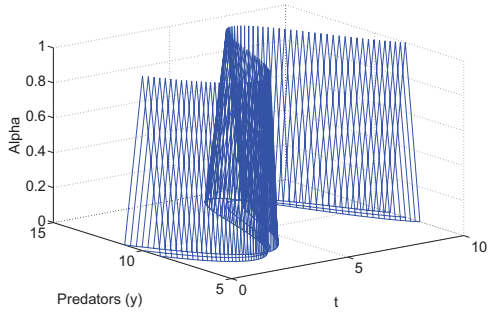

Figure 2: The evolution of the predator population over time.

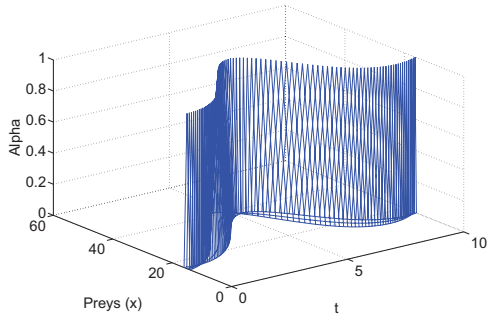

Figure 3: The evolution of the prey population over time.

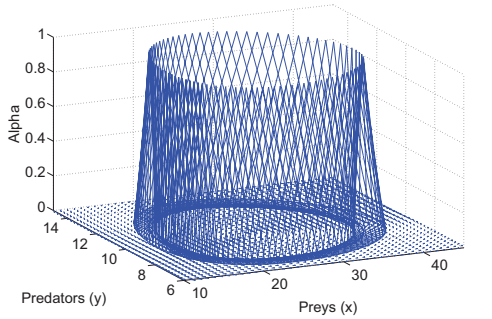

Figure 4: Fuzzy phase-plane with direction field ($N = 100$, $t = 10$, $h = 0.1$).

7 Conclusions

In this paper, we have proposed a new way of studying predator-prey population models, which takes into account the uncertainty that arises when determining the initial populations of predator and prey. By using the concept of interactivity of fuzzy intervals proposed by Majlender [14], we have developed a generalised numerical method, based on a 4^{th}-order Runge-Kutta method, to approximate the number of predators and preys over time.

E-mails: {gfenza, loia, ssenatore}@unisa.it.

Abstract—*This paper proposes an algorithm for concept matching, applied in the ontology mapping domain. Basic idea is to seek the effective semantics embedded in the concept name by analyzing the context in which it appears. Through simple interactions with the known lexicon WordNet, the right meaning associated to a concept is unequivocally elicited by exploring their local semantic context, viz. the surrounding concepts.*

This approach reveals interesting results for the word sense disambiguation, when polysemy problems requires a semantic interpretation.

Keywords— Semantic Web, concept matching, ontology mapping, WordNet, concept similarity.

1 Introduction

The Web comprises huge and disparate collections of information, whose size is estimated to overcome 11.5 billion web pages [1], though the search engines do not seem to cover the whole size (for instance, Google indexes approximately 9 billion pages). The diffusion of the Semantic Web has promised new models to support integrated access to web resources and services as well as intelligent applications for information processing on the Web.

Ontologies represents a conceivable solution for data representation as well as the knowledge sharing, aimed at the integration of the Web content in a unique and coherent view. Nevertheless, due to the decentralized nature of the Web, a plethora of ontologies has been defined and disseminated on the net; often they describe overlapped application domains; sometimes are specialized for specific domain.

It is evident the exigency to find some semantic correspondence among concepts which refer to different ontologies in order to get a "semantic reconciliation", aimed at establishing interoperability between semantic Web applications and a more homogeneous integration of information [22].

Ontology mapping has been proposed as an effective way of handling the semantic heterogeneity problem. It plays a central role in many application domains, such as e-commerce, semantic web services matchmaking [22], information integration, query mediation [23], etc..

It is the process that discovers a set of semantic correspondence between some entities of different ontologies. Many research studies have yield approaches and tools for (semi) automatic ontology matching [2], [3]; structural and linguistic matching has been taken into account; often combined approaches for the matching valuation provide efficient results too.

This paper presents a simple approach to concept matching, based on the linguistic similarity. The main idea is to discriminate the effective meaning of a word by analyzing the context in which it appears, in order to overcome the polysemy problems and the lexical ambiguity.

The approach achieves a primitive ontology mapping, by discovering semantic correspondences between concepts of two ontologies (implemented as graph-like structures). A graphical interface presents the discovered mapping.

The paper is organized as follows. Section 2 sketches a state of art in the ontology matching domain. Section 3 introduces our approach, describing the basic algorithm and then in Section 4, implementation details and some relevant case studies are presented in order to validate its applicability. Finally, conclusions close the paper.

2 Related works

In the last years, ontologies are increasingly being used to support the integration of information. Yet, their diffusion in many Web areas emphasizes impressive heterogeneity among information sources and in particular in the formal model exploited to encode the domain conceptualizations.

In literature, different types of heterogeneity have been identified, mainly split in the following classes.

- *Syntactic heterogeneity*: represents the heterogeneity due to differences at the language level; for instance, when two ontologies are defined by using different knowledge representation formalisms even though the meaning is the same [4].
- *Terminological heterogeneity*: occurs when different names are given to similar ontology entities [6].
- *Semantic heterogeneity*: is often called conceptual heterogeneity. It occurs when the same domain of interest is modelled in different way, for instance, exploiting different types of axioms for defining concepts or just giving diverse expressive values to them [5].

Many efforts have been done from the research communities to find a solution to the matching problem by developing a variety of tools and mostly providing a well-founded formalization [7, 8, 9]. Matching ontologies (or schemas) has been recognized as a critical operation in many

ISBN: 978-989-95079-6-8

application domains. It takes as input two ontologies, each one consisting of a set of entities and produces as output the "connections" (which may represent equivalences or just relations such as consequence, subsumption, or disjointness) holding between these entities.
Systems for ontology matching such as Cupid [11], OntoBuilder [10], Similarity Flooding [2], Clio [12], Glue [13], S-Match [3], OLA [14] and Prompt [15] aim at providing an alignment, namely a set of correspondences between semantically related entities of different ontologies. Finding the correspondences which are effective from the user's viewpoint is often not easy.
In [17] a tree-based classification of elementary matching approaches is given. At granularity level, matching techniques can be distinguished into the following classification criteria:
– Element-level vs. structure-level: Element-level matching techniques discover correspondences by analyzing entities or their relative instances, without considering their relations with other entities or their instances. Structure-level techniques instead compute correspondences by studying the structure in which the concepts or their instances appear [16].
– Syntactic vs. external vs. semantic: The syntactic techniques consider the input with regard to its sole structure, according to some well stated algorithm. On the other hand, external techniques exploit external resources (such as human support, thesaurus, etc.) and common knowledge in order to interpret the input [17]. Finally, semantic techniques use some formal semantics (i.e. model-theoretic approaches) to interpret the input and justify their results. Semantic matching [3] is based on the idea that labels at concept nodes, which are written in natural language, are translated into propositional formulas which codify the intended meaning of the labels themselves. This way the matching problem becomes a propositional unsatisfiability problem, which can then be efficiently implemented through propositional satisfiability (SAT) solvers [18].
Although many advances in the ontology matching research topic have been addressed, nevertheless, there are still open issues to investigate in order to get a more efficient and effective integration of ontology matching tools in the web applications domain.

3 Ontology Matching

The ontology matching problem can be seen as a problem of concept matching. Two concepts match, if they are similar. In this section some formal notions are given to delineate a common background, useful to describe our ontology matching approach. Then the ontology matching method is detailed.

3.1 Scope of a concept into an ontology

Concept matching requires the evaluation of the similarity between two concepts. This approach aims at discovering linguistic similarities between the involved entities. In general, linguistic similarities are based on morphology and semantics, which are associated to the words that describe the relative entities. Thus, in this approach the similarity between two entities of different ontologies is evaluated not only by investigating the semantics of the entities names, but also taking into account the local context, through which the effective meaning is described.
Often the same word placed in different textual contexts assumes completely different meanings. In addition, lexicons are not able to disambiguate situations in which homonyms occur.
In order to deal with lexical ambiguity, this approach introduces the notion of "scope" of a concept which represents the context where the concept is placed.

Definition 1: *Let O be ontology and c is a concept in O. The scope of c, with radius r,* ***scope(c, r)*** *is a set of all the concepts outgoing from c included in a path of length r, with centre c. More formally:*

$$scope(c,r) = \{c' |\, c' \in O\ , dist(c,c') < r\}$$

where $dist(c,c')$ *is the number of edges that are in the path from concept c to concept c'. Let us note that* $dist(c,c') = 0\ iff\ c = c'$.

Figure 1 sketches the idea. The scope defines a round area composed of all concepts that are connected directly or indirectly to the central node. This area represents the context. Increasing the radius means to enlarge the scope (i.e. this area) and, consequently, the set of neighbour concepts that intervene in the description of the context.
Fixed the radius of the scope of two concepts α and β, belonging to different ontologies, our goal is to find out a semantic relationship exist between them.

Definition 2. Let *α be a concept in the ontology O. The concept name of α,* ***a= label(α)*** *is the linguistic label associated to the concept α.*

Definition 3. Given two concepts *α , β belonging respectively to* ontologies *O and O', let* $\mathcal{L}$ *be a lexicon and a= label(α) and b= label(β). Then, let lex (a, b) ∈ [0, 1] be a lexical similarity associated to the pair of concept names (α, β), with α∈O , β∈O'. The set L is composed of all pairs, defined as follows:*

$$L = \{(\alpha', \beta') | \forall\ \alpha \in scope(\alpha', r)\ and\ \forall\ \beta \in scope(\beta', r)\ and\ \exists lex(a, b) \neq 0)\}$$

WordNet is the lexicon exploited in this approach. It is one of the most common lexical databases, used for research studies in computational linguistics, text analysis, etc. The function *lex(a, b)* is the similarity metric.
Many similarity functions have been implemented in the WordNet package. In particular, a measure specifically developed for WordNet is the similarity proposed by Wu and Palmer [19]. It is simple to compute and results an efficacy metric for ontology matching.

ISBN: 978-989-95079-6-8

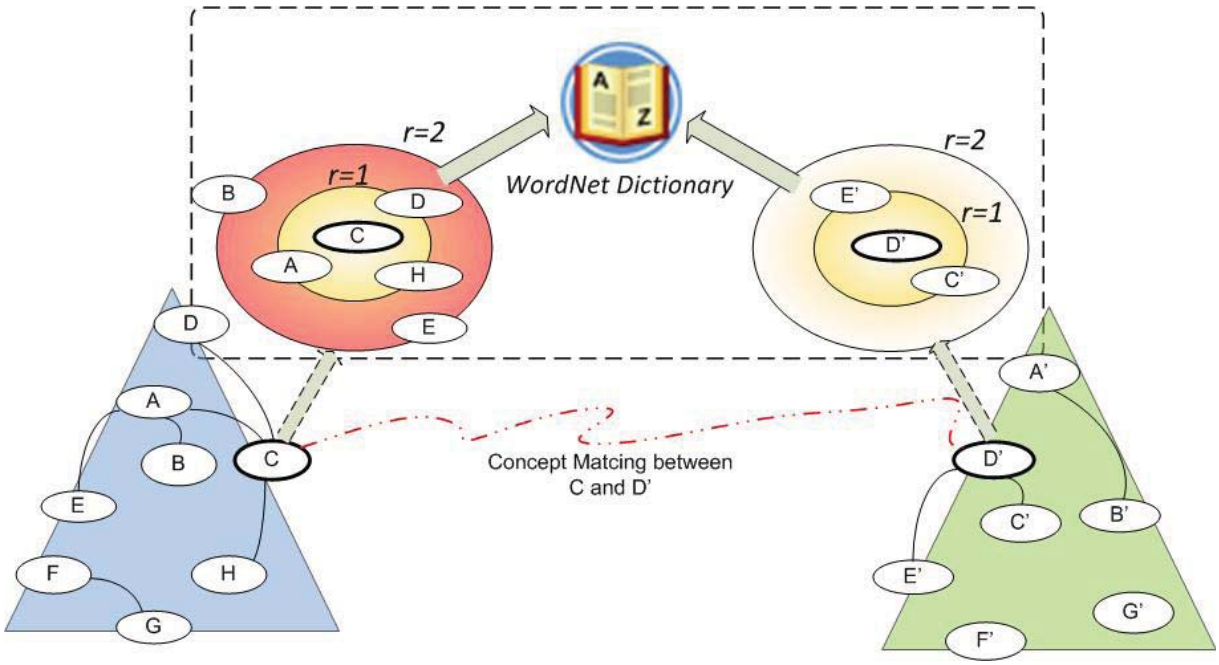

Figure 1: Intuitive idea of concept matching, exploiting the *scope* and the effective *sense* of the concept names

The Wu-Palmer similarity is based on the observation that although two concepts near the root of a hierarchy are close to each other in terms of edges, they can be very different semantically; conversely, two classes under one concept that are distant as number of edges, could be more similar conceptually. The idea is to find a common closest hyperonym in the path from them to the root.
The principle of similarity computation between two nodes is based on the distance which separates these two nodes from the root node and the distance which separates their closest common ancestor from the root too.
Let us assume that the arcs in ontology represent uniform distances (i.e. all the semantic edges have the same weight).

Definition 4. *Let c_1 and c_2 be two ontology elements in the ontology O. The distance between two nodes $\delta(c_1, c_2)$ is represented by the minimum number of edges that connect them.*

Definition 5. *Given an ontology O formed by a set of nodes and a root node R. Let c_1 and c_2 be two ontology concepts of which we will calculate the similarity. Then, g is the common ancestor of c and c'. The Wu–Palmer similarity is defined by the following expression[19]:*

$$sim(c_1, c_2) = \frac{2 \times \delta(g, R)}{\delta(c_1, R) + \delta(c_2, R)}$$

3.2 Concept Sense Discrimination

Through the given definitions, it is possible to individuate the meaning of a name associated to an ontology concept. Given a word, WordNet provides a list of all the synsets and word senses, related to that word. Just to give an example, submitting the word "table" to WordNet, the result is the following list.

```
The noun table has 6 sense (first 3 form tagged
texts)

1. (57) table, tabular array -- (a set of data
   arranged in rows and columns; "see table 1")
2. (25) table -- (a piece of furniture having a
   smooth flat top that is usually supported by
   one or more vertical legs; "it was a sturdy
   table")
3. (5) table -- (a piece of furniture with
   tableware for a meal laid out on it; "I
   reserved a table at my favorite restaurant")
4. mesa, table -- (flat tableland with steep
   edges; "the tribe was relatively safe on the
   mesa but they had to descend into the valley
   for water")
5. table -- (a company of people assembled at a
   table for a meal or game; "he entertained the
   whole table with his witty remarks")
6. board, table -- (food or meals in general;
   "she sets a fine table"; "room and board")
```

Let us note all the senses are ranked with respect to the frequency of the term (shown in the parenthesis for the first three senses) in the reference context (according to the spoken common sense).
The following pseudo-code details the algorithm for discriminate the actual sense of a word associated to a given concept. The algorithm takes as input an ontology O, a reference concept α in that ontology and a word *w*. The word *w* represents the name associated to the concept α (i.e. w=label(α)).
Let us note the semantic difference between the concept (or class) in an ontology and the label associated to that concept. The algorithm replies to question like "I would like to know the effective sense of the word w, placed in the context (or scope) of the concept α".

ISBN: 978-989-95079-6-8

Algorithm1

```
Input: Ontology O, concept α ∈ O, radius r and the
word w

Output: sense number of w

1: build an array N[|synset(w)|];
2: for each t1 in synset(w)
3:    initialize N[senseNumber(t1)] = 0;
4:    for i = 1 to r
5:       set M = ∅;
6:       for each c in scope(α,i) - scope(α,i-1)
7:          set S = ∅;  //set of similarity values
8:          for each t2 in synset(label(c))
9:             sim = similarity_WP(t1, t2)
10:            S = S U {sim};
11:         end for each
12:
13:         set max = maximum in S;
14:         max = max / |scope(α, i)|;
15:         M = M U {max};
16:      end for each
17:      set Sum = summation of all the values in M
18:      Sum = Sum /i;
19:      N[senseNumber(t1)] += Sum;
20:   end for
21: end for each
22: i1 = sense number with the highest
                              frequency in N.
23: return i1
```

First step (line 1) is to declare a vector structure whose size corresponds to the number of synsets (or senses) associated to the given word w. Goal is to maintain in each cell of the vector a pertinence value that represents how much the word w is semantically related to that sense (or belongs to that synset).
The algorithm selects all the concepts in the scope of α (belonging to the reference ontology O) by varying the radius (lines 4-6), in order to get different set of terms. Then compute the Wu-Palmer similarity between two terms coming from the concept name of α and the word *w* (line 9).
Just to give an idea about how the algorithm works, let us look at Figure 2. For simplicity, let us suppose *w* = *label(α)* = "Table". The algorithm evaluates the similarity between all the terms coming from both the WordNet synset of "Table" and the scope of concept "Table" in the ontology.
In particular, Figure 2 shows the flat ring shaped areas in different colours, by varying the radius.
For each concept *c* in the ring shaped area (computed as the difference of the areas between two successive radii, see line 6), the max similarity values between the name associated to *c* and a concept name in synset of α are maintained in M (line 15).
At the end of the two loops (lines 6-11) the variable *Sum* contains the sum of all the max similarity values computed for each couple of terms coming from the fixed term t1 of synsets of α and all the terms in the synset of *w*.
The *Sum* is "weighted" with respect to the current radius (line 18). The final value of *Sum* is added to the value stored in the cell associated to the sense of some term t1. This is repeated for each t1 in the synset of *w*. At the end, in each cell of the vector N there is a value, associated to each term in the synset of *w*.

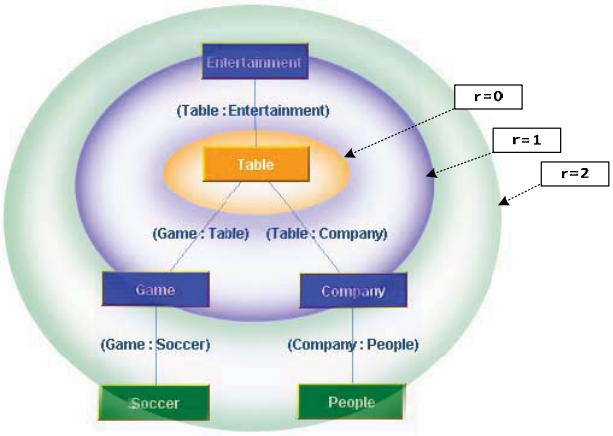

Figure 2. A sketched ontology and the scope of concept "Table" at different radius r.

The index of the vector cell, whose value is the maximum, represents the sense number to give as output.
Applying the algorithm on the ontology of Figure 2, the retuned index value is 5.
Abstractly speaking, the approach helps the user to individuate the right meaning of a word, given the context.

3.3 Ontology mapping

As said, the ontology mapping outlines correspondences or matches between concepts coming from two different ontology. In this approach, the concept matching is measured by computing a similarity between concepts at linguistic level.
The algorithm described in the previous section has been exploited to evaluate the concept matching. More formally, given two ontologies *O* e *O'* and two concepts *c* and *c'*, belonging respectively to these two ontologies, there is a match between *c* and *c'* if a similarity between them exists, computed as follows:

1. Algorithm1 is invocated twice: one time it takes as input the concept *c* and the ontology *O* and another time, by giving the concept *c'* and the ontology *O'*. Outputs of these two independent executions of Algorithm1 are two indexes, *i* for the synset of *c* and *i'* for the synset of c'. As said, they identify the sense number associated to each concept.

2. Once discovered the sense of involved concepts, the affinity between the concepts is computed by a similarity measure (for instance, the Wu-Palmer similarity defined in Section 3.1) between *c* and *c'*.

In order to obtain all the semantic correspondences among the concepts in the two ontologies, this procedure can be applied for each couple of concepts coming from two reference ontologies. Final result is an ontology mapping; a similarity value is assigned to each discovered correspondence between concepts in the two ontologies.

ISBN: 978-989-95079-6-8

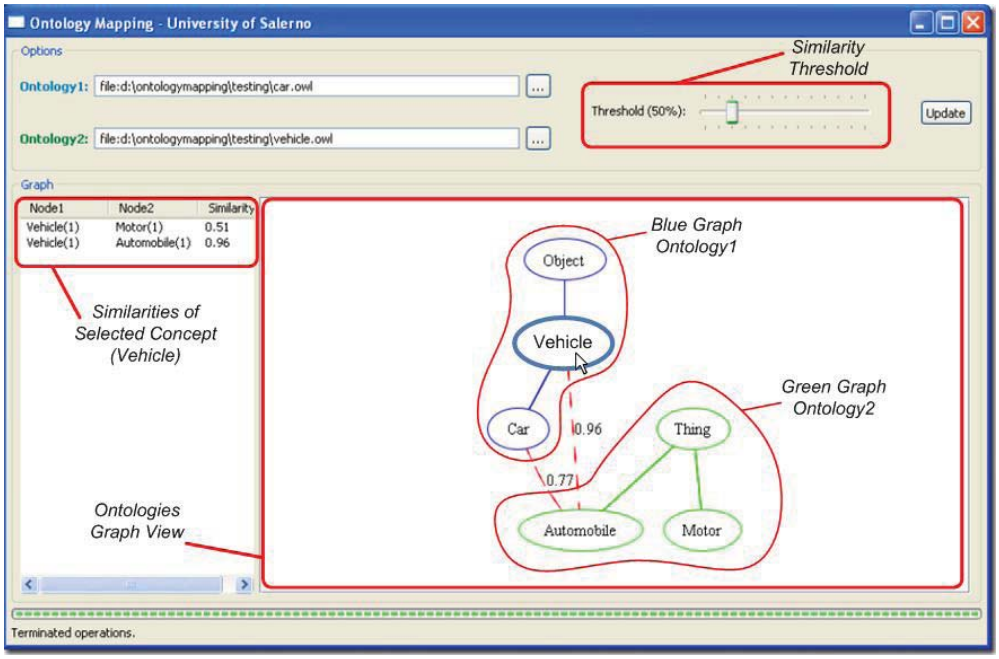

Figure 3. Ontology Mapping GUI

4 User interface and application details

The algorithm has been implemented in Java language. It exploits Java WordNet Similarity Library (JWSL) [20] for accessing the WordNet database. JSWL implements the most commons similarity and relatedness measures between words and get information about *synsets*.

A simple graphical interface has been designed for the user interaction (see Figure 3). It has been implemented by exploiting Graphviz library [21]. It is an open source graph visualization software which provides several main graph layout programs.

Let us note the ontologies have been represented (and implemented) as graphs, whose nodes represent the concepts whereas the edges connects two nodes when a relationship exists between them. In this version, a restriction on just hierarchies or taxonomies (i.e. only IS-A relationships) is considered.

The user can load the two ontologies and the final mapping is drafted in the *Ontology Graph View* panel (see Figure 3). The correspondences discovered by the mapping are sketched in Figure 3 as dotted lines between the concepts. A weight (value of similarity) is associated to each arc.

Figure 3 shows on the right hand of the interface, a sliding bar for setting the similarity threshold. Moving the cursor, the threshold is modified, returning in the graph view panel just the arcs whose similarity values are greater than this threshold.

Moreover, when the user clicks on a concept (node) in the graph view panel, all its connections with other concepts and the relative similarity values are shown on the left of the interface.

4.1 Some case studies

The algorithm has been applied on some sketched ontologies. The application acquires the ontologies in OWL format, although this prototypal version is limited to work on hierarchical structure.

In the interface of Figure 3, a simple example of ontology mapping is shown. The case study has been built ad-hoc; just the relevant portions of two ontologies are shown.

The Ontology1 (in blue color in Figure 3) is described by the concepts named “Object”, “Vehicle” and “Car” , whereas the Ontology2 (green color) is composed of the concept with names “Thing”, “Automobile” and “Motor”.

The application adds an arc between two concepts of different ontologies, when a similarity value (in the range [0, 1]) is found.

Let us note there exists an arc between the concept names “Vehicle” and “Automobile” with an high similarity (0.96), but the arc between “Vehicle” and “Motor” is not inserted in the graph view, because the similarity between these concept names assumes values lower than the selected threshold.

Similar considerations can be done on the ontology mapping shown in Figure 4 (although the GUI is not shown).

Two ontologies are drafted in different colors. Both of them describe a similar domain (the living beings).

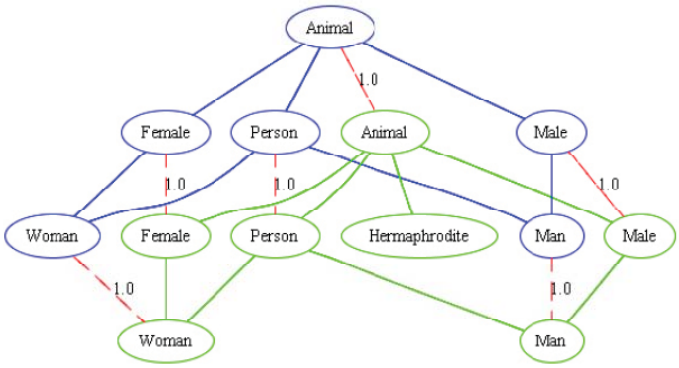

Figure 4: Example of Ontology Matching on the human beings domain.

ISBN: 978-989-95079-6-8

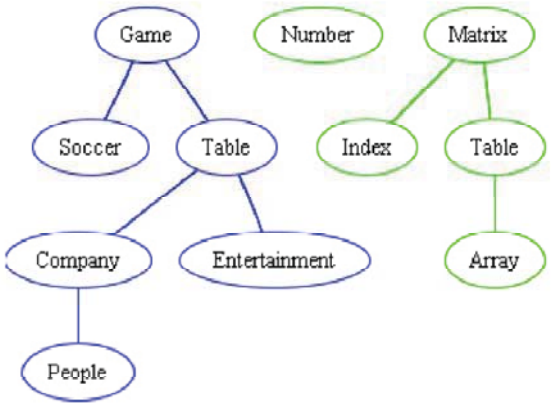

Figure 5: No concept matching occurs between these two ontologies, due to different meanings of the reference ontology domains.

Because the ontologies present concepts with similar names and meanings, the similarity values on the added arcs (in red) are equal to 1 (the maximum similarity).
Finally, Figure 5 shows a case of no concept match. The two ontologies share the same concept name "Table", but the reference context is completely different. In fact, Algorithm1 returns the sense number 5 for the ontology on the left (colored blue) and the sense number 1 for the ontology on the right, respectively (see Section 3.2 for details). Thus no arcs can be placed between them.
Let us note, in the example in Figure 5, the node with concept name "Number" is disconnected by the others, because the algorithm does not analyzes the OWL ontology relationships that are not hierarchical.

5 Conclusions

The paper describes a study for ontology mapping based on the discovering of linguistic similarity. A graphical interface allows the user to see the final mapping, presenting a similarity value for each discovered concept matching.
This algorithm represents an initial version of an ontology matching method and needs some extension for processing all the ontology relationships. Its efficacy would be visible if it was exploited in combination with structure based ontology matching. Further developments are addressed to reach these issues. Nevertheless, its applicability may not restricted to ontology matching problems. The basic algorithm could be used for Information Retrieval problems, for instance when the textual analysis requires the word sense disambiguation. The context of a word could be described by defining a "sliding window" on the text surrounding the analyzed word, in order to discover its appropriate sense. Furthermore, the algorithm could be exploited for discriminating common sense words, in specialized contexts where the word meaning depends on the application domain (or the reference ontology).

Abstract— *We propose a new, human consistent method for the evaluation of similarity of time series that uses a fuzzy quantifier base aggregation of trends (segments), within the authors' (cf. Kacprzyk, Wilbik, Zadrożny [1, 2, 3, 4, 5, 6] or Kacprzyk, Wilbik [7, 8, 9]) approach to the linguistic summarization of trends based on Zadeh's protoforms and fuzzy logic with linguistic quantifiers. The results obtain are very intuitively appealing and justified by valuable outcomes of similarity analyses between quotations of an investment fund and the two main indexes of the Warsaw Stock Exchange.*

1 Introduction

Among various application areas of advanced data mining and knowledge discovery tools and techniques, all kinds of finance related areas are of primordial and growing importance. For instance, in an interesting statistical report [10] on top data mining applications in 2008, the first two positions are, in the sense of yearly increase:

• *Investment/Stocks*, up from 3% of respondents in 2007 to 14% of respondents in 2008% (350% increase),

• *Finance*, up form 7.2% in 2007 to 16.8% in 2008 (108% increase).

This trend will presumably continue in view of serious difficulties on financial/investment market which is expected to continue well after 2009.

This paper is a continuation of our previous works (cf. Kacprzyk, Wilbik, Zadrożny [1, 2, 3, 4, 5, 6] or Kacprzyk, Wilbik [7, 8, 9]) which deal with the problem of how to effectively and efficiently support a human decision maker in making decisions concerning investments. We deal mainly with investments in investment (mutual) funds. Clearly, decision makers are here concerned with possible future gains/losses, and their decisions is related to what might happen in the future. However, our aim is not the forecasting of the future daily prices, which could have been eventually used directly for a purchasing decision. Instead, in our works, we follow a decision support paradigm, that is we try to provide the decision maker with some information that can be useful for his/her decision on whether and how many units to purchase. We do not intend to replace the human decision maker.

This problem is very complex. First of all, there may be two general approaches. The first one, which may seem to be the most natural is to provide means to derive a price forecast for an investment unit so that the decision maker could "automatically' purchase what has been forecast, and as much as he/she could afford. Unfortunately, the success in such a straightforward approach is much less than expected. Basically, statistical methods employed usually for this purpose are primitive in the sense that they just extrapolate the past and do not use domain knowledge, intuition, some inside information, etc. A natural solution may be to try to just support the human decision maker in making those investment decisions by providing him/her with some additional useful information, and not getting involved in the actual investment decision making.

Various philosophies in this respect are possible. Basically, from our perspective, the following one will be followed. In all investment decisions the future is what really counts, and the past is irrelevant. But, the past is what we know, and the future is (completely) unknown. Behavior of the human being is to a large extend driven by his/her (already known) past experience. We usually assume that what happened in the past will also happen (to some, maybe large extent) in the future. This is basically, by the way, the very underlying assumption behind the statistical methods too!

This clearly indicates that the past can be employed to help the human decision maker find a good solution. We follow here this path, i.e. we present a method to subsume the past, to be more specific the past performance of an investment (mutual) fund, by presenting results in a very human consistent way, using natural language statements.

It should be noted that this line of reasoning has often been articulated by many well known investment practitioners, and one can quote here some more relevant opinions. In any information leaflets of investment funds, one may always notice a disclaimer stating that "Past performance is no indication of future returns" which is true. However, on the other hand, for instance, in a well known posting "Past Performance Does Not Predict Future Performance" [11], they state something that may look strange in this context, namely: "... according to an Investment Company Institute study, about 75% of all mutual fund investors mistakenly use short-term past performance as their primary reason for buying a specific fund". But, in an equally well known posting "Past performance is not everything" [12], they state: "... disclaimers apart, as a practice investors continue to make investments based on a schemes past performance. To make matters worse, fund houses are only too pleased to toe the line by actively advertising the past performance of their schemes leading investors to conclude that

*Partially supported by the Ministry of Science and Higher Education Grant no. NN 516 4309 33.

ISBN: 978-989-95079-6-8

it is the single-most important parameter (if not the most important one) to be considered while investing in a mutual fund scheme".

As strange as this apparently is, we may ask ourselves why it is so. Again, in a well known posting "New Year's Eve: Past performance is no indication of future return" [13], they say "...if there is no correlation between past performance and future return, why are we so drawn to looking at charts and looking at past performance? I believe it is because it is in our nature as human beings ...because we don't know what the future holds, we look toward the past ...".

And, continuing along this line of reasoning, we can find many other examples of similar statements supporting our position. For instance, Myers [14] says: "...Does this mean you should ignore past performance data in selecting a mutual fund? No. But it does mean that you should be wary of how you use that information ...While some research has shown that consistently good performers continue to do well at a better rate than marginal performers, it also has shown a much stronger predictive value for consistently bad performers ...*Lousy performance in the past is indicative of lousy performance in the future...*". And, further: Bogle [15] states: "... there is an important role that past performance can play in helping you to make your fund selections. While you should disregard a single aggregate number showing a fund's past long-term return, you can learn a great deal by studying the *nature of its past returns*. Above all, look for consistency.". In [16], we find: "While past performance does not necessarily predict future returns, it can tell you how volatile a fund has been". In the popular "A 10-step guide to evaluating mutual funds" [17], they say in the last, tenth, advise: "Evaluate the funds performance. Every fund is benchmarked against an index like the BSE Sensex, Nifty, BSE 200 or the CNX 500 to cite a few names. Investors should compare fund performance over varying time frames vis-a-vis both the benchmark index and peers. Carefully evaluate the funds performance across market cycles particularly the downturns".

One can give many more quotations from all kinds of investment guides, analyses, etc. by leading experts. Virtually all of them emphasize the importance of looking at the past to help make future decisions. Moreover, they also generally advocate a more comprehensive look in the sense that what might be useful would rather be not particular single values but some deeper meaning, even nature of past behavior and returns.

We have followed this line of reasoning in our past papers (cf. Kacprzyk, Wilbik, Zadrożny [1, 2, 3, 4, 5, 6] or Kacprzyk, Wilbik [7, 8, 9]), i.e. to try to find a human consistent, fuzzy quantifier based scheme for a linguistic summarization of the past in terms of various aspects of how the time series representing daily quotations of the investment fund(s) behave. However, we have mainly concentrated on a sheer absolute performance, i.e. the time evolution of the quotations themselves. This may be relevant, and sometimes attractive to the users who can see a summary of their gains/loses and their temporal evolution.

However, for many more detailed analyses we need to relate the performance of an investment fund to the performance (time evolution) of some benchmark(s) against which the particular investment fund is to be compared, as stated in its prospectus. These benchmarks are usually some stock exchange indexes, or a composition thereof.

One of more interesting and relevant questions that may be posed by both a professional analyst or a customer whose money is being invested may be: how similar was the temporal evolution of quotations of the particular investment fund and its benchmark(s)? This has clearly to do with the measuring of similarity of time series.

The problem of similarity of time series or finding similar subsequences of time series is an important issue in many problems, e.g., in indexing [18, 19], clustering [20] or motif discovery [21, 22]. A similarity measure should allow for the imprecise match, i.e., should indicate time series sequences that are similar to some extent. Moreover, the algorithm should be very efficient [23], as we may consider very long time series.

Different approaches to the similarity measures of time series were considered and proposed in the literature. A simple solution is to view each sequence as a point in an n-dimensional Euclidean space, where n is the length of the segment (trend). The similarity or dissimilarity is based on the Euclidean distance, and computed as the norm in this space [24]. This approach can be used for various time series but normally some extensions should be applied providing various transformations such as scaling or shifting were proposed [21].

Another methods use, for instance, the Dynamic Time Wraping (DTW) [19] and Longest Common Subsequence (LCS) measures [24], and they allows gaps in sequences. They are successfully used in other domains such as speech recognition and text pattern matching [25].

Other approaches developed for similarity search in time series data are based on dimension reduction. This can be achieved in numerous ways, e.g. using the Discrete Fourier Transform (DFT) [23], wavelets [26], etc.

One can also mention here approaches based on the piecewise linear representation of time series [27]. In this approach time series are represented by segments (trends), not the particular values. The method proposed here falls into this category.

In this paper we propose new method of calculating the similarity of time series; as we have already indicated, this concerns the quotations of an investment fund and some benchmark. The degree of similarity of two time series is meant here as the degree to which, for instance, "most" of the long, overlapping segments are similar (for instance, such that "almost all" of their features are similar). Notice that this has very much to do with a soft definition of consensus meant as a degree to which, for instance, "*most* of the *important* individuals agree as to *almost all* of the *relevant* options". This was introduced by Kacprzyk and Fedrizzi [28, 29, 30], Kacprzyk, Fedrizzi and Nurmi [31], and recently by Kacprzyk and Zadrożny [32] and has been found useful in many areas.

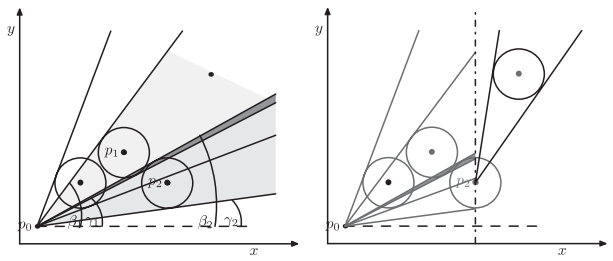
We will now discuss first the segmentation of time series, as the similarity will proceed in terms of segments (trends), not all the consecutive values. Then, we will propose some new, linguistic quantifier based measures of similarity, followed by examples on real data, and conclusions.

ISBN: 978-989-95079-6-8

2 Segmentation of time series

In our approach (cf. Kacprzyk, Wilbik, Zadrożny [1, 2, 3, 4, 5, 6] or Kacprzyk, Wilbik [7, 8, 9]) we summarize the trends (segments) extracted from a time series, and we have to extract these segments assumed to be represented by a fragment of a straight line. There are many algorithms for a piecewise linear segmentation of time series, including, e.g., on-line (sliding window) algorithms, bottom-up or top-down strategies (cf. Keogh [33, 34]). We may either divide the time series into k segments (using, e.g., bottom-up or top-down strategies), where k is specified by the user, or divide it so that the maximum error for any segment does not exceed some threshold value ε, also specified by the user. In our works [1, 2, 3, 4, 5, 6, 7, 8, 9] we used a simple on-line algorithm, a modification of one proposed by Sklansky and Gonzalez [35] in the contest of image analysis. The method is simple and fast, and fully satisfies our needs though many other methods are possible.

Our algorithm constructs the segments so that the maximum distance between the segment line and the observed time point is smaller than a user specified ε value. It works by constructing the intersection of cones starting from point p_i of the time series and including a circle of radius ε around the subsequent data points p_{i+j}, $j = 1, 2, \ldots$, until the intersection of all cones starting at p_i is empty. If for p_{i+k} the intersection is empty, then we construct a new cone starting at p_{i+k-1}. Figure 1 present the idea of the algorithm. The family of possible solutions is indicated as a gray area. Clearly other algorithms can also be used, and there is a lot of them in the literature (cg. [18, 36]).



(a) the intersection of the cones is indicated by the dark grey area

(b) a new cone starts in point p_2

Figure 1: Illustration of the segmentation algorithm used

To present details of the algorithm, let us first denote:
- `p_0` – a point starting the current cone,
- `p_1` – the last point checked in the current cone,
- `p_2` – the next point to be checked,
- `Alpha_01` – a pair of angles (γ_1, β_1), meant as an interval, that defines the current cone as shown in Figure 1(a),
- `Alpha_02` – a pair of angles of the cone starting at the point `p_0` and inscribing the circle of radius ε around the point `p_2` (cf. (γ_2, β_2) in Figure 1(a)),
- function `read_point()` reads a next point of data series,
- function `find()` finds a pair of angles of the cone starting at the point `p_0` and inscribing the circle of radius ε around the point `p_2`.

A pseudocode of the algorithm that extracts trends is depicted in Figure 2.

```
read_point(p_0);
read_point(p_1);
while(1)
{
  p_2=p_1;
  Alpha_02=find();
  Alpha_01=Alpha_02;
  do
  {
    Alpha_01 = Alpha_01 ∩ Alpha_02;
    p_1=p_2;
    read_point(p_2);
    Alpha_02=find();
  } while(Alpha_01 ∩ Alpha_02 ≠ ∅);
  save_found_trend();
  p_0=p_1;
  p_1=p_2;
}
```

Figure 2: Pseudocode of the modified Sklansky and Gonzalez [35] algorithm for extracting trends

The bounding values of `Alpha_02` (γ_2, β_2), computed by function `find()` correspond to the slopes of two lines that (1) are tangent to the circle of radius ε around point $p_2 = (x_2, y_2)$ and (2) start at the point $p_0 = (x_0, y_0)$. Thus

$$\beta_2, \gamma_2 = arctg\left(\frac{\Delta x \cdot \Delta y - \pm\varepsilon\sqrt{(\Delta x)^2 + (\Delta y)^2 - \varepsilon^2}}{(\Delta x)^2 - \varepsilon^2}\right)$$

where $\Delta x = x_0 - x_2$ and $\Delta y = y_0 - y_2$.

The resulting linear ε-approximation of a group of points `p_0, ..., p_1` is either a single segment, chosen as, e.g., a bisector of the cone, or one that minimizes the distance (e.g., the sum of squared errors, SSE) from the approximated points, or the whole family of possible solutions, i.e., rays of the cone.

This method is effective and efficient as it requires only a single pass through the data. From now on we will identify (partial) *trends* with the line segments of the constructed piecewise linear function.

3 Linguistic summarization of time series

First, we will outline the very essence of our approach to the linguistic summarization of time series which is based on the two types of protoforms of linguistic summaries of trends:
- a short form:

$$\text{Among all segments, } Q \text{ are } P \tag{1}$$

e.g.: "Among all segments, *most* are *slowly increasing*".
- an extended form:

$$\text{Among all } R \text{ segments, } Q \text{ are } P \tag{2}$$

e.g.: "Among all *short* segments, *most* are *increasing*".
whose truth values are, respectively:

$$\mathcal{T}(\text{Among all } y\text{'s, } Q \text{ are } P) = \mu_Q\left(\frac{1}{n}\sum_{i=1}^{n}\mu_P(y_i)\right) \tag{3}$$

$$\mathcal{T}(\text{Among all } Ry\text{'s, } Q \text{ are } P) = \mu_Q\left(\frac{\sum_{i=1}^{n}\mu_R(y_i) \wedge \mu_P(y_i)}{\sum_{i=1}^{n}\mu_R(y_i)}\right) \tag{4}$$

where $\wedge$ is the minimum operation (more generally it can be another appropriate operator, notably a t-norm).

ISBN: 978-989-95079-6-8

For more information on this approach, and on the advantages of using protoforms as general forms of linguistic summaries, see Kacprzyk, Wilbik, Zadrożny [1, 2, 3, 4, 5, 6] or Kacprzyk, Wilbik [7, 8, 9].

4 A new fuzzy quantifier based method for the evaluation of similarity of time series

The degree of similarity of two time series is meant here as the degree to which, say "most" of the long, simultaneous segments are similar (i.e., "majority" of their features are similar).

The time series is represented by its segments (trends). Each segment is described by the following four values:
• starting time, called here a partition point,
• duration of the segment (expressed in time units),
• dynamics of change (expressed as the slope of the segment),
• variability occurring in the segment, describing the variability of differences between the trend (segment line) and the particular time series values over the duration of this trend.

Let us assume, we wish to compare two time series A and B. As the result of the segmentation procedure time series A was divided into k segments, represented by a_j, $j = 1, \ldots, k$ and time series B was divided into l segments, represented by b_j, $j = 1, \ldots, l$.

Next we create the set of partition points of the two time series considered, i.e. this set contains the time points when at least one segment has started. There are at most $k + l$ such partition points. Those times are sorted, so that the earlier ones come first.

Now between any consecutive partition points (e.g. p_i and p_{i+1}) there is only one segment (or a part of it) of each time series. We may denote those segments as a_{p_i} and b_{p_i}, i.e., a_{p_i} is the segment representing time series A that take place between p_i and p_{i+1}. Now we can compute the similarity of such simultaneous segments.

We compute the degree of similarity of two segments (trends), as the degree to which "most" of their features are similar. Here we consider for simplicity the three features only: duration, dynamics and variability. The values of the features of segment a_{p_i} are $dur_{a_{p_i}}$ for duration, $dyn_{a_{p_i}}$ for dynamics, and $var_{a_{p_i}}$ for variability. R_{dur}, R_{dyn} and R_{var} are the ranges of possible values of duration, dynamics and variability. The degree of similarity of segments a_{p_i} and b_{p_i} with respect to duration is computed as

$$sim^{dur}(a_{p_i}, b_{p_i}) = \mu^{dur}_{sim}\left(\frac{|dur_{a_{p_i}} - dur_{b_{p_i}}|}{R_{dur}}\right) \quad (5)$$

Similarly, separate functions can be defined for the similarity for each feature, here μ^{dyn}_{sim} and μ^{var}_{sim}. Let $\mu_{Q_1}(.)$ be the membership function of quantifier "most", i.e regular, nondecreasing and monotone. Thus the degree of similarity of segments a_{p_i} and b_{p_i} is computed as

$$\begin{aligned} sim(a_{p_i}, b_{p_i}) = \mu_{Q_1}\Bigg(& w_{dur}\left(\mu^{dur}_{sim}\left(\frac{|dur_{a_{p_i}} - dur_{b_{p_i}}|}{R_{dur}}\right)\right) + \\ &+ w_{dyn}\left(\mu^{dyn}_{sim}\left(\frac{|dyn_{a_{p_i}} - dyn_{b_{p_i}}|}{R_{dyn}}\right)\right) + \\ &+ w_{var}\left(\mu^{var}_{sim}\left(\frac{|var_{a_{p_i}} - var_{b_{p_i}}|}{R_{var}}\right)\right)\Bigg) \end{aligned} \quad (6)$$

where $w_{dur} + w_{dyn} + w_{var} = 1$, here all are equal, $w_{dur} = w_{dyn} = w_{var} = \frac{1}{3}$.

Next, to obtain the similarity of A and B, we need to aggregate above similarity values between the overlapping segments, and again we use a linguistic quantifier driven aggregation.

$$sim(A, B) = \mu_Q\left(\frac{\sum_{i=1}^{n} \frac{p_{i+1}-p_i}{T} sim(a_{p_i}, b_{p_i})}{\sum_{i=1}^{n} \frac{p_{i+1}-p_i}{T}}\right) \quad (7)$$

where $p_{i+1} - p_i$ is the difference between the two consecutive partition points p_i and p_{i+1}, and T is the total time span considered.

As $\sum_{i=1}^{n} p_{i+1} - p_i = T$ we may simplify this formula and we obtain

$$sim(A, B) = \mu_Q\left(\sum_{i=1}^{n} \frac{p_{i+1} - p_i}{T} sim(a_{p_i}, b_{p_i})\right) \quad (8)$$

5 Numerical results

The method proposed in this paper was tested on data on quotations of an investment (mutual) fund that invests at most 50% of assets in shares listed at the Warsaw Stock Exchange (WSE). We have used two benchmark time series, the index of WSE companies (WIG), that is the benchmark for this fund mentioned in the fund prospectus, and the index of 20 biggest and most liquid companies (WIG20). More information can be found on the WSE Web page (`http://www.gpw.pl`).

Data shown in Fig. 3 were collected from the beginning of 2007 until the end of 2008 (501 quotations); notice that one can see when world wide financial problems begun. They are measured in different units, and in order to compare them, we have scaled them using the following formula. The new value of the quotation

$$\bar{v}_i = \frac{v_i - v_0}{v_0} 10 + 10$$

where v_0 is the quotation value of the first observation, i.e. on January, 2, 2007. Those scaled time series may be interpreted as the amount of money that would be earned if we invested PLN 10 (PLN stands for the Polish Zloty) in the mutual fund or stocks of the index on January 2, 2007.

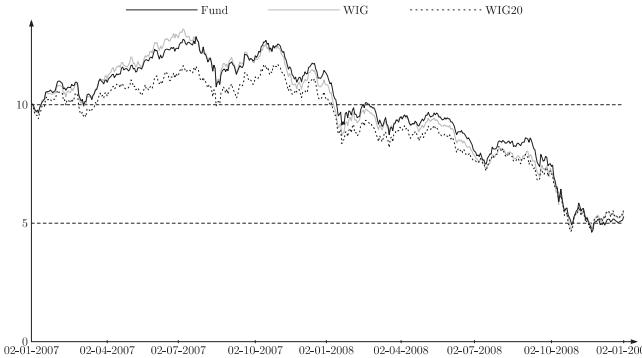


Figure 3: Daily quotations of an investment fund considered and the WIG and WIG20 indexes

The value of the mutual fund time series was equal PLN 5.28 at the end of the time span considered. The minimal value

ISBN: 978-989-95079-6-8

recorded was PLN 4.63 while the maximal one during this period was PLN 12.86.

The values of the benchmark time series were equal to PLN 5.46 and PLN 5.61 at the end of the time span considered for the WIG and WIG20, respectively. The minimum value of WIG recorded was PLN 4.71 while the maximum one during this period was PLN 13.20. The minimum and maximum values for WIG20 were PLN 4.62 and PLN 11.70, respectively.

Using the modified Sklansky and Gonzalez algorithm (cf. [2]) and $\varepsilon = 0.25$ we obtained 43 extracted trends (segments) for the fund time series, 51 for the WIG time series and 49 for the WIG 20 time series.

We can describe each time series independently using linguistic summaries of time series (cf. Kacprzyk, Wilbik, Zadrożny [1, 2, 3, 4, 5, 6] or Kacprzyk, Wilbik [7, 8, 9]). As those data sets serve only the purpose of example and are small, we applied the granulation with 3 labels for each feature only, namely *decreasing*, *constant* and *increasing* for the dynamics of change; *short*, *medium length* and *long* for duration and *low*, *moderate* and *high* for the variability.

The summaries obtained for the fund time series along with their truth values $\mathcal{T}$ are shown in Table 1.

Table 1: Linguistic summaries for the mutual fund time series

linguistic summary	$\mathcal{T}$
Among all y, most are constant	1
Among all medium y, most are constant	1

Among all short y, most are constant and low	0.8850
Among all constant y, most are medium	0.7333

The degree of similarity between the fund quotation time series and the WIG time series is equal 0.8622, while the degree of similarity of the fund quotation time series and the WIG20 time series is equal to 0.7529. This result clearly confirms our intuition. This may be viewed, on the one hand, as a proof of usefulness of our method, and on the other hand is quite natural because the investment fund considered in based on the WIG index. Luckily enough, the similarity with the WIG20 index, that of the biggest and most liquid companies, is also at a similarly high level.

6 Concluding remarks

We have proposed a new, human consistent method for the evaluation of similarity of time series, within our approach to the linguistic summarizatioon of time series that uses a fuzzy quantifier based aggregation of trends. The results obtained are very intuitively appealing. This is justified by the analysis of similarity between quotations of an investment fund and the two main indexes of the Warsaw Stock Exchange, WIG and WIG20. It also seems that a relation to natural language generation (NLG), along the lines of Kacprzyk and Zadrożny [37], may be very promising.

Abstract— *In this paper we present a procedure to deal with a kind of single-stage decision problems with imprecise utilities. In this type of problems the product measurability of the utility function is not required. So that, the involved expectations are calculated by means of iterated integrals instead of integrals over product spaces.*

Keywords— Bayesian decision analysis, Iterated expectation, Kudo-Aumann's integral, Random upper semicontinuous function, Uncertainty modeling.

1 Introduction

There are situations in which product measurability of certain mappings is not satisfied, but iterated integrals are well-defined (see [10]). This type of situations appear in single-stage decision problems where we need conditions which allows us to exchange iterated expectations in order to perform a Bayesian analysis. This paper studies the case of Bayesian analysis of single-stage decision problems with imprecise utilities and non product-measurable utility funtion.

Several studies have been developed before to evaluate imprecise utilities, see for instance Watson *et al.* [27], Tong and Bonissone [26], Dubois aand Prade [7, 8, 9], Gil and Jain [11], Billot [1], Chen and Klein [3], Gil *et al.* [13], Krätschmer [16], Bordley [2], Rébillé [22] or Rodríguez-Muñiz and López-Díaz [25].

Here we model the imprecise utilities by means of fuzzy-valued utility functions (based on the concept of random upper semicontinuous functions or fuzzy random variable). However, only in [25] the non-product measurable case has been analyzed for this type of furrzy utilities, based on the theoretical results on iterated integrals of random upper semicontinuous functions given in [24].

In this paper we gather theoretical and applied results about how to deal with the type of problems referred above.

The paper is organized as follows: Preliminaries and notation constitutes Section 2, Section 3 contains theoretical results and Section 4 gather the statistical decision analysis results.

2 Preliminaries

Let us consider $\mathcal{K}_c$ the class of nonempty compact convex subsets of $\mathbb{R}$, endowed with a semilinear structure by means of the Minkowski addition and the product by a scalar. Also, consider the *Hausdorff metric* on $\mathcal{K}_c$ (see [6]). On a measurable space $(\Omega, \mathcal{A})$ we can define $S : \Omega \to \mathcal{K}_c$ a randon set as a $\mathcal{A}|\mathcal{B}_{d_H}$-measurable mapping ([14]).

A random set S is said to be *integrably bounded with respect to measure* μ, if $\|S\| \in L^1(\Omega, \mathcal{A}, \mu)$, where $\|S\|(\omega) = \sup_{x \in S(\omega)} \|x\|$. The *integral*, or *expected value* in case of μ being a probability, of S, is given by the *Kudo-Aumann integral* and it will be denoted either by $\int_\Omega S(\omega)\, d\mu(\omega)$ or $E(S|\mu)$ ([14]).

Let $\mathcal{F}_c$ denote the class of upper semicontinuous functions or *fuzzy sets* $U : \mathbb{R} \to [0,1]$ such that $U_\alpha \in \mathcal{K}_c$ for all $\alpha \in [0,1]$, where $U_\alpha = \{x \in \mathbb{R} : U(x) \geq \alpha\}$ for $\alpha \in (0,1]$, and $U_0 = \mathrm{cl}\,\{x \in \mathbb{R} : U(x) > 0\}$, cl denoting the topological closure.

The class $\mathcal{F}_c$ can be endowed with a semilinear structure, where addition and product by a scalar can be defined by means of Zadeh's extension principle ([28, 19]). On $\mathcal{F}_c$ we consider the d_∞ metric ([19]). The *magnitude* of $U \in \mathcal{F}_c$ is given by $\|U\| = d_\infty(U, \mathbf{1}_{\{0\}}) = d_H(U_0, \{0\})$.

Given a measurable space $(\Omega, \mathcal{A})$, a mapping $X : \Omega \to \mathcal{F}_c$ is said to be a *random upper semicontinuous function* (r.u.s.f. for short) if $X_\alpha : \Omega \to \mathcal{K}_c$ with $X_\alpha(\omega) = (X(\omega))_\alpha$ for all $\omega \in \Omega$, is a random set for all $\alpha \in [0,1]$ ([21, 4]).

A r.u.s.f. X is said to be *integrably bounded* with respect to a measure $\mu : \mathcal{A} \to \mathbb{R}$, if the mapping $\|X\| \in L^1(\Omega, \mathcal{A}, \mu)$, where $\|X\| : \Omega \to \mathbb{R}$ is given by $\|X\|(\omega) = \|X(\omega)\|$ for all $\omega \in \Omega$.

For an integrably bounded r.u.s.f., in [21] is defined its *integral*, denoted by $\int_\Omega X(\omega)\, d\mu(\omega)$ or $E(X|\mu)$, as the unique set in $\mathcal{F}_c$ such that $E(X|\mu)_\alpha = E\big(X_\alpha \big| \mu\big)$ for every $\alpha \in [0,1]$. When $\Omega = [a,b]$, we will use also the notation $\int_a^b X(\omega)\, d\mu(\omega)$.

If μ is a probability measure, an r.u.s.f. is also referred to as a *fuzzy random variable* and its integral as *the fuzzy expected value of* X.

It is possible to extend to upper semicontinuous functions the concept of *Hukuhara difference* or *Minkowski difference* for subsets ([15, 20]), so given $U, V \in \mathcal{F}_c$, its *Hukuhara difference*, denoted by $U -_h V$, is the set $W \in \mathcal{F}_c$ (if it exists) such that $U = V + W$.

Let T be a nonempty open subset of $\mathbb{R}$. A mapping $G : T \to \mathcal{F}_c$ is said to be *Hukuhara differentiable* at $t_0 \in T$ if there exists $G'(t_0) \in \mathcal{F}_c$, which is called the *Hukuhara differential of* G *at* t_0, such that

$$\lim_{\Delta t \to 0^+} d_\infty\left(\frac{G(t_0 + \Delta t) -_h G(t_0)}{\Delta t}, G'(t_0)\right)$$
$$= \lim_{\Delta t \to 0^+} d_\infty\left(\frac{G(t_0) -_h G(t_0 - \Delta t)}{\Delta t}, G'(t_0)\right) = 0.$$

The above definition ([20, 23]) is an extension of the Hukuhara's differentiability criterion for set-valued mappings ([15]).

ISBN: 978-989-95079-6-8

If a mapping G depends on more than one argument, we will make use of the usual symbol of partial derivative to indicate with respect to which argument the Hukuhara differential is considered.

Throughout the paper, for any set $\Omega \subset \mathbb{R}^k$ with $k \in \mathbb{N}$, $\mathcal{B}_\Omega$ will denote the Borel σ-field on Ω. Given $(\Omega, \mathcal{B}_\Omega)$ and $m_1, m_2 : \mathcal{B}_\Omega \to [0, \infty]$ two σ-finite measures, $m_1 \ll m_2$ will indicate that m_1 is absolutely continuous with respect to m_2, and $\frac{dm_1}{dm_2}$ will denote a Radon-Nikodym derivative of m_1 with respect to m_2. If it is supposed that there exists a continuous Radon-Nikodym derivative, then $\frac{dm_1}{dm_2}$ will denote this particular function.

As we will model the imprecise utilities by means of fuzzy-valued functions it should be necessary to rank fuzzy sets. For this purpose the ranking criterion introduced by De Campos and González [5] will be considered. Therefore, we will say that $U \in \mathcal{F}_c$ is *greater than or equal to* $W \in \mathcal{F}_c$ *in the* λ, μ*-average sense*, we will denote it by $U \geq_{\lambda,\mu} W$, if $V_\mu^\lambda(U) \geq V_\mu^\lambda(W)$, where $\lambda \in [0,1]$ represents a kind of degree of optimism/pessimism and μ is a measure on $[0,1]$ (see [18] for more details).

3 Theoretical results

We include in this section those theoretical results regarding the exchange of iterated integrals that are necessary to prove the applied results in Section 4.

The first result is about differentiating under the integral sign, by using Hukuhara derivative.

Proposition 3.1 *Let $(\Omega, \mathcal{A}, P)$ be a probability space with $\Omega \subset \mathbb{R}^k$, and let m denote the Borel measure on the interval $[a,b]$. For every $\omega \in \Omega$, let P_ω be a probability measure on $([a,b], \mathcal{B}_{[a,b]})$ with $P_\omega \ll m$, such that there exists a continuous Radon-Nikodym derivative.*

If $X : \Omega \times [a,b] \to \mathcal{F}_c$ satisfies the following conditions:

i) for every $\omega \in \Omega$, the mapping $X_\omega : [a,b] \to \mathcal{F}_c$, with $X_\omega(t) = X(\omega, t)$, is an integrably bounded r.u.s.f. with respect to P_ω, and X_ω is continuous $a.s.\,[P]$,

ii) there exists $h \in L^1(\Omega, \mathcal{A}, P)$, such that $\left\|X(\omega,t)\frac{dP_\omega}{dm}(t)\right\| \leq h(\omega)\ a.s.\,[P]$ for every $t \in [a,b]$, and the mapping $\omega \mapsto X(\omega,t)\frac{dP_\omega}{dm}(t)$ is continuous $a.e.\,[m]$,

iii) there exists $g \in L^1([a,b], \mathcal{B}_{[a,b]}, m)$ with $\left\|X(\omega,t)\frac{dP_\omega}{dm}(t)\right\| \leq g(t)\ a.e.\,[m]$ for every $\omega \in \Omega$,

then, the mapping

$$t \in [a,b] \mapsto \int_\Omega \Big(\int_a^t X(\omega,s)\, dP_\omega(s) \Big)\, dP(\omega)$$

is Hukuhara differentiable on (a,b), and for every $t \in (a,b)$ it holds that

$$\frac{\partial}{\partial t} \int_\Omega \left(\int_a^t X(\omega,s)\, dP_\omega(s) \right)\, dP(\omega)$$

$$= \int_\Omega X(\omega,t) \frac{dP_\omega}{dm}(t)\, dP(\omega).$$

Starting from last result, we can go one step further to prove a exchange of iterated integrals:

Theorem 3.2 *Let $(\Omega, \mathcal{B}_\Omega, P)$ be a probability space with $\Omega \subset \mathbb{R}^k$ and let m denote the Borel measure on the interval $T = [a,b]$. For every $t \in T$, let P_t be a probability measure on $(\Omega, \mathcal{B}_\Omega)$ such that $P_t \ll P$ and there exists a continuous Radon-Nikodym derivative. For every $\omega \in \Omega$, let P_ω be a probability on $(T, \mathcal{B}_T)$ such that $P_\omega \ll m$ and there exists a continuous Radon-Nikodym derivative.*

Let $X : \Omega \times T \to \mathcal{F}_c$ be a mapping satisfying that:

i) for every $t \in T$, X_t is an integrably bounded r.u.s.f. with respect to P_t,

ii) for every $\omega \in \Omega$, X_ω is an integrably bounded r.u.s.f. with respect to P_ω and it is continuous $a.s.\,[P]$,

iii) there exists $h_1 \in L^1(\Omega, \mathcal{B}_\Omega, P)$ such that $\left\|X(\omega,t)\frac{dP_\omega}{dm}(t)\right\| \leq h_1(\omega)\ a.s.\,[P]$ for every $t \in T$, and the mapping $\omega \mapsto X(\omega,t)\frac{dP_\omega}{dm}(t)$ is continuous $a.e.\,[m]$,

iv) there exists a mapping $g \in L^1([a,b], \mathcal{B}_{[a,b]}, m)$ such that for every $\omega \in \Omega$, $\|X(\omega,t)\frac{dP_\omega}{dm}(t)\| \leq g(t)\ a.e.\,[m]$ for every $\omega \in \Omega$,

v) the mapping $t \mapsto X(\omega,t)\frac{dP_t}{dP}(\omega)$ is continuous on T $a.s.\,[P]$,

vi) there exists $h_2 \in L^1(\Omega, \mathcal{B}_\Omega, P)$ such that $\|X(\omega,t)\frac{dP_t}{dP}(\omega)\| \leq h_2(\omega)\ a.s.\,[P]$ for every $t \in T$.

Let m' be a probability measure on $(T, \mathcal{B}_T)$ such that $m' \ll m$ and there exists a continuous Radon-Nikodym derivative. If for every $t \in T$, the equality

$$\frac{dP_\omega}{dm}(t) = \frac{dP_t}{dP}(\omega)\frac{dm'}{dm}(t) \quad a.s.\,[P]$$

holds, then

$$\int_\Omega \left(\int_a^t X(\omega,s)\, dP_\omega(s) \right) dP(\omega)$$

$$= \int_a^t \left(\int_\Omega X(\omega,s)\, dP_s(\omega) \right) dm'(s)$$

for every $t \in T$.

And also an unbounded version of previous theorem can be obtained.

Theorem 3.3 *Assume the conditions in Theorem 3.2 with the interval T being not necessarily bounded, and suppose that there exists $g' \in L^1(\Omega, \mathcal{B}_\Omega, P)$ such that*

$$\int_T \|X(\omega,s)\| dP_\omega(s) \leq g'(\omega)\ \ a.s.\,[P]\,.$$

Then, the following equality holds,

$$\int_\Omega \left(\int_T X(\omega,s)\, dP_\omega(s) \right) dP(\omega)$$

$$= \int_T \left(\int_\Omega X(\omega,s)\, dP_s(\omega) \right) dm'(s)\,.$$

It should be remarked that the conditions in Theorems 3.2 and 3.3 do not imply that X is an r.u.s.f. on the product measurable space as is illustrated in [24].

ISBN: 978-989-95079-6-8

4 Applied results

In this section we are using the theoretical results obtained in Section 3 to obtain applied results to the single-stage decision problem under non-product measurability conditions. Obviously, different conditions than in the Fubini-applicable case will be obtained, but it is again very important to underline that under the conditions stated here product measurability is not implied.

We first introduce the concept of fuzzy utility function considered in this communication. We will use the following notation: Θ is the state space and it will be considered an interval of $\mathbb{R}$, $\mathcal{B}_\Theta$ is the Borel σ-field on Θ, with m the Borel measure and $\mathbf{A}$ is the action space.

Definition 4.1 *A mapping $U : \Theta \times \mathbf{A} \to \mathcal{F}_c$ is said to be a fuzzy utility function on $\Theta \times \mathbf{A}$ if*

i) for every $a \in \mathbf{A}$, the projection $U_a : \Theta \to \mathcal{F}_c$ is an r.u.s.f. on $(\Theta, \mathcal{B}_\Theta)$,

ii) for every pair $a_1, a_2 \in \mathbf{A}$, a_1 will be considered preferred or indifferent to a_2 with respect to a probability distribution ξ on $(\Theta, \mathcal{B}_\Theta)$, if $E(U_{a_1}|\xi) \geq_{\lambda,\mu} E(U_{a_2}|\xi)$ (for fixed $\lambda \in [0,1]$ and measure μ).

The decision problem with fuzzy utilities will be denoted by $(\Theta, \mathbf{A}, U)$.

On the other hand, it will be considered a Bayesian context, so the existence of a probability distribution π on $(\Theta, \mathcal{B}_\Theta)$, *the prior distribution*, will be assumed. Then the "value" of the decision problem will be the fuzzy value $E(U_{a^\pi}|\pi)$, where a^π is a *prior Bayes action* in the λ, μ-average sense, this is, $a^\pi \in \mathbf{A}$ verifies $E(U_{a^\pi}|\pi) \geq_{\lambda,\mu} E(U_a|\pi)$ for all $a \in \mathbf{A}$.

Similar to the case of real-valued utilities, it is useful for increasing the expected utility to incorporate *sample information*. Let $\mathbf{X}$ be a statistical experiment characterized by a probability space $(\mathbb{X}, \mathcal{B}_\mathbb{X}, P_\theta)$, where $\theta \in \Theta$, $\mathcal{B}_\mathbb{X}$ is the Borel σ-field on $\mathbb{X} \subset \mathbb{R}^k$ and the experimental distribution P_θ depends on the true unknown state θ. We will denote by P the *marginal (predictive)* distribution of the experiment.

After the experiment is performed, if $\mathbf{X} = x$ is the available sample information, the fuzzy expected utility associated with an action $a \in \mathbf{A}$ is given by $E(U_a|\pi_x)$, where π_x is the *posterior distribution* of θ given $\mathbf{X} = x$, obtained on the basis of Bayes' formula. So, a *posterior Bayes action* is any $a^{\pi_x} \in \mathbf{A}$ such that $E(U_{a^{\pi_x}}|\pi_x) \geq_{\lambda,\mu} E(U_a|\pi_x)$ for every $a \in \mathbf{A}$.

In order to generalize the choice of an action for each possible sample, the concept of *decision rule,* as a mapping from $\mathbb{X}$ to $\mathbf{A}$ satisfying several conditions (based on Theorems 3.2 and 3.3) is formalized. These conditions will allow the proper extension of the normal and extensive forms of the Bayesian analysis.

Definition 4.2 *Let $(\mathbb{X}, \mathcal{B}_\mathbb{X}, P_\theta)$ be the probability space of a statistical experiment $\mathbf{X}$ associated with the decision problem $(\Theta, \mathbf{A}, U)$. A decision rule is a mapping $d : \mathbb{X} \to \mathbf{A}$ satisfying that*

i) for every $\theta \in \Theta$, $U(\theta, d()) : \mathbb{X} \to \mathcal{F}_c$ is an integrably bounded r.u.s.f. with respect to P_θ,

ii) for every $x \in \mathbb{X}$, $U(, d(x)) : \Theta \to \mathcal{F}_c$ is an integrably bounded r.u.s.f. with respect to π_x, moreover, it is continuous a.s. $[P]$,

iii) there exists $h_1 \in L^1(\mathbb{X}, \mathcal{B}_\mathbb{X}, P)$ such that $\left\|U(\theta, d(x))\frac{d\pi_x}{dm}(\theta)\right\| \leq h_1(x)$ a.s. $[P]$ for every $\theta \in \Theta$, and the mapping $x \mapsto U(\theta, d(x))\frac{d\pi_x}{dm}(\theta)$ is continuous a.e. $[m]$,

iv) there exists $g \in L^1(\Omega, \mathcal{B}_\Omega, m)$ such that for every $x \in \mathbb{X}$, it holds that $\|U(\theta, d(x))\frac{d\pi_x}{dm}(\theta)\| \leq g(\theta)$ a.e. $[m]$ for every $x \in \mathbb{X}$,

v) the mapping $\theta \mapsto U(\theta, d(x))\frac{dP_\theta}{dP}(x)$ is continuous on Θ a.s. $[P]$,

vi) there exists $h_2 \in L^1(\mathbb{X}, \mathcal{B}_\mathbb{X}, P)$ such that $\left\|U(\theta, d(x))\frac{dP_\theta}{dP}(x)\right\| \leq h_2(x)$ a.s. $[P]$ for every $\theta \in \Theta$,

vii) there exists $g' \in L^1(\mathbb{X}, \mathcal{B}_\mathbb{X}, P)$ with $\int_\Theta \|U(\theta, d(x))\| \, d\pi_x(\theta) \leq g'(x)$.

Now, on the one hand we can consider the *normal Bayesian analysis*. In this case we should find a *Bayes decision rule*, that is, a rule d_B such that

$$\int_\Theta \left(\int_\mathbb{X} U(\theta, d_B(x)) \, dP_\theta(x) \right) d\pi(\theta)$$

$$\geq_{\lambda,\mu} \int_\Theta \left(\int_\mathbb{X} U(\theta, d(x)) \, dP_\theta(x) \right) d\pi(\theta)$$

for every decision rule d. In this case, the "value" of the problem is

$$\int_\Theta \left(\int_\mathbb{X} U(\theta, d_B(x)) \, dP_\theta(x) \right) d\pi(\theta). \qquad (1)$$

On the other hand, we can consider the *extensive Bayesian analysis*. We should obtain for each sample information x a posterior Bayes action a^{π_x}, and consider the decision rule which associates with each x an action a^{π_x}. In this analysis, the "value" of the experiment $\mathbf{X}$ is quantified by the fuzzy expected terminal utility, defined as follows:

Definition 4.3 *Given $(\Theta, \mathbf{A}, U)$ a decision problem and $\mathbf{X} = (\mathbb{X}, \mathcal{B}_\mathbb{X}, P_\theta)$, an associated experiment, the fuzzy expected terminal utility of $\mathbf{X}$ is given by*

$$U_t(\mathbf{X}) = \int_\mathbb{X} \left(\int_\Theta U(\theta, a^{\pi_x}) \, d\pi_x(\theta) \right) dP(x). \qquad (2)$$

We are now showing the equivalence between the two forms of the Bayesian analysis in the sense that (1) and (2) are equal in the λ, μ-average sense. Previously, the following result for the exchange of the integrals is stated.

Theorem 4.4 *Let $(\Theta, \mathbf{A}, U)$ be a decision problem, let $\Theta \subset \mathbb{R}$ and let π be a prior probability on $(\Theta, \mathcal{B}_\Theta)$ such that $\pi \ll m$ with a continuous Radon-Nikodym derivative. Let $\mathbf{X} = (\mathbb{X}, \mathcal{B}_\mathbb{X}, P_\theta)$ be an associated experiment, and let P be the marginal distribution. For every $\theta \in \Theta$, suppose that $P_\theta \ll P$ and there exists a continuous Radon-Nikodym derivative. For every $x \in \mathbb{X}$, let π_x be the posterior distribution on $(\Theta, \mathcal{B}_\Theta)$ such that $\pi_x \ll m$ with a continuous Radon-Nikodym derivative.*

ISBN: 978-989-95079-6-8

If for every $\theta \in \Theta$*, it holds that* $\frac{d\pi_x}{dm}(\theta) = \frac{dP_\theta}{dP}(x)\frac{d\pi}{dm}(\theta)$ $a.s.\,[P]$*, then*

$$\int_{\mathbb{X}} \left(\int_{\Theta} U(\theta, d(x))\, d\pi_x(\theta) \right) dP(x)$$
$$= \int_{\Theta} \left(\int_{\mathbb{X}} U(\theta, d(x))\, dP_\theta(x) \right) d\pi(\theta)$$

whatever the decision rule $d : \mathbb{X} \to \mathbf{A}$ *may be.*

As a consequence, the following key result, which states the equivalence between the normal and extensive forms of Bayesian analysis, is obtained.

Theorem 4.5 *Assume the conditions of Theorem 4.4. Let us consider the mapping which associates with each sample* $x \in \mathbb{X}$ *a posterior Bayes action* a^{π_x}*. If this mapping satisfies the definition of decision rule, then it is a Bayes decision rule. Moreover,* $U_t(\mathbf{X})$ *is equal, in the* λ, μ*-average sense, to the fuzzy expected utility associated with any Bayes decision rule, this is*

$$U_t(\mathbf{X}) =_{\lambda,\mu} \int_{\mathbb{X}} \left(\int_{\Theta} U(\theta, d_B(x))\, d\pi_x(\theta) \right) dP(x)$$

Thus, the fuzzy expected terminal utility, so calculated, can be interpreted as the "value" of the decision problem once the experiment $\mathbb{X}$ is performed and one Bayes decision rule is calculated. This lead us not only to express the information of the problem by a value but also as a criterium to rank experiments in order to obtain the more informative.

5 Conclusions

By using a theoretical result about exchanging iterated integrals of $[0,1]^{\mathbb{R}}$-valued r.u.s.f., the model established in this paper provides a framework for single-stage decision problems in which both forms of Bayesian analysis (normal and extensive) are proved to be equivalent when imprecise utilities are not necessarily product measurable. Thus, these results together with those in [12, 17, 13] cover most of the situations which one can found when analyzing single-stage decision problems with imprecise utilities modeled by fuzzy random variables.

60 years "A Mathematical Theory of Communication" – Towards a "Fuzzy Information Theory"

Rudolf Seising

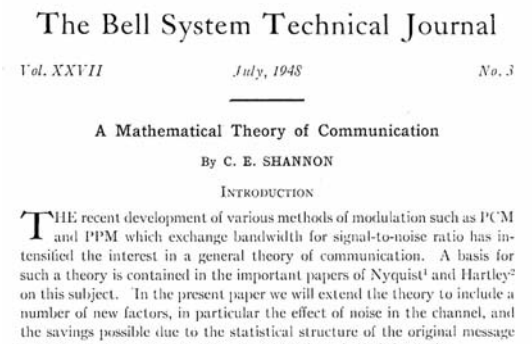
European Centre for Soft Computing
Mieres, Asturias, Spain
Email: rudolf.seising@softcomputing.es

Abstract*—When 60 years ago Shannon established "A Mathematical Theory of Communication" nobody could know the consequences for science and technology in the second half of the century. Shannon published his article in two parts in the July and October 1948 editions of the* Bell System Technical Journal*. However, it is very probable that this article wouldn't have become famous without the help of Weaver, whose popular text "The Mathematics of communication" re-interpreted Shannon's work for broader scientific audiences. Weaver's "preface" and Shannon's article were published together in the book* The Mathematical Theory of Communication *(1949) that represents the beginning of the then so-called "Information theory". However, in his "introduction" Weaver went over and above Shannon´s mathematical theory mentioning not only the technical but also the semantic and influential problems of communication. This classification is very similar to the foundations of the* Theory of Signs *(1938) that was established by Morris. This paper deals with the connectivity between this Information theory and the Theory of Fuzzy sets and systems that appeared in the first half of the 1950s.Then the paper focuses to the non-technical but philosophical aspects of information theory and it advocates a fuzzy information theory that has to be appropriate to cover the concept of information – particularly with regard to the philosophical aspects.*

***Keywords*—** communication, fuzziness, information, philosophy, semiotics, signs, signals

1 Introduction

60 years ago, in July 1948, the mathematician and electrical engineer Claude Elwood Shannon (1916-2001) published "A Mathematical Theory of Communication" in the *Bell System Technical Journal* [1] (Fig. 1) and in July of the following year "The Mathematics of Communication" by the mathematician and physicist Warren Weaver (1894-1978) appeared in the *Scientific American* [2] (Fig. 2).



The Bell System Technical Journal

Vol. XXVII July, 1948 No. 3

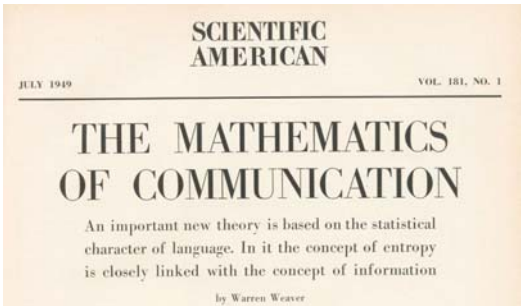
A Mathematical Theory of Communication

By C. E. SHANNON

INTRODUCTION

THE recent development of various methods of modulation such as PCM and PPM which exchange bandwidth for signal-to-noise ratio has intensified the interest in a general theory of communication. A basis for such a theory is contained in the important papers of Nyquist[1] and Hartley[2] on this subject. In the present paper we will extend the theory to include a number of new factors, in particular the effect of noise in the channel, and the savings possible due to the statistical structure of the original message

Figure 1: Title of Shannon's publication in July 1948 [1].



SCIENTIFIC AMERICAN

JULY 1949 VOL. 181, NO. 1

THE MATHEMATICS OF COMMUNICATION

An important new theory is based on the statistical character of language. In it the concept of entropy is closely linked with the concept of information

by Warren Weaver

Figure 2: Title of Weaver's publication in July 1949 [2].

However, other roots of the later so-called "Information Theory" can be found also in the *Cybernetics* of Norbert Wiener (1894-1964) [3], in the work of the Russian mathematician Andrei N. Kolmogorov (1903-1987) [4] and of the British statistician Ronald A. Fisher (1890-1962) [5].
Wiener wrote: "This idea occurred at about the same time to several writers, among them the statistician R. A. Fisher, Dr. Shannon of the Bell Telephone Laboratories, and the author. Fisher's motive in studying this subject is to be found in classical statistical theory; that of Shannon in the problem of coding information; and that of the author in the problem of noise and message in electrical filters. Let it be remarked parenthetically that some of my speculations in this direction attach themselves to the earlier work of Kolmogorov in Russia, although a considerable part of my work was done before my attention was called to the work of the Russian school." ([3], p. 18.)[1]
Shannon's "Mathematical Theory of Communication" and Wiener's *Cybernetics* had appeared simultaneously, but in both cases the publication was delayed by the war. However, Wiener mentioned the fact that, since Shannon was a Bell employee, his research projects were geared toward realizing and marketing his findings as quickly as possible, whereas Wiener, as a college professor, was able to approach his research freely. He had "found the new realm of communication ideas a fertile source of new concepts not only in communication theory, but in the study of the living organism and in many related problems".[2] In the manuscript

[1] Wiener cited Kolmogorov's article [4].
[2] Wiener in conversation with Bello (technology editor of the journal *Fortune*) on 13 October 1953, Box 4.179, MC22, Wiener Papers, MIT. Quoted from [6], p. 138.

ISBN: 978-989-95079-6-8

for his book *Invention: The Care and Feeding of Ideas*, which he never finished, Wiener wrote in 1957:
"Once I had alerted myself and the public in general to the statistical element in communication theory, conformation began to flow in from all sides. At the Bell Telephone Laboratories there was, and is, a young mathematical physicist by the name of Claude Shannon. He had already applied mathematical logic to the design of switching systems, and throughout all his work he has shown a love for the discrete problems, the problems with a small number of variable quantities, which come up in switching theory. I am inclined to believe that from the very start, a large part of his ideas in communication theory and its statistical basis were independent of mine, but whether they were or not, each of us appreciated the significance of the work of the other. The whole subject of communication began to assume a new statistical form, both for his sorts of problems and for mine. This is not the point for me to give the genealogy of every single piece of apparatus which this new statistical communication theory has fostered, but I can say that the impact of the work has gone from one end of communication theory to the other, until now there is scarcely a recent communication invention which has not been touched by statistical considerations. Thus, this whole wide spreading branch of science represents a subtle working out of concepts implicit in Gibbs and in the Lebesque-Borel team, but if I may say so, implicitly implicit, so that until some forty years had passed, no one could have seen the direction in which the earlier thought was bound to lead. This is, in my mind, a key example of a change in intellectual climate, and of the effect it has had both in discovery and in invention." ([7], p. 22f)
Today Shannon's name is associated almost unanimously with mathematical information and communication theory – these terms are often considered synonyms – although people had spoken at first of the "Wiener-Shannon Communication Theory".

Figure 3: C. E. Shannon, W. Weaver and N. Wiener.

However, it was not least Warren Weaver's article that popularized Shannon's theory and therefore it became – with little changes and the new title "Recent Contributions to the Mathematical Theory of Communication" – as an "introduction" to Shannon's text in their joint book-publication *The Mathematical Theory of Communication* [8]. Even more Weaver's manuscript was not only a brief and understandable sketch of Shannon's theory and their technical problems – in this text Weaver presented self-contained and more philosophical considerations on the semantic and influential problems with the concept of information that is in the core of Shannon's theory and that was called in the following years "Information theory". We will deal with these philosophical subjects in section 3. Beforehand we will give a few remarks on the genesis of the theory of fuzzy sets and systems, especially against the background of the developments of information theory in the 1950s.

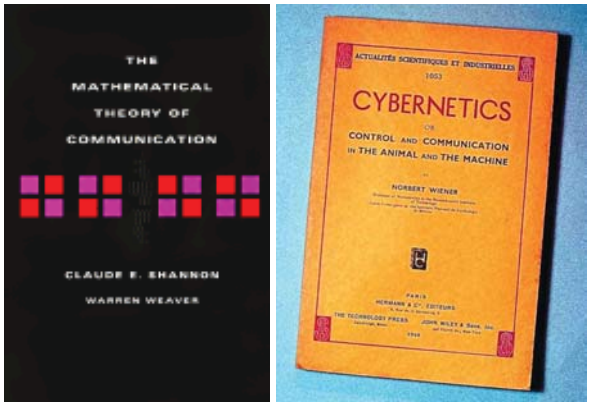


Figure 4: The books of Shannon and Weaver and Wiener.

2 Information theory and the theory of Fuzzy Sets and Systems

2.1 A Historical Sketch - in General

Inspired by Wiener's *Cybernetics*, Shannon's and Weaver's *Mathematical Theory of Communication* and the digital computer era that started during the wartime with the *Electronic Numerical Integrator and Computer* (ENIAC) and the *Electronic Discrete Variable Computer* (EDVAC), both designed by John P. Eckert (1919-1995) and John W. Mauchly (1907-1980), the young emigrant Lotfi A. Zadeh continued his studies in electrical engineering at MIT in Boston after his emigration from Iran into the USA in the 1940s. When he started his doctoral studies at the Columbia University in 1946, he became acquainted with these new milestones in science and technology. Shannon and Wiener delivered lectures in New York about the new theories they had developed during the War. In 1950 Zadeh acted as a moderator at a debate on digital computers at Columbia University, held between Shannon, Edmund Callis Berkeley (1923-1988), the author of the book *Giant Brains or Machines That Think* published in 1949 [9], and Francis Joseph Murray (1911-1996), mathematician and consultant to IBM.
15 years later Zadeh, who was then a professor of electrical engineering at Berkeley, established the new mathematical theory of Fuzzy Sets and Systems [10-12]. Already in 1962 he described the basic necessity of a new scientific tool to handle very large and complex systems in the real world: ''we need a radically different kind of mathematics, the mathematics of fuzzy or cloudy quantities which are not describable in terms of probability distributions. Indeed, the

ISBN: 978-989-95079-6-8

need for such mathematics is becoming increasingly apparent even in the realm of inanimate systems, for in most practical cases the a priori data as well as the criteria by which the performance of a man-made system are judged are far from being precisely specified or having accurately-known probability distributions'' [13].

The potential of the new techniques of the theory of Fuzzy sets and Fuzzy systems urged Ebrahim H. Mamdani, a professor of electrical engineering at Queen Mary College in London, to attempt the implementation of a fuzzy system under laboratory conditions. He expressed the intention to his doctor student Sedrak Assilian, who designed a fuzzy algorithm to control a small steam engine within a few days. The concepts of so-called linguistic variables and Zadeh's max-min composition were suitable to establish fuzzy control rules because *input*, *output* and *state* of the steam engine system range over fuzzy sets. Thus, Assilian and Mamdani designed the first real fuzzy application when they controlled the system by a fuzzy rule base system [14]. In 1974, Assilian completed his Ph. D. thesis on this first fuzzy control system [15].

The steam engine heralded the Fuzzy boom that started in the 1980s in Japan and later pervaded the Western hemisphere. Many fuzzy applications, such as domestic appliances, cameras and other devices appeared in the last two decades of the 20th century. Of greater significance, however, was the development of fuzzy process controllers and fuzzy expert systems that served as trailblazers for scientific and technological advancements of fuzzy sets and systems.[3]

Very little is known about the historical connectivity between the Information theory and the theory of Fuzzy Sets and Systems. In the following paragraph we review some links across the boundaries of these fields.

2.2 *In detail: Signals, Noise and Uncertainty*

Shannon intended to establish a general theory of communication and a basis for such a theory was already given in two former papers of other Bell-engineers, Harry Nyquist and Ralph V. L. Hartley [17, 18].[4] 20 years later, Shannon extended this theoretical basis. He included "new factors, in particular the effect of noise in the channel, and the savings possible due to the statistical structure of the original message and due to the nature of the final destination of the information." ([1], p. 379) To illustrate this mathematical theory, Shannon had drawn a diagram of a general communication model (Fig. 5):

- An information source produces a series of messages that are to be delivered to the receiver side. Transmission can occur via a telegraph or teletypewriter system, in which case it is a series of letters. Transmission can also occur via a telephone or radio system, in which case it is a function of time $f(t)$, or else it is a function $f(x, y, t)$, such as in a black and white television system, or it consists of complicated functions.
- The transmitter transforms the message in some way so that it can produce signals that it can transmit via the channel. In telegraphy, these are dotdash codes; in telephony, acoustic pressure is converted into an electric current.
- The channel is the medium used for transmission. Channels can be wires, light beams and other options.
- The receiver must perform the opposite operation to that of the transmitter and in this way reconstructs the original message from the transmitted signal.
- The destination is the person or entity that should receive the message.

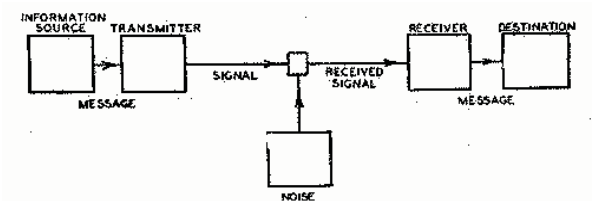

Figure 5: Shannon's diagram ([1], p. 381).

According to this, Shannon conceived of communication purely as the transmission of messages – completely detached from the meaning of the symbols!

In the second paragraph of his paper Shannon states: "The fundamental problem of communication is that of reproducing at one point either exactly or approximately a message selected at another point." ([1], p. 379) Eventually, in chapter 12 that is entitled "Equivocation and Channel Capacity", he applies his theoretical framework to this problem: "If the channel is noisy it is not in general possible to reconstruct the original message or the transmitted signal with *certainty* by any operation on the received signal *E*. There are, however, ways of transmitting the information which are optimal in combating noise." His solution of the problem is as follows: "We consider a communication system and an observer (or auxiliary device) who can see both what is sent and what is recovered (with errors due to noise). This observer notes the errors in the recovered message and transmits data to the receiving point over a "correction channel" to enable the receiver to correct the errors." ([1], p. 408) Shannon also indicated this situation schematically (Fig. 6).

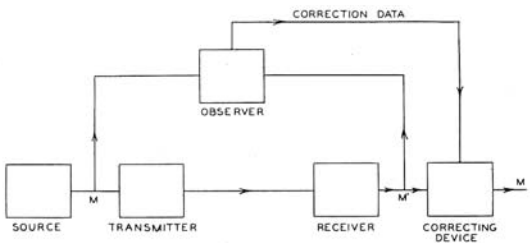

Figure 6: Shannon's diagram of a communication system with correction device ([1], p. 409).

[3] A more detailed presentation of the history of the theory of Fuzzy sets and systems can be found in [16].

[4] A more detailed presentation of the aspect of these papers is given in my paper for the 2009 annual meeting of NAFIPS [19].

ISBN: 978-989-95079-6-8

Shannon's introduction of the observer is of great theoretical interest but – of course – the system has to transmit the data on errors and the correction data via communication channels to the observer. When Warren Weaver explained the mathematics of Communication in the first version of his paper [2], he wrote: "If noise is introduced, then the received message contains certain distortions, certain errors. Certain extraneous material, that would certainly lead to increased uncertainty. […] To get the useful information in the received signal we must subtract the spurious portion. This is accomplished, in the theory, by establishing a quantity known as the "equivocation", meaning the amount of ambiguity introduced by noise." ([2], p. 13) And some paragraphs later he emphasized: "However clever one is with the coding process, it will always be true that after the signal is received there remains some undesirable uncertainty about what the message was". ([2], p. 13)

Let's see how Lotfi Zadeh dealt with this fundamental problem of communication in the 1950s!

In 1949, the year when the book of Shannon and Weaver appeared, Zadeh wrote the Ph. D. thesis on *Frequency Analysis of Variable Networks*, under supervision of Professor John Ralph Ragazzini, and in 1950 he was appointed to an assistant professor. He was enhanced by Wiener's cybernetics and Shannon's information theory. In February 1952, he presented *Some Basic Problems in Communication of Information* at the meeting of the Section of Mathematics and Engineering of the New York Academy of Sciences and in the following, one of these problems will be sketched, that deals with the *recovery process* of transmitted signals. In the proceedings of this meeting, Zadeh wrote: "Let $X=\{x(t)\}$ be a set of signals. An arbitrarily selected member of this set, say $x(t)$, is transmitted through a noisy channel Γ and is received as $y(t)$. As a result of the noise and distortion introduced by Γ, the received signal $y(t)$ is, in general, quite different from $x(t)$. Nevertheless, under certain conditions it is possible to recover $x(t)$ – or rather a time-delayed replica of it – from the received signal $y(t)$." ([20], p. 201)

In this paper, he didn't examine the case where $\{x(t)\}$ is an ensemble; he restricted his view to the problem to recover $x(t)$ from $y(t)$ "irrespective of the statistical character of $\{x(t)\}$"[5, p. 201]. Corresponding to the relation $y = \Gamma x$ between $x(t)$ and $y(t)$ he represented the recovery process of $y(t)$ from $x(t)$ by $x = \Gamma^{-1}y$, where $\Gamma^{-1}y$ is the inverse of Γ, if it exists, over $\{y(t)\}$.

Zadeh represented signals as ordered pairs of points in a signal space Σ, which is imbedded in a function space with a delta-function basis, and to measure the disparity between $x(t)$ and $y(t)$ he attached a distance function $d(x, y)$ with the usual properties of a metric. Then he considered the special case in which it is possible to achieve a perfect recovery of the transmitted signal $x(t)$ from the received signal $y(t)$. He supposed that "$X = \{x(t)\}$ consist of a finite number of discrete signals $x_1(t)$, $x_2(t)$, …, $x_n(t)$, which play the roles of symbols or sequences of symbols. The replicas of all these signals are assumed to be available at the receiving end of the system. Suppose that a transmitted signal x_k is received as y. To recover the transmitted signal from y, the receiver evaluates the 'distance' between y and all possible transmitted signals x_1, x_2, …, x_n, by the use of a suitable distance function $d(x, y)$, and then selects that signal which is 'nearest' to y in terms of this distance function (Fig. 7). In other words, the transmitted signal is taken to be the one that results in the smallest value of $d(x, y)$. This in brief, is the basis of the reception process." ([20], p. 201) By this process the received signal x_k is always 'nearer' – in terms of the distance functional $d(x, y)$ – to the transmitted signal $y(t)$ than to any other possible signal x_i, i.e. $d(x_k, y) < d(x_i, y)$, $i \neq k$,*for all k and i.*

But at the end of his reflection of this problem Zadeh conceded that "in many practical situations it is inconvenient, or even impossible, to define a quantitative measure, such as a distance function, of the disparity between two signals. In such cases we may use instead the concept of neighborhood, which is basic to the theory of topological spaces" ([20], p. 202). Spaces such as these, Zadeh surmised, could be very interesting with respect to applications in communication engineering. Therefore, this problem of the recovery process of transmitted signals which is a special case of Shannon's *fundamental problem of communication*, the problem "of reproducing at one point either exactly or approximately a message selected at another point", was one of the problems that initiated Zadeh's thoughts about not precisely specified quantitative measures, i. e. or cloudy or fuzzy quantities. – About 15 years later he proposed his new 'concept of neighborhood' which is now basic to the theory of fuzzy systems!

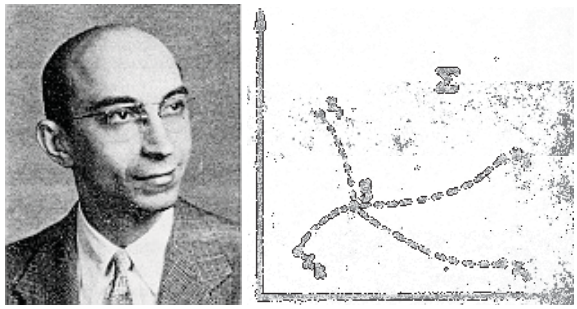

Figure 7: Lotfi A. Zadeh (born 1921) and his illustration: "Recovery of the input signal by means of the comparison of the distances between the received signal y and all possible transmitted signals" [20].

3 Fuzziness and Information Theory

In this section we concentrate our attention from the problem of communication to some philosophical considerations in the first half of the 20th century by Charles William Morris (1901-1976) and Warren Weaver. However, Morris was an engineer by training and he did his Ph. D. in philosophy under George Herbert Mead (1863-1931), the founder of social psychology, and Weaver was a mathematician and physicist. Nevertheless, both scientists wrote philosophical

ISBN: 978-989-95079-6-8

works on the subjects of signs and their transmission. Moreover, there is a distinct similarity between the two theoretical works that has to be underlined.

3.1 Theory of Signs, semiotics, and Information theory

The study of sign processes, or signification and communication is called "semiotics" since the 1930s. Great work to formalize this field was done by members of the Vienna Circle but also by the philosophers and linguists Charles Sanders Peirce (1839–1914), Ferdinand de Saussure (1857–1913) and Louis Hjelmslev (1899–1965), but here we will limit our considerations to the fundamental work of semiotics by Morris.

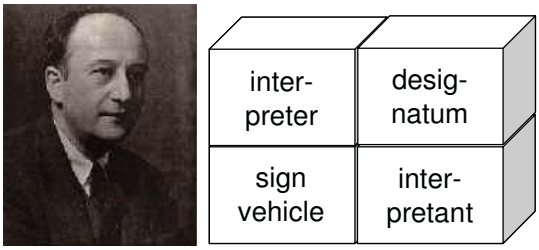

Figure 8: Ch. W. Morris; an illustration of the four components of the semiosis process.

Morris was in touch with some members of the Vienna Circle and he was a member of the Unity of Science movement. When he intended in his 1938 published *Foundations of the Theory of Signs* [21] a science of signs "on a biological basis and specifically with the framework of the science of behavior", he defined *semiotics* as a *universal* theory of signs and an *interdisciplinary* undertaking. In his view, the mission of semiotics as a science of signs is analyzing language as a social system of signs. Language is a system of signs which produces dispositions to social behavior, and in order to understand the uses and effects of signs we have to understand that and how signs influence social behavior. The process by which a sign-vehicle may function as a sign is called *semiosis*.[5] In Morris' foundation there are four components of the semiosis (Fig. 8):

1) the *sign vehicle* − this is the object or event which functions as a sign,
2) the *designatum* − this is the kind of object or class of objects which the sign designates,
3) the *interpretant* − this is the disposition of an interpreter to initiate a response-sequence as a result of perceiving the sign, and
4) the *interpreter* − this is the person for whom the sign-vehicle functions as a sign.

He also divided *semiotics* into three interrelated disciplines:

1) syntactics − the study of the methods by which signs may be combined to form compound signs,
2) semantics − the study of the signification of signs,
3) pragmatics − the study of the origins, uses, and effects of signs.

3.2 Weaver's three levels in Information theory

It seems that Warren Weaver was familiar with Morris' 10 years old classification of the semiosis when he wrote his paper on Shannon's Mathematical theory of communication [2]. Already in the third paragraph of his paper he wrote "In communication there seem to be problems at three levels: 1) technical, 2) semantic, and 3) influential. The technical problems are concerned with the accuracy of transference of information from sender to receiver. They are inherent in all forms of communication, whether by sets of discrete symbols (written speech), or by a varying two-dimensional pattern (television). The semantic problems are concerned with the interpretation of meaning by the receiver, as compared with the intended meaning of the sender. This is a very deep and involved situation, even when one deals only with the relatively simple problems of communicating through speech. […] The problems of influence or effectiveness are concerned with the success with which the meaning conveyed to the receiver leads to the desired conduct on his part. It may seem at the first glance undesirable narrow to imply that the purpose of all communication is to influence the conduct of the receiver. But with any reasonably broad definition of conduct, it is clear that communication either affects conduct or is without any discernible and provable effect at all." ([2], p. 11)

In the revised version of the paper that was published in [8], Weaver explained the trichotomy of the communication problem in extenso and he divided it into three levels:

- **Level *A*** contains the purely technical problem involving the exactness with which the symbols can be transmitted,
- **Level *B*** contains the semantic problem that inquires as to the precision with which the transmitted signal transports the desired meaning,
- **Level *C*** contains the pragmatic problem pertaining to the effect of the symbol on the destination side: What influence does it exert?

He underscored very clearly the fact that Shannon's theory did not even touch upon any of the problems contained in levels *B* and *C*, that the concept of information therefore must not be identified with the "meaning" of the symbols: "In fact, two messages, one of which is heavily loaded with meaning and the other of which is pure nonsense, can be exactly equivalent, from the present viewpoint, as regards information." [8] However, there is plenty of room for fuzziness in the levels *B* and *C*. The interpretation of meaning of signs, e. g. linguistic signs, names, words, is obviously a fuzzy process, and influence or effectiveness the exerted to the receiver's side is a fuzzy process, too. We will have this fuzziness at the back of our mind following Weaver's continuing considerations.

[5] The term *semiosis* was introduced by Ch. S. Peirce to describe "a process that interprets signs as referring to their objects" [22].

ISBN: 978-989-95079-6-8

3.3 Fuzziness in the diagram of a communication system

It is quite plain: Weaver went over and above Shannon´s theory: "The theory goes further. Though ostensibly applicable only to problems at the technical level, it is helpful and suggestive at the levels of semantics and effectiveness as well." Weaver stated, that Shannon's formal diagram of a communication system (Fig. 5) "can, in all likelihood, be extended to include the central issues of meaning and effectiveness. […] One can imagine, as an addition to the diagram, another box labeled "Semantic Receiver" interposed between the engineering receiver (which changes signals to messages) and the destination. This semantic receiver subjects the message to a second decoding the demand on this one being that it must match the statistical semantic characteristics of the message to the statistical semantic capacities of the totality of receivers, or of that subset of receivers which constitutes the audience one wishes to affect.

Similarly one can imagine another box in the diagram which inserted between the information source and the transmitter, would be labeled "Semantic Noise" (not to be confused with "engineering noise". This would represent distortions of meaning introduced by the information source, such as a speaker, which are not intentional but nevertheless affect the destination, or listener. And the problem of semantic decoding must take this semantic noise into account. It is also possible to think of a treatment or adjustment of the original message that would make the sum of message meaning plus semantic noise equal to the desired total message meaning at the destination." ([2], p. 13)

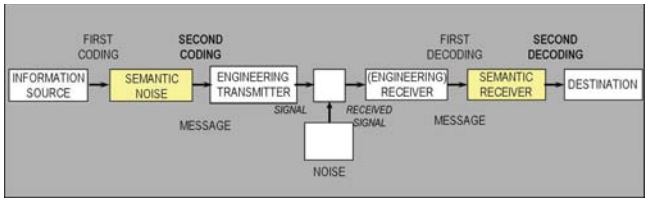

Figure 9: Shannon's diagram with Weaver's addition of the two boxes "Semantic Receiver" and "Semantic Noise".

Fig. 9 shows Weaver's two additional "fuzzy" boxes in Shannon's diagram of a communication system. We will interpret the "first coding" between the information source and the "Semantic Noise" as a *fuzzification* and the "second decoding" between the "Semantic Receiver" and the destination as a *defuzzification*.

4 Outlook

In future work we will proceed with this generalization of Weaver's philosophical considerations on Shannon's Mathematical theory of communication to a "Fuzzy information theory".

***Abstract*—*In this paper we consider physical systems and the concept of their states in the context of the theory of fuzzy sets and systems. In section 1 we give a brief sketch on the fundamental difference between the theories of classical physics and quantum mechanics. In section 2 and 3 we introduce very shortly systems and their states in classical and quantum mechanics, respectively. Section 4 presents the concept of fuzzy systems. We propose to fuzzify the classical systems in section 5 and quantum systems in section 6. In section 7 we start to consider a fuzzy interpretation of the uncertainty principle.*

Keywords— Fuzzy sets and systems, quantum mechanics, system theory, philosophy.

1 Introduction

Due to the scientific revolution brought about by the discovery of quantum mechanics in the first third of the 20th century, a basic change took place in the relationship between the exact scientific theory of physics and the phenomena observed in basic experiments. Systems of quantum mechanics – "quantum systems" – do not behave like systems of classical theories in physics – their elements are not particles and they are not waves, they are different. This change led to a new mathematical conceptual fundament in physics.

Niels Bohr, Max Born, Louis de Broglie, Paul A. M. Dirac, Werner Heisenberg, Pacual Jordan, Wolfgang Pauli, Erwin Schrödinger, John von Neumann and others introduced new objects and theoretical terms to the new mathematical theory of atomic physics and rather quantum physics, then so-called "quantum mechanics" that differ significantly from those in classical physics. Their properties are completely new and not comparable with those of observables in classical theories such as Newton's mechanics or Maxwell's electrodynamics.

The new theoretical term is the quantum mechanical state function ψ that is an element of the abstract Hilbert space H. The theory of quantum mechanics is completely abstract: it is a theory of mathematical state functions that have no exact counterpart in reality. This means that per se ψ is not observable but, nonetheless, we can experiment with a quantum mechanical object having a state function in order to measure its position value, and we can also experiment with this object in order to measure its momentum value. However, we cannot conduct both experiments simultaneously and thus are not able to get both values for the same point in time. But we can predict these values as outcomes of experiments at this point in time. Since predictions are targeted on future events, we cannot valuate them with the logical values "true" or "false," but must use probabilities. The probability distribution to measure a certain position, e.g. value $\boldsymbol{r}$ (t) = (x (t), y (t), z (t)) at point t in time is given by $|\psi(\boldsymbol{r}, t)|^2$ and the probability distribution to measure a certain momentum value $\boldsymbol{p}$ at time point t is given by $|\psi(\boldsymbol{p}, t)|^2$, where $\psi(\boldsymbol{x}, t)$ or $\psi(\boldsymbol{p}, t)$, are representtations of the abstract Hilbert space element ψ in the position or momentum representation respectively.

2 Classical Systems

In classical physics, the state of a "system" or an "object" is represented by a set of observables. For example, in Newtonian mechanics the state of an object (a particle with mass m) is given by the pair of 3-component vector values of the object's position vector $\boldsymbol{r}$ and its momentum vector $\boldsymbol{p}$. These two vectors imply all other properties of the object that are relevant in the Newtonian theory of mechanics. We can formulate that the state of a physical object is the collection of all the object's properties P_i. In order to represent these properties P_i in terms of the physical theory, we must determine the formally possible functions F_i in this mechanical theory, and in order to know the object's properties at a given point in time t, we must measure the values of these functions F_i. Thus, the representation of the "state of a classical object" is related to the measurement process or the perception process of the observer.

Due to the possible errors of measurement and the systematic errors occurring in every experiment, we can attribute their probability of this being the real value to all measured values of observables. Thus, the state of an object in Newtonian mechanics is given by the pair of the probability distributions of position $\boldsymbol{r}$ and momentum $\boldsymbol{p}$.

3 Quantum Systems

3.1 The concept of state in quantum mechanics

The state of a quantum mechanical system is much more difficult to determine than that of classical systems as we cannot measure sharp values for both variables simultaneously. This is the meaning of Heisenberg's uncertainty principle.

However, we can experiment with quantum mechanical objects in order to measure a position value, and we can also experiment with these systems in order to measure their momentum value. But: we cannot conduct both experiments

ISBN: 978-989-95079-6-8

simultaneously and thus are not able to get both values for the same point in time respectively. We can predict these values as outcomes of experiments at this point in time. Since predictions are targeted on future events, we cannot valuate them with logical values "true" or "false", but with probabilities.
Accordingly, in quantum mechanics, we have to use a modified concept of the state: the state of a quantum mechanical system consists of the probability distributions of all the object's properties that are formally possible in this physical theory.

- Max Born ([1, 2]) proposed an interpretation of this non-classical peculiarity of quantum mechanics – the quantum mechanical wave function is a "probability-amplitude": The absolute square of its value equals the probability of it having a certain position or a certain momentum if we measure the position or momentum respectively. The higher the probability of the position value, the lesser that of the momentum value and vice versa.
- In 1932, John von Neumann published the *Mathematical Foundations of Quantum Mechanics* [3], in which he defined the quantum mechanical wave function as a one-dimensional subspace of an abstract Hilbert space, which is defined as the state function of a quantum mechanical system (or object). Its absolute square equals the probability density function of it having a certain position or a certain momentum in the position or momentum representation of the wave function respectively.

Unfortunately there is no joint probability distribution for events in which both variables have a certain value simultaneously, as there is no classical probability space that comprises these events. Such pairs would describe classical states. Thus, the quantum mechanical system's state function embodies the probabilities of all properties of the object, but it delivers no joint probability distribution for all these properties. Therefore we claim here: "We need a radically different kind of mathematics, the mathematics of […] quantities which are not describable in terms of [classical] probability distributions.[1]

3.2 Quantum logic and Quantum probability theory

After the establishment of quantum mechanics there appeared some approaches to achieve a new logic and later also a new probability theory to handle quantum mechanical propositions and quantum mechanical events.

- 1936, Garett Birkhoff and John von Neumann proposed the introduction of a "quantum logic", as the lattice of quantum mechanical propositions is not distributive, and therefore not Boolean [5].
- In 1963, George Whitelaw Mackey attempted to provide a set of axioms for the propositional system of predictions of experiment's outcomes. He was able to show that this system is an orthocomplemented partially ordered set. [6]

In these logico-algebraic approaches, the "probabilities" of evaluating the predictions of the properties of a quantum mechanical system do not satisfy Kolmogorov's well-known axioms. The double-slit experiment shows that they are not additive and together with their non-distributivity it is indicated that the probabilistic structure of quantum mechanics is more complicated than that of the classical probability space as it was defined by Kolmogorov.

- Already in the 1960s, the philosopher and statistician Patrick Suppes discussed the "probabilistic argument for a non-classical logic of quantum mechanics" [7, 8]. He introduced the concept of a "quantum mechanical σ-field" as an "orthomodular partial ordered set" covering the classical σ-fields as substructures.
- In the 1980s, a "quantum probability theory" was proposed and developed by Stanley Gudder and Imre Pitowski [9, 10].[2]

The quantum mechanical lattice of predictions is Suppes' "quantum mechanical σ-field", which can be restricted to a Boolean lattice corresponding to a given observable. The quantum probabilities became classical probabilities again, only applying to predictions of compatible observables.
The theory of Fuzzy sets and systems pertains to "quantities which are not describable in terms of probability distributions" and theory of Quantum mechanics pertains to quantities which are not describable in terms of classical probability distributions.
Quantum logic and Quantum probability theory represent important approaches to manage quantum mechanical uncertainties within limits of usual mathematics and the developments in the last decades show numerous and also very difficult results. Thus, quantum logic and quantum probability theory are new theories in classical mathematics that became more and more complex. On the other hand there was the new theory of fuzzy sets and systems available at the same time and the question arose in the 1980s and 1990s of whether fuzzy sets could be useful in the interpretation of quantum mechanics. However, at that time this approach was not successful. The disappointing results may have stemmed from the fact that fuzzy set theory was not as well accepted as a mathematical tool the as it is today and from a lack of interest in using the new theory on the part of theoretical physicists. Moreover, until recently there was also no interest in fuzzy set theory in the philosophy of science. But now the theory of fuzzy sets is broadly accepted, particularly in applied sciences and technology and in the history of science the theory of fuzzy sets attracts

[1] This is analogue to Zadeh's requirement: ". . . we need a radically different kind of mathematics, the mathematics of fuzzy or cloudy quantities which are not describable in terms of probability distributions" in his 1962 article [4], p. 857.

[2] These developments regarding a theory of probabilistic structures of quantum mechanics became very complex, as the reader can see in the authors Ph. D thesis [11].

ISBN: 978-989-95079-6-8

attention [12, 13, 14]. In physics, the results of new experiments (Alain Aspect's test of Bell's inequality in 1982 [15, 16] and Anton Zeilinger's experiments on quantum teleportation since 1997 [17] have sparked a new debate on the interpretation of quantum mechanics and there is growing interest in the theory of fuzzy sets in the field of scientific history [29]. In the next sections we will evolve some ideas towards a "fuzzy view" on quantum systems.

4 Fuzzy Systems

In his talk on "A New View on System Theory," for the *Symposium on System Theory* that took place in Brooklyn in April 1965, Lotfi Zadeh defined fuzzy systems as follows:

Definition: A system S is a fuzzy system if input $u(t)$, output $y(t)$, or state $x(t)$ of S or any combination of them ranges over fuzzy sets. ([18], p. 33)[3]

He explained that "these concepts relate to situations in which the source of imprecision is not a random variable or a stochastic process but rather a class or classes which do not possess sharply defined boundaries." ([18], p. 29

Eight years later, in "Outline of a New Approach to the Analysis of Complex Systems and Decision Processes," he introduced "linguistic variables" that are variables whose values may be sentences in a specific natural or artificial language. [19] To illustrate, the values of the linguistic variable "age" might be expressible as *young*, *very young*, *not very young*, *somewhat old*, *more or less young*.

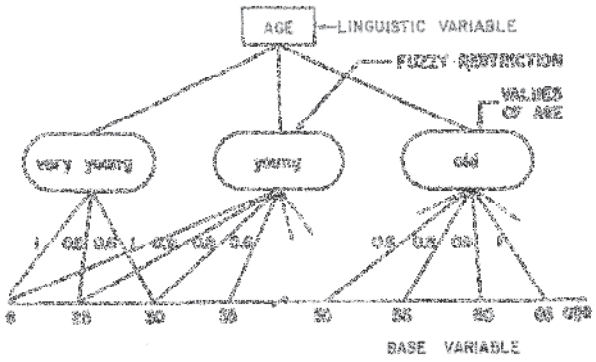

Figure 1: Example of the linguistic variable "Age" [20].

These values are formed with the label *old*, the negation *not*, and the hedges *very*, *somewhat*, and *more or less*. In this sense the variable "age" is a linguistic variable (see Fig. 1).

Linguistic variables became a proper tool for reasoning without exact values. Since in many cases, it is either impossible or too time-consuming (and therefore too expensive) to measure or compute exact values, the concept of linguistic variables has been successful in many fuzzy application systems, e.g., in control and (medical) decision making. In the next section we seek to apply the concept of linguistic variables in quantum mechanics where exact values of observables do not exist. The situation is that outcomes of a physicist's experiments have to be values of observables, i.e., an observing physicist assigns sharp values (and their classical probability distributions of the classical variables (e.g. its position $\boldsymbol{r}$ or its momentum $\boldsymbol{p}$) due to the possible errors of measurement and the systematic errors occurring in every experiment)[4] to a quantum theoretical object. This value is not sufficient to determine the quantum object's state. This is only one representation – among many others – and none of these representations of the state of the quantum system is complete!

5 Fuzzy Classical Systems

In this section a new approach to the interpretation of uncertainty in quantum mechanics using the methodology of fuzzy sets and systems is outlined.

We will interpret the "fuzzy state variable" of a physical system as a vector of linguistic variables instead of numerical variables. This interpretation yields to the interpretation of the "fuzzy state" of a classical physical object as a pair of the two linguistic variables – position and momentum

In a manner similar to Zadeh's extension of systems to fuzzy systems, the definition of a linguistic variable operating on a fuzzy set, and assignment of membership degrees and elements of the term set of the linguistic variable, the "fuzzy state" of a physical system is interpreted as a vector of linguistic variables instead of numerical variables.

A concrete system a has a certain number of properties P^i, $i \in \{1, \ldots, n\}$. In classical physics we attach classical numerical variables (observables) $V_P{}^i$ to these properties that can be measured. To use the methods of fuzzy set theory, now we attach can find also a linguistic variable $LV_P{}^i$ to representing the property P^i. These linguistic variables operate on fuzzy sets and assign membership degrees and elements of a term set, for example:

$$T(LV_P{}^i) = \{\text{very small, small, big, very big, … etc .}\}$$

We can imagine the n-tuple $\boldsymbol{LVP_n} = \langle LV_P{}^1, LV_P{}^2, \ldots, LV_P{}^n \rangle$ to be a "linguistic vector" in an n-dimensional Cartesian space. The value $\boldsymbol{LVP_n}$ (a, t) for a system a at time point t is called the "linguistic state" or "fuzzy state" of this system at this time. During this time, the linguistic state of a system moves in the "linguistic state space" or "fuzzy state space" $\Sigma_{\boldsymbol{n}}{}^L(\mathrm{a}) = \{\boldsymbol{LVP_n}(\mathrm{a}, t) \mid t \in T\}$ of the system.

In the case of a classical particle in Newtonian mechanics, the "fuzzy state" is the pair (2-tupel) $(LV_{\boldsymbol{r}}, LV_{\boldsymbol{p}})$ of the two linguistic variables position $LV_{\boldsymbol{r}}$ and momentum $LV_{\boldsymbol{p}}$ that operate on fuzzy sets and assign membership degrees and elements of a term set, for example:

$$T(LV_{\boldsymbol{r}}) = \{\text{very small, small, null, big, very big, … etc.}\}$$

and

$$T(LV_{\boldsymbol{p}}) = \{\text{very small, small, null, big, very big, … etc.}\}$$

Usually the shape of the fuzzy set's membership functions is subjectively chosen or dependant on the problem. In a very special case, the membership function may have the shape of the classical Gaussian probability distribution and thus the

[3] We assume that the reader is familiar with the basic principles of the theory of fuzzy sets.

[4] In the next sections we sometimes will omit this completion about the classical errors of measurement and the systematic errors.

ISBN: 978-989-95079-6-8

fuzzy state variable yields the probabilities of measuring the observables position ***r*** and momentum ***p*** due to the calculation of errors. However, in general, membership functions of fuzzy sets do not represent probability distributions of measurement errors or randomness, but more general uncertainties that are deeply rooted in the absence of the theoretical concept's strict boundaries.

We know already that classical concepts such as position and momentum, having strict boundaries in Newtonian mechanics, do not have such boundaries in the theory of quantum mechanics. Therefore this pair of concepts does not match the quantum mechanical state variable – to represent the quantum mechanical "state", position and momentum are in use with some uncertainty. This concept of uncertainty in quantum mechanics is often represented by classical probability, but, in the strict sense, the quantum mechanical uncertainty is different from the concept of classical probability.

6 Fuzzy Quantum Systems

Let's try to extend our approach of "fuzzy states" of systems to quantum systems to include the assumption that the classical theoretical concepts are not the right concepts, but that we have no better concepts to interpret the outcomes of classical experiments. Thus, we can use fuzzy sets and linguistic variables to convert classical observables to systems of quantum mechanics.

In the case of a quantum system, the "fuzzy quantum state" is an infinite dimensional vector $\boldsymbol{LVP_\infty}\ (a,t)$ of linguistic variables in the abstract Hilbert space, with an infinite tuple $\boldsymbol{LVP_\infty} = \langle LV_P^1, LV_P^2, \ldots, LV_P^n, \ldots \rangle$ of linguistic variables LV_i, but not all linguistic variables LV_i and LV_j are compatible, i.e. they are in an uncertainty relation with each other, e.g., $LV_1 = LV_{\boldsymbol{r}}$ (position observable) and $LV_j = LV_{\boldsymbol{p}}$ (momentum observable).

In general, at one point in time we can measure one of these LV_i and this measurement reduces the membership function to a numerical value of this observable. This is an effect that is known in usual quantum mechanics as the "collapse" of the quantum mechanical state function.

Let's use the fuzzy state concept for quantum systems! After the measurement of an observable, say V_P^i, there is no "collapse" of the fuzzy quantum state. We still have it's complete representation as the infinite tuple of linguistic variables $\boldsymbol{LVP_\infty} = \langle LV_P^1, LV_P^2, \ldots, LV_P^n, \ldots \rangle$. However, after the measurement of observable V_P^i, this component of the fuzzy quantum state is not any longer a linguistic but a numeric term: the measurement, just a number (associated with a unit).

7 Fuzzy Uncertainty Principle

First we consider the classical uncertainty principle that was found by Heisenberg in 1925. This uncertainty principle states that the values of certain pairs of conjugate variables[5] (e.g. position ***r*** and momentum ***p***) cannot both be known with arbitrary precision. That is, the more precisely one variable is known, the less precisely the other is known. We already noticed that this is not the uncertainty of the measurement of particular observables of a system.

Heisenberg's uncertainty principle was very often formulated in usual mathematics (classical probability theory and statistics) as follows: every quantum state has the property that the *root-mean-square deviation* of the position ***r*** from its mean (the standard deviation of the ***r***-distribution) times the root-mean-square deviation of the momentum ***p*** from its mean (the standard deviation of ***p***) can never be smaller than a small fixed fraction of Planck's constant:

$$\Delta r \cdot \Delta p \geq \tfrac{\hbar}{2}, \tag{1}$$

where $\Delta r = \sqrt{\left\langle (r - \langle r \rangle)^2 \right\rangle}$ and $\Delta p = \sqrt{\left\langle (p - \langle p \rangle)^2 \right\rangle}$.

Any measurement of the position with accuracy $\Delta\boldsymbol{r}$ collapses the quantum state making the standard deviation of the momentum $\Delta\boldsymbol{p}$ larger than $\frac{\hbar}{2}$.

This view is using classical probability theory what is adequate for each one of the two variables ***r*** and ***p*** but what is not appropriate to the combination of the two "pictures". There is no joint probability distribution for the two variables ***r*** and ***p*** and therefore the product of their *root-mean-square deviations* has no meaning in classical probability theory. That is, what is meant by the logico-algebraic result that there is no Boolean lattice of quantum mechanics.

Let's consider the uncertainty principle in our approach of fuzzy quantum states! In our view position and momentum, ***r*** and ***p***, are associated with linguistic variables, $LV_{\boldsymbol{r}}$ and $LV_{\boldsymbol{p}}$. Hence we can consider $\Delta r = \sqrt{\left\langle (r - \langle r \rangle)^2 \right\rangle}$ and $\Delta p = \sqrt{\left\langle (p - \langle p \rangle)^2 \right\rangle}$ as being linguistic variables as well.

Because Heisenberg's uncertainty relation (1) is a proposition of the possible values of $\Delta\boldsymbol{r}\cdot\Delta\boldsymbol{p}$, we can also consider this product of the two linguistic variables $\Delta\boldsymbol{r}$ and $\Delta\boldsymbol{p}$ as being a linguistic variable ***S*** ("action"[6]).

Heisenberg's inequality claims that $\boldsymbol{S} = \Delta\boldsymbol{r}\cdot\Delta\boldsymbol{p}$ can never be smaller than $\frac{\hbar}{2}$, i.e. the minimal value of ***S*** equals $\frac{\hbar}{2}$, but this result was never derived by Heisenberg himself. Moreover, in his famous 1930 lecture in Chicago he refined his principle to the following inequality [21]:

$$\Delta x \Delta p \gtrsim h. \tag{2}$$

The formulation (1) of the uncertainty relations was proved by E. H. Kennard in 1927 but in this prove it was postulated that $\Delta\boldsymbol{r}$ and $\Delta\boldsymbol{p}$ are the standard deviations of position and momentum, therefore this formulation uses classical probability theory [21]

What does this mean? – The value of the linguistic variable ***S*** at a given point of time is the composition of the values of the linguistic variables $\Delta\boldsymbol{r}$ and $\Delta\boldsymbol{p}$ but to get both of the two

[5] In physics, conjugate variables are pair of variables mathematically defined in such a way that they become Fourier transform duals of one-another.

[6] "Action" is the name of this particular quantity (product of position and momentum or of energy and time) in physics.

ISBN: 978-989-95079-6-8

values is not possible in the theory of quantum mechanics. (Remark: To compute the value of $\Delta \boldsymbol{r}$ or $\Delta \boldsymbol{p}$ we have to measure the value of $\boldsymbol{r}$ or $\boldsymbol{p}$ respectively.)
Thus, it is only possible to know one of the linguistic values of $\Delta \boldsymbol{r}$ or $\Delta \boldsymbol{p}$ and therefore it is not possible to compute the value of the linguistic variable $\boldsymbol{S} = \Delta \boldsymbol{r} \cdot \Delta \boldsymbol{p}$.

8 Conclusions

During the last decade the literature on combining the theories of quantum mechanics and fuzzy sets was growing, e.g. [23- 29].[7] Of course there might be many more papers on the meeting of the two theories but unfortunately – as one of the reviewers to this paper, "it seems to be sometimes the application of ideas from quantum theory to fuzzy sets than the other way around". This paper was written to plea for applications of ideas from Fuzzy set theory to quantum mechanics. Of course, we gave only some preliminary ideas to establish a fuzzy approach to physics and particularly to quantum mechanics.
We presented a rough idea of what the methodologies of fuzzy sets and systems, along with linguistic variables, could contribute to the project to represent phenomena in physics that can not be represented in classical mechanics. Quantum mechanics is a very successful theory to represent these phenomena but there are difficulties with the using of the concept of probability. It seems that the concepts of fuzzy sets and linguistic variables can be more appropriate for the representation of quantum phenomena in the framework of quantum mechanics than the classical concept of probability. Our definition of the fuzzy state of a quantum mechanical system avoids the difficulties that arise in classical probability theory in attempts to define this state. On the other hand, with this fuzzy approach new difficulties arise, e.g. with the experimental side of physics and also with its interpretative side. Of course, scientists should take such problems seriously. At the other hand, these are the usual and well-known problems of all fuzzy-approaches in the field of science and technology of the last 40 year. From the point of view of a historian and philosopher of science this is also a big challenge!

Possibility and Necessity Evaluations based on Ordinal Comparability

Masaaki Ida

National Institution for Academic Degrees and University Evaluation
1-29-1, Gakuen-nishimachi, Kodaira, Tokyo 187-8587 Japan
Email: ida@niad.ac.jp

Abstract— *Subjective uncertainty is one of the most essential subjects for evaluation that was the reason Fuzzy theory was proposed. Related research areas are widely spread such as decision making, data analysis, information retrieval, psychology, and human computer interaction and so on. As a basis for various researches mathematical interpretation of evaluation methods occupies an important position. In Possibility theory, possibility and necessity evaluations have been utilized as ways for evaluating a vague achievement in an ambiguous situation. However, mathematical interpretations for these evaluations have been insufficient. In this article, possibility and necessity evaluations are examined based on the ordinal comparability in social choice theory. Equivalent conditions to the evaluations are deduced so that axiomatic interpretations for the evaluations become possible, and order relations related to the two evaluations are deduced.*

Keywords— evaluation, measure, necessity, ordinal comparability, ordinal utility, possibility.

1 Introduction

In Possibility theory [1, 2, 3, 4, 5], subjective value of attainment or satisfaction of an evaluation item in state x is represented by the membership function $\mu(x)(0 \leqq \mu(x) \leqq 1)$. And occurrence degree of subjective possibility is represented by the membership function $\pi(x)(0 \leqq \pi(x) \leqq 1)$. Tuple of these functions, $(\mu(x), \pi(x))$, can be regarded as a representation of state x with two kinds of uncertainties (vagueness and ambiguity) and be applied for evaluation and decision making.

An evaluation value for (μ, π) is defined as follows:

Definition 1

$$\Pi(\mu, \pi) = \sup_x \min(\mu(x), \pi(x)) \tag{1}$$

This can be regarded as an extension of possibility measure for fuzzy sets. This is also interpreted as a fuzzy integral for fuzzy set on possibility measure.

In Possibility theory, necessity measure is defined as dual for possibility evaluation:

Definition 2

$$N(\mu, \pi) = \inf_x \max(\mu(x), 1 - \pi(x)) \tag{2}$$

These two evaluations (possibility and necessity) also can be interpreted as optimistic (positive) and pessimistic (negative) evaluations respectively.

In this paper, we investigate generalized possibility and necessity evaluations. As seen in these definitions, generally in Fuzzy theory, *max* operation and *min* operation are used frequently. For example, they are used in the synthetic rule of fuzzy reasoning.

Moreover, some restrictions, e.g., *normality*, are assumed on membership functions in many cases. A continuity and convexity are sometimes assumed on membership functions. [3].

Definition 3 *A membership function $\pi(x)$ is normal means that there exists x such that $\pi(x) = 1$.*

In order to perform the mathematical interpretation on possibility and necessity evaluations and to examine the validity of the evaluations, it is necessary to consider on the property of functions $\mu(x)$ and $\pi(x)$ determined subjectively. For example, whether it is a cardinal utility function or ordinal utility function.

In Possibility theory, considerations for improving qualitative possibilistic criteria are discussed. Axiomatic approach has been made in order to examine decision theoretic foundation [6]. Generalized concordance rules that request comparisons within possible values for components and comparisons between sets of attributes is proposed [7]. The injection of lexicographic ingredients in the possibilistic criteria has been studied [8].

It is necessary to consider the conditions at the time of unifying the functions and performing synthetic evaluation, e.g., evaluation level comparability on evaluation items. In social choice theory or voting theory, the comparability of utility functions was introduced with ordinal number based on extended ordering [9, 10]. and examination has been made about how synthetic evaluation should be performed [11].

This paper newly defines possibility and necessity evaluations based on ordinal comparability and deduces equivalent conditions to them. Therefore, the applicable conditions of possibility and necessity evaluations are clarified. Moreover, relations between these two evaluations are discussed.

Hereafter, Section 2 examines necessary and sufficient condition of the evaluations based on extended ordering. In Section 3, interpretations of the conditions for evaluations, possibility, and necessity evaluation, are discussed. Section 4 considers order relations between possibility evaluation and necessity evaluation.

2 Extended ordering and preference relation

We denote that X is a set of states or a set of alternatives. We define *preference relation* as a binary relation.

Definition 4 *Preference relation R on X ($x, y \in X, xRy$: x is preferred to y) is a binary relation which is reflective*

ISBN: 978-989-95079-6-8

($\forall x \in X : xRx$), transitive ($\forall x, y, z \in X : (xRy \wedge yRz) \rightarrow xRz$). and total ($\forall x, y \in X : (x \neq y) \rightarrow (xRy \vee yRx)$). Strong preference relation P and indifference relation I are defined by: $xPy \equiv (xRy \wedge \neg(yRx))$, and $xIy \equiv (xRy \wedge yRx)$.

We denote H as a set of evaluation items. In social choice theory [9], X is called *a set of social states*, and H is called *a set of individuals*. In this paper, we make fundamental investigations on preference relation, so that the number of elements of the set H is restricted to two.

We consider $(x, i) \in X \times H$. A binary relation $\tilde{R}$ on $X \times H$ is assumed to be a preference relation. This relation is called *extended ordering* [9]. In similar meaning, it is also called extended sympathy [10].

Definition 5 *Preference relation $(x, i)\tilde{R}(y, j)$ means that an evaluation item i on a state x is preferred to j on a state y. Strong preference relation $\tilde{P}$ and indifference relation $\tilde{I}$ on $X \times H$ are defined by: $(x, i), (y, j) \in X \times H$ and $\tilde{R}$, $(x, i)\tilde{P}(y, j) \equiv ((x, i)\tilde{R}(y, j) \wedge \neg((y, j)\tilde{R}(x, i)))$, $(x, i)\tilde{I}(y, j) \equiv ((x, i)\tilde{R}(y, j) \wedge (y, j)\tilde{R}(x, i))$.*

Here, we consider generalized function $f : \tilde{R} \rightarrow R$, which corresponds the preference relation $\tilde{R}$ ($\tilde{P}$ and $\tilde{I}$) on $X \times H$ to the preference relation R (P and I) on X. The function f is called *Generalized Social Welfare Function* (GSWF) in social choice theory [9].

In the following section, higher evaluation on state x is denoted as $2(x) \in \{1, 2\}$ and lower evaluation is denoted as $1(x) \in \{1, 2\}$. This means that $(x, 2(x))\tilde{R}(x, 1(x))$.

Definition 6 *GSWF f^P is defined as follows. For all $x, y \in X$,*
(1) if for all $i \in \{1, 2\}$ $(x, i(x))\tilde{I}(y, i(y))$, then xIy,
(2) if $(x, 1(x))\tilde{I}(y, 1(y))$ and $(x, 2(x))\tilde{P}(y, 2(y))$, then xPy,
(3) if $(x, 1(x))\tilde{P}(y, 1(y))$, then xPy.

GSWF f^P corresponds to *leximin rule*, because we compare preference from lower level to higher level [9, 11].

Next, we consider following five conditions on the two preference relations $\tilde{R}$ and R. We denote $(x, i)\tilde{R}(y, i)\tilde{R}(z, i)$ for short as $(x, i)\tilde{R}(y, i)$ and $(y, i)\tilde{R}(z, i)$. We denote for $\tilde{P}$ and $\tilde{I}$ in similar way.

(C1) *Preference relation $\tilde{R}$ can take any logically possible relation.*

(C2) *If the restrictions of $\tilde{R}$ and $\tilde{R}'$ on any pair in X are the same, then the restrictions of R and R' on that pair are also same.*

(C3) *For any x, y in X, if $(x, 1)\tilde{R}(y, 1) \wedge (x, 2)\tilde{R}(y, 2)$, then xRy. If one of the two relations is a strong preference relation $\tilde{P}$, then xPy.*

(C4) *For any x, y in X, if $(y, 2)\ \tilde{P}\ (x, 2)\ \tilde{R}\ (x, 1)\ \tilde{P}\ (y, 1)$ or if $(y, 1)\ \tilde{P}\ (x, 1)\ \tilde{R}\ (x, 2)\ \tilde{P}\ (y, 2)$, then xPy.*

(C5) *For any x, y in X, if $(x, 1)\tilde{I}(y, 2) \wedge (x, 2)\tilde{I}(y, 1)$ and $\neg((x, 1)\tilde{I}(x, 2))$, then xIy.*

We note that if $(x, 1)\tilde{R}(y, 1) \wedge (x, 2)\tilde{R}(y, 2)$ and $(y, 1)\tilde{R}(x, 1) \wedge (y, 2)\tilde{R}(x, 2)$, then xIy by (C3). Furthermore we note that the conditions (C3), (C4), and (C5) are mutually independent.

For GSWF f^P and the five conditions, following theorem is stated [12].

Theorem 1 *Assume that $|X| > 2$, only GSWF that satisfies (C1), (C2), (C3), (C4), and (C5) is f^P.*

Next, from the view of symmetry, we consider a different condition only for (C4) in the above five conditions. We define the following converse condition (C4').

(C4') *For any x, y in X, if $(x, 2)\ \tilde{P}\ (y, 2)\ \tilde{R}\ (y, 1)\ \tilde{P}\ (x, 1)$ or if $(x, 1)\ \tilde{P}\ (y, 1)\ \tilde{R}\ (y, 2)\ \tilde{P}\ (x, 2)$, then xPy.*

In this case we consider the followings.

Definition 7 *GSWF f^N is defined as follows. For all $x, y \in X$,*
(1) for any $i \in \{1, 2\}$, if $(x, i(x))\tilde{I}(y, i(y))$, then xIy,
(2) if $(x, 2(x))\tilde{I}(y, 2(y))$ and $(x, 1(x))\tilde{P}(y, 1(y))$, then xPy,
(3) if $(x, 2(x))\tilde{P}(y, 2(y))$, then xPy.

For GSWF f^N and the five conditions, following theorem is stated.

Theorem 2 *Assume $|X| > 2$, only GSWF that satisfies conditions (C1), (C2), (C3), (C4'), (C5) is f^N.*

By the above two theorems, conditions equivalent to two GSWFs, f^P and f^N, were obtained. Based on these results we can discuss what kind of conditions are assumed when each GSWF is applied for evaluation.

3 Interpretation of possibility and necessity evaluation based on extended ordering

3.1 Ordinal utility function

In this section, as an application of the knowledge obtained in the previous section to Possibility theory, we consider the case that $H = \{\mu, \pi\}$. In the case we define GSWF f^P as a possibility evaluation.

We can say from (1) and the definition of f^P that if xPy for f^P, then $\min(\mu(x), \pi(x)) \geqq \min(\mu(y), \pi(y))$.

In the following, we discuss the interpretation of possibility evaluation based on the theorem obtained in the previous section.

We consider that $(x, i) \in X \times H$ corresponds to (x, μ) and (x, π). The relations between the preference relation $\tilde{R}$ and membership functions are defined as follows;
$(x, \mu)\tilde{R}(y, \mu) \equiv \mu(x) \geqq \mu(y)$,
$(x, \pi)\tilde{R}(y, \pi) \equiv \pi(x) \geqq \pi(y)$,
$(x, \mu)\tilde{R}(x, \pi) \equiv \mu(x) \geqq \pi(x)$,
$(x, \pi)\tilde{R}(x, \mu) \equiv \pi(x) \geqq \mu(x)$.
We denote strong preference relation and indifference relation as "$>$" and "$=$" respectively.

ISBN: 978-989-95079-6-8

We should note that membership functions μ and π can be regarded as **ordinal level comparable utility functions** based on extended ordering.

3.2 Possibility evaluation

In this subsection we discuss the conditions in Theorem 1.

Conditions (C1) and (C2) are naturally acceptable conditions.

Condition (C3) (if $\mu(x) \geqq \mu(y)$ and $\pi(x) \geqq \pi(y)$, then xRy) is so-called Pareto condition, so that this is naturally acceptable for the functions μ and π.

However, (C4) (if $\mu(y) > \mu(x) \geqq \pi(x) > \pi(y)$ or $\pi(y) > \pi(x) \geqq \mu(x) > \mu(y)$, then xRy) means that we must compare two evaluation elements of μ and π on one state.

And condition (C5) (if $\mu(x) = \pi(y)$ and $\pi(x) = \mu(y)$, then xIy) means that in indifferent two states, two evaluation elements of μ and π can be exchanged as same.

Therefore conditions (C4) and (C5) for the functions μ and π are restrictions on two evaluations, then these restrictions are strongly imposed on setting these two membership functions.

If conditions (C1), (C2), (C3), (C4), (C5) are acceptable for μ and π, then by Theorem 1, we can utilize the function f^P as a preference functions on $x, y \in X$.

On the other hand, in the case that we use the function f^P as a preference relation, the conditions (C1), (C2), (C3), (C4), (C5) should be satisfied.

Consequently, for $x, y \in X$ we clarify the conditions for evaluation of (1) based on comparing $\min(\mu(x), \pi(x))$ and $\min(\mu(y), \pi(y))$.

3.3 Necessity evaluation

Similarly we can discuss necessity evaluation. In case of necessity, for π in (2) we can see $1 - \pi(x)$. Therefore, as a converse order relation we defined an ordinal utility function $\pi^*(x)$ as follows.

Definition 8 *$\pi^*(x)$ is defined by:*

$$\pi^*(x) < \pi^*(y) \quad \equiv \quad \pi(x) > \pi(y), \tag{3}$$

$$\pi^*(x) = \pi^*(y) \quad \equiv \quad \pi(x) = \pi(y). \tag{4}$$

Similarly as possibility evaluation we can discuss the interpretation of necessity evaluation based on Theorem 2 obtained in the previous section.

We consider that $(x, i) \in X \times H$ corresponds to (x, μ) and (x, π^*) in the same way as possibility. The relation between the preference relation $\tilde{R}$ and membership functions are defined as follows;

$(x, \mu)\tilde{R}(y, \mu) \equiv \mu(x) \geqq \mu(y)$,
$(x, \pi^*)\tilde{R}(y, \pi^*) \equiv \pi^*(x) \geqq \pi^*(y)$,
$(x, \mu)\tilde{R}(x, \pi^*) \equiv \mu(x) \geqq \pi^*(x)$,
$(x, \pi^*)\tilde{R}(x, \mu) \equiv \pi^*(x) \geqq \mu(x)$.

We denote strong preference relation and indifference relation as "$>$" and "$=$" respectively.

We should note that membership functions μ and π^* can be regarded as ordinal comparable utility functions based on extended ordering. As similar with possibility, we can discuss μ, π^*, and conditions (C1), (C2), (C3), (C4'), (C5).

4 Order relation between possibility evaluation and necessity evaluation

In this section, as discussed in earlier sections we assume that $H = \{\mu, \pi\}$ and that extended ordering on (x, μ) and (x, π) satisfies conditions (C1), (C2), (C3), (C4), and (C5) for preference relations $\tilde{R}$ and R.

Definition 9 *$x^P \in X$ is defined by: for all $y(\neq x^P) \in X$, $x^P R y$.*

Similarly we assume that $H = \{\mu, \pi^*\}$ and that extended ordering on (x, μ) and (x, π^*) satisfies conditions (C1), (C2), (C3), (C4'), and (C5) for preference relations $\tilde{R}^*$ and R^*. We discriminate $\tilde{R}, R$ and $\tilde{R}^*, R^*$.

Definition 10 *$x^N \in X$ is defined by: for all $y(\neq x^N) \in X$, $y R^* x^N$.*

We should recall that $\mu(x)$ and $\pi(x)$ are ordinal functions.

In Possibility theory, optimistic evaluation and pessimistic evaluation are discussed. In this section, order relation between possibility evaluation and necessity evaluation is discussed.

We obtain the following result with respect to $\mu(x^P)$ and $\mu(x^N)$.

Lemma 3

$$\mu(x^P) \geqq \mu(x^N). \tag{5}$$

(Proof)
Assuming $\mu(x^P) < \mu(x^N)$ we deduce contradiction. In this case, $x^P \neq x^N$. If $\pi(x^P) \leqq \pi(x^N)$, then $(x^N, \mu)\tilde{P}(x^P, \mu)$ and $(x^N, \pi)\tilde{R}(x^P, \pi)$. Therefore, by (C3) of GSWF f^P, $x^N P x^P$. This contradicts the definition of x^P. Next, we consider the case that $\pi(x^P) > \pi(x^N)$. In this case, $\pi^*(x^P) < \pi^*(x^N)$ and $\mu(x^P) < \mu(x^N)$, then $(x^N, \mu)\tilde{P}^*(x^P, \mu)$ and $(x^N, \pi)\tilde{P}^*(x^P, \pi)$. By (C3) of GSWF f^N, $x^N P^* x^P$, so that this contradicts the definition of x^N.

For order relations with respect to $\max(\mu(x^N), \pi^*(x^N))$ and $\min(\mu(x^P), \pi(x^P))$, we obtain the following results.

Lemma 4 *If $\pi^*(x) > \pi(x)$, then*

$$\max(\mu(x^N), \pi^*(x^N)) > \min(\mu(x^P), \pi(x^P)). \tag{6}$$

Lemma 5 *If there exists x' which satisfies the condition $\pi(x') \geqq \mu(x') \geqq \pi^*(x')$, then*

$$\min(\mu(x^P), \pi(x^P)) \geqq \mu(x') \geqq \max(\mu(x^N), \pi^*(x^N)). \tag{7}$$

(Proof)
By the definition of x^P, we have $\min(\mu(x^P), \pi(x^P)) \geqq \min(\mu(x'), \pi(x')) \geqq \mu(x')$. Similarly with respect to x^N, $\max(\mu(x^N), \pi^*(x^N)) \leqq \max(\mu(x'), \pi^*(x')) \leqq \mu(x')$. Consequently we obtain the result.

Next we discuss in the framework of conventional Possibility theory, i.e., we consider $\pi^*(x) = 1 - \pi(x)$. x^P is most preferable on X with respect to GSWF f^P. Then x^P takes the optimal value of (1) in Definition 1. Similarly, x^N is most unpreferable on X with respect to GSWF f^N. Then x^N takes the optimal value of (2) in Definition 2.

ISBN: 978-989-95079-6-8

Some assumptions are sometimes taken in Possibility theory. In this section we assume that the membership function $\pi(x)(0 \leqq \pi(x) \leqq 1)$ satisfies normality condition, i.e., there exists the $x' \in X$ such that $\pi(x') = 1$. Then we obtain the following result by Lemma 5.

Theorem 6 *If $\pi(x)$ is normal, then*

$$\Pi(\mu, \pi) \geqq N(\mu, \pi). \tag{8}$$

(Proof) By the definition of normality there exists x' that $\pi^*(x') = 0$ and $\pi(x') = 1$, and $0 \leqq \mu(x') \leqq 1$, then the prerequisite condition of Lemma 5 is satisfied.

5 Conclusion

This paper described the mathematical foundation of subjective uncertainty. Axiomatic interpretations on possibility evaluation and necessity evaluation, and the relation between these evaluations were examined based on the extended ordering in social choice theory.

The obtained results are as follows:

In section 2, based on extended ordering we obtained the equivalent conditions for two kinds of GSWF f^P and f^N; conditions (C1), (C2), (C3), (C4), (C5), and conditions (C1), (C2), (C3), (C4'), (C5).

In section 3, we examined generalized possibility evaluation and necessity evaluation, and discussed the conditions obtained in section 2.

In section 4, we defined x^P and x^N, and discussed the order relations between possibility evaluation and necessity evaluation, and obtained some results on the relations.

By these results obtained in this paper, mathematical interpretations and applicable conditions of the evaluations became clear. These are important when the evaluations are applied in various practical situations.

Abstract— In the current approaches to fuzzy answer set programming (FASP) one can state preferences amongst rules to denote their relative importance. However, in many situations we need more complex preferences such as those in the answer set optimization framework proposed by Brewka for crisp answer set programming. Unfortunately, these complex preferences do not readily fit into the current FASP approaches. In this paper we propose a language to state such preferences and show that programs with these preferences can be translated into equivalent general fuzzy answer set programming (gFASP) programs. This not only provides an implementation method, but also shows that this extension can be added as syntactic sugar on top of general fuzzy answer set programming solvers.

Keywords— Logic Programming, Fuzzy Logic, Answer Set Programming, Preference-based Logic Programming.

1 Introduction

Answer set programming [1] is a logic programming language based on the stable model semantics [2]. Roughly speaking, in answer set programming a program contains a set of *rules* of the form $a \leftarrow b_1, \ldots, b_n, \mathit{not}\ c_1, \ldots, \mathit{not}\ c_m$ describing a problem whose solution is generated by an *answer set solver*. For example, if one is interested in finding solutions to the problem of assigning a seat s to either of two persons p_1 and p_2, the following program could be used:

$$\begin{array}{lcl} sit(p_1, s) & \leftarrow & \mathit{not}\ sit(p_2, s) \\ sit(p_2, s) & \leftarrow & \mathit{not}\ sit(p_1, s) \end{array}$$

This program has two *answer sets*, which correspond to the solutions of the modeled problem, $S_1 = \{sit(p_1, s)\}$ and $S_2 = \{sit(p_2, s)\}$.

In recent work, answer set programming and, more general, logic programming have been extended to deal with fuzzy [3, 4], probabilistic [5] and many-valued logics [6, 7, 8, 9], allowing for a more flexible description of both the problem domain and the proposed solutions of the problem domain. Specifically, in [4] degrees are attached to answer sets describing the quality of prospective solutions. For example, in case one is interested in only allowing solutions in which people are seated close to friends, one could write a program containing fuzzy *constraints*, as follows:

$$0 \leftarrow sit(p_1, s_1) \wedge sit(p_2, s_2) \wedge \mathit{friend}(p_1, p_2) \wedge \sim near(s_1, s_2)$$

where $sit(p, s)$ means that person p sits on seat s, $\mathit{friend}(p_1, p_2)$ that person p_1 is a friend of p_2 (to a certain degree), $near(s_1, s_2)$ denotes the proximity of seats s_1 and s_2 and $\sim$ is a negator. The constraint above would then attach a higher degree of quality to answer sets in which friends are close together. Note that $\sim near(s_1, s_2)$ should be used and not $near(s_1, s_2)$ since the satisfaction of the constraint rule should increase with the value of $near(s_1, s_2)$. More details can be found in Section 2.

Although the quality degree allows to express preference amongst solutions, the current proposals only allow this preference to be based on the degree of rule fulfillment. However, in many practical situations, we would like to express preferences based on the truth degrees of literals. Furthermore, we might want to express that the importance of some preferences depends on the context, i.e. we would like to have conditional preferences. For example, we wish to be able to state that if we are sitting on a seat, we prefer it to be by the window, but only consider this important when the scenery is nice, as follows:

$$scene : (sit(p, s) \rightarrow nearWin(s)) \triangleleft nicescenery \qquad (1)$$

where $nearWin(s)$ denotes that seat s is near the window, the $nicescenery$ literal determines the weight of importance of the rule and $\rightarrow$ is an implicator. The exact semantics of such rules are given in Section 3.

In the crisp case, Brewka proposed rules like (1) in [10]. However, to the best of our knowledge no such proposal exists for fuzzy answer set programs, which we remedy in this paper. The main contributions of this paper are the following:

- In Section 3 we propose a generalisation of the *Preference Description Language* (PDL) of Brewka to the fuzzy case.
- In Section 4 we show how programs containing these preferences can be translated to standard general fuzzy answer set programming (gFASP) programs [11], providing an implementation method and hence also showing that this extension is actually syntactic sugar on the general fuzzy answer set programming language.

2 General Fuzzy Answer Set Programming

General fuzzy answer set programming (gFASP) programs over a complete lattice $\mathcal{L}$ consist of *rules*, which are objects of the form

$$r\colon a \leftarrow f(b_1, \ldots, b_n)$$

where r is the label of the rule, a and b_i, $1 \leq i \leq n$, are either elements from $\mathcal{L}$ or propositional symbols called *literals* (where $b_i = b_j$ for $i \neq j$ is possible), f is a (computable) function from $\mathcal{L}^n$ to $\mathcal{L}$ such that for $b_k, b'_k \in \mathcal{L}$ it holds that if $b_k \leq b'_k$, either $f(b_1, \ldots, b_k, \ldots, b_n) \leq f(b_1, \ldots, b'_k, \ldots, b_n)$ or $f(b_1, \ldots, b_k, \ldots, b_n) \geq f(b_1, \ldots, b'_k, \ldots, b_n)$ and $\leftarrow$ denotes a residual implicator over $\mathcal{L}$. If $a \in \mathcal{L}$, the rule is called a *constraint*. The head a of a rule r is denoted as r_h and the body $f(b_1, \ldots, b_n)$ is denoted as r_b.

The semantics are given by *interpretations*, i.e. fuzzy sets over the literals of a program. These are extended to give meaning to rules in a straightforward fashion, i.e. if I is an interpretation, $[a \leftarrow f(b_1, \ldots, b_n)]_I = [a]_I \leftarrow [f(b_1, \ldots, b_n)]_I$, where $[a]_I = I(a)$ if a is a literal and $[a]_I = a$ if $a \in \mathcal{L}$, and $[f(b_1, \ldots, b_n)]_I = f([b_1]_I, \ldots, [b_n]_I)$.

Models of a program P are defined using an *aggregator expression* $\mathcal{A}_P$ which maps *rule propositions* (corresponding to rule labels) to a value in a quasi-ordered set $\mathcal{Q}$. For example, given a program P_1 with two rules r_1 and r_2, a possible aggregator would be $\mathcal{A}_{P_1} = r_1 + r_2$. Such an expresssion can be evaluated by an interpretation, e.g. for I an interpretation of P we obtain $[\mathcal{A}_{P_1}]_I = \gamma([r_1]_I) + \gamma([r_2]_I)$, with γ an order-preserving $\mathcal{L} \rightarrow \mathcal{Q}$ mapping. A *k-model*, $k \in \mathcal{Q}$, is then an interpretation for which $[\mathcal{A}_P]_I \geq k$.

k-Answer sets of a program P are k-models that contain the maximal amount of knowledge inferrable from a program through forward chaining, without resorting to external hypotheses, i.e. they are models for which the truth value of every literal is supported by the application of a rule in the program.

As an example, consider program P_{seat}, describing seating arrangements, with the following rulebase $\mathcal{R}_{P_{seat}}$ over the lattice $([0,1], \leq)$:

$$
\begin{array}{rrll}
gen\colon & sit(P,S) & \leftarrow_g & 1 \\
c_1\colon & 0 & \leftarrow_g & sit(P,S) \wedge sit(P',S) \wedge P \neq P' \\
c_2\colon & 0 & \leftarrow_g & sit(P,S) \wedge sit(P,S') \wedge S \neq S' \\
cr\colon & 0 & \leftarrow_g & sit(P,S) \wedge (1 - sit(P,S)) \\
u\colon & unh(P) & \leftarrow_g & sit(P,S) \wedge friend(P,P') \\
 & & & \wedge sit(P',S') \wedge (1 - near(S,S')) \\
q\colon & 0 & \leftarrow_l & unh(P) \\
s\colon & s(P) & \leftarrow_g & sit(P,S) \\
a\colon & 0 & \leftarrow_g & 1 - s(P)
\end{array}
$$

where $\wedge$ is the minimum t-norm over $([0,1,\leq)$ and $\leftarrow_l$, $\leftarrow_g$ are resp. the Łukasiewicz and Gödel implicator. The aggregator is defined as $\mathcal{A}_{P_{seat}} = \inf_{r \in \mathcal{R}_{P_{seat}} \setminus \{gen\}} r$. Due to the fact that the gen-rule is not incorporated in the aggregation expression, this rule generates random truth degrees for $sit(P,S)$. To ensure that $sit(P,S)$ is either 0 or 1, we use the cr (crispify) rule. Rules c_1 and c_2 guarantee that a seat is occupied by a single person, resp. that a person only occupies one seat. The a and s rules ensure that everyone has a seat and the u and q rules are used to prefer solutions where friends are seated close together. Note that due to grounding a rule such as $s(P) \leftarrow_g sit(P,S)$ actually denotes a set of rules $\{s(p_i) \leftarrow_g sit(p_i, s_j)\}$ for a set of persons $(p_i)_{i \in I}$ and a set of seats $(s_j)_{j \in J}$.

If we have three seats s_1, s_2 and z, only two of which are near, viz. $near(s_1, s_2)^{\cdot 8}$ and $near(s_2, s_1)^{\cdot 8}$ and there are three persons a, b and c connected by friendship degrees $friend(a,b)^{\cdot 8}$, $friend(a,c)^{\cdot 5}$, and $friend(b,c)^0$, then from program P_{seat} one could e.g. derive the .2-answer set $A_1 = \{sit(a,s_1)^1,\ sit(b,z)^1,\ sit(c,s_2)^1,\ unh(a)^{\cdot 8},\ \ldots\}$ and the (better) .5-answer set $A_2 = \{sit(a,s_1)^1,\ sit(b,s_2)^1,\ sit(c,z)^1,\ unh(a)^{\cdot 5}, \ldots\}$.

For more details on the gFASP framework, we refer the reader to [11].

3 Complex Preferences on Literals

3.1 Fuzzy preference rules: syntax

In this section, we build a fuzzy preference framework based on a *fuzzy preference description language* ($FPDL$) which is an extension of the language PDL proposed by Brewka in [10]. Formally, a gFASP program with literal preferences consists of a tuple (P, e), where P is a gFASP program and e is an expression from $FPDL$. This expression determines a preference ordering on answer sets based on truth degrees of literals.

The basic elements of this language are *fuzzy preference rules*. Note that although they are called *rules*, they should not be confused with the rules of a fuzzy answer set program introduced in Section 2: the former are used for creating preference expressions (the e in (P, e)), whereas the latter are used to create (general) fuzzy answer set programs (the P in (P, e)). Formally the fuzzy preference rules are defined over a set of literals L and the complete lattice $\mathcal{L}$ as expressions of the following form:

$$r : g(a_1, \ldots, a_n) \triangleleft f(b_1, \ldots, b_m) \tag{2}$$

In this rule, the a_is ($1 \leq i \leq n$) and b_js ($1 \leq j \leq m$) are literals from L, the function g is a mapping from $\mathcal{L}^n$ to $\mathcal{L}$, f is a mapping from $\mathcal{L}^m$ to $\mathcal{L}$ and r is the label of the rule. For convenience, for a given fuzzy preference rule r we also refer to $g(a_1, \ldots, a_n)$ as r_h (the *head* of the rule) and to $f(b_1, \ldots, b_m)$ as r_b (the *body* of the rule).

Intuitively, the g-function denotes an expression determining the *suitability* of an answer set with respect to a certain preference and the f-function denotes the *applicability* of the rule, meaning the conditions under which this preference rule is considered important or relevant. For example, consider the following preference rule:

$$scene : (sit(p,s) \rightarrow nearWin(s)) \triangleleft nicescenery$$

This rule states that by default we (with "we" being person p) would like to have a seat near the window. However, we only consider this requirement important to the degree that the scenery is actually nice. The reason for choosing g to be an implication in this rule is that we want to state that this specific rule is also fulfilled (thus the answer set considered is still "suitable") if we are not sitting at this seat. Note that there is a difference between the $\rightarrow$ in the head and the $\triangleleft$ of the rule: if we would rewrite the scene rule as

$$scene' : (sit(p,s) \wedge nicescenery \rightarrow nearWin(s)) \triangleleft 1$$

it would denote that the nicer the scenery, the closer to the window we would like to sit rather than that we only find it important to sit near the window when the scenery is nice.

ISBN: 978-989-95079-6-8

This can also be seen from the fact that if $\rightarrow$ is a residual implicator and $nicescenery$ is true to a degree of 0.5, the $scene$ rule is only fully fulfilled when $nearWin(s)$ is 1 (or $sit(p,s)$ is 0), whereas in the $scene'$ rule it suffices that $nearWin(s)$ is 0.5 (or $sit(p,s)$ is 0).

Intuitively we thus prefer answer sets with a better suitability score, but can forgive the answer set a low suitability score if the applicability degree is rather low. Formally the semantics of rules are dependent on a function $suit$ and app defined for a given fuzzy preference rule r and an arbitrary answer set A as

$$suit(A,r) = [g(a_1,\ldots,a_n)]_A = g(A(a_1),\ldots,A(a_n))$$

$$app(A,r) = [f(b_1,\ldots,b_m)]_A = f(A(b_1),\ldots,A(b_m))$$

In the approach of Brewka [10], the semantics of preference rules are defined by attaching a *penalty* score in $\mathbb{R}$ to each applicable rule. Such a penalty reflects how good an answer set fulfills a preference rule, where lower penalties correspond to better fulfillment. Inapplicable rules are not considered important and are therefore attached penalty 0, i.e. they are always optimally fulfilled.

Unfortunately, the same approach is not possible when generalizing from crisp to fuzzy answer set programming: in the fuzzy case the applicability value is in $[0,1]$ and by reducing the values $suit(A,r)$ and $app(A,r)$ to a single number (i.e. penalty score in $\mathbb{R}$), we lose the important semantic distinction between suitability of answer sets and applicability of preference rules. In the following sections, we define an alternative semantics for fuzzy preference rules which does adhere to this distinction. We will first give the semantics for rules with a crisp applicability score and then define penalty expressions built from rules; starting from the semantics thus obtained we then introduce the semantics for rules with a fuzzy applicability score using the recently introduced concept of gradual number [12]; finally we introduce the general penalty expressions built from rules with fuzzy applicabilities.

3.2 Rules with crisp applicability

Suppose r is a rule with a crisp applicability condition (i.e. $app(A,r)$ is either 1 or 0), then we define the penalty score as:

$$pen^c(A,r) = \begin{cases} \Xi(suit(A,r)) & \text{if } app(A,r) = 1 \\ 0 & \text{otherwise} \end{cases}$$

where Ξ is a decreasing $\mathcal{L}$ to $[0,+\infty[$ mapping, such that $\Xi(1) = 0$, in the examples in this paper usually assumed to be $\Xi(x) = 1 - x$.

As an example, consider the following rule:

$$VIP_p : goodSeat(p) \triangleleft vip(p)$$

where $goodSeat(p) \in [0,1]$ reflects how good the seat of person p is and $vip(p) \in \{0,1\}$ denotes whether person p is a VIP. This rule encodes that we find it important that VIPs have good seats. If $A(goodSeat(p)) = 0.8$ and $A(vip(p)) = 1$, we know from the definition of pen^c that $pen^c(A,r) = 1 - 0.8 = 0.2$. Hence, answer set A has a low penalty score and thus represents a seating configuration that satisfies our wishes.

Starting from rules with crisp applicability, we can define the set of complex penalty expresssions $FPDL^p$ as follows:

1. If r is a fuzzy preference rule whose applicability condition takes only crisp values, r is in $FPDL^p$;
2. If $e_1, e_2, \ldots, e_k$ are in $FPDL^p$, then so are $(sum\ e_1,\ldots,e_k)$ and $(max\ e_1,\ldots,e_k)$.

We extend the definition of pen^c to cover complex penalty expressions in a straightforward way, e.g.

$$pen^c(A, sum\ e_1, ..., e_k) = pen^c(A,e_1) + ... + pen^c(A,e_k)$$

For example, suppose we have two VIP_p rules for persons p_1 and p_2, then we can combine these into one penalty expression summing the penalties as

$$e_v : (sum\ VIP_{p_1}, VIP_{p_2})$$

If we then have an answer set A for which $pen^c(A, VIP_{p_1}) = 0.2$ and $pen^c(A, VIP_{p_2}) = 0.5$, the total penalty of this expression is $pen^c(A, (sum\ VIP_{p_1}, VIP_{p_2}) = 0.7$.

3.3 Rules with vague applicability

In the general case, where applicability conditions are vague, we define penalties as gradual numbers in the sense of [12], i.e. as mappings from $]0,1]$ to $\mathbb{R}$. For each threshold λ in $]0,1]$, we convert preference rules r of the form (2) to preference rules r_λ with a crisp applicability condition:

$$r_\lambda : g(a_1,\ldots,a_n) \triangleleft (f(b_1,\ldots,b_m) \geq \lambda) \tag{3}$$

The (gradual) penalty of A w.r.t. a preference rule r is then given by the gradual number $pen(A,r)$, defined for each λ in $]0,1]$ as

$$pen(A,r)(\lambda) = pen^c(A, r_\lambda) \tag{4}$$

In Figure 1, one can see an example of the penalty thus induced by an answer set A on the rule VIP_p where $A(vip(p)) = app(A, VIP_p) = 1/2$ and $A(goodSeat(p)) = suit(A, VIP_p) = 0.75$. Note that for each rule the set $\{\lambda \mid pen(A,r)(\lambda) = \Xi(suit(A,r))\}$ is the half-open interval $]0, app(A,r)]$ and the set $\{\lambda \mid pen(A,r)(\lambda) = 0\}$ is the half-open interval $]app(A,r), 1]$. Hence, an answer set is only accountable (gets a penalty) w.r.t. a rule to the extent that the rule is applicable for the answer set.

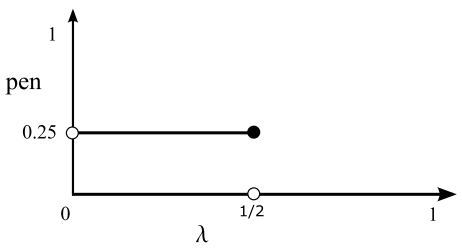

Figure 1: Example rule penalty

These penalties can easily be extended to complex preference expressions from a set $FPDL^{gp}$, defined analogously as $FPDL^p$ above, but starting from arbitrary preference rules. To define the semantics for expressions from $FPDL^{gp}$, we rely on the semantics of corresponding expressions from

ISBN: 978-989-95079-6-8

$FPDL^p$. Specifically, for e in $FPDL^{gp}$ and λ in $\mathcal{L}$, we define

$$pen(A, e)(\lambda) = pen^c(A, e^\lambda)$$

where e^λ is obtained from e by replacing all occurrences of preference rules r by the corresponding preference rules r_λ. Note that in principle, aggregation strategies that operate directly on gradual penalties could be defined as well.

Figure 2 depicts $pen(A, e)$ (the solid line) and $pen(A', e)$ (the dashed line) for an expression of the form $e = (sum\ dance, win)$ where the rule

$$dance : (sit(p, s) \rightarrow nearDanceFl(s)) \triangleleft nearFriends(p)$$

encodes that person p would like to sit near the dancefloor, but only finds this important if he is sitting close to his friends. The other rule is defined as

$$win : (sit(p, s) \rightarrow nearWin(s)) \triangleleft nearColleagues(p)$$

and denotes that person p likes a window seat, but only finds this important if he is sitting close to his colleagues. The answer sets A and A' take on the following applicability and suitability values:

app	$dance$	win
A	0.375	0.625
A'	0.75	0.5

$suit$	$dance$	win
A	0.18	0.82
A'	0.8	0.95

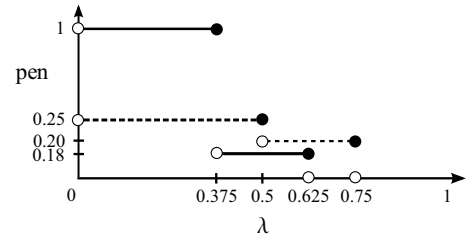

Figure 2: Example complex penalties

Now, given Figure 2, which answer set is preferred: A or A'? This depends on the application: if one only wants to look at the higher (more important) lambdas, we would prefer A as for $\lambda = 0.75$ this answer set has penalty 0; however if the global penalty score over all lambdas is important, we would prefer A' as A has a high penalty for values lower than 0.375 (viz. 1). Hence many options are viable, depending on the application. Furthermore there is a need to state preferences amongst expressions themselves so that we can e.g. state that only satisfying the $dance$ rule is better than only satisfying the win rule. In the next section we show how such orderings of answer sets based on the penalties and the preferences amongst preference expressions can be stated.

3.4 Preference strategies

Using penalties, we can define preference orderings on answer sets, which are referred to as *strategies*. Various such strategies can be specified. A natural strategy if we are comparing answer sets on the basis of one expression is to define the preference ordering $\leq$ between answer sets, based on an ordering $\preceq$ of gradual numbers. This strategy is denoted by $(\preceq\ e)$, and the corresponding preference ordering $\leq$ is defined for answer sets A_1 and A_2 as

$$A_1 \leq A_2 \equiv pen(A_1, e) \succeq pen(A_2, e)$$

Several partial and total orderings between gradual numbers can be used to this end. When the applicability values are interpreted as priorities, the total ordering $\preceq_1$ can be used, where $g_1 \preceq_1 g_2$ for gradual numbers g_1 and g_2 whenever

1. $g_1 = g_2$; or
2. $g_1(\lambda) < g_2(\lambda)$ for some λ in $]0, 1]$, and $g_1(\lambda') = g_2(\lambda')$ for all $\lambda' > \lambda$.

A useful partial ordering is the pointwise extension of the natural ordering $\leq$ on $\mathbb{R}$, denoted by $\preceq_2$, i.e. $g_1 \preceq_2 g_2$ iff $g_1(\lambda) \leq g_2(\lambda)$ for all λ in $]0, 1]$. Finally, an averaging strategy $\preceq_3$ could be used where $g_1 \preceq_3 g_2$ iff $\int_0^1 g_1(\lambda)w(\lambda)\,\mathrm{d}\lambda \leq \int_0^1 g_2(\lambda)w(\lambda)\,\mathrm{d}\lambda$. Intuitively, we may want to give more weight to the values of g_1 and g_2 for larger values of λ. This is encoded by using an increasing $]0, 1]$–$]0, 1]$ mapping w, defined, for instance, by $w(\lambda) = \lambda$ for all λ in $]0, 1]$.

As an example, consider Figure 2 with expression e from Section 3.3 again. From the picture one can see that if $\preceq_1$ is used, answer set A would be preferred over A' as for $\lambda = 0.75$ we have that $pen(A, e)(\lambda) < pen(A', e)(\lambda)$ and for any $\lambda > 0.75$ it holds that $pen(A, e)(\lambda) = 0 = pen(A', e)(\lambda)$. Hence $\preceq_1$ encodes a form of priority where we discriminate answer sets on their penalties for rules with a high applicability. Using $\preceq_2$, we would obtain that A and A' are incomparable. Thus $\preceq_2$ takes a more global approach, only considering preference when one of the two answer sets globally imposes a lower penalty score. With $\preceq_3$ and $w(\lambda) = \lambda$ for each $\lambda \in]0, 1]$ then, we obtain that A' would be preferred over A, due to the fact that A has a very high penalty at lower λ scores and is close to the penalty of A at the more important λ values. We can thus conclude that $\preceq_3$ can be used when one is not only interested in the fact that one penalty is higher than the other, but also in the exact value of these penalties.

The $\preceq_i$ $(1 \leq i \leq 3)$–strategies are not sufficient however: if we have two preference rules r_1 and r_2 and we want r_1 to be more important than r_2, we cannot readily encode this using a combination of the sum or max expressions and one of the orderings on the gradual penalties. To this end, we introduce other strategies, encoded as expressions from the set $FPDL$. First we have $(\preceq\ e) \in FPDL$ for $e \in FDPL^{gp}$ and $\preceq$ a partial ordering between gradual numbers. In analogy with Brewka [10], we also consider the following expressions:

1. If $e_1, \ldots, e_k$ are in $FPDL$, then $(pareto\ e_1, \ldots, e_k)$ and $(lex\ e_1, \ldots, e_k)$ are in $FPDL$
2. If $e_1, \ldots, e_k$ are in $FPDL^{gp}$ then $(rinc\ e_1, \ldots, e_k)$ and $(rcard\ e_1, \ldots, e_n)$ are in $FPDL$

The semantics of $(pareto\ e_1, \ldots, e_k)$ and $(lex\ e_1, \ldots, e_k)$ are defined analogously to the crisp case. In particular, the ordering $\leq$ induced by $(pareto\ e_1, \ldots, e_k)$ is defined by

$$A_1 \leq A_2 \equiv A_1 \leq_1 A_2 \wedge \ldots \wedge A_1 \leq_k A_2$$

ISBN: 978-989-95079-6-8

where $\preceq_i$ is the ordering induced by e_i. As an example, consider the expression $(pareto\ \ (\preceq_1\ \ dance), (\preceq_1\ \ win))$ with $dance$ and win as defined in Section 3.3. The preference ordering induced by this expression does not favor either of the expressions $(\preceq_1\ \ dance)$ and $(\preceq_1\ \ win)$.

Similarly, the ordering induced by $(lex\ e_1, \ldots, e_k)$ is given by

$$A_1 \leq A_2 \equiv \forall j \in 1..k \cdot A_1 \preceq_j A_2 \\ \vee \exists j \in 1..k \cdot A_1 \prec_j A_2 \wedge \forall j' < j \cdot A_1 \preceq_{j'} A_2$$

Expression $(lex\ (\preceq_1\ \ dance), (\preceq_1\ \ win))$ states that we first need to look whether we can prefer one of two answer sets A and A' by the expression $(\preceq_1\ \ dance)$. If this is not the case, we look whether $(\preceq_1\ \ win)$ can be used to prefer one of the two. Intuitively we thus prefer answer sets where person p is close to the dancefloor, even if that means he is sitting far from the window and close to his colleagues.

The $pareto$ and lex strategies both take arbitrary $FPDL$ expressions as their arguments. The next two strategies we introduce, $rinc$ and $rcard$, however, have expressions from $FPDL^{gp}$ as arguments. The difference with the $\preceq_i$ ($1 \leq i \leq 3$) strategies introduced earlier is that $rinc$ and $rcard$ base the preferences on more than one penalty expression and thus allow to have some interplay between rules and penalty expressions.

The semantics of $(rinc\ e_1, \ldots, e_k)$ and $(rcard\ e_1, \ldots, e_k)$ are defined in terms of the interval-valued fuzzy set P^a_A in the finite universe $\{1, \ldots, k\}$, where A is an answer set, $a \in [0, +\infty[$ and $L^a_A(i) = \{\lambda \mid pen(A, e_i)(\lambda) = a\}$:

$$P^a_A(i) = \begin{cases} [\inf L^a_A(i), \sup L^a_A(i)] & \text{if } L^a_A(i) \neq \emptyset \\ [0, 0] & \text{otherwise} \end{cases}$$

Intuitively, P^a_A is the set of (indices of) subexpressions e_i that attach a penalty a to an answer set A. Due to penalties being gradual numbers and because of the specific form of $pen(A, e)(\lambda)$ for any penalty expression e, P^a_A is an interval-valued fuzzy set.

The preference ordering induced by $(rinc\ \ e_1, \ldots, e_k)$ is defined as $A_1 \leq A_2$ iff

1. $P^a_{A_1} = P^a_{A_2}$ for all a in $[0, +\infty[$; or
2. $P^a_{A_1} \subset P^a_{A_2}$ for some a in $[0, +\infty[$, and $P^b_{A_1} = P^b_{A_2}$ for all $b < a$

where $\subset$ is an inclusion measure on interval-valued fuzzy sets, such as those proposed in [13]. As an example, consider $(rinc\ \ dance, win, boss)$ with $dance$ and win as in Section 3.4 and $boss$ the rule

$$boss : (sit(p, s) \rightarrow nearSpeechStand(s)) \triangleleft nearBoss(p)$$

Furthermore, we have answer sets A and A' with the following applicability and suitability values

app	r_1	r_2	r_3
A	0.25	0.5	0.5
A'	0.75	0.25	1

$suit$	r_1	r_2	r_3
A	0.5	0.5	0.25
A'	1	0.1	0.5

By definition of $rinc$ we first need to check whether we can discriminate between A and A' on the basis of P^0_A and $P^0_{A'}$. From the definition we easily obtain that:

P^0	r_1	r_2	r_3
A	$[0.25, 1]$	$[0.5, 1]$	$[0.5, 1]$
A'	$[0, 1]$	$[0.25, 1]$	$[0, 0]$

Note that $P^0_{A'}(1) = [0, 1]$ as the penalty of A' is 0 over the whole interval. Likewise $P^0_{A'}(3) = [0, 0]$ as the rule is fully applicable and penalty 0 is thus never reached. We use the inclusion measure $A \subseteq B \equiv \forall x \in X \cdot A(x) \leq B(x)$ for interval-valued fuzzy sets A and B over a universe X where $[a, b] \leq [a', b'] \equiv b \leq b' \wedge (b - a) \leq (b' - a')$ in this example, i.e. we take both the more important high λs and the amount of lambdas into account. By this definition $P^0_A(2) < P^0_{A'}(2)$ and $P^0_{A'}(3) < P^0_A(3)$ meaning that using $rinc$ the answer sets A and A' are incomparable.

For $(rcard\ e_1, \ldots, e_k)$, which uses a cardinality based approach, the ordering is given by $A_1 \leq A_2$ iff

1. $|P^a_{A_1}| = |P^a_{A_2}|$ for all a in $[0, +\infty[$; or
2. $|P^a_{A_1}| < |P^a_{A_2}|$ for some a in $[0, +\infty[$, and $|P^b_{A_1}| = |P^b_{A_2}|$ for all $b < a$

where $|U|$ denotes a measure of cardinality for the interval-valued fuzzy set U, such as those defined in [14]. Note that $rcard$ induces a partial order, whereas $rinc$ induces a total order.

As an example, consider $(rcard\ dance, win, boss)$, A and A' defined as before and a cardinality measure of the form $|A| = \sum_{x \in X} f(A(x))$ on an interval-valued fuzzy set A. When interval-valued membership degrees are used to encode uncertainty or bipolarity, $f_1([a, b]) = \frac{a+b}{2}$ is a natural choice. However, in our case, we need a notion of cardinality which is increasing in both b and $b - a$: a given penalty value is more representative for a penalty expression when it corresponds to more λ values, and to higher λ values. A suitable function is therefore given by $f_2([a, b]) = b(b - a)$. To further justify this choice, we provide the outcomes of both f_1 and f_2 in this example. For $rcard$ we obtain with f_1 that $|P^0_A| = \frac{4.25}{2} > \frac{2.25}{2} = |P^0_{A'}|$ whereas with f_2 we get $|P^0_A| = 1.75 = |P^0_{A'}|$, hence with f_1 answer set A would be preferred over A', whereas with f_2 no difference can be made by looking at penalty 0 and thus we must look for a higher penalty that does make a difference. The first penalty we should consider is 0.5 as this is the first penalty actually occurring for some rules. Computing $P^{0.5}$ gives:

$P^{0.5}$	r_1	r_2	r_3
A	$[0, 0.25]$	$[0, 0.5]$	$[0, 0]$
A'	$[0, 0]$	$[0, 0]$	$[0, 1]$

From this table we see that with f_2 we get $|P^0_A| = 0.25 * 0.25 + 0.5 * 0.5 = 0.3125$ and $|P^0_{A'}| = 1$, hence $A \leq A'$ and thus A' is preferred over A.

4 Translating Literal Preferences to a gFASP Program

In this section, we show that the gFASP framework we summarized in Section 2 is sufficiently general to encode $FPDL$–

ISBN: 978-989-95079-6-8

rules, an observation which immediately leads to an implementation method. Consider the gFASP program P, comprised of a rule base $\mathcal{R}_P$ and an aggregator expression $\mathcal{A}_P$ over the quasi-order $\mathcal{Q}_P$, and the expression e from $FPDL$. Specifically, we will show that a set of rules $\mathcal{R}_{P'}$ can be found, and an aggregator expression $\mathcal{A}_{P'}$ over a quasi-order $\mathcal{Q}_{P'}$, such that for any two answer sets A_1 and A_2

$$[\mathcal{A}_{P'}]_{A_1} \leq [\mathcal{A}_{P'}]_{A_2} \equiv [\mathcal{A}_P]_{A_1} \leq [\mathcal{A}_P]_{A_2} \wedge A_1 \leq_e A_2$$

Intuitively, $\mathcal{A}_P$ encodes which rules are more important, and how answer sets should be penalized when some rules are violated, while e encodes preferences between the actual solutions, i.e. preferences on the truth values of the literals.

As a first step, we need to provide the means to refer to the value of a certain function over literals $f(a_1, \ldots, a_n)$ from the aggregator expression. This is done by creating a constraint of the form $c_f : 0 \leftarrow \sim f(a_1, \ldots, a_n)$ where $\sim$ is an involutive negator and $\leftarrow$ is an implicator satisfying $0 \leftarrow x = \sim x$. It is easy to see that, in this way, the interpretation of rule proposition c_f, which we can refer to in the aggregator expression, will always be equal to the corresponding interpretation of $f(a_1, \ldots, a_n)$. Since the aggregator expression is increasing in all rule propositions, this procedure only works if we prefer answer sets with higher values of $f(a_1, \ldots, a_n)$. If, on the other hand, lower values of $f(a_1, \ldots, a_n)$ are preferred, we introduce the constraint $c_f : 0 \leftarrow f(a_1, \ldots, a_n)$ and use $\sim c_f$ in the aggregator.

Let $\mathcal{R}_e = \{r_1, \ldots, r_n\}$ be the set of preference rules occurring in e. Given that the preference of answer sets increases with increasing suitability of the rules and decreasing applicability, the aforementioned procedure leads to the rulebase $\mathcal{R}_{P'}$, defined by

$$\mathcal{R}_{P'} = \mathcal{R}_P \cup \{g_i : 0 \leftarrow \sim r_{ih} \mid i \in 1..n\} \cup \{f_i : 0 \leftarrow r_{ib}\}$$

The second part of our embedding consists of constructing a suitable aggregator expression $\mathcal{A}_{P'}$ and corresponding quasi-order $\mathcal{Q}_{P'}$. The aggregator $\mathcal{A}_{P'}$ is straightforwardly obtained from $\mathcal{A}_P$ by extending it with the various suitability and applicability values, i.e.:

$$\mathcal{A}_{P'} = (\mathcal{A}_P, (g_1, \ldots, g_n, \sim f_1, \ldots, \sim f_n))$$

The corresponding quasi-order is given by $\mathcal{Q}_{P'} = (\mathcal{Q}_P \times \mathcal{L}^{2n}, \leq_{\mathcal{Q}_{P'}})$ where

$$(a, b) \leq_{\mathcal{Q}_{P'}} (a', b') \equiv (a \leq_{\mathcal{Q}_P} a') \wedge (b \leq_e b')$$

Note how we can discriminate between answer sets on the basis of their rule fulfillment, using the first element of tuples from $\mathcal{Q}_{P'}$, as well as on the basis of the fulfillment of preference expression e, using the second element. The ordering $\leq_e$ is defined in the same way as the orderings on preference expressions, taking as arguments tuples with applicability and suitability scores, instead of answer sets.

The following proposition shows that the proposed embedding indeed preserves the intended semantics:

Proposition 1 *Let P be a gFASP program and e a fuzzy preference expression from FPDL. For the program P', obtained in the way described above, it holds for any two answer sets A_1 and A_2 that*

$$[\mathcal{A}_{P'}]_{A_1} \leq [\mathcal{A}_{P'}]_{A_2} \equiv [\mathcal{A}_P]_{A_1} \leq [\mathcal{A}_P]_{A_2} \wedge A_1 \leq_e A_2$$

5 Concluding remarks

In this paper, we generalized Brewka's answer set optimization framework to the fuzzy domain. The resulting formalism combines the flexibility of fuzzy answer set programming with the expressiveness of conditional preferences. We emphasized the conceptual difference between applicability and suitability of preference rules. This difference, which collapses in the two-valued case, played a crucial role in our fuzzification, leading to a generalization of penalty values using the notion of gradual numbers.

Although our extension is independent of any particular approach to fuzzy answer set programming, we showed that the recently introduced gFASP framework can provide a convenient implementation. One of the core elements in this approach is the use of an aggregator expression to discriminate between answer sets. We have shown how fuzzy preference expressions can be seen as particular choices of this aggregator expression. Hence, fuzzy preference expressions should be regarded as a convenient way to encode complex quasi-orders between answer sets, in a truely declarative way, rather than as a fundamental extension to this earlier work.

Abstract— *We discuss some optimization problems for fuzzy variable functions and show two interesting results. First result is related to conditions for existence of global optimal solutions for some general class of optimization problems on $\mathbb{E}^n$, the space of compacts, upper semicontinuous and normal fuzzy sets of $\mathbb{R}^n$. The second result is about preservation of local optimality points, via Zadeh's principle of extension.*

Keywords— Coercitivity of fuzzy variable functions, compacity in fuzzy metric spaces, fuzzy optimization, optimization of fuzzy variable functions, principle of extension.

1 Introduction

In most optimization problems, the coefficients, parameters and variable decisions involved are assumed to be precise elements of some real space $\mathbb{R}^n$. However in many real situations there is not such certainty about those values and is necessary to consider some models or methods to deal with optimization problems under uncertainty. Two main approaches have been deeply developed when we consider uncertainty in the parameters, in the constraints or in the values of the objective function, these are stochastic programming and fuzzy optimization. We may refer [1] or [2] for stochastic programming and [3], [4] or [5] for an overview of fuzzy optimization.

By the other hand, in connection with applications and modelling using fuzzy theory, a different kind of fuzzy optimization problems has been appeared in which some of the decision variables are itself fuzzy, this means, optimization of fuzzy variable functions. Some situations like this can be found in problems of depend or constraints programming as is shown in [6] or [7]), in estimation and regression models for fuzzy random variables as in [8], [9], [10], [11] or [12], or in problems of optimal control for fuzzy differential equations as in [13] or [14].

In most of the cases those fuzzy variable optimization problem was faced successfully using some *ad hoc* techniques or properties, some heuristic algorithm, or considering just specific classes of fuzzy numbers such as triangular or L-R fuzzy numbers. We believe that fuzzy variable optimization problems have not been thoroughly studied yet, and they deserve a systematic study in itself, because a general approach to this issue can leave a fertile field for their application and theoretical developments.

In this work we are dealing with fuzzy quantities in $\mathbb{R}^n$, specifically we are considering $\mathbb{E}^n$ the spaces of compacts, upper semicontinuous and normal fuzzy sets of $\mathbb{R}^n$. It is well known that $\mathbb{E}^n$ with usual arithmetic between fuzzy numbers is not a vector space, so many of general results in optimization theory are not availables immediately on this context, precisely because most of them use the vector space structure. Taking advantage of the special characteristics and properties of $\mathbb{E}^n$ we will be able to show two interesting theoretical results in optimization of fuzzy variable functions.

In section 2 we set the two problems under consideration and we recall some basic notation and definitions. In section 3 we recall some results about compacity in $\mathbb{E}^n$. Section 4 presents our first main result related to conditions for existence of optimal global solutions for some general class of optimization problems on $\mathbb{E}^n$. In section 5 we recall the Zadeh's principle of extension and some related properties and in section 6 we present our second main result related to preservation of local optimality points, via Zadeh's principle of extension.

2 Preliminaries

We are going to consider first the following optimization problem:

$$\min f(u) \qquad \text{subject to} \qquad u \in D \tag{1}$$

with $D \subset \mathbb{E}^n$ and $f : \mathbb{E}^n \to \mathbb{R}$. Later we will consider a given function $f : \mathbb{R}^n \to \mathbb{R}$ and study the problem of optimal local points of the function $\hat{f} : \mathbb{E}^n \to \mathbb{E}$ defined by Zadeh's principle of extension from f.

Besides of the space $\mathbb{E}^n$ we will also use the metric space $K(\mathbb{R}^n)$ of compacts subsets of $\mathbb{R}^n$ with the Hausdorff metric h defined by $h(A,B) = \max\{d(A,B), d(B,A)\}$ where A, B are compacts subsets of $\mathbb{R}^n$, $d(A,B) = \sup_{a\in A} d(a,B)$ and $d(a,B) = \inf_{b\in B} d(a,b)$.

Let u be an element of $\mathbb{E}^n$. For every $\alpha \in (0,1]$ the α-level of u is defined by $u_\alpha = \{x \in \mathbb{R}^n : u(x) \geq \alpha\}$ and $u_0 = supp(u) = \overline{\{x \in \mathbb{R}^n : u(x) > 0\}}$.

ISBN: 978-989-95079-6-8

The supremum metric d_∞ on $\mathbb{E}^n$ is defined in terms of Hausdorff metric between α-level sets:

$$d_\infty(u,v) = \sup_{\alpha\in[0,1]} h(u_\alpha, v_\alpha),$$

where $u, v \in \mathbb{E}^n$.

3 Compacity in $\mathbb{E}^n$

Definition 3.1. *A set $U \subset \mathbb{E}^n$ is said to be **compact-supported** if there is a compact subset K of $\mathbb{R}^n$ such that $supp(u) \subset K$ for every $u \in U$.*

If a subset U of $\mathbb{E}^n$ is compact-supported then is bounded. We explain this in the next theorem to be used later.

Theorem 3.2. *Let U be a subset of $\mathbb{E}^n$. If U is not compact-supported then exist a sequence $\{u^k\} \subset U$ such that $||u^k|| := d_\infty(u^k, 0) \to \infty$ as $k \to \infty$.*

Proof: If U is not compact-supported then for every compact set $K \subset \mathbb{R}^n$ there exist some $u^K \in U$ such that $supp(u^K) \not\subset K$. If we take $K = \overline{B_k(0)}$ the closed ball with center 0 an radius k, then for each $k \in \mathbb{N}$ there is a $u^k \in U$ such that $supp(u^k) \not\subset \overline{B_k(0)}$.

We have that $d(0, \overline{B_k(0)}) = 0$ and $d(\overline{B_k(0)}, 0) = k$ so $h(0, \overline{B_k(0)}) = k$, and by the other hand we have that at least one element x of $supp(u^k)$ is not an element of $\overline{B_k(0)}$ so $d(x, 0) > k$ and this implies that $d(supp(u^k), 0) = d((u^k)_0, 0) > k$ and furthermore $h((u^k)_0, 0) > k$.

By definition of supremum metric we have that

$$d_\infty(u^k, 0) = \sup_{\alpha\in[0,1]} h((u^k)_\alpha, 0) > k,$$

so, $||u^k|| := d_\infty(u^k, 0) \to \infty$ as $k \to \infty$ □

We consider also the level-set mapping $u_{(\cdot)} : [0,1] \to K(\mathbb{R}^n)$ which associate with each α the level-set u_α.

Definition 3.3. *A set $D \subset \mathbb{E}^n$ is called **equicontinuous** if the family of level-sets functions $\{u_{(\cdot)} : u \in D\}$ is a family of equicontinuous functions of [0,1] in $K(\mathbb{R}^n)$.*

The following is a well known result of metric spaces writen in terms of our fuzzy optimization problem:

Theorem 3.4. *Let D be a compact subset of $\mathbb{E}^n$ and f a continuous function on D. Then exists an optimal global solution for problem 1.*

An also well known corollary it follows, but first we need an additional notation. For $c \in \mathbb{R}$ and $f : D \to \mathbb{R}$ the set $L_{f,D}(c)$ is defined by

$$L_{f,D}(c) := \{x \in D : f(x) \leq c\}$$

Corollary 3.5. *If f is continuous and exist $c \in \mathbb{R}$ such that $L_{f,D}(c)$ is not empty and compact then exists an optimal global solution for problem 1.*

Proof: If $L_{f,D}(c)$ is not empty and compact then previous theorem implies that the function f reaches a minimum at some $x^* \in L_{f,D}(c)$ when f is restricted to $L_{f,D}(c)$. By definition if $x \notin L_{f,D}(c)$ then $f(x) > c$. But $f(x^*) \leq c < f(x)$ so x^* is an optimal global solution of problem 1 □

So far what we have just write are old compacity results. Those results can be easy to understand but maybe hard to apply because until now we have not talked about the meaning of compacity on $(\mathbb{E}^n, d_\infty)$.

An interesting characterizations of compacity in $(\mathbb{E}^n, d_\infty)$ in terms of concepts previously defined is the following.

Theorem 3.6. *A subset D of $(\mathbb{E}^n, d_\infty)$ is relatively compact if D is compact-supported and equicontinuous.*

Proof: See Corollary 10 in [15] □

Corollary 3.7. *If a subset D of $(\mathbb{E}^n, d_\infty)$ is closed, compact-supported and equicontinuous then D is compact.*

4 A Coercitivity Condition

In this section we will prove our first main result. We need to recall some definitions.

Definition 4.1. *A sequence $\{x^k\} \subset \mathbb{E}^n$ is called critic in relation to a set D if $\{x^k\} \subset D$ and $||x^k|| := d_\infty(0, x^k) \to \infty$ or $x^k \to x$ with $x \in \overline{D}$ but $x \notin D$.*

Definition 4.2. *A function f is coercive in a set D if for all sequence $\{x^k\}$ critics in relation to D, $\limsup_{k\to\infty} f(x^k) = +\infty$.*

Previous ones are well known definitions on normed vector spaces but even if $\mathbb{E}^n$ is not exactly a vector space, this concepts can be used in this context because of the special characteristics of $\mathbb{E}^n$. Let's see how this can be done.

Theorem 4.3. *If f is continuous and coercive in D and exist $c \in \mathbb{R}$ such that $L_{f,D}$ is not empty and equicontinuous, then problem 1 has an optimal global solution.*

Proof: We will show that under this hypothesis $L_{f,D}(c)$ is compact and then we use corollary 3.5.

ISBN: 978-989-95079-6-8

If $L_{f,D}(c)$ is not compact then because corollary 3.7 and hypothesis, $L_{f,D}(c)$ is not closed or is not compact-supported.

If $L_{f,D}(c)$ is not closed, as we assume that $L_{f,D}(c)$ is not empty, then exist a sequence $\{u^k\} \subset L_{f,D}(c)$ such that $u^k \to u$ and $x \notin L_{f,D}(c)$. If $u \in D$ then continuity of f in D and the fact that $f(u^k) \leq c$ for all $k = 0, 1, ...$, allow us to conclude $f(u) \leq c$ but $u \notin L_{f,D}(c)$ by definition of u, so $u \notin D$.

This means that $\{u^k\}$ is a critic sequence in relation to D and by coercitivity of f in D we have that $f(u^k) \to \infty$, which is a contradiction because $f(u^k) \leq c$.

Now, if $L_{f,D}(c)$ is not compact-supported then for theorem 3.2 there is a sequence $\{u^k\} \subset L_{f,D}(c)$ such that $||u^k|| := d_\infty(u^k, 0) \to \infty$ and again because of coercitivity of f we conclude that $f(u^k) \to \infty$ which is again a contradiction because $f(u^k) \leq c$.

So $L_{f,D}(c)$ has to be compact and the desired result it follows from corollary 3.5 □

5 Zadeh's Principle of Extension and Ordering in $\mathbb{E}$

We recall now for the case of $f : \mathbb{R}^n \to \mathbb{R}$ one of the cornerstones of fuzzy theory.

Zadeh's Principle of Extension: Given a function $f : \mathbb{R}^n \to \mathbb{R}$ we define the Zadeh's extension of f by:

$$\hat{f} : \mathbb{E}^n \to \mathbb{E},$$

$$\hat{f}(u)(x) = \begin{cases} \sup_{z \in f^{-1}(x)} u(z), & \text{if } f^{-1}(x) \neq \emptyset, \\ 0, & \text{if } f^{-1}(x) = \emptyset, \end{cases}$$

for each $u \in \mathbb{E}^n$.

Next theorem is now a well known result and establishes conditions on f in order to $\hat{f}$ be a well-defined and continuous function.

Theorem 5.1. *If $f : \mathbb{R}^n \to \mathbb{R}$ is continuous then $\hat{f} : (\mathbb{E}^n, d_\infty) \to (\mathbb{E}, d_\infty)$ is a well-defined continuous function and*

$$[\hat{f}(u)]_\alpha = f(u_\alpha),$$

for all $u \in \mathbb{E}^n$ and $\alpha \in [0, 1]$.

Proof: Proof of this result is an easy adaptation of theorems 2.1 and 3.3 at [16] and a famous result of Nguyen at [17] □

A usual partial order on $\mathbb{E}^n$ is defined by α-cuts inclusion in the following way:

$$u \leq v \Leftrightarrow u_\alpha \subseteq v_\alpha \quad \text{for all } \alpha \in [0, 1]],$$

with $u, v \in \mathbb{E}^n$.

Nevertheless, even that this order has been used succesfully for theoretical developments as in [18], it is still a little unsatisfactory at least in the case $n = 1$ because in this case this order is not a generalization of usual order on $\mathbb{R}$. In fact, number 2 is not longer greater than 1, they are not even comparable using this order.

There is, however, a generalization of natural order on $\mathbb{R}$ that we are going to consider now. Before, is necessary to note that if $u, v \in \mathbb{E}$ this implies that all their α-cuts are bounded closed interval of real line, this means that for all $\alpha \in [0, 1]$

$$u_\alpha = [a_\alpha, b_\alpha], v_\alpha = [c_\alpha, d_\alpha]$$

with $a_\alpha, b_\alpha, c_\alpha, d_\alpha \in \mathbb{R}$.

Definition 5.2. *Given $u, v \in \mathbb{E}$ and $\alpha \in [0, 1]$ we consider $u_\alpha = [a_\alpha, b_\alpha]$ and $v_\alpha = [c_\alpha, d_\alpha]$. We define a partial order relation on $\mathbb{E}$ by:*

$$u \leq_1 v \Leftrightarrow \quad a_\alpha \leq c_\alpha \quad \textit{and} \quad b_\alpha \leq d_\alpha$$

for all $\alpha \in [0, 1]$.

It is easy to show that previous order is in fact a partial order on $\mathbb{E}$ and that it is indeed a generalization of natural order on $\mathbb{R}$.

6 Local Optimality Preservation

Now we are going to prove our second main result. We are still considering the order defined in definition 5.2 and the supremum metric on $\mathbb{E}^n$

Theorem 6.1. *If $f : \mathbb{R}^n \to R$ is continuous and has a local minimum (maximum) at x^* then $\hat{f} : (\mathbb{E}^n, d_\infty) \to (\mathbb{E}, d_\infty, \leq_1)$ has also a local minimum (maximum) at x^*.*

Proof: We will just make the proof for local minimum. The other part is identical.

If f has a local minimum at x^* then exist a closed ball $B_r(x^*) \subset \mathbb{R}^n$ such that $f(x^*) \leq f(x)$ for all $x \in B_r(x^*)$.

Because $\hat{f}$ is just an extension of f to $\mathbb{E}^n$ and the order $\leq_1$ is a generalization or usual order of $\mathbb{R}$ to $\mathbb{E}$ then obviously $\hat{f}(x^*) \leq_1 \hat{f}(x)$ for all $x \in B_r(x^*)$ so we need to find a neighborhood of x^* in $(\mathbb{E}^n, d_\infty)$ with the same property.

We consider simply the closed ball $\tilde{B}_r(x^*) \subset (\mathbb{E}^n, d_\infty)$ with the same radius and center than the previous one, this means

$$\begin{aligned} \tilde{B}_r(x^*) =& \{u \in \mathbb{E}^n : d_\infty(u, x^*) \leq r\} \\ =& \{u \in \mathbb{E}^n : \sup_{\alpha \in [0,1]} h(u_\alpha, x^*) \leq r\} \\ =& \{u \in \mathbb{E}^n : \forall \alpha \in [0, 1] \quad h(u_\alpha, x^*) \leq r\} \\ \tilde{B}_r(x^*) =& \{u \in \mathbb{E}^n : \forall \alpha \in [0, 1] \quad u_\alpha \subset B_r(x^*), \} \end{aligned} \tag{2}$$

ISBN: 978-989-95079-6-8

and we have that $B_r(x^*) \subset \tilde{B}_r(x^*)$ when elements of $B_r(x^*)$ are considered as fuzzy as well.

If $u \in \tilde{B}_r(x^*)$, we have that for all $\alpha \in [0,1]$, $u_\alpha \subset B_r(x^*)$ so $f(u_\alpha) \subset f(B_r(x^*))$ and by definition of $B_r(x^*)$ this implies that for all $\alpha \in [0,1]$, $f(x^*) \leq y$ for all $y \in f(u_\alpha)$.

By theorem 5.1 we have that $[\hat{f}(u)]_\alpha = f(u_\alpha)$ so, for all $\alpha \in [0,1]$

$$f(x^*) \leq y \quad \text{for all} \quad y \in [\hat{f}(u)]_\alpha. \tag{3}$$

If we write $[\hat{f}(u)]_\alpha$ as an interval, this means, $[\hat{f}(u)]_\alpha = [a_\alpha, b_\alpha]$ for some $a_\alpha, b_\alpha \in \mathbb{R}$ the previous expression in the specific case of a_α and b_α becomes

$$\forall \alpha \in [0,1], \quad f(x^*) \leq a_\alpha \quad \text{and} \quad f(x^*) \leq b_\alpha. \tag{4}$$

Because $f(x^*) = \hat{f}(x^*)$ and because $f(x^*)$ considered as a fuzzy set has α-level sets always equals to $[f(x^*), f(x^*)]$, the previous considerations and the expression 4 implies that for $u \in \tilde{B}_r(x^*)$

$$\hat{f}(x^*) \leq_1 \hat{f}(u),$$

so $\hat{f}$ has a local minimum at x^*. □.

7 Conclusions and Future Work

In this work has been shown that a classical result of vector space optimization about coercitivity can be extended also for optimization problems on $\mathbb{E}^n$, even if this spaces is not a vector space. We believe that many other results can be generalized in this way and we will continue to study this subject and its applications.

This kind of problem can be seen also as general metric spaces optimization problems, a subject that is lately getting attention again (See [19]), however because of the fact that $\mathbb{E}^n$ is indeed more than just a metric space (after all it has some arithmetic structure) we will try to take advantage of its particular structure to obtain better results and applications.

We also believe that there are interesting questions about the way that a fuzzy extension of a function and orderings are related to optimal points and others qualitative characteristics of a function. We will keep study this subject deeply and we hope to find interesting interpretations and future applications.

Abstract *— Industrial monitoring of complex processes with hundreds or thousands of variables is a hard task faced in this work through evolving fuzzy systems. The Visbreaker process of the Sines Oil Refinery is the case studied. Firstly dimension reduction is performed by multidimensional scaling, obtaining the process evolution in a three dimensional space. Then an evolving fuzzy system (eFS) is developed to detect eventual malfunction of sensors. This eFS takes the data in the three reduced dimensions as antecedents and classifies the process state into normal and abnormal states. A software platform- the eFSLab (Evolving Fuzzy Systems Laboratory) - , with which this work has been developed, is presented and discussed. Several strategies for rule creation and evolution of rules, for Takagi-Sugeno (and for Mamdani system obtained from these) , are implemented in eFSLab. The obtained eFS shows a promising performance in the case studied, classifying in some simulations the state of the process into abnormal-normal condition in about 95% of the cases, with a number of rules between 5 and 8.*

Keywords — Evolving fuzzy systems; multidimensional scaling; industrial monitoring; fuzzy logic software.

1 Introduction

The growing complexity of industrial processes, the market competition, the more strict quality and safety rules, enhance the needs for sophisticated maintenance functions, including online process monitoring, failure detection and failure diagnosis [1] [11] [12]. This turns to be a complex problem mainly because of its non-linear high dimensional characteristics, since industrial systems are described using a large number of variables, which can be determined by various parameters and measurements.

According to [2] the main problem is to find the clusters of states in order to reflect the measurements and determine the general behavior of the system. Fuzzy systems may play here an important role, if iterative, real time techniques for rule base creation and evolution can be found. The eFSLab, Evolving Fuzzy Systems Laboratory, is a computational framework with that aim, briefly presented in this work.

The Visbreaker process of the Sines Refinery (Galp) is used to obtain real data for testing the performance of eFSLab to classify the state of the process into abnormal-normal condition. This classification is done through fuzzy systems produced by an evolving algorithm which is implemented in the platform.

An analysis is made of the performance of the fuzzy systems as classifier for this problem concluding that this algorithm has the potential to support maintenance activities as a failure detector.

The paper is organized as follows. Section 2 reviews briefly the eFS algorithm and in section 3 the eFSLab environment will be described. In section 4 the results obtained with eFSLab for data from Sines Refinery are presented and in section 5 these results are discussed and some conclusions and directions for future work are proposed.

2 The eFS algorithm

The algorithm to create Takagi-Sugeno fuzzy models is based on the approach proposed by Angelov et al. for online learning [3] and improved by [4] [5]. This algorithm allows creating zero or first orders Takagi-Sugeno fuzzy models with global or local recursive estimation parameters.

Fuzzy models are created with a data-driven approach, composed of an iterative process with 7 main stages [3] .

The procedure begins with the initialization of the rule-base structure (antecedent part of the rules) with a single rule, based on the first data sample. The second stage is to read the next data sample. Then, the potential of each new data sample is recursively calculated and in stage 4 occurs a recursively update of the potentials of the focal points (centers) of the existing rules/clusters.

After this, the potential of the new data sample is compared with the updated potential of existing centers, in order to decide if the rule-base is modified or upgraded. In the next stage consequence's parameters are recursively updated by Recursive Least Squares (RLS) or weighted RLS for globally or locally optimal parameters, respectively. Finally, the last stage is to predict the output of the system. By reading the next data sample at the next time step, the procedure returns to stage 2.

The algorithm intends to approach the subtractive clustering technique applied in a batch onset. Since it is to be applied in real-time environments, the data appears successively and at each time the new available data is used to improve the fuzzy system, in such a way that the new informative content of data should be reflected in the fuzzy rules, whether by change some of them, whether by creating new rules if there is sufficiently novelty in the process behavior. There are here some scientific challenges. The main one is how to

ISBN: 978-989-95079-6-8

measure the informative novelty in the new data. The second is how to change/create the rules consequently. The proposed techniques by [3] and [4] are based basically on heuristics and experimentation and as a consequence are case dependent. In the present work the same approach is followed. More conditions for rule update/create have been investigated and implemented in the computational framework eFSLab.

eFSLab allows to develop a Mamdani fuzzy model from a zero order Takagi-Sugeno (TS) fuzzy model. The Mamdani system is made based on the same antecedents of TS system previously created and by centering the fuzzy sets of Mamdani consequents in the Takagi-Sugeno constant consequent (only zero order models can be considered).

3 The eFSLab interface

The eFSLab interface is presented in Fig. 1(at the end of the paper). It was intended to create an interface as complete as possible, where the user could set the great majority of parameters needed to create a Takagi-Sugeno fuzzy system and transform it into a Mamdani system (in case of zero order TS systems), in a simple way.
The first step to use eFSLab interface is to select the file to import data. This file can be an Excel or a text file.
Then the user can choose TS order (zero or first), the recursive parameter estimations method, and set some other parameters needed to the recursive process.
Conditions for creation or modification of rules can also be chosen or defined by the user. There is a set of predefined conditions or the user can build up his (her) own conditions, as shown in Fig. 2

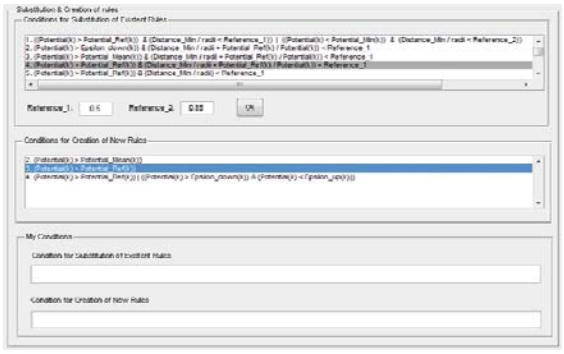

Figure 2. Creating or modifying rules in eFSLab.

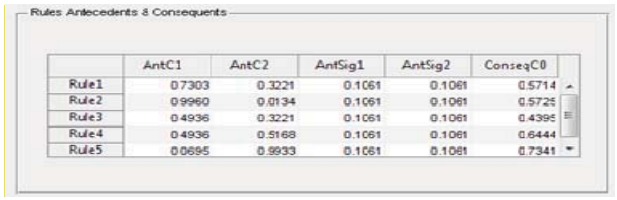
The fuzzy system is created and its characteristics can be analysed using the Matlab Fuzzy Logic Toolbox, with all its functionalities (viewing the graphics, consulting antecedents and consequents fuzzy sets, etc). A diagnosis text file is created by eFSLab. The created rules are shown in a table in the interface, shown in Figure 3 for the case of two antecedents, Gaussian membership functions and five rules.



Rules Antecedents & Consequents

	AntC1	AntC2	AntSig1	AntSig2	ConseqC0
Rule1	0.7303	0.3221	0.1061	0.1061	0.5714
Rule2	0.9960	0.0134	0.1061	0.1061	0.5725
Rule3	0.4936	0.3221	0.1061	0.1061	0.4395
Rule4	0.4936	0.5168	0.1061	0.1061	0.6444
Rule5	0.0695	0.9933	0.1061	0.1061	0.7341

Figure 3. Table containing antecedents and consequents for each rule created by eFS procedure.

eFSLab produces a set of graphical information about the evolution of the TS systems, such as the number of rules, the instants of modification or creation of rules, the potential evolution of the data samples, the model output versus real output for validation data, the norm of covariance matrix and rules parameters evolution, the obtained cluster in input space. Some of them are shown in figures below.
The algorithm is based on recursive subtractive clustering [3]. At the end of the learning phase, the collection of points that has been used, together with the obtained clusters, can be observed as in Fig. 4.

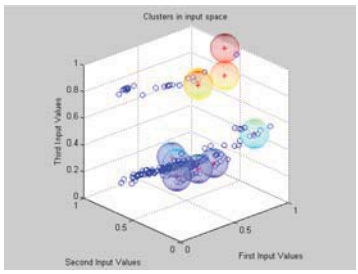


Figure 4. Clusters in input space after training. The dimensions of the spheres depend on the parameters of the clusters in a subtractive clustering environment.

In an on-line (iterative) implementation, the new rules can be created or the existent rules can be modified, and the instant when that happens can be shown as in Fig. 5

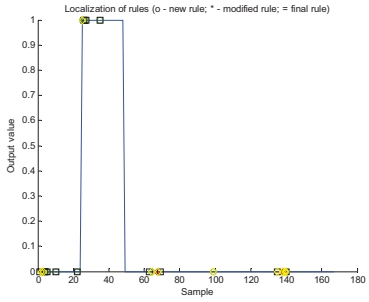

Figure 5. Localization of rules (new rules, rules modified and rules deleted).

The evolution of the number of rules during the process can be visualized as in Fig. 6.
To transform a zero-order TS fuzzy system into a Mamdani one, the *SugenoToMamdani* interface is opened as Fig. 7.
The user can choose the type of membership functions, the correspondent parameters and can preview their shape.

ISBN: 978-989-95079-6-8

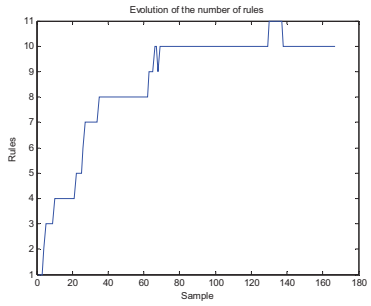

Figure 6. Evolution of the number of rules.

The Mamdani fuzzy system produced can be opened in the Matlab Fuzzy Logic Toolbox, benefiting from its functionalities for a deeper analysis .

4 Applicatiom to the Visbreaker process

The Visbreaker Unit is intended to reduce the viscosity of the residual coming from the vacuum column. With this objective a thermal cracking process is used with a relatively low temperature, and a long residence time. As a result of the thermal process a low viscosity Visbreaker residual is obtained, as well as lighter products, such as hydrocarbonets (gas oil diesel, gasoline and gases).The great economical advantage of the Visbreaker process is in fact that it produces a residual with a lower viscosity that the load feed. By this way, it is possible to use a lower quantity of "cutterstocks" (some of them of high benefit) for the production of fuel oil.
Fig. 8 [9] presents its flow sheet. It is composed of several sub-processes, and its main part is a kiln operating at about 310 ºC.

Data averaged for each hour, between the 1st of January and the 5th of June of 2008 was collected. Actually, data from 160 tags is available. From these, after correlation analysis and process expertise, 59 were selected as sufficiently representative of the process. Multidimensional scaling is then applied to those 59 dimensions to obtain a three dimensional representation by using VisRed [6]. The three dimensional data is then fed to eFSLab that finds a zero-order TS fuzzy model.

Multidimensional scaling reduces an *n*-dimensional data set to *p*-dimensional data set, with $p<<n$, such that the distance (for example Euclidian) between each pair of points in the reduced space is similar to the distance in the high dimensional space. This means that the topology of the original data set is preserved, as well as the information embedded in the topology. The technique consists in the minimization of the Euclidian distance between two matrices: the dissimilarity matrix in the original space and the dissimilarity matrix in the reduced space. The (*i,j*) element of a dissimilarity matrix is the distance between points *i* and *j*.

Three simulated scenarios have been considered with increasing time horizon and number of faults: one week with one fault in one sensor (Case 1), two weeks with two faults in two sensors (Case 2), and one month with two sensors faults during one day (Case 3). In Case 1 a 20% reduction in data from one temperature sensor in the kiln, during one day, was introduced into the data between the 1st and the 6th of June 2008. In Case 2 a 20% reduction in data from two temperature sensors in the kiln, during one day, was introduced into the data between the 22nd of May and the 4th of June 2008. In Case 3, the process data between the 5th of May and the 5th of June 2008 was changed in the same way in the same two sensors. These scenarios allow to measure the diagnosis capability of the eFS, as a classifier, as the size of data set increase.

For each test, there are some parameters of eFSLab that had to be set in order to produce the fuzzy system. The first parameter to be set is the order of the TS fuzzy model (zero) and the parameter estimation (Global estimation) for all the three cases. Other parameters controlling the rule base evolutions were fixed at their default values in eFSLab.
Radii value (controlling the region of influence of each cluster in input space) changed from test to test in order to evaluate its influence on the process. The conditions for creation and modification of rules were chosen to have the capability to produce rules in regions with less data points, improving the classification performance.
Some results of the three cases are presented in the following. In Case 1 and Case 3was introduced perturbation both in test and train data sets. In Case 2 the perturbation was only introduced in test data set

Case 1. Data is from the 1st to the 6th of June 2008 (one week). In train data set it was added a reduction of 20% to data from the 2nd of June and in test data set the same perturbation was added to data from the 4th of June, in a temperature sensor.
Dimension reduction by multidimensional scaling was performed with cosine dissimilarity metric without normalization. Fig. 9 represents data after dimension reduction. Two different groups corresponding to normal and abnormal data can be observed.
The reduced data is then presented to eFSLab, obtaining a zero order TS system with 8 rules to classify the data into two classes 1 and 2. A Radii value of 0.3 was used. These rules can be visualized in Fig. 10 (using Matlab Fuzzy Logic Toolbox).
In Fig. 11 shows the real output and the fuzzy system output It can be seen that the fault was detected. This classifier shows here 95% of successful classification, although there

ISBN: 978-989-95079-6-8

are also some false faults detected, reducing the performance of the system.

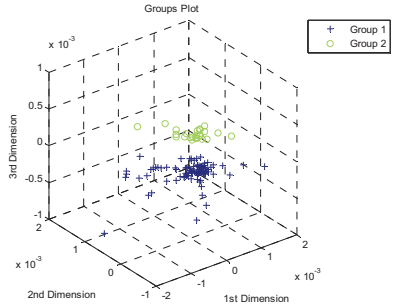

Figure 9. The three-dimensional state space for Case 1. Blue points (Group 1) are normal operating point. Group 2 are points of a simulated sensor fault.

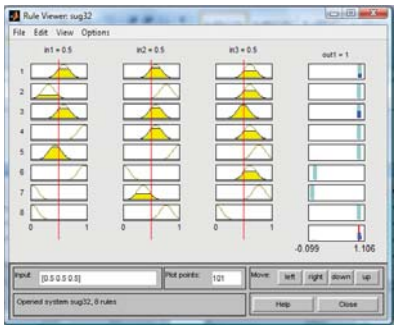

Figure 10. The 8 rules Takagi-Sugeno eFS obtained to classify the points in Case 1.

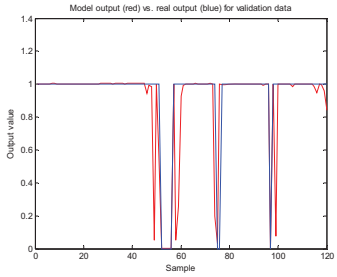

Figure 11. Real output (blue) and simulation output (red) obtained with zero-order TS system created for Case 1.

Case 2. Data from 22nd of May to 4th of June 2008 (two weeks) is considered, with a perturbation of 20% in data from two sensors in 23 of May and 4 of June.
Dimension reduction was made with Euclidean dissimilarity metric without normalization. Fig. 12 is a three dimensional representation of the reduced data.
Giving to eFSLab the reduced data, with Radii of 0.1, a 10 rules zero order TS system was obtained, shown in Fig. 13.

Case 3. Now all the data from 5th of May to the 5th of June (one month) is considered. Perturbation is the same as in the Case 2, but in 20th of May and 4th of June. Also the Radii value and the dissimilarity metric for dimension reduction are the same as in Case 2. In Fig. 15 is represented data set after dimension reduction.
Fig.14 compares the real output with the fuzzy system output. The classification is successful in 98.8% of the points.
The obtained zero-order TS system has now 11 rules, presented in Fig. 16.

Fig. 17 compares the output of the fuzzy system with the prepared data. The performance of the created fuzzy system is now substantially decreased: although the fault was detected, so have been many false positives. Overall 80.80% of the points have been correctly classified.

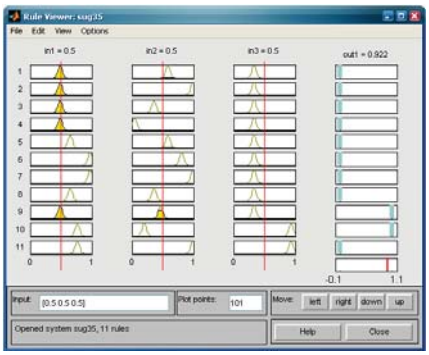

Figure 16: The 11 rules Takagi-Sugeno eFS for Case 3.

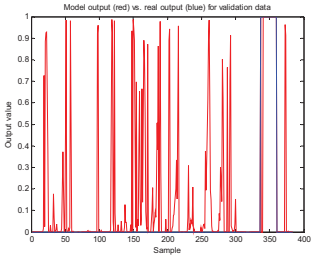

Figure 17. Case 3 :real output (blue) and fuzzy system output in Case 3.

Table 1 presents a summary of the results.

Table 1: Summary of results for the three cases.

Test	Data Set Size	MD Scaling Dissimilarity Metric	Radii	Output Matching (%)
1	1 week	Cosine	0.3	95%
2	2 weeks	Euclidean	0.1	98.8%
3	1 month	Euclidean	0.1	80.80%

When the time horizon increases (the data sets size increases proportionally), the performance of the fuzzy system as classifier seems to be worse. The way how the rules are created probably needs improvements. This is also supported by the distribution of the final clusters in the input space (see for example Fig. 4), that does not cover all the relevant space. However the results show a promising performance of the fuzzy system in terms of output (classification) matching. Furthermore, the low number of rules produced in each test contributes to a lower fuzzy sets superposition, increasing eventually interpretability and transparency, which is a main concern in fuzzy modelling [7] [8] [9]. Further work is needed to improve the iterative clustering technique, looking for better approximations to the subtractive clustering method.

5 Conclusions

Development of fuzzy systems from data is still an unattained aim of the fuzzy logic communities. Accuracy, interpretability and transparency are characteristics with an important practical relevance, allowing to give sense and credibility to the fuzzy systems. In the case of industrial monitoring, in big complexes of basic process industry, they may play an important role supporting the decision making in daily operation of the plants. *eFSLab* can be a useful computational framework to this goal. It is built with friendly user interfaces and allows an easy configuration and application to any data set built in proper form.

Evolving fuzzy systems, where rules are based on clusters, need more elaborated techniques for iterative clustering methods. This is not an easy task, since here neighbour points do not appear at the same time. Some kind of manageable memory must be developed to approach the iterative results to the non-iterative ones. This is one research direction of the authors.

New ways to measure novelty in data is needed. In a real time set the size of datasets tends to infinity. It is possible to maintain in memory only a finite time window of data Deleted points are forgotten history and new points may simply repeat pas behaviour but leading to new rules that are not only unnecessary but also prejudicial. This is another challenge to future work. The fuzzy community can have here a rich field of research to make fuzzy systems a credible and useful tool for data mining and knowledge discovery, whether in batch, whether in real-time.

Probabilistic Decision Making with the OWA Operator and its Application in Investment Management

José M. Merigó

Department of Business Administration, University of Barcelona
Av. Diagonal 690, 08034 Barcelona, Spain
Email: jmerigo@ub.edu

Abstract—*We develop a new model for decision making under risk environment and under uncertainty. We introduce a new aggregation operator that unifies the probabilities and the ordered weighted averaging (OWA) operator in the same formulation. We call it the probabilistic ordered weighted averaging (POWA) operator. This aggregation operator provides a more complete representation of the decision problem because it is able to consider probabilistic information and the attitudinal character of the decision maker. We study different properties and families of the POWA operator. We also develop an illustrative example of the new approach in a decision making problem about selection of investments.*

Keywords— Decision making; OWA operator; Probabilities; Investment selection.

1 Introduction

Decision making problems [2-8,14,16,18] are very common in the literature. There are different ways and methods for solving the decision process. Usually, the method used for solving the decision problem depends on the available information. For example, when the decision maker has probabilistic information he will solve the problem calculating the expected value for each alternative. Thus, he will be in a problem of decision making under risk environment. However, in other problems the decision maker may not have probabilistic information. Therefore, he must use another approach for solving the problem such as the use of the ordered weighted averaging (OWA) operator [13] that reflects the attitudinal character (degree of optimism) of the decision maker. In this case, we are in a situation of decision making under uncertainty.

The OWA operator is a very useful technique for aggregating the information. It provides a parameterized family of aggregation operators between the maximum and the minimum. In decision making it is very useful for representing the attitudinal character of the decision maker. Since its appearance, the OWA operator has been studied and applied in a wide range of problems [1-4,6-7,9-18].

In [4], they presented a new model that tried to unify the concept of probability with the OWA operator. They introduced the immediate probabilities. This method formulates an aggregation operator that uses probabilities and OWA operators at the same time. Therefore, this approach permits to consider decision making problems under risk environment and under uncertainty at the same time. The concept of immediate probabilities has been further studied in [6-7,16]. It is very useful in some particular situations. However, further analysis (as those shown in the paper) show that it can only unify probabilities and OWAs giving a neutral degree of importance to each case. But the real situation is that sometimes the decision maker believes more on the probabilistic information or on the OWAs. Therefore, the real unification must consider the degree of importance of these to concepts in the aggregation process. The aim of this paper is to present a new formulation that unifies the probabilities and the OWA operators considering the degree of importance of each case in the aggregation process. We call this new approach as the probabilistic ordered weighted averaging (POWA) operator. The main advantage of this approach is that it provides more complete information of the decision process because we can unify the probabilistic information and the attitudinal character according to the available information in the decision process. We study some of its main properties and we see that the OWA operator and the usual probabilistic decision making are particular cases of this approach. We study other particular cases of the POWA operator such as the Hurwicz-POWA, the olympic-POWA and the S-POWA.

We study the applicability of the POWA operator and we see that it is incredibly broad because it can be used in most of the problems where it appears the probability. In this paper, we focus on a decision making problem about selection of investments. We see the usefulness of the POWA operator because we can use situations of risk and uncertainty at the same time.

This paper is organized as follows. In Section 2 we briefly review the OWA operator and the immediate probability. Section 3 presents the POWA operator and Section 4 different particular cases. In Section 5 we present a decision making problem with the POWA operator in investment selection and in Section 6 we give the main conclusions.

2 Preliminaries

2.1 The OWA operator

The OWA operator [13] is an aggregation operator that provides a parameterized family of aggregation operators between the minimum and the maximum. It can be defined as follows.

ISBN: 978-989-95079-6-8

Definition 1. An OWA operator of dimension n is a mapping OWA: $R^n \to R$ that has an associated weighting vector W of dimension n such that $w_j \in [0, 1]$ and $\sum_{j=1}^{n} w_j = 1$, then:

$$\text{OWA}(a_1, \ldots, a_n) = \sum_{j=1}^{n} w_j b_j \quad (1)$$

where b_j is the jth largest of the a_i.
Note that different properties can be studied such as the distinction between descending and ascending orders, different measures for characterizing the weighting vector and different families of OWA operators. Note that it is commutative, monotonic, bounded and idempotent. For further reading, refer, e.g., to [1-4,6-7,9-18].

2.2 Immediate probabilities

An immediate probability is a type of probability that includes the attitudinal character of the decision maker by using the OWA operator in the aggregation process. Therefore, it is an attemp to unify the probabilities with the OWA operator. It can be defined as follows.

Definition 2. An IPOWA operator of dimension n is a mapping IPOWA: $R^n \to R$ that has an associated weighting vector W of dimension n such that $w_j \in [0, 1]$ and $\sum_{j=1}^{n} w_j = 1$, according to the following formula:

$$\text{IPOWA}(a_1, \ldots, a_n) = \sum_{j=1}^{n} \hat{v}_j b_j \quad (2)$$

where b_j is the jth largest of the a_i, each argument has associated a probability v_i with $\sum_{i=1}^{n} v_i = 1$ and $v_i \in [0, 1]$, $\hat{v}_j = (w_j v_j / \sum_{j=1}^{n} w_j v_j)$ and v_j is the probability v_i ordered according to b_j, that is, according to the jth largest of the a_i.
Note that the IPOWA operator is a good approach for unifying probabilities and OWAs in some particular situations. But it is not always useful, especially in situations where we want to give more importance to the OWA operators or to the probabilities. One way to see why this unification does not seem to be a final model is considering other ways of representing $\hat{v}_j$. For example, we could also use $\hat{v}_j = [w_j + v_j / \sum_{j=1}^{n} (w_j + v_j)]$ or other similar approaches.

3 The probabilistic OWA operator

The probabilistic ordered weighted averaging (POWA) operator is an extension of the OWA operator for situations where we find probabilistic information. It can also be seen as a unification between decision making problems under uncertainty (with OWA operators) and under risk (with probabilities). This approach seems to be complete, at least as an initial real unification between OWA operators and probabilities.

However, note that some previous models already considered the possibility of using OWA operators and probabilities in the same formulation. The main model is the concept of immediate probability explained in Section 2 [4,6-7,16]. Although it seems to be a good approach it is not so complete than the POWA because it can unify OWAs and probabilities in the same model but it can not take in consideration the degree of importance of each case in the aggregation process. Other methods that could be considered are the hybrid averaging (HA) operator and the weighted OWA (WOWA) operator. These methods are focused on the weighted average (WA) but it is easy to extend them to probabilities because sometimes the WA is used as a subjective probability. As said before, these an other approaches are useful for some particular situations but they does not seem to be so complete than the POWA because they can unify OWAs with probabilities (or with WAs) but they can not unify them giving different degrees of importance to each case. Note that in future research we will also prove that these models can be seen as a special case of a general POWA operator (or its respective model with WAs) that uses quasi-arithmetic means. Obviously, it is possible to develop more complex models of the IP-OWA, the HA and the WOWA that takes into account the degree of importance of the OWAs and the probabilities (or WAs) in the model but they seem to be artificial and not a natural unification as it will be shown below.
In the following, we are going to analyze the POWA operator. It can be defined as follows.

Definition 3. A POWA operator of dimension n is a mapping POWA: $R^n \to R$ that has an associated weighting vector W of dimension n such that $w_j \in [0, 1]$ and $\sum_{j=1}^{n} w_j = 1$, according to the following formula:

$$\text{POWA}(a_1, \ldots, a_n) = \sum_{j=1}^{n} \hat{v}_j b_j \quad (3)$$

where b_j is the jth largest of the a_i, each argument a_i has an associated probability v_i with $\sum_{i=1}^{n} v_i = 1$ and $v_i \in [0, 1]$, $\hat{v}_j = \beta w_j + (1 - \beta) v_j$ with $\beta \in [0, 1]$ and v_j is the probability v_i ordered according to b_j, that is, according to the jth largest of the a_i.
Note that it is also possible to formulate the POWA operator separating the part that strictly affects the OWA operator and the part that affects the probabilities. This representation is useful to see both models in the same formulation but it does not seem to be as a unique equation that unifies both models.

Definition 4. A POWA operator is a mapping POWA: $R^n \to R$ of dimension n, if it has an associated weighting vector W, with $\sum_{j=1}^{n} w_j = 1$ and $w_j \in [0, 1]$ and a probabilistic vector V, with $\sum_{i=1}^{n} v_i = 1$ and $v_i \in [0, 1]$, such that:

ISBN: 978-989-95079-6-8

$$\text{POWA}(a_1, \ldots, a_n) = \beta \sum_{j=1}^{n} w_j b_j + (1-\beta) \sum_{i=1}^{n} v_i a_i \qquad (4)$$

where b_j is the jth largest of the arguments a_i and $\beta \in [0, 1]$.
In the following, we are going to give a simple example of how to aggregate with the POWA operator. We consider the aggregation with both definitions.

Example 1. Assume the following arguments in an aggregation process: (20, 40, 50, 30). Assume the following weighting vector W = (0.2, 0.2, 0.2, 0.4) and the following probabilistic weighting vector P = (0.4, 0.2, 0.3, 0.1). Note that the probabilistic information has a degree of importance of 60% while the weighting vector W a degree of 40%. If we want to aggregate this information by using the POWA operator, we will get the following. The aggregation can be solved either with (3) or (4). With (3) we calculate the new weighting vector as:

$$\hat{v}_1 = 0.4 \times 0.2 + 0.6 \times 0.3 = 0.26$$
$$\hat{v}_2 = 0.4 \times 0.2 + 0.6 \times 0.2 = 0.2$$
$$\hat{v}_3 = 0.4 \times 0.2 + 0.6 \times 0.1 = 0.14$$
$$\hat{v}_4 = 0.4 \times 0.4 + 0.6 \times 0.4 = 0.4$$

And then, we calculate the aggregation process as follows:

POWA = 0.26 × 50 + 0.2 × 40 + 0.14 × 30 + 0.4 × 20 = 33.2.

With (4), we aggregate as follows:

POWA = 0.4 × (0.2 × 50 + 0.2 × 40 + 0.2 × 30 + 0.4 × 20) + 0.6 × (0.4 × 20 + 0.2 × 40 + 0.3 × 50 + 0.1 × 30) = 33.2.

Obviously, we get the same results with both methods.
From a generalized perspective of the reordering step, it is possible to distinguish between the descending POWA (DPOWA) and the ascending POWA (APOWA) operator by using $w_j = w^*_{n-j+1}$, where w_j is the jth weight of the DPOWA and w^*_{n-j+1} the jth weight of the APOWA operator.
If B is a vector corresponding to the ordered arguments b_j, we shall call this the ordered argument vector and W^T is the transpose of the weighting vector, then, the POWA operator can be expressed as:

$$\text{POWA}(a_1, \ldots, a_n) = W^T B \qquad (5)$$

Note that if the weighting vector is not normalized, i.e., $W = \sum_{j=1}^{n} w_j \neq 1$, then, the POWA operator can be expressed as:

$$\text{POWA}(a_1, \ldots, a_n) = \frac{1}{W} \sum_{j=1}^{n} \hat{v}_j b_j \qquad (6)$$

The POWA is monotonic, commutative, bounded and idempotent. It is monotonic because if $a_i \geq u_i$, for all a_i, then, POWA(a_1, a_2,…, a_n) ≥ POWA(u_1, u_2…, u_n). It is commutative because any permutation of the arguments has the same evaluation. That is, POWA(a_1, a_2,…, a_n) = POWA(u_1, u_2,…, u_n), where (u_1, u_2,…, u_n) is any permutation of the arguments (a_1, a_2,…, a_n). It is bounded because the POWA aggregation is delimitated by the minimum and the maximum. That is, Min$\{a_i\}$ ≤ POWA(a_1, a_2,…, a_n) ≤ Max$\{a_i\}$. It is idempotent because if $a_i = a$, for all a_i, then, POWA(a_1, a_2,…, a_n) = a.
Another interesting issue to analyze are the measures for characterizing the weighting vector W. Following a similar methodology as it has been developed for the OWA operator [7,13] we can formulate the attitudinal character, the entropy of dispersion, the divergence of W and the balance operator. Note that these measures affect the weighting vector W but not the probabilities because they are given as some kind of objective information.

4 Families of POWA operators

First of all we are going to consider the two main cases of the POWA operator that are found by analyzing the coefficient β. Basically, if $\beta = 0$, then, we get the probabilistic approach and if $\beta = 1$, the OWA operator.
By choosing a different manifestation of the weighting vector in the POWA operator, we are able to obtain different types of aggregation operators. For example, we can obtain the probabilistic maximum, the probabilistic minimum, the probabilistic average and the probabilistic weighted average.

Remark 1. The probabilistic maximum is found when $w_1 = 1$ and $w_j = 0$ for all $j \neq 1$. The probabilistic minimum is formed when $w_n = 1$ and $w_j = 0$ for all $j \neq n$.

Remark 2. More generally, the step-POWA is formed when $w_k = 1$ and $w_j = 0$ for all $j \neq k$. Note that if $k = 1$, the step-POWA is transformed to the probabilistic maximum, and if $k = n$, the step-POWA becomes the probabilistic minimum operator.

Remark 3. The probabilistic average is obtained when $w_j = 1/n$ for all j, and the probabilistic weighted average is obtained when the ordered position of i is the same as the ordered position of j.

Remark 4. For the median-POWA, if n is odd we assign $w_{(n+1)/2} = 1$ and $w_{j^*} = 0$ for all others. If n is even we assign for example, $w_{n/2} = w_{(n/2)+1} = 0.5$ and $w_{j^*} = 0$ for all others.

Remark 5. For the weighted median-POWA, we select the argument b_k that has the kth largest argument such that the sum of the weights from 1 to k is equal or higher than 0.5 and the sum of the weights from 1 to $k - 1$ is less than 0.5.

Remark 6. The olympic-POWA is generated when $w_1 = w_n = 0$, and for all others $w_{j^*} = 1/(n - 2)$. Note that it is possible

ISBN: 978-989-95079-6-8

to develop a general form of the olympic-POWA by considering that $w_j = 0$ for $j = 1, 2, \ldots, k, n, n-1, \ldots, n-k+1$, and for all others $w_{j^*} = 1/(n-2k)$, where $k < n/2$. Note that if $k = 1$, then this general form becomes the usual olympic-POWA. If $k = (n-1)/2$, then this general form becomes the median-POWA aggregation. That is, if n is odd, we assign $w_{(n+1)/2} = 1$, and $w_{j^*} = 0$ for all other values. If n is even, we assign, for example, $w_{n/2} = w_{(n/2)+1} = 0.5$ and $w_{j^*} = 0$ for all other values.

Remark 7. Note that it is also possible to develop the contrary case, that is, the general olympic-POWA operator. In this case, $w_j = (1/2k)$ for $j = 1, 2, \ldots, k, n, n-1, \ldots, n-k+1$, and $w_j = 0$, for all other values, where $k < n/2$. Note that if $k = 1$, then we obtain the contrary case for the median-POWA.

Remark 8. Another interesting family is the S-POWA operator. It can be subdivided into three classes: the "or-like," the "and-like" and the generalized S-POWA operators. The generalized S-POWA operator is obtained if $w_1 = (1/n)(1-(\alpha+\beta)) + \alpha$, $w_n = (1/n)(1-(\alpha+\beta)) + \beta$, and $w_j = (1/n)(1-(\alpha+\beta))$ for $j = 2$ to $n-1$, where $\alpha, \beta \in [0, 1]$ and $\alpha + \beta \leq 1$. Note that if $\alpha = 0$, the generalized S-POWA operator becomes the "and-like" S-POWA operator, and if $\beta = 0$, it becomes the "or-like" S-POWA operator.

Remark 9. Another family of aggregation operator that could be used is the centered-POWA operator. We can define a POWA operator as a centered aggregation operator if it is symmetric, strongly decaying and inclusive. Note that these properties have to be accomplished for the weighting vector W of the OWA operator but not necessarily for the weighting vector P of the probabilities. It is symmetric if $w_j = w_{j+n-1}$. It is strongly decaying when $i < j \leq (n+1)/2$ then $w_i < w_j$ and when $i > j \geq (n+1)/2$ then $w_i < w_j$. It is inclusive if $w_j > 0$. Note that it is possible to consider a softening of the second condition by using $w_i \leq w_j$ instead of $w_i < w_j$. We shall refer to this as softly decaying centered-POWA operator. Another particular situation of the centered-POWA operator appears if we remove the third condition. We shall refer to it as a non-inclusive centered-POWA operator.

Remark 10. Another type of aggregation that could be used is the E-Z POWA weights. In this case, we should distinguish between two classes. In the first class, we assign $w_{j^*} = (1/q)$ for $j^* = 1$ to q and $w_{j^*} = 0$ for $j^* > q$, and in the second class, we assign $w_{j^*} = 0$ for $j^* = 1$ to $n-q$ and $w_{j^*} = (1/q)$ for $j^* = n-q+1$ to n.

Remark 11. A further interesting type is the non-monotonic-POWA operator. It is obtained when at least one of the weights w_j is lower than 0 and $\sum_{j=1}^{n} w_j = 1$. Note that a key aspect of this operator is that it does not always achieve monotonicity. Therefore, strictly speaking, this particular case is not a POWA operator. However, we can see it as a particular family of operators that is not monotonic but nevertheless resembles a POWA operator.

Remark 12. Note that other families of POWA operators could be used following the recent literature about different methods for obtaining OWA weights. Some of these methods are explained in [1,7,9,15,18].

5 Decision making with the POWA operator in investment selection

The POWA operator is applicable in a wide range of situations where it is possible to use probabilistic information and OWA operators. Therefore, we see that the applicability is incredibly broad because all the previous models, theories, etc., that uses the probability can be extended by using the POWA operator. The reason is that all the problems with probabilities deal with uncertainty. Usually, in most of the problems it is assumed a neutral attitudinal character against the probabilistic information but we are still under uncertainty. Thus, sometimes we may prefer to be more or less optimistic against the probabilistic information. Note that this problem can be proved by looking to utility theory. In this theory, people prefer more safety results independently that the expected results (obtained with probabilities) give better results to a more risky alternative. For example, people prefer 100.000 euros with probability 1 instead of 90% probability of obtaining 1.000.000 euros and 10% probability of obtaining 0 euros. If we calculate the expected result (with probabilities) we get that the first alternative gives 100.000 euros and the second one 900.000 euros. However, most of the people will prefer the first alternative because there is no risk involved. This problem has been solved by the economists by using utility theory but as we can see, the use of the POWA operator is also useful for solving this type of problems.

Summarizing some of the main fields where it is possible to apply the POWA operator, we can mention:

- Statistics (especially in probability theory).
- Mathematics
- Economics
- Decision theory
- Engineering
- Physics
- Etc.

In this paper, we focus on an application in decision making about selection of investments. The main reason for using the POWA operator is that we are able to assess the decision making problem considering probabilities and the attitudinal character of the decision maker. Thus, we get a more complete representation of the decision problem.

In the following, we present a numerical example of the new approach in investment selection. We analyze a company that operates in Europe and North America that wants to invest some money in a new market. They consider five alternatives.

ISBN: 978-989-95079-6-8

- A_1 = Invest in the Asian market.
- A_2 = Invest in the South American market.
- A_3 = Invest in the African market.
- A_4 = Invest in all three markets.
- A_5 = Do not invest money in any market.

In order to evaluate these investments, the investor has brought together a group of experts. This group considers that the key factor is the economic situation of the world economy for the next period. They consider 5 possible states of nature that could happen in the future: S_1 = Very bad economic situation, S_2 = Bad economic situation, S_3 = Regular economic situation, S_4 = Good economic situation, S_5 = Very good economic situation.
The results of the available investments, depending on the state of nature S_i and the alternative A_k that the decision maker chooses, are shown in Table 1.

Table 1: Available investment alternatives

	S_1	S_2	S_3	S_4	S_5
A_1	20	40	60	70	80
A_2	50	70	90	40	20
A_3	30	40	50	80	60
A_4	40	40	50	60	70
A_5	80	60	50	40	30

In this problem, the experts assume the following weighting vector: W = (0.3, 0.2, 0.2, 0.2, 0.1). They assume that the probability that each state of nature will happen is: P = (0.1, 0.3, 0.3, 0.2, 0.1). Note that the OWA operator has an importance of 40% and the probabilistic information an importance of 60%. With this information, we can calculate how the attitudinal character of the decision maker may affect the probabilistic information. For doing so, we will use (3) to calculate the "attitudinal probabilities". The results are shown in Table 2.

Table 2: Attitudinal probabilities

	$\hat{v}_1$	$\hat{v}_2$	$\hat{v}_3$	$\hat{v}_4$	$\hat{v}_5$
A_1	0.18	0.2	0.26	0.26	0.1
A_2	0.3	0.26	0.14	0.2	0.1
A_3	0.24	0.14	0.26	0.26	0.1
A_4	0.18	0.2	0.26	0.26	0.1
A_5	0.18	0.26	0.26	0.2	0.1

With this information, we can aggregate the expected results for each state of nature in order to make a decision. In Table 3, we present different results obtained by using different types of IOWAAC operators.

Table 3: Aggregated results

	Prob.	OWA	PAM	POWA
A_1	54	60	54	56.4
A_2	63	61	59.4	62.2
A_3	52	57	52	54
A_4	50	55	50.8	52
A_5	52	57	52	54

Note that we can also obtain these results by using (4). Then, we will calculate separately the OWA and the probabilistic approach as shown in Table 4.

Table 4: First aggregation process

	Prob.	AM	OWA
A_1	54	54	60
A_2	63	54	61
A_3	52	52	57
A_4	50	52	55
A_5	52	52	57

After that, we will aggregate both models in the same process considering that the OWA model has a degree of importance of 40% and the probabilistic information 60% as shown in Table 5.

Table 5: Final aggregated results

	Prob.	OWA	PAM	POWA
A_1	54	60	54	56.4
A_2	63	61	59.4	62.2
A_3	52	57	52	54
A_4	50	55	50.8	52
A_5	52	57	52	54

Obviously, we get the same results with both methods. If we establish an ordering of the alternatives, a typical situation if we want to consider more than one alternative, then, we get the results shown in Table 6. Note that the first alternative in each ordering is the optimal choice.

Table 6: Ordering of the investments

	Ordering
Probabilistic	$A_2 \succ A_1 \succ A_3 = A_5 \succ A_4$
OWA	$A_2 \succ A_1 \succ A_3 = A_5 \succ A_4$
PAM	$A_2 \succ A_1 \succ A_3 = A_5 \succ A_4$
POWA	$A_2 \succ A_1 \succ A_3 = A_5 \succ A_4$

As we can see, depending on the aggregation operator used, the ordering of the investments may be different. Therefore, the decision about which investment select may be also different. Note that in this example, we get the same results for all the cases but in other problems or other types of aggregation operators we may find different results and decisions.

6 Conclusions

We have presented an approach for decision making with probabilities and OWA operators. We have developed a new aggregation operator that unifies the probabilities with the OWA operators. We have called it the POWA operator. The main advantage is that it gives a more complete representation of the decision problem because we are taking into account the probabilistic information and the attitudinal character of the decision maker. We have studied this new formulation and we have seen that it includes decision making problems under risk environment and under uncertainty as particular cases. We have studied some of its main properties and different families of POWA operators.

ISBN: 978-989-95079-6-8

We have also studied the applicability of the POWA operator and we have seen that there are a lot of potential applications that can be developed because in almost all the studies where it appears the probabilities, it is possible to extend the analysis by using the POWA operator. The reason is that the probabilistic information is always affected by the uncertainty. Therefore, it is always possible to consider the attitudinal character of the decision maker by using the OWA operator. We have focused on a decision making problem about selection of investments. We have seen the usefulness of using the POWA operator because we are able to consider probabilities and OWAs at the same time.

In future research, we expect to develop further extensions to this approach by adding new characteristics in the problem such as the use of order inducing variables, uncertain information (interval numbers, fuzzy numbers, linguistic variables, etc.), generalized and quasi-arithmetic means and distance measures. We will also extend this approach to situations where we use the WA instead of probabilities and further developments that have been initially developed in [7]. We will also consider different applications giving special attention to business decision making problems such as strategic and product management.

Abstract— *We present in this paper some properties of k-Lipschitz quasi-arithmetic means. The Lipschitz aggregation operations are stable with respect to input inaccuracies, what is a very important property for applications. Moreover, we provide sufficient conditions to determine when a quasi–arithemetic mean holds the k-Lipschitz property and allow us to calculate the Lipschitz constant k.*

Keywords— k-Lipschitz aggregation functions, quasi-arithmetic means, stability, triangular norms.

1 Introduction

Aggregation of several input values into a single output value is an indispensable tool in many disciplines and applications such as decision making [1], pattern recognition, expert and decision support systems, information retrieval, etc [2]. There is a wide range of aggregation functions which provide flexibility to the modeling process, including different types of aggregation functions. There are several recent books that provide details of many aggregation methods [3, 4, 5, 6, 7].

For applications it is important to design aggregation functions that are stable with respect to small perturbations of inputs (e.g., due to input inaccuracies). Such aggregation functions need not only be continuous, but Lipschitz continuous [8]. Kernel and 1-Lipschitz aggregation functions have been studied in [9, 10, 11]. It is known, for instance, that 1-Lipschitz triangular norms are copulas [12, 3, 7]. More recently, k-Lipschitz t-norms and t-conorms were studied [13, 14, 15]. k-Lipschitz t-norms do not increase the perturbation of inputs by more than a factor of k, which is suitable for many applications.

There are many other generated functions constructed similarly to the Archimedean triangular norms with the help of additive generators. In this article we examine quasi-arithmetic means and establish conditions under which these functions are Lipschitz or not Lipschitz.

Firstly, in Section 2 we recall some basic notions to develop the rest of the work. Section 3 contains the main results involving quasi–arithmetic means. At the end we provide some conclusions.

2 Preliminaries and related works

We restrict ourselves to aggregation functions defined on $[0,1]^n$.

Definition 1 *A function $f : [0,1]^n \to [0,1]$ is called an aggregation function if it is monotone non-decreasing in each variable and satisfies $f(0,\ldots,0) = 0$, $f(1,\ldots,1) = 1$.*

Now, we will pay attention to a special class of aggregation function, -the class of weighted quasi–arithmetic means-, for this we need to consider a continuous strictly monotone function $g : [0,1] \to [-\infty,\infty]$, which we call a *generating function* or generator. Of course, g is invertible, but it is not necessarily a bijection (i.e., its range may be $Ran(g) \subset [-\infty,\infty]$). Other two examples of generated functions are Archimedean t-norms and t-conorms. Further there exists a class of uninorms, known as *representable uninorms* or *generated uninorms*, that can also be built by means of additive generators. Further, a vector $\vec{w} = (w_1,\ldots,w_n)$ is called a weighting vector if $w_i \in [0,1]$ and $\sum_{i=1}^{n} w_i = 1$.

Definition 2 *For a given generating function g, and a weighting vector $\vec{w}$, the weighted quasi-arithmetic mean is the function*

$$M_{\vec{w},g}(\vec{x}) = g^{-1}\left(\sum_{i=1}^{n} w_i g(x_i)\right). \qquad (1)$$

From this definition, we have the following particular quasi–arithmetic means:

Arithmetic mean	$M(\vec{x}) = \frac{1}{n}\sum_{i=1}^{n} x_i$
Geometric mean	$G(\vec{x}) = (\prod_{i=1}^{n} x_i)^{\frac{1}{n}}$
Harmonic mean	$H(\vec{x}) = n(\sum_{i=1}^{n} \frac{1}{x_i})^{-1}$
Power mean	$M_r(\vec{x}) = \frac{1}{n}(\sum_{i=1}^{n} x_i^r)^{\frac{1}{r}}$, if $r \neq 0$ and $M_0(\vec{x}) = G(\vec{x})$.

Another class of aggregation operators is the following

Definition 3 *Let $g : [0,1] \to [-\infty,\infty]$ be a continuous strictly monotone function and let $\vec{w}$ be a weighting vector. The function*

$$GenOWA_{\vec{w},g}(\vec{x}) = g^{-1}\left(\sum_{i=1}^{n} w_i g(x_{(i)})\right) \qquad (2)$$

is called a generalized OWA (also known as ordered weighted quasi-arithmetic mean [4]). As for OWA, $x_{(i)}$ denotes the i-th largest value of $\vec{x}$.

Another aggregation operator that include the previous one for the case of a symmetric fuzzy measure is the generalized discrete Choquet integral which is defined as follows

ISBN: 978-989-95079-6-8

Definition 4 *Let $g : [0,1] \to [-\infty,\infty]$ be a continuous strictly monotone function. The generalized Choquet integral with respect to a fuzzy measure v is the function*

$$C_{v,g}(\vec{x}) = g^{-1}\left(C_v(g(\vec{x}))\right),$$

where C_v is the discrete Choquet integral with respect to v and $g(\vec{x}) = (g(x_1),\ldots,g(x_n))$.

Now, we consider the crucial concept of this work

Definition 5 *An aggregation function f is called Lipschitz continuous if there is a positive number k, such that for any two vectors $\vec{x},\vec{y}$ in the domain of definition of f:*

$$|f(\vec{x}) - f(\vec{y})| \leq kd(\vec{x},\vec{y}), \tag{3}$$

where $d(\vec{x},\vec{y})$ is a distance between $\vec{x}$ and $\vec{y}$. The smallest such number k is called the Lipschitz constant of f (in the distance d). We shall call such functions k-Lipschitz.

Typically the distance is chosen as a p-norm $d(\vec{x},\vec{y}) = ||\vec{x}-\vec{y}||_p$, with $||\vec{x}||_p = \left(\sum_{i=1}^{n}|x_i|^p\right)^{1/p}$, for finite p, and $||\vec{x}||_\infty = \max_{i=1,\ldots,n}|x_i|$. In this work we concentrate on the 1–norm.

Definition 6 *A function f is called locally Lipschitz continuous on Ω if for every $x \in \Omega$ there exists a neighbourhood $D(x)$ such that f restricted to $D(x)$ is Lipschitz.*

Of course, duality w.r.t. standard negation preserves Lipschitz property (and the Lipschitz constant). It is easy to see that if an aggregation function A is k–Lipschitz, it is also m–Lipschitz for any $m \geq k$. Also any convex combination of $k-$Lipschitz aggregation functions $f = \alpha f_1 + \beta f_2$, $\alpha+\beta = 1, \alpha,\beta \geq 0$, is $k-$Lipschitz.

The class of k–Lipschitz t–norms, whenever $k > 1$, has been already characterized (see [13]). Note that 1–Lipschitz t–norms are copulas, see, e.g., [3, 5]. A strictly decreasing continuous function $g : [0,1] \to [0,1]$ with $g(1) = 0$ is an additive generator of a 1–Lipschitz Archimedean t–norm if and only if g is convex.

The k–Lipschitz property implies continuity of the t–norm. Recall that a continuous t–norm can be represented by means of an ordinal sum of continuous Archimedean t–norms, and that a continuous Archimedean t–norm can be represented by means of a continuous additive generator [3, 16]. Characterization of all k–Lipschitz t–norms can be reduced to the problem of characterization of all Archimedean k–Lipschitz t–norms.

Definition 7 *Let $g : [0,1] \to [0,+\infty]$ be a strictly monotone function and let $k \in]0,+\infty[$ be a real constant. Then g will be called k–convex if*

$$g(x+k\varepsilon) - g(x) \leq g(y+\varepsilon) - g(y)$$

holds for all $x \in [0,1[, y \in]0,1[$, with $x \leq y$ and $\varepsilon \in]0, \min(1-y, \frac{1-x}{k})]$.

Obviously, if $k = 1$ the function g is convex.

Observe that, a k–convex monotone function is also continuous in $]0,1[$, as was earlier. A decreasing function g can be k–convex only for $k \geq 1$. Moreover, when a decreasing function g is k–convex, it is also m–convex for all $m \geq k$. In the case of a strictly increasing function $g^\star$, it can be k-convex only for $k \leq 1$. Moreover, when $g^\star$ is k–convex, it is m–convex for all $m \leq k$.

Considering $k \geq 1$ and a strictly decreasing function g, we provide the following characterization given in [13].

Proposition 1 *Let $T : [0,1]^2 \to [0,1]$ be an Archimedean t–norm and let $g : [0,1] \to [0,+\infty], g(1) = 0$ be an additive generator of T. Then T is k–Lipschitz if and only if g is k–convex.*

Another useful characterizations are the following

Corollary 1 *(Y.-H. Shyu) [17] Let $g : [0,1] \to [0,\infty]$ be an additive generator of a t–norm T which is differentiable on $]0,1[$ and let $g'(x) < 0$ for $0 < x < 1$. Then T is k–Lipschitz if and only if $g'(y) \geq kg'(x)$ whenever $0 < x < y < 1$.*

Corollary 2 *Let $T : [0,1]^2 \to [0,1]$ be an Archimedean t–norm and let $g : [0,1] \to [0,\infty]$ be an additive generator of T such that g is differentiable on $]0,1[\backslash S$, where $S \subset [0,1]$ is a discrete set. Then T is k–Lipschitz if and only if $kg'(x) \leq g'(y)$ for all $x,y \in [0,1], x \leq y$ such that $g'(x)$ and $g'(y)$ exist.*

The following useful results follow from Corollary 1, with it we can determine whether a given piecewise differentiable t–norm is k–Lipschitz.

Corollary 3 *Let $T : [0,1]^2 \to [0,1]$ be an Archimedean t–norm and let $g : [0,1] \to [0,\infty]$ be its additive generator differentiable on $]0,1[$, and $g'(t) < 0$ on $]0,1[$. If*

$$\inf_{t\in]x,1[} g'(t) \geq k \sup_{t\in]0,x[} g'(t)$$

holds for every $x \in]0,1[$ then T is k–Lipschitz.

Corollary 4 *Let $g : [0,1] \to [0,\infty]$ be a strictly decreasing function, differentiable on $]0,a[\cup]a,1[$. If g is k-convex on $[0,a[$ and on $]a,1]$, and if*

$$\inf_{t\in]a,1[} g'(t) \geq k \sup_{t\in]0,a[} g'(t),$$

then g is k–convex on $[0,1]$.

Remark 1 *Generated uninorms are not k–Lipschitz since that they are not continuous at (0,1) and (1,0) (in the binary case). Nullnorms are aggregation functions related to t–norms and t–conorms. In this case, it is clear that a nullnorm V is k–Lipschitz if and only if the underlying t-norm and t–conorm are k–Lipschitz, and the k–Lipschitz constant of V is the maximum of Lipschitz constants of the underlying t–norm and t–conorm.*

3 Quasi-arithmetic means

Consider a univariate continuous strictly monotone function $g : [0,1] \to [-\infty, \infty]$, called generator.

For a given g, the quasi-arithmetic means are defined in Definition 2, and are denoted by M_g. We start with bivariate quasi-arithmetic means of such operations. Quasi-arithmetic means are continuous if and only if $Ran(g) \neq [-\infty, \infty]$ [18]. Moreover, its generator is not defined uniquely, i.e., if $g(t)$ is a generating function of some weighted quasi-arithmetic mean, then $ag(t) + b$, $a, b \in \Re$, $a \neq 0$ is also a generating function of the same mean provided $Ran(g) \neq [-\infty, \infty]$. For this reason, one can assume that g is monotone increasing, as otherwise we can simply take $-g$.

We shall consider two cases: I) $g(0) = 0$, $g(1) = 1$, and II) $g(0) = -\infty, g(1) = 0$. Of course, by duality we also cover the case $g(1) = \infty, g(0) = 0$, and by using appropriate linear transformations, all generators can be reduced to the mentioned cases.

Let us make some preliminary remarks on convexity. As opposed to the case of convex additive generators of t-norms, where the resulting t-norms are 1-Lipschitz, convexity of the generator g does not play any role by itself for quasi-arithmetic means. Since both g and $-g$ are generators of the same mean, and obviously when g is convex $-g$ is concave, convexity of g by itself does not lead to the Lipschitz condition. Also note that $g(x) = -\ln(x)$ is a convex generator of the geometric mean $G(x, y) = \sqrt{xy}$, which is not Lipschitz. Further, even if g is convex and increasing or convex and decreasing, this does not imply Lipschitz condition either: note that $g_d(x) = 1 - g(1 - x)$ is a generator of a quasi-arithmetic mean dual to the one generated by g, and Lipschitz condition is preserved under duality. If g is convex increasing, then g_d is convex decreasing and vice versa. Thus we will look for a different condition.

3.1 Case of finite generators

We start with the case I) of g finite. First, let us show that g must be Lipschitz on [0,1]. For short, we will denote $M_{\vec{w},g}$ by M_g.

Lemma 1 *Let g be finite locally Lipschitz and continuously differentiable except at a point $a \in [0;1]$. Then M_g is not k–Lipschitz for any k.*

Proof. Suppose that M_g is k-Lipschitz, which means it is differentiable almost everywhere in its domain (Rademacher's theorem), and we must have

$$\frac{\partial M_g}{\partial x}(x, y) \leq k, \ x, y \neq a$$

whenever such a derivative exists, and similarly for the other partial derivative. Since M_g is symmetric, only the derivative with respect to x is needed.

$$\frac{\partial M_g}{\partial x} = \frac{1}{g'\left(M_g(x, y)\right)} \cdot \frac{1}{2} g'(x) \leq k.$$

Since g is strictly increasing we must have

$\frac{1}{2} g'(x) \leq k g'(M_g(x, y))$ for all $x, y \in [0, 1]$ such that $x \neq a$ and $M_g(x, y) \neq a$ or

$$\frac{1}{2} g'(x) \leq k \cdot \inf_{y \in [0,1]} g'(M_g(x, y)). \tag{4}$$

Since g is finite, M_g does not have an absorbing element. Let $\lim_{x \to a} g'(x) = \infty$.

$\exists y \neq a : z = M_g(a, y) \neq a$ such that $g'(z) \leq M < \infty$ (because g is locally Lipschitz). Then inequality (4) fails, because we can always choose such $x \neq a$ that $g'(x) > 2kM$, which would give us

$$kM < \frac{1}{2} g'(x) \leq k g'(z) \leq kM,$$

which is false. Then $\frac{\partial M_g}{\partial x} > k$, hence M_g is not Lipschitz. □

Now, since g is Lipschitz on $[0, 1]$, it is differentiable almost everywhere, which means that the left- and right-derivatives exist in $[0, 1]$. We start with the case of g differentiable on $[0, 1]$, and then adapt it to g differentiable almost everywhere by using left- and right-derivatives. Let M_g be k-Lipschitz. Then we must have

$$\frac{\partial M_g}{\partial x}(x, y) \leq k.$$

Following the same procedure as in Lemma 1, we get the condition

$$\frac{1}{2} g'(x) \leq k \cdot \inf_{y \in [0,1]} g'(M_g(x, y)) \tag{5}$$

for all $x \in [0, 1]$. Finally, by using left- and right- derivatives g'_-, g'_+ we obtain a general condition for non-smooth increasing generators

$$\begin{aligned} \frac{1}{2} g'_-(x) &\leq k \inf_{z \in [M(x,0), M(x,1)]} g'_-(z) \\ \frac{1}{2} g'_+(x) &\leq k \inf_{z \in [M(x,0), M(x,1)]} g'_+(z) \end{aligned} \tag{6}$$

for all $x \in]0, 1[$, and only one of the above inequalities for $x = 0$ and $x = 1$.

Remark 2 *If g is finite and concave increasing, then it is sufficient to check*

$$\frac{1}{2} g'(x) \leq k g'(M(x, 1)) = k(g' \circ g^{-1}) \left(\frac{g(x)}{2} + \frac{1}{2} \right),$$

(and similarly for left- and right-derivatives if g is not smooth). If g is finite and convex increasing, it is sufficient to check

$$\frac{1}{2} g'(x) \leq k g'(M(x, 0)) = k(g' \circ g^{-1}) \left(\frac{g(x)}{2} \right).$$

Let us provide some examples of Lipschitz and non-Lipschitz quasi-arithmetic means.

Example 1 *If g is linear (M_g is the arithmetic mean), $g'(x) = const$, and M_g is k-Lipschitz for $k = \frac{1}{2}$.*

Example 2 *If $g(x) = x^p, p > 1$ (M_g is a power mean $M_{[p]}$), $g'(x) = px^{p-1}$, and M_g is k-Lipschitz for $k = \left(\frac{1}{2}\right)^{\frac{1}{p}}$. It follows from*

$$\frac{1}{2} p x^{p-1} \leq kp \left(\frac{x^p}{2} \right)^{\frac{p-1}{p}} = kp x^{p-1} \left(\frac{1}{2} \right)^{\frac{p-1}{p}}.$$

Example 3 *If $g(x) = x^p, 0 < p < 1$ (M_g is a power mean $M_{[p]}$), M_g is not Lipschitz by Lemma 1.*

ISBN: 978-989-95079-6-8

3.2 Case of generators infinite at 0

Now we turn to the case II), g increasing with $g(0) = -\infty$, which entails that 0 is the absorbing element of M_g. We have an analogue of Lemma 1. The proof is similar, except that it fails for $a = 0$, hence the modification.

Let g be finite locally Lipschitz and continuously differentiable except at a point a 2 [0; 1]. Then Mg is not kLipschitz for any k

Lemma 2 *Let g be locally Lipschitz and continuously differentiable except at a point $a \in]0,1]$. Then M_g is not k-Lipschitz for any k.*

Let g be finite locally Lipschitz and continuously differentiable except at a point $a \in [0;1]$.

For $x \in]0,1]$ we have condition (6), to which we add condition

$$\frac{1}{2} \lim_{x \to 0^+} \frac{g'_+(x)}{g'_+(M(x,y))} \leq k \tag{7}$$

for any fixed $y \in]0,1]$. This condition may or may not be satisfied depending on the rate at which $M(x,y) \to 0$ as $x \to 0$. The choice of $y > 0$ is irrelevant as $g(y)$ is finite and disappears under the limit.

Example 4 *If $g(x) = -x^p, p < -1$ (M_g is a power mean $M_{[p]}$), $g'(x) = -px^{p-1}$, and M_g is k-Lipschitz for $k = \left(\frac{1}{2}\right)^{\frac{1}{p}}$. Differentiating M_g*

$$\begin{aligned}
\tfrac{\partial M_g}{\partial x} &= \tfrac{1}{p}\left(\tfrac{x^p+y^p}{2}\right)^{\frac{1}{p}-1} \tfrac{p}{2}x^{p-1} \\
&= \left(\tfrac{1}{2}\right)^{\frac{1}{p}} x^{-p(\frac{1}{p}-1)}(x^p+y^p)^{\frac{1}{p}-1} \\
&= \left(\tfrac{1}{2}\right)^{\frac{1}{p}} (1+x^{-p}y^p)^{\frac{1}{p}-1}.
\end{aligned}$$

Given $p < -1$,

$$k = \left(\tfrac{1}{2}\right)^{\frac{1}{p}} \lim_{x\to 0} (1+x^{-p}y^p)^{\frac{1}{p}-1} = \left(\tfrac{1}{2}\right)^{\frac{1}{p}}.$$

Example 5 *Let $M_{[p]}$, $-1 < p < 0$ be a power mean with a generator given by $g(x) = -x^p = -x^{-\frac{1}{q}}$, $q > 1$). The Lipschitz constant will be $k = \sup \frac{\partial M}{\partial x} = 2^q$. To see this*

$$\begin{aligned}
\tfrac{\partial M_g}{\partial x} &= \tfrac{-q}{2}\left(\tfrac{x^{-\frac{1}{q}}+y^{-\frac{1}{q}}}{2}\right)^{-q-1} \cdot \left(-\tfrac{1}{q}x^{-\frac{1}{q}-1}\right) \\
&= 2^q x^{\frac{1}{q}(-q-1)}(x^{-\frac{1}{q}}+y^{-\frac{1}{q}})^{-q-1} \\
&= 2^q\left(1+\left(\tfrac{x}{y}\right)^{\frac{1}{q}}\right)^{-q-1}. \\
k &= \sup\left\{2^q\left(1+\left(\tfrac{x}{y}\right)^{\frac{1}{q}}\right)^{-q-1}\right\} \\
&= 2^q = (\tfrac{1}{2})^{\frac{1}{p}}.
\end{aligned}$$

Condition 7 deals with the asymptotic behavior of the additive generators near 0. Its direct verification for a given g may be difficult. In the remainder of this section we will establish two sufficient conditions that guarantee that a quasi-arithmetic mean is not Lipschitz (although it is continuous). These conditions are easier to verify, and they provide a tool for a quick screening of additive generators with respect to their suitability for applications. One sufficient condition involves an inequality on the derivatives of the inverse of an additive generator. The other condition is that a decreasing additive generator cannot decrease slower than a certain rate (1/polynomial) when $x \to 0$. We will express this rate through the growth of an auxiliary function $1/g^{-1}$, for which the growth is expressed in traditional terms (e.g., polynomial) when $x \to \infty$. First, two simple auxiliary results.

Lemma 3 *If two functions f, g are continuous and differentiable at $x = 0$ and, $f(0) = g(0)$ and $f(x) \geq g(x)$ for $x > 0$, then $f'(0) \geq g'(0)$.*

Proof: Follows directly from the definition of the derivative.

The next result is a well-known condition for comparability of quasi-arithmetic means, see, e.g., [19].

Theorem 1 *Let g_1, g_2 be the generators of quasi-arithmetic means M_{g_1} and M_{g_2},and g_1 decreasing. Then $M_{g_1} \leq M_{g_2}$ if and only if $g_1 \circ g_2^{-1}$ is convex.*

Theorem 2 *Let g be an increasing (decreasing) twice continuously differentiable on $]0,1]$ generator of a quasi-arithmetic mean M_g where $g^{-1} = h$, and $\lim_{x\to 0} g(x) = -\infty$ ($\lim_{x\to 0} g(x) = +\infty$). If $h'^2 - hh'' \geq 0$ then M_g is not Lipschitz.*

Proof. We will show that $M_{[p]} \leq M_g$ for any $-1 < p < 0$ decreasing, and hence by Lemma 3 is not Lipschitz. If $x^p \circ g^{-1}$ is convex, for $-1 < p < 0$ by Theorem 1, with $g_1(x) = x^p$, $M_{[p]} \leq M_g$. Let us show that $(x^p \circ h)'' \geq 0$.

$$\begin{aligned}
(x^p \circ h)' &= ph^{p-1}h' \\
(x^p \circ h)'' &= p(p-1)h^{p-2}h'^2 + ph^{p-1}h'' \\
&= ph^{p-2}\left((p-1)h'^2 + hh''\right) \geq 0.
\end{aligned}$$

Given $ph^{p-2} < 0$ for $p < 0, h > 0$, convexity will hold if for all $p < 0$

$$(1-p)h'^2 - hh'' \geq 0. \tag{8}$$

Therefore $h'^2 - hh'' \geq 0$ implies $(x^p \circ h)'' \geq 0$ and $M_{[p]} \leq M_g$, and by Lemma 3 the Lipschitz constant of M_g is greater than that of $M_{[p]}$, which is $2^{-\frac{1}{p}}$, and $p \to 0^-$. □

Remark 3 *The generator g can be either increasing or decreasing. Clearly when changing g to $-g$, we change $h(x)$ to $h(-x)$. Then $h^{'}$ changes the sign but $h^{''}$ does not, hence the inequality in Theorem 2is the same for either increasing or decreasing generators.*

Example 6 *Using the geometric mean M_g, take $g(x) = \ln x$ with $h(x) = h^{'}(x) = h^{''}(x) = e^x$. Then $(h'^2 - hh'')(x) = e^{2x} - e^{2x} = 0$. Therefore M_g is not Lipschitz.*

For the sake of convenience, we will formulate our next result for decreasing additive generators satisfying $g(0) = \infty$. To obtain the respective condition on the increasing generators, we simply invert the sign of g.

Theorem 3 *Let $h = g^{-1}$ be the inverse of a decreasing generator g of a quasi-arithmetic mean M_g. If the function $\tilde{h} = \frac{1}{h}$ grows faster than any power $x^q, q > 0$, then M_g is not Lipschitz.*

ISBN: 978-989-95079-6-8

Proof. Fix y so that $g(y) = h^{-1}(y) = 0$, which is always possible (we remind that g is defined up to an arbitrary linear transformation).

$$\begin{aligned}\lim_{x\to 0}\frac{\partial M_g(x,y)}{\partial x} &= \lim_{x\to 0}\frac{dh\left(\frac{h^{-1}(x)}{2}\right)}{dx},\\ &= \lim_{x\to 0}\tfrac{1}{2}h'\left(\frac{h^{-1}(x)}{2}\right)(h^{-1})'(x)\\ &= \tfrac{1}{2}\lim_{x\to 0}h'\left(\frac{h^{-1}(x)}{2}\right)\tfrac{1}{h'(h^{-1}(x))}.\end{aligned}$$

Let $z = \frac{h^{-1}(x)}{2}$. Then

$$\lim_{x\to 0}\frac{\partial M_g(x,y)}{\partial x} = \frac{1}{2}\lim_{z\to\infty}\frac{h'(z)}{h'(2z)}.$$

Since h decreases faster than the power function $p(z) = Cz^r$, l'Hôpital's rule gives

$$0 = \lim_{z\to\infty}\frac{h(z)}{p(z)} = \lim_{z\to\infty}\frac{h'(z)}{p'(z)} = \lim_{z\to\infty}\frac{h'(2z)}{p'(2z)}.$$

For convenience of notation take p such that $p'(z) = \frac{1}{z^q}$. Then $p'(z) = p'(2z)2^q$.

$$\begin{aligned}\lim_{x\to 0}\frac{\partial M_g(x,y)}{\partial x} &= \tfrac{1}{2}\lim_{z\to\infty}\tfrac{h'(z)}{h'(2z)} = \tfrac{1}{2}\lim_{z\to\infty}\tfrac{h'(z)}{h'(2z)}\tfrac{p'(2z)2^q}{p'(z)}\\ &= 2^{q-1}.\end{aligned}$$

Since q can be arbitrarily large, the derivative is unbounded and M_g is not Lipschitz.

□

Example 7 *Let the generator be $g(x) = -\ln x$ as in Example 6. Clearly its inverse is $\exp(-x)$, and the auxiliary function $\frac{1}{h(x)} = \exp(x)$, which grows faster than any polynomial, hence the corresponding geometric mean is not Lipschitz.*

Further take any power of the logarithm $g(x) = (-\ln x)^r, r > 1$. The auxiliary function $\frac{1}{h(x)} = \exp(x^{\frac{1}{r}})$, it grows faster than a polynomial, hence the resulting mean is not Lipschitz either. Note that this quasi-arithmetic mean is related to the Aczél-Alsina family of t-norms [3, 5] by the equation

$$M_g = (T_r^{AA})^{\frac{1}{\sqrt{2}}},$$

which shows directly that M_g is not Lipschitz ($f(x) = M_g(x,1) = T_r^{AA}(x,1)^{\frac{1}{\sqrt{2}}} = x^{\frac{1}{\sqrt{2}}}$ is not Lipschitz).

Example 8
Consider the generator $g(x) = (-\ln x)^2, \tilde{h}(x) = e^{\sqrt{x}}$. From the previous example, $r = 2$ and we know the resulting mean is not Lipschitz, however this would not have been apparent from the application of Theorem 2, as

$$\begin{aligned}h'^2 - hh'' &= \tfrac{1}{4x}e^{-2\sqrt{x}} - \tfrac{1}{4x}e^{-2\sqrt{x}} - \tfrac{1}{4\sqrt{x^3}}e^{-2\sqrt{x}}\\ &= -\tfrac{1}{4\sqrt{x^3}}e^{-2\sqrt{x}} < 0.\end{aligned}$$

3.3 Weighted quasi-arithmetic means

We adapt conditions (6) and (7) for the case of unequal weights. For this we take partial derivatives with respect to all arguments. The Lipschitz constant is the largest, hence we have conditions

$$\begin{aligned}g'_-(x) &\le \frac{k}{\max w_i}\min_z g'_-(z) \qquad (9)\\ g'_+(x) &\le \frac{k}{\max w_i}\min_z g'_+(z)\end{aligned}$$

where
the minimum for z is over $[M(x,0,\dots,0), M(x,1,\dots,1)]$, and

$$\lim_{x\to 0^+}\frac{g'_+(x)}{g'_+(M(x,c,\dots,c))} \le \frac{k}{\max w_i} \qquad (10)$$

with $c \in]0,1]$.

Conditions (9) and (10) can also be used for symmetric means in the multivariate case, where $\max w_i = \frac{1}{n}$. It is clearly seen that the higher the number of variables, the smaller is the Lipschitz constant, if it exists.

Remark 4 *Similar, results can be obtained for generalized OWAs and generalized Choquet integrals.*

4 Conclusions

k-Lipschitz aggregation functions are important for applications because they can control the changes in the outputs due to input inaccuracies, to a fixed factor of k. k-Lipschitz triangular norms and conorms have been already characterized by k-convex additive generators, however no analogous results were available for quasi-arithmetic means. We have found verifiable conditions which guarantee that an aggregation function is $k-$Lipschitz for a given k, or alternatively, not Lipschitz. We also presented various examples of both Lipschitz and non-Lipschitz aggregation functions. Our results will benefit those who design aggregation functions for practical applications, as they allow one to make an informed choice on suitability of specific functions for these applications.

***Abstract*— *This paper demonstrates that several known sequence kernels can be expressed in a unified framework in which the position specificity is modeled by fuzzy equivalence relations. In addition to this interpretation, we address the practical issues of positive semi-definiteness, computational complexity, and the extraction of interpretable features from the final support vector machine classifier.*

***Keywords*—** fuzzy equivalence relation, kernel, sequence classification, support vector machines.

1 Introduction

The classification of biological sequences — in particular, nucleotide sequences (DNA and RNA) and amino acid sequences (proteins) — is one of the fundamental tasks in computational biology [1]. In the early days of computational biology, sequence statistics were employed. These approaches were later improved by Hidden Markov Models (HMM) and Artificial Neural Networks (ANN). In the last decade, *Support Vector Machines* (SVM) have become increasingly popular for sequence classification [2]. In many tasks — in computational biology, but also in many other domains — SVMs have outperformed all competing methods. It is justified to state that SVMs are nowadays widely considered the most powerful class of classification methods.[1] SVMs have been applied successfully in a wide spectrum of sequence classification tasks, ranging from promoter and splice site detection (both on DNA data) [3, 4, 5] to protein fold and secondary structure prediction (both on amino acid sequences) [6, 7, 8].

SVM classifiers, in their simplest form, are nothing else but linear classifiers. What distinguishes SVMs from other linear classifiers like perceptrons or logistic regressors is the fact that SVMs determine the classification function by maximizing the margin between the classes — a principle that is known to be optimal in terms of bounds on the generalization error [9, 10]. Since linear SVMs use input vectors only to compute scalar products, SVMs facilitate the so-called *kernel trick*, i.e. the replacement of the scalar products by a *kernel*, i.e. a nonlinear two-place function that is positive semi-definite. The use of kernels enables support vector machines to be applicable to almost any kind of data, including raw sequence data, signals, images, or graphs — only an appropriate kernel is needed. It is not surprising, therefore, that the design of appropriate sequence kernels is one of the central research topics in sequence classification with SVMs. Most of these sequence kernels are based on comparing sub-sequences and do not take the positions of these occurrences into account. In many applications, however, the occurrence of a specific sub-sequence is only indicative if it is at a specific position or region.

[1] although one has to admit that there are applications and circumstances/requirements under which other methods may be preferable

This paper repeats established sequence kernels that are based on occurrences of specific patterns along with some position-specific variants. We demonstrate that these kernels can be expressed in a unified framework in which the position specificity is modeled by fuzzy equivalence relations. This framework, on the one hand, allows for an interpretation of existing position-specific sequence kernels from the viewpoint of fuzzy equivalence relations. On the other hand, and more importantly from the practical viewpoint, this framework gives rise to new position-specific sequence kernels by allowing to use fuzzy equivalence relations that have not been considered for modeling position specificity previously.

2 Support vector classification

Suppose that we have to do binary classification of samples from a given arbitrary non-empty set $\mathcal{X}$. The two classes are denoted with $+1$ (positive class) and -1 (negative class). For a given training set

$$\{(x_i, y_i) \mid 1 \leq i \leq l\}$$

with $x_i \in \mathcal{X}$ and $y_i \in \{-1,+1\}$ for all $i = 1,\ldots,l$, the support vector machine classifier is represented as the following discriminant function:

$$f(x) = b + \sum_{i=1}^{l} \alpha_i \cdot y_i \cdot k(x, x_i) \tag{1}$$

In this formula, b is a real value, α_i are non-negative factors, and $k(.,.)$ is the so-called *kernel*, that is, a symmetric $\mathcal{X} \times \mathcal{X} \to \mathbb{R}$ mapping fulfilling *positive semi-definitenes*, i.e.

$$\sum_{i=1}^{n} \sum_{j=1}^{n} z_i \cdot z_j \cdot k(x_i, x_j) \geq 0 \tag{2}$$

for all $n \in \mathbb{N}$, all $(z_1,\ldots,z_n) \in \mathbb{R}^n$, and all $(x_1,\ldots x_n) \in \mathcal{X}^n$. With the notations $\mathbf{z} = (z_1,\ldots,z_n)^T$ and $\mathbf{K} = (k(x_i,x_j))_{i=1,\ldots,n}^{j=1,\ldots,n}$, Eq. (2) can be written as $\mathbf{z}^T\mathbf{K}\mathbf{z} \geq 0$. Hence, the positive semi-definiteness of k corresponds to the positive semi-definiteness of any kernel matrix $\mathbf{K}$.

The factors $\alpha_1,\ldots,\alpha_n$ are the Lagrange multipliers of a convex quadratic optimization problem arising from margin maximization. For details, the reader is referred to introductory tutorials [11, 12] and standard SVM literature [9, 10, 13, 14]. We only note shortly that samples contributing to the final classifier, obviously those x_i for which $\alpha_i > 0$, are called *support vectors*.

The positive semi-definiteness of the kernel k serves for two purposes. First, it ensures that the SVM optimization problem is a convex quadratic one, which ensures the existence

ISBN: 978-989-95079-6-8

of a global solution that can be determined efficiently. More importantly, by the famous *Mercer theorem* [15], it guarantees that there exists a Hilbert space $(\mathcal{H}, \langle .,. \rangle)$ and a mapping $\varphi : \mathcal{X} \to \mathcal{H}$ such that the representation

$$k(x,y) = \langle \varphi(x), \varphi(y) \rangle \tag{3}$$

holds for all $x, y \in \mathcal{X}$. This means that the kernel k can be understood as a scalar product in a feature space $\mathcal{H}$.

3 An overview of sequence kernels

In this paper, we restrict ourselves to sequence kernels that are based on the occurrence of specific patterns. Assume in the following that we have a certain finite alphabet $\mathcal{A}$ and that $\mathcal{X}$ is a set of finite strings over the alphabet $\mathcal{A}$. Further assume that $\mathcal{M}$ is a finite set of patterns. A pattern can either be a string over $\mathcal{A}$ itself (i.e. an *exact pattern*) or contain *wildcards*, i.e. positions that match to an arbitrary symbol or a subset of symbols from the alphabet $\mathcal{A}$. We consider sequence kernels that can be expressed as

$$k(x,y) = \sum_{m \in \mathcal{M}} N(m,x) \cdot N(m,y), \tag{4}$$

where $N(m,x)$ denotes the number of occurrences/matches of pattern m in string x. It is obvious that, according to the representation (3), such a kernel is nothing else but a scalar product in an $|\mathcal{M}|$-dimensional real feature space, where the feature mapping φ is explicitly given as

$$\varphi(x) = (N(m,x))_{m \in \mathcal{M}}. \tag{5}$$

In order to accommodate different matching criteria used in existing sequence kernels, let us express $N(m,x)$ as

$$N(m,x) = \sum_{p=1}^{\text{length}(x)} \mathbf{1}(m,x,p), \tag{6}$$

where $\mathbf{1}(m,x,p)$ is a kernel-specific indicator function whose value is 1 if pattern m matches string x at position p and 0 if not. So, in the framework presented here, a sequence kernels is basically given by its pattern set $\mathcal{M}$ and its match indicator function $\mathbf{1}$. This representation accommodates the following well-known sequence kernels:

Spectrum kernel [6]: $\mathcal{M} = \mathcal{A}^K$, i.e. the set of patterns is the set of all K-length strings; the indicator function is given as[2]

$$\mathbf{1}(m,x,p) = \begin{cases} 1 & \text{if } p+K-1 \leq \text{length}(x) \text{ and} \\ & m = x[p \ldots p+K-1], \\ 0 & \text{otherwise.} \end{cases}$$

In other words, the spectrum kernel maps each of the two sequences to the numbers of occurrences of all strings of length K and computes the scalar product of these two feature vectors.

[2]For a given string x, we define $x[r]$ to be the r-th character in x and $x[r \ldots q]$ to be the substring that starts with the r-th and ends with the q-th position.

Mismatch kernel [7]: this kernel is analogous to the spectrum kernel with the exception that matches are considered up to a maximal number of M mismatches, i.e. $\mathcal{M} = \mathcal{A}^K$ and

$$\mathbf{1}(m,x,p) = \begin{cases} 1 & \text{if } p+K-1 \leq \text{length}(x) \text{ and} \\ & |\{1 \leq r \leq K \mid m[r] \neq x[p+r-1]\}| \leq M, \\ 0 & \text{otherwise.} \end{cases}$$

Motif kernel [16]: $\mathcal{M}$ is a set of predefined patterns known or assumed to be related to the given classification task; the indicator mapping $\mathbf{1}$ is given as follows:[3]

$$\mathbf{1}(m,x,p) = \begin{cases} 1 & \text{if } p+\text{length}(m)-1 \leq \text{length}(x) \text{ and} \\ & m[r] = x[p+r-1] \text{ for all } 1 \leq r \leq \text{length}(m) \\ & \text{such that } m[r] \neq \text{“}*\text{”} \\ 0 & \text{otherwise} \end{cases}$$

Beside these three prominent kernels, also some others comply with the representation (4), e.g. spatial sample kernels [8].

The class of kernels (4) facilitates easy feature extraction, which is not surprising given the fact that the feature mapping φ is known explicitly. Suppose we are given a support vector machine with Lagrange multipliers $\alpha_1, \ldots, \alpha_l$ and an offset b. Then we can make the following rearrangements:

$$\begin{aligned} f(x) &= b + \sum_{i=1}^{l} \alpha_i \cdot y_i \cdot k(x,x_i) \\ &= b + \sum_{i=1}^{l} \alpha_i \cdot y_i \cdot \sum_{m \in \mathcal{M}} N(m,x) \cdot N(m,x_i) \\ &= b + \sum_{m \in \mathcal{M}} N(m,x) \cdot \underbrace{\sum_{i=1}^{l} \alpha_i \cdot y_i \cdot N(m,x_i)}_{=w(m)} \end{aligned} \tag{7}$$

So we obtain $w(m)$ as the linear scaling factor with which every occurance/match of m in the sequence x is scored. Obviously, the higher the absolute value $w(m)$, the more important the pattern m is for the final classification. If $w(m)$ is positive, the pattern m is indicative for the positive class and, if $w(m)$ is negative, m is indicative for the negative class.

Note that the representation (7) is not only beneficial for feature extraction, i.e. for determining which patterns are indicative for the classification tasks. If the total number of patterns actually occurring in the training set is not excessively large, the explicit representation (7) also has strong advantages in terms of computational complexity: the weights $w(m)$ can be stored in a simple hash table indexed by the patterns. For a new sample x, it is then only necessary to sum up the weights for all occurrences of all patterns in x. For the spectrum kernel, for instance, this means adding up $\text{length}(x) - K + 1$ numbers, whereas the direct implementation of the general SVM (1) requires the computation of all $k(x,x_i)$ for which $\alpha_i > 0$ and, therefore, much more computational effort.

[3]We restrict to fixed-length motifs with only regular characters and the wildcard “$*$” that matches all single characters, although the generalization to more sophisticated patterns, e.g. by regular expressions, is straightforward.

4 Fuzzy position preference

The position-independent kernels presented in Section 3 have been used successfully in protein classification. Many protein classification tasks are concerned with inferring the structure and/or function of proteins from their amino acid sequences. Structure and function of proteins are largely determined by shorter sub-sequences (patterns/motifs), mostly irrespective of their exact position in the sequence, so position specificity is not an important issue.

When analyzing DNA or RNA nucleotide sequences, the situation is quite different. There is a rather small alphabet (four nucleic acids instead of twenty amino acids), so some patterns (in particular, shorter ones) are less indicative as they may occur by chance. The position where a pattern occurs, for example, relative to the start or end of a gene, plays a much bigger role. Therefore, there is a strong need for position-specific sequence classification.

We now want to illustrate how position specificity can be integrated into the class of kernels introduced in the previous section. So let us assume that all sequences we consider have the same length L, i.e. $\mathcal{X} = \mathcal{A}^L$, and are *aligned in a way meaningful for the given classification task*.

The simplest way to include position dependence is to consider each pattern at each position completely independent of the other occurrences at other positions (similar to the philosophy behind the *weighted degree kernel* [3]). This means that, instead of mapping a sequence to the total numbers of occurrences of all patterns (cf. (5)), each pattern induces L features, one for each position. The explicit feature mapping can be formulated as follows:

$$\varphi(x) = \Big(\underbrace{(\mathbf{1}(m,x,1),\ldots,\mathbf{1}(m,x,L))}_{\text{binary list of occurrences of pattern } m} \Big)_{m\in\mathcal{M}} \tag{8}$$

Then the corresponding position-specific kernel is given as follows:

$$\bar{k}(x,y) = \sum_{m\in\mathcal{M}} \sum_{p=1}^{L} \mathbf{1}(m,x,p)\cdot\mathbf{1}(m,y,p) \tag{9}$$

So this kernel basically counts the number of positions where the same pattern matches both sequences x and y. It is clear that the number of features (i.e. the dimension of the feature space $\mathcal{H}$) grows by a factor of L compared to the position-independent kernel (4) — potentially increasing the risk of overfitting. Moreover, this approach is not ideally suited for tasks in which patterns are indicative if they appear in certain regions (but not necessarily at exact positions).

The *oligo kernel* [5] solves this challenge by replacing the binary indicators in the feature mapping (8) by the sum of proximity functions around the occurrences of the pattern, with Gaussian bell functions being the standard choice. We leave this variant aside for a moment and concentrate on a different approach in line with the *shifted weighted degree (SWD) kernel* [4]. As in the kernel $\bar{k}$, a pattern m occurring at the same position in both sequences contributes 1 to the sum, but also an occurrence of a pattern m at position p in the sequence x and an occurrence of the same pattern m at position q in the sequence y may contribute a non-zero value to the sum. This is solved by a two-place weighting function $E : \{1,\ldots,L\}^2 \to [0,1]$ which corresponds to the closeness of positions p and q. The farer p and q are apart, the lower the value $E(p,q)$ should be. If $p = q$, i.e. if the positions coincide exactly, $E(p,q) = 1$ holds. So we may generalize the kernel $\bar{k}$ in the following way:

$$\tilde{k}(x,y) = \sum_{m\in\mathcal{M}} \sum_{p=1}^{L} \sum_{q=1}^{L} \mathbf{1}(m,x,p)\cdot E(p,q)\cdot\mathbf{1}(m,y,q) \tag{10}$$

If we leave some constant factors and the SWD kernel's option to define importance factors for each position aside, the position preference weights used by the SWD kernel essentially come down to

$$E_{\mathrm{SWD}}(p,q) = 2^{-|p-q|}.$$

It is easy to see that the kernel $\bar{k}$ given in (9) is a special case of $\tilde{k}$ with the position weighting function

$$E_{=}(p,q) = \begin{cases} 1 & \text{if } p = q, \\ 0 & \text{otherwise,} \end{cases}$$

i.e. the ordinary equality relation, and the position-independent variant defined in (4) is also a special case of (10) with the trivial position-independent weighting function $E_1(p,q) = 1$ (for all $p,q \in \{1,\ldots,L\}$).

Since the range of the weighting function E is the unit interval and since it is intended to be a model of the closeness of the two positions, it is immediate to ask the question whether fuzzy equivalence relations [17, 18] would be reasonable choices for E. As usual, a mapping $E : \mathcal{X}^2 \to [0,1]$ is called *fuzzy equivalence relation* with respect to a given triangular norm T if it has the following properties (for all $x,y,z \in \mathcal{X}$):

(i) Reflexivity: $E(x,x) = 1$

(ii) Symmetry: $E(x,y) = E(y,x)$

(iii) T-transitivity: $T(E(x,y),E(y,z)) \le E(x,z)$

It is trivial that the two special cases $E_=$ and E_1 highlighted above are fuzzy equivalence relations, no matter which triangular norm (t-norm) we consider.

It is also straightforward to prove that E_{SWD} is a fuzzy equivalence relation with respect to the product t-norm $T_{\mathbf{P}}(x,y) = x\cdot y$. This can be proved directly, but it is essentially a consequence of the well-known correspondence between pseudo-metrics and fuzzy equivalence relations with respect to continuous Archimedean t-norms [19]. As further consequences of this result, we can deduce some more examples (generally for $x,y \in \mathbb{R}$, containing the special case of natural numbers $1,\ldots,L$):

- $E_{\mathrm{lin},\sigma}(x,y) = \max(1 - \frac{1}{\sigma}|x-y|, 0)$ is a fuzzy equivalence relation with respect to the Łukasiewicz t-norm $T_{\mathbf{L}}(x,y) = \max(x+y-1,0)$.
- $E_{\exp,\sigma}(x,y) = \exp(-\frac{|x-y|}{\sigma})$ is a fuzzy equivalence relation with respect to the product t-norm $T_{\mathbf{P}}$.
- $E_{\mathrm{Gauss},\sigma}(x,y) = \exp(-\frac{(x-y)^2}{\sigma^2})$ is a fuzzy equivalence relation with respect to the t-norm

  $$T(x,y) = \exp\big(-(\sqrt{-\ln x} + \sqrt{-\ln y})^2\big),$$

  which is nothing else but the Aczél-Alsina t-norm with parameter $\lambda = \frac{1}{2}$ [20].

ISBN: 978-989-95079-6-8

The question arises which choices of E are feasible. In principle, every choice for which $E(p,q)$ is a non-increasing transformation of $|p-q|$ seems reasonable, and all examples mentioned above are of that kind.[4] However, there is also a technical requirement that should not be forgotten: the resulting function $\tilde{k}$ must be positive semi-definite. In order to deduce meaningful requirements on the fuzzy equivalence relation E, let us make a simple reformulation of $\tilde{k}$. It is trivial that the two inner sums are just a vector-matrix-vector product

$$\sum_{p=1}^{L}\sum_{q=1}^{L}\mathbf{1}(m,x,p)\cdot E(p,q)\cdot\mathbf{1}(m,y,q)=\varphi_m(x)^T\cdot\mathbf{E}\cdot\varphi_m(y),$$

with

$$\varphi_m(x)=\big(\mathbf{1}(m,x,1),\ldots,\mathbf{1}(m,x,L)\big)^T,$$
$$\varphi_m(y)=\big(\mathbf{1}(m,y,1),\ldots,\mathbf{1}(m,y,L)\big)^T,$$
$$\mathbf{E}=\begin{pmatrix}E(1,1)&\cdots&E(1,L)\\ \vdots&\ddots&\vdots\\ E(L,1)&\cdots&E(L,L)\end{pmatrix}.$$

Hence, we can rewrite $\tilde{k}$ as

$$\tilde{k}(x,y)=\sum_{m\in\mathcal{M}}\underbrace{\varphi_m(x)^T\cdot\mathbf{E}\cdot\varphi_m(y)}_{=\tilde{k}_m(x,y)}.$$

The sum of kernels is again a kernel [21]. So if we can guarantee that each $\tilde{k}_m$ is a kernel, $\tilde{k}$ is guaranteed to be a kernel. It is clear that, if the matrix $\mathbf{E}$ is positive semi-definite, $\tilde{k}_m$ is a scalar product, hence a kernel. Then the positive semi-definiteness of E, i.e. that E can be understood as a kernel itself, is a sufficient criterion for $\mathbf{E}$ to be positive semi-definite — and finally for $\tilde{k}$ to be a kernel.

For the first two examples above, the situation is clear: $E_=$ induces the identity matrices, E_1 induces matrices containing only 1's; both classes of matrices are trivially positive semi-definite. For non-trivial situations, fortunately, several results are known as well:

- Every fuzzy equivalence relation with respect to the minimum t-norm $T_{\mathbf{M}}(x,y)=\min(x,y)$ is positive semi-definite [22].
- $E_{\exp,\sigma}$ and $E_{\text{Gauss},\sigma}$ are long known to be positive semi-definite [23], where the latter is one of the most used kernels — the RBF kernel.
- $E_{\text{lin},\sigma}$ has recently been proved to be positive semi-definite [24].
- E_{SWD} is also positive semi-definite, as obviously every matrix $\mathbf{E}$ induced by E_{SWD} is diagonally dominant.

So we can conclude that the three choices $E_{\exp,\sigma}$, $E_{\text{Gauss},\sigma}$, $E_{\text{lin},\sigma}$ and E_{SWD} are reasonable and technically feasible. Further note that the former three choices have in common that the resulting kernels tend to the position-independent variant (4) as σ goes to infinity, and the resulting kernels tend to the most position-specific variant (9) as $\sigma\to 0$. So the parameter σ allows for adjusting the degree of position specificity in a continuous manner.

We further note that also the oligo kernel [5] can be accommodated in the framework introduced above. This kernel uses an explicit feature representation for each pattern that convolves the occurrences with Gaussian neighborhood (for some a priori chosen σ). So we can integrate the oligo kernel into the above framework with

$$\mathbf{E}_{\text{oligo},\sigma}=\mathbf{E}_{\text{Gauss},\sigma}\cdot\mathbf{E}_{\text{Gauss},\sigma}.$$

So, from the computational point of view, everything said here is also valid for the oligo kernel. However, since entries of the matrix $\mathbf{E}_{\text{oligo},\sigma}$ can exceed the unit interval, this distance weighting matrix cannot be interpreted as a fuzzy equivalence relation.

5 Feature extraction and computational issues

There is no doubt that the position-specific variant introduced in the previous section is more complicated than the position-independent variant presented in Section 3. The question arises whether the position-specific framework also allows for simple feature extraction and computational efficiency like the position-independent variant. Fortunately, this is the case. The basis of this result is the following rearrangement of the SVM discriminant function (analogous to Section 3):

$$\begin{aligned}f(x)&=b+\sum_{i=1}^{l}\alpha_i\cdot y_i\cdot\tilde{k}(x,x_i)\\&=b+\sum_{i=1}^{l}\alpha_i\cdot y_i\cdot\sum_{m\in\mathcal{M}}\sum_{p=1}^{L}\sum_{q=1}^{L}\mathbf{1}(m,x,p)\cdot E(p,q)\cdot\mathbf{1}(m,x_i,q)\\&=b+\sum_{m\in\mathcal{M}}\sum_{p=1}^{L}\mathbf{1}(m,x,p)\cdot\underbrace{\sum_{i=1}^{l}\sum_{q=1}^{L}\mathbf{1}(m,x_i,q)\cdot\alpha_i\cdot y_i\cdot E(p,q)}_{=\tilde{w}(m,p)}\end{aligned}$$

A value $\tilde{w}(m,p)$ can be interpreted as the weight to which an occurrence of pattern m at position p contributes to the final result. Analogously to Section 3, $\tilde{w}(m,p)>0$ means that an occurrence of pattern m at position p is indicative for the positive class, whereas $\tilde{w}(m,p)<0$ tells us that an occurrence of pattern m at position p is indicative for the negative class. The absolute value of $\tilde{w}(m,p)$ corresponds to the strength of this influence.

It is worth to point out that the way the weights $\tilde{w}(m,p)$ are computed has a very intuitive interpretation too. Suppose that pattern m occurs at position q in a support vector x_i. Obviously, if we consider p a free variable, $E(p,q)$ is the proximity (equivalence class) of position q. In case $E=E_{\text{lin},\sigma}$ is used, it is nothing else but a triangle with width σ; in the case $E=E_{\exp,\sigma}$, it is a Gaussian bell. So the term $\alpha_i\cdot y_i\cdot E(p,q)$ is nothing else but this proximity scaled by the Lagrange multiplier α_i and the sign y_i. Thus, the list $(\tilde{w}(m,p))_{p=1,\ldots,L}$ is the superimposition of proximities of all occurrences of pattern m in the training set scaled by corresponding Lagrange multipliers and signs/classes.

The list $(\tilde{w}(m,p))_{p=1,\ldots,L}$ can be plotted as a graph over the sequence showing the influence of pattern m at each position, indicating in which regions of the sequence the pattern is indicative for either class or not indicative at all. Thus,

[4] More generally, we could also apply a transformation to the positions first.

ISBN: 978-989-95079-6-8

the framework presented here allows for the same simple feature extraction as the position-independent variant. For other methods to extract features from SVM-based sequence classifiers, see [25, 26].

Moreover, it is obvious from the reformulation above that the discriminant function $f(x)$ can be evaluated in the same way as the position-independent variant — by adding up weights over all patterns occurring in the sequence x. So there is no difference in computational complexity between the position-specific and the position-independent variant. However, we have to store L times as many weights. This may be an obstacle if the number of patterns occurring in the training set and the sequence length L are both high.

For the position-specific spectrum kernel, for instance, the situation is very convenient. A sequence contains exactly $L-K+1$ sub-strings. Thus, the computation of $f(x)$ can be done by summing up $L-K+2$ values (again assuming that the lists of weights are stored in a convenient hash table). Obviously, the choice of K is of little influence on this complexity, which is is not true if we consider memory requirements. For low K's, the memory needed to store the weights grows exponentially (as $|\mathcal{M}| = \mathcal{A}^K$), but the total number of patterns that need to be considered is bounded above by the total number of patterns occurring in all support vectors.

All said above is valid for the spectrum kernel only. The mismatch kernel, for instance, is a much more difficult matter, as every sub-string of length K can match several patterns (where this number grows exponentially with M). Thus, the total number of patterns to be considered can be much higher and, more importantly, the number of patterns that need to be taken into account for computing $f(x)$ according to the above principle is much higher. Moreover, the extraction of features in the above manner is possible in principle, but impeded by the fact that the sets of sub-strings matching two different patterns may have large overlaps.

6 A DNA classification example

In this section, we demonstrate the concept introduced above by means of a case study. We consider the task of characterizing long nucleosome-free DNA segments.

Nucleosomes are a DNA packing mechanism in eukaryotic genomes. A nucleosome basically consists of a protein complex (a histone octamer) around which approximately 147 DNA base pairs (bp) are wrapped in $1\frac{2}{3}$ turns. Nonchalantly speaking, the histone complex acts as a reel around which DNA is wrapped. The DNA segment around the histone is mostly inaccessible for interactions with other molecules, most importantly, RNA polymerase. That is why the positions of nucleosomes and possible change of those positions play an essential role in transcription regulation. Therefore, it is of essential interest for the systems biology of eukaryotic cells which mechanisms determine the positioning and repositioning of nucleosomes. An interesting sub-topic is whether there are specific feature of the DNA that favor or hamper the positioning of nucleosomes.

For the yeast sub-species *Saccharomyces cerevisiae*, a commonly used model organism, data are available about where nucleosomes are located [27]. Instead of trying to find out which DNA features favor nucleosomes [28, 29], we tried to elicit DNA features that hamper the positioning of nucleosomes. To this end, we selected a total number of 10226 nucleosome-free sub-sequences of 100 bp length which occur before (on either strand) a well-positioned nucleosome (with the end of the sequence aligned to the start of the nucleosome coming thereafter). This was done using the data published along with [27]. These sequences were labeled as $+1$. The data set was complemented by the same number of random 100 bp long DNA fragments occurring in nucleosomes or in between two nucleosomes that are less than 100 bp apart. These sequences were labeled as -1.

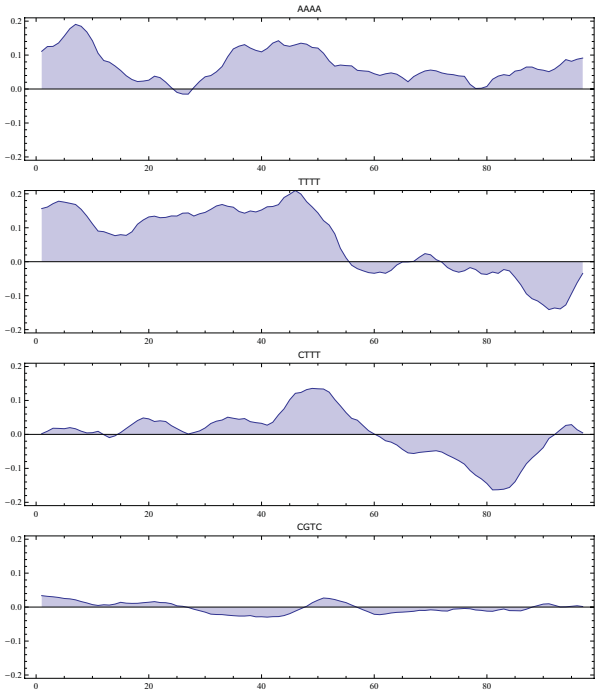

Figure 1: Weight profiles for the four patterns "AAAA", "TTTT", "CTTT" and "CGTC" (from top to bottom).

Our investigations were carried out as follows. The choices $\mathcal{A} = \{\text{"A"}, \text{"G"}, \text{"C"}, \text{"T"}\}$ and $L = 100$ were given by the data set under consideration. We used the spectrum kernel, both position-independent and position-specific, with different values for K ranging from 2 to 6. For the position-specific variant, we used $E = E_{\text{lin},\sigma}$ with σ's of 5, 10, and 20. We employed libSVM [30] to train standard soft margin SVMs. The best cross validation accuracy of 79.2% was obtained for the position-specific variant with $K = 4$ and $\sigma = 10$.

Let us have a closer look at the best setting $K = 4$. Obviously, we have $|\mathcal{M}| = 4^4 = 256$ different patterns. Hence, in order to realize the principle described in the previous section we have to store at most $256 \cdot 100 = 25,600$ numbers, which is easily manageable. Computing the discriminant function $f(x)$ for a new sequence x requires only to slide a window of length $K = 4$ over the sequence and to sum up the corresponding weights, hence only 98 additions are necessary, which is negligible compared to directly applying Eq. (1).

Figure 1 shows four examples of such weight profiles obtained for the given classification task. It is obvious that "AAAA" is indicative for the positive class (longer nucleosome-free positions), more or less regardless of the position. This is in line with the result of Peckham et al. [29]

ISBN: 978-989-95079-6-8

who have found out that poly-A occurrences are indicative for non-nucleosome sequence regions. One would expect the same situation for the complementing pattern "TTTT", but the profile in Figure 1 shows that this pattern is indicative for the positive class only in the first half of the sequence, whereas it is not indicative for the last 45 bases before a nucleosome. The pattern "CTTT" is not indicative for either class in the first half of the sequence, it seems to occur frequently around 50 bases before a nucleosome, and it occurs with less-than-random probability in the last 40 bases before a nucleosome (note that the negative class is randomly sampled from nucleosomes and shorter nucleosome-free fragments). The last graph shows that pattern "CGTC" seems to be of no significance at all. Although the biological interpretation of these results is a more advanced topic, the examples demonstrate how easily claims about the significance of specific patterns can be deduced from the weight profiles.

7 Concluding remarks

In this paper, we have formulated a generalization of position-specific sequence kernels by using fuzzy equivalence relations for modeling position specificity. This is not only an interesting link, but also gives rise to new kernels, e.g. the one based on $E_{\mathrm{lin},\sigma}$. We have obtained that these kernels facilitate an explicit representation which allows for computational efficiency and easy feature extraction.

Abstract—*Neural Networks (NN), Type-1 Fuzzy Logic Systems (T1FLS) and Interval Type-2 Fuzzy Logic Systems (IT2FLS) are universal approximators, they can approximate any non-linear function. Recent research shows that embedding T1FLS on an NN or embedding IT2FLS on an NN can be very effective for a wide number of non-linear complex systems, especially when handling imperfect information. In this paper we show that an Interval Type-2 Fuzzy Neural Network (IT2FNN) is a universal approximator with some precision using a set of rules and Interval Type-2 membership functions (IT2MF) and the Stone-Weierstrass Theorem. Also, simulation results of non-linear function identification using the IT2FNN for one and three variables with 10-fold cross-validation are presented.*

Keywords— Interval Type-2 Fuzzy Logic Systems, Interval Type-2 Fuzzy Neural Networks, Neural Networks, Universal Approximation.

1 Introduction

It has been shown that a three layer NN can approximate any real continuous function [1]. The same has been shown for a T1FLS [2, 3] using Stone-Weierstrass Theorem [6]. A similar analysis was made by Kosko [4, 5] using the concept of fuzzy regions. In [6, 7] Buckley shows that, with a Sugeno model [9], a T1FLS can be built with the ability to approximate any non-linear continuous function. Also, combining neural and fuzzy logic paradigms [10, 11], an effective tool can be created for approximating any non-linear function [8]. In this sense, an expert can use a Type-1 Fuzzy Neural Network (T1FNN) [13, 14] or IT2FNN systems and find interpretable solutions [12, 17-20]. In general, Takagi-Sugeno-Kang (TSK) T1FLS's approximate well by the use of polynomial consequent rules [9, 23].

This paper uses the Levenberg-Marquardt backpropagation learning algorithm for adapting antecedent and consequent parameters for an adaptive IT2FNN, since its efficiency and soundness characteristics made them fit for these optimizing problems.

An Adaptive IT2FNN is used as a universal approximator of any non-linear functions. A set Ψ of IT2FNN is universal if and only if (iff), given any process Ω, there is a system $\Phi \in \Psi$ such that the difference between the output from IT2FNN and output from Ω is less than a given ε.

2 Interval Type-2 Fuzzy Neural Networks

An IT2FNN [12] combines a TKS interval type-2 fuzzy inference system (TSKIT2FIS) [15,16] with an adaptive NN in order to take advantage of both models best characteristics. Even though Mamdami and Tsukamoto are much complex models [13, 14, 16], TSK is preferred due to the lower computational cost in type reduction.

2.1 IT2FNN-2:A2C0 Architecture

An IT2FNN-2:A2C0 (IT2FNN-0) is a seven layer IT2FNN, which integrates a first order TSKIT2FIS (interval type-2 fuzzy antecedents and real consequents), with an adaptive NN. The IT2FNN-2:A2C0 (Figure 1) layers are described as follows:

Layer 0: Inputs

$$o_i^0 = x_i \quad ; i = 1,...,n$$

Layer 1: Adaptive type-1 fuzzy neuron (T1FN)

for i=1,…,n
  for k=s_i+1,…,s_{i+1}
    $net_k^1 = w_{k,i}^{1,0}\, x_i + b_k^1$
    $o_k^1 = \mu(net_k^1)$
  end
end

Layer 2: Non-adaptive T1FN

$o_{2k-1}^2 = o_{2k-1}^1 \cdot o_{2k}^1 \quad \forall\, k = 1,...,\vartheta$
$o_{2k}^2 = o_{2k-1}^1 + o_{2k}^1 - o_{2k-1}^2$

for k=1,…,r
  for i=1,…,n
    $\tau = 1_{k,i} \quad ; \quad \pi = \sum_{j=1}^{i-1} v_j + |\tau|$
    if $\tau > 0$
      $\underline{\mu}_{k,i} = o_{i_l(\pi)}^2 \,;\, \overline{\mu}_{k,i} = o_{i_u(\pi)}^2$
    else
      $\underline{\mu}_{k,i} = null \,;\, \overline{\mu}_{k,i} = null$
    end
  end
end

Layer 3: Lower-upper firing strength rule normalization. Nodes in this layer are non-adaptive and the output is defined as a the ratio between the k^{th} lower-upper firing strength rule and the sum of lower-upper firing strength of all rules:

ISBN: 978-989-95079-6-8

$$o_{2k-1}^3 = \underline{w}^k = \frac{\underline{f}^k}{\sum_{l=1}^{r} \underline{f}^l} \quad ; \quad k = 1,...,r$$

$$o_{2k}^3 = \overline{w}^k = \frac{\overline{f}^k}{\sum_{l=1}^{r} \overline{f}^l}$$

Layer 4: Rule consequents. Each node is adaptive and its parameters are $\{c_i^k, c_0^k\}$. The node's output corresponds to partial output of k[th] rule y^k.

$$y^k = \sum_{i=1}^{n} c_i^k x_i + c_0^k \quad ; \quad k = 1,...,r$$

$$o_{2k-1}^4 = y^k$$

$$o_{2k}^4 = y^k$$

Layer 5: Type reduction. Estimates left-right interval values $[\hat{y}_l, \hat{y}_r]$, nodes are non-adaptive with outputs $\hat{y}_l, \hat{y}_r$. Layer 5 output is defined by:

$$o_1^5 = \hat{y}_l = \sum_{k=1}^{r} \underline{w}^k \cdot y^k$$

$$o_2^5 = \hat{y}_r = \sum_{k=1}^{r} \overline{w}^k \cdot y^k$$

Layer 6: Defuzzification. This layer's node is adaptive, where the output $\hat{y}$ is defined as weighted average of left-right values and parameter γ. Parameter γ (default value 0.5) adjusts the uncertainty interval defined by left-right values $[\hat{y}_l, \hat{y}_r]$.

$$o_1^6 = \hat{y} = \gamma \hat{y}_l + (1-\gamma)\hat{y}_r$$

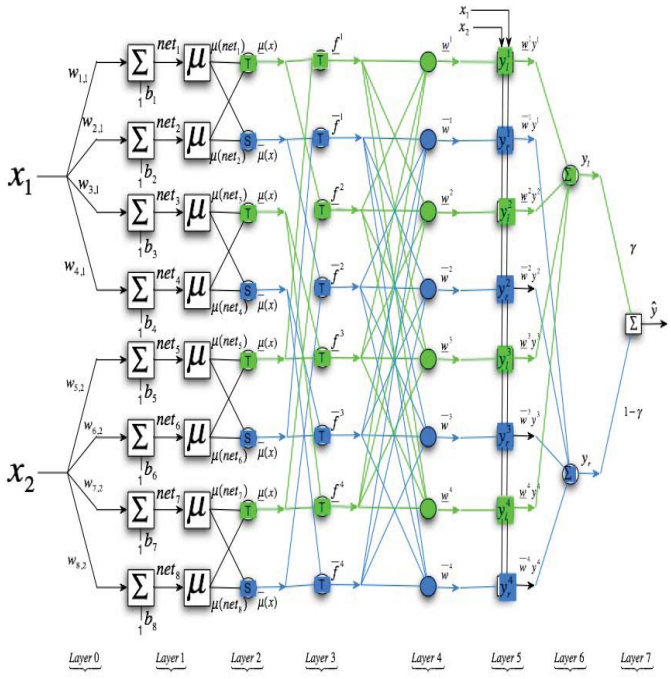

Figure 1: IT2FNN-2:A2C0 (IT2FNN-0) Architecture

2.2 IT2FNN-2:A2C1 Architecture

An IT2FNN-2:A2C1 (IT2FNN-2) [12] is a six layer IT2FNN, which integrates a first order TSKIT2FIS (interval type-2 fuzzy antecedents and interval type-1 fuzzy consequents), with an adaptive NN. The IT2FNN-2:A2C1 (Figure 2) layers are described as follows:

Layers 0-2 of IT2FNN-2:A2C1 architecture are the same as layers 0-2 of IT2FNN-2:A2C0 architecture.

Layer 3: Rule consequents. Each node is adaptive with parameters $\{c_i^k, c_0^k\}$ and $\{s_i^k, s_0^k\}$. Node's output corresponds to k[th] rule's partial output, $\tilde{y}^k \in [y_l^k, y_r^k]$.

$$o_{2k-1}^3 = y_l^k = \sum_{i=1}^{n} c_i^k x_i + c_0^k - \sum_{i=1}^{n} s_i^k |x_i| - s_0^k \quad ; \quad k = 1,...,r$$

$$o_{2k}^3 = y_r^k = \sum_{i=1}^{n} c_i^k x_i + c_0^k + \sum_{i=1}^{n} s_i^k |x_i| + s_0^k$$

Layer 4: Type reduction. Estimates left-right values of interval $[\hat{y}_l, \hat{y}_r]$ and left(f_l^k)-right(f_r^k) firing strength that are used for computing $[\hat{y}_l, \hat{y}_r]$ using KM algorithm [15, 16].

$$f_l^k = leftpoint(\underline{f}^k, \overline{f}^k, y_l^k) \quad ; \quad f_r^k = rightpoint(\underline{f}^k, \overline{f}^k, y_r^k)$$

$$o_1^4 = \hat{y}_l = \frac{\sum_{k=1}^{r} f_l^k y_l^k}{\sum_{k=1}^{r} f_l^k} \quad ; \quad o_2^4 = \hat{y}_r = \frac{\sum_{k=1}^{r} f_r^k y_r^k}{\sum_{k=1}^{r} f_r^k}$$

Layer 5: Defuzzification. This layer's node is adaptive with output $\hat{y}$ defined by:

$$o_1^5 = \hat{y} = \gamma \hat{y}_l + (1-\gamma)\hat{y}_r$$

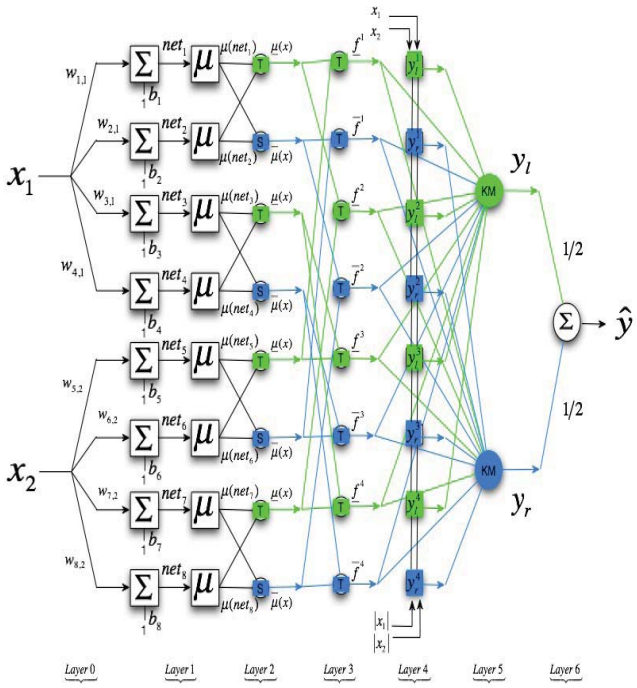

Figure 2: IT2FNN-2:A2C1 (IT2FNN-2) Architecture

ISBN: 978-989-95079-6-8

3 IT2FNN as a Universal Approximator

With this simplified interval type-2 fuzzy if-then rule, it is possible to prove that under certain circumstances, the resulting IT2FIS has unlimited approximation power to match any non-linear functions on a compact [24, 25] set using the Stone-Weierstrass theorem [13, 14, 21, 22] as follows:

3.1 Stone-Weierstrass Theorem.

Let the domain **D** be a compact space of **N** dimensions, and let $\mathfrak{I}$ be a set of continuous real-valued function on **D**, satisfying the following criteria [24, 25]:

1. **Identity function:** The constant $f(x) = 1$ is in $\mathfrak{I}$.
2. **Separability:** For any two points $x_1 \neq x_2$ in ***D***, there is an ***f*** in $\mathfrak{I}$ such that $f(x_1) \neq f(x_2)$.
3. **Algebraic closure:** If ***f*** and ***g*** are any two functions in $\mathfrak{I}$, then ***fg*** and ***af + bg*** are in $\mathfrak{I}$ for any two real numbers ***a*** and ***b***.

Then $\mathfrak{I}$ is dense in ***C***(***D***), the set of continuous real-value functions on **D**. In other words, for any $\varepsilon > 0$, and any function ***g*** in ***C***(***D***), there is a function ***f*** in $\mathfrak{I}$ such that $|g(x) - f(x)| < \varepsilon$ for all $\mathbf{x} \in \mathbf{D}$.

3.2 Applying Stone-Weierstrass Theorem used on IT2FNN-2:A2C0 Architecture.

In the IT2FNN, the domain in which we operate is almost always compact. It is a standard result in real analysis that every closed and bounded set in $\Re^n$ is compact. Now we shall apply the Stone-Weierstrass theorem to show the representational power of IT2FNN with simplified fuzzy if-then rules.

3.2.1 Identity Function

The first requirement of Stone-Weierstrass theorem needs our IT2FNN to be able to compute the identity function f(x)=1. An obvious way to compute the function is to set the consequence part of each rule equal to [1-δ, 1+δ], where δ is the uncertainty spread. In fact, an IT2FNN with only one rule suffices to satisfy this requirement.

3.2.2 Separability

The second requirement of the Stone-Weierstrass theorem needs the IT2FNN to be able to compute functions that have different values for different points. Without this requirement, the trivial set of functions f: f(x)= [c-δ, c+δ] c $\in \Re$ would satisfy Stone-Weierstrass theorem. Separability is satisfied whenever IT2FNN can compute strictly monotonic functions of each input variable. This can easily be achieved by adjusting the membership functions of the premise part.

3.2.3 Algebraic Closure-Additive

The third requirement of Stone-Weierstrass theorem needs the IT2FNN to be able to approximate sums and products of functions. Suppose we have two IT2FNNs S and $\overline{S}$ each of which has two rules. The output of each system can be expressed as

$$S: z = \gamma \cdot y_l + (1-\gamma) y_r = \gamma \frac{\underline{f}^1 y^1 + \underline{f}^2 y^2}{\underline{f}^1 + \underline{f}^2} + (1-\gamma) \frac{\overline{f}^1 y^1 + \overline{f}^2 y^2}{\overline{f}^1 + \overline{f}^2}$$

$$\overline{S}: \overline{z} = \overline{\gamma} \cdot \overline{y}_l + (1-\overline{\gamma}) \overline{y}_r = \overline{\gamma} \frac{\underline{g}^1 \overline{y}^1 + \underline{g}^2 \overline{y}^2}{\underline{g}^1 + \underline{g}^2} + (1-\overline{\gamma}) \frac{\overline{g}^1 \overline{y}^1 + \overline{g}^2 \overline{y}^2}{\overline{g}^1 + \overline{g}^2}$$

then the sum of z and $\overline{z}$ is equal to

$$az + b\overline{z} = \frac{\underline{f}^1 \overline{f}^1 \underline{g}^1 \overline{g}^1}{fg}\left[a y^1 + b\overline{y}^1\right] + \frac{\underline{f}^1 \overline{f}^1 \underline{g}^1 \overline{g}^2}{fg}\left[a y^1 + b\left(\overline{\gamma}\overline{y}^1 + (1-\overline{\gamma})\overline{y}^2\right)\right] +$$

$$\frac{\underline{f}^1 \overline{f}^1 \overline{g}^1 \underline{g}^2}{fg}\left[a y^1 + b\left(\overline{\gamma}\overline{y}^2 + (1-\overline{\gamma})\overline{y}^1\right)\right] + \frac{\underline{f}^1 \overline{f}^1 \underline{g}^2 \overline{g}^2}{fg}\left[a y^1 + b\overline{y}^2\right] +$$

$$\frac{\underline{f}^1 \overline{f}^2 \underline{g}^1 \overline{g}^1}{fg}\left[a\left(\gamma y^1 + (1-\gamma)y^2\right) + b\overline{y}^1\right] + \frac{\underline{f}^1 \overline{f}^2 \underline{g}^1 \overline{g}^2}{fg}\left[a\left(\gamma y^1 + (1-\gamma)y^2\right) + b\left(\overline{\gamma}\overline{y}^1 + (1-\overline{\gamma})\overline{y}^2\right)\right] +$$

$$\frac{\underline{f}^1 \overline{f}^2 \overline{g}^1 \underline{g}^2}{fg}\left[a\left(\gamma y^1 + (1-\gamma)y^2\right) + b\left(\overline{\gamma}\overline{y}^2 + (1-\overline{\gamma})\overline{y}^1\right)\right] + \frac{\underline{f}^1 \overline{f}^2 \underline{g}^2 \overline{g}^2}{fg}\left[a\left(\gamma y^1 + (1-\gamma)y^2\right) + b\overline{y}^2\right] +$$

$$\frac{\overline{f}^1 \underline{f}^2 \underline{g}^1 \overline{g}^1}{fg}\left[a\left(\gamma y^2 + (1-\gamma)y^1\right) + b\overline{y}^1\right] + \frac{\overline{f}^1 \underline{f}^2 \underline{g}^1 \overline{g}^2}{fg}\left[a\left(\gamma y^2 + (1-\gamma)y^1\right) + b\left(\overline{\gamma}\overline{y}^1 + (1-\overline{\gamma})\overline{y}^2\right)\right] +$$

$$\frac{\overline{f}^1 \underline{f}^2 \overline{g}^1 \underline{g}^2}{fg}\left[a\left(\gamma y^2 + (1-\gamma)y^1\right) + b\left(\overline{\gamma}\overline{y}^2 + (1-\overline{\gamma})\overline{y}^1\right)\right] + \frac{\overline{f}^1 \underline{f}^2 \underline{g}^2 \overline{g}^2}{fg}\left[a\left(\gamma y^2 + (1-\gamma)y^1\right) + b\overline{y}^2\right] +$$

$$\frac{\underline{f}^2 \overline{f}^2 \underline{g}^1 \overline{g}^1}{fg}\left[a y^2 + b\overline{y}^1\right] + \frac{\underline{f}^2 \overline{f}^2 \underline{g}^1 \overline{g}^2}{fg}\left[a y^2 + b\left(\overline{\gamma}\overline{y}^1 + (1-\overline{\gamma})\overline{y}^2\right)\right] +$$

$$\frac{\underline{f}^2 \overline{f}^2 \overline{g}^1 \underline{g}^2}{fg}\left[a y^2 + b\left(\overline{\gamma}\overline{y}^2 + (1-\overline{\gamma})\overline{y}^1\right)\right] + \frac{\underline{f}^2 \overline{f}^2 \underline{g}^2 \overline{g}^2}{fg}\left[a y^2 + b\overline{y}^2\right]$$

therefore we can construct an IT2FNN that computes $az + b\overline{z}$.

3.2.4 Algebraic Closure-Multiplicative

Modeling the product of $z\overline{z}$ of two IT2FNNs is the last capability we must demonstrate before we can conclude that the Stone-Weierstrass theorem can be applied to the proposed reasoning mechanism. The product $z\overline{z}$ can be expressed as

$$z\overline{z} = \frac{\underline{f}^1 \underline{g}^1 \left(\overline{f}^1 + \overline{f}^2\right)\left(\overline{g}^1 + \overline{g}^2\right)}{fg} \gamma y^1 \overline{\gamma}\overline{y}^1 + \frac{\underline{f}^1 \underline{g}^2 \left(\overline{f}^1 + \overline{f}^2\right)\left(\overline{g}^1 + \overline{g}^2\right)}{fg} \gamma y^1 \overline{\gamma}\overline{y}^2 +$$

$$\frac{\underline{f}^2 \underline{g}^1 \left(\overline{f}^1 + \overline{f}^2\right)\left(\overline{g}^1 + \overline{g}^2\right)}{fg} \gamma y^2 \overline{\gamma}\overline{y}^1 + \frac{\underline{f}^2 \underline{g}^2 \left(\overline{f}^1 + \overline{f}^2\right)\left(\overline{g}^1 + \overline{g}^2\right)}{fg} \gamma y^2 \overline{\gamma}\overline{y}^2 +$$

$$\frac{\underline{f}^1 \overline{g}^1 \left(\overline{f}^1 + \overline{f}^2\right)\left(\underline{g}^1 + \underline{g}^2\right)}{fg} \gamma y^1 (1-\overline{\gamma})\overline{y}^1 + \frac{\underline{f}^1 \overline{g}^2 \left(\overline{f}^1 + \overline{f}^2\right)\left(\underline{g}^1 + \underline{g}^2\right)}{fg} \gamma y^1 (1-\overline{\gamma})\overline{y}^2 +$$

ISBN: 978-989-95079-6-8

$$\frac{\underline{f}^2\underline{g}^1\left(\overline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}{fg}\gamma y^2(1-\bar{\gamma})\bar{y}^1+\frac{\underline{f}^2\underline{g}^2\left(\overline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}{fg}\gamma y^2(1-\bar{\gamma})\bar{y}^2+$$

$$\frac{\overline{f}^1\underline{g}^1\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}{fg}(1-\gamma)y^1\bar{\gamma}\bar{y}^1+\frac{\overline{f}^1\underline{g}^2\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}{fg}(1-\gamma)y^1\bar{\gamma}\bar{y}^2+$$

$$\frac{\overline{f}^2\underline{g}^1\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}{fg}(1-\gamma)y^2\bar{\gamma}\bar{y}^1+\frac{\overline{f}^2\underline{g}^2\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}{fg}(1-\gamma)y^2\bar{\gamma}\bar{y}^2+$$

$$\frac{\overline{f}^1\overline{g}^1\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}{fg}(1-\gamma)y^1(1-\bar{\gamma})\bar{y}^1+\frac{\overline{f}^1\overline{g}^2\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}{fg}(1-\gamma)y^1(1-\bar{\gamma})\bar{y}^2+$$

$$\frac{\overline{f}^2\overline{g}^1\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}{fg}(1-\gamma)y^2(1-\bar{\gamma})\bar{y}^1+\frac{\overline{f}^2\overline{g}^2\left(\underline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}{fg}(1-\gamma)y^2(1-\bar{\gamma})\bar{y}^2$$

therefore we can construct an IT2FNN that computes $z\bar{z}$.

3.3 Applying Stone-Weierstrass theorem to the IT2FNN-2:A2C1 architecture

As in the case of IT2FNN-2:A2C0, let there be two distinct IT2FNN-2:A2C1, S and $\overline{S}$, each with two rules; we can proceed in this case as follows:

3.3.1 Algebraic Closure-Additive

$$S: z = \frac{1}{2}\left[\frac{\overline{f}^1 y_l^1+\underline{f}^2 y_l^2}{\overline{f}^1+\underline{f}^2}+\frac{\underline{f}^1 y_r^1+\overline{f}^2 y_r^2}{\underline{f}^1+\overline{f}^2}\right]$$

$$\overline{S}: \bar{z} = \frac{1}{2}\left[\frac{\overline{g}^1 \bar{y}_l^1+\underline{g}^2 \bar{y}_l^2}{\overline{g}^1+\underline{g}^2}+\frac{\underline{g}^1 \bar{y}_r^1+\overline{g}^2 \bar{y}_r^2}{\underline{g}^1+\overline{g}^2}\right]$$

then the sum of z and $\bar{z}$ is equal to

$$az+b\bar{z}=\frac{1}{2}\frac{\overline{f}^1\overline{g}^1}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}\left(ay_l^1+b\bar{y}_l^1\right)+\frac{1}{2}\frac{\overline{f}^1\underline{g}^2}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}\left(ay_l^1+b\bar{y}_l^2\right)+$$

$$\frac{1}{2}\frac{\underline{f}^2\overline{g}^1}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}\left(ay_l^2+b\bar{y}_l^1\right)+\frac{1}{2}\frac{\underline{f}^2\underline{g}^2}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}\left(ay_l^2+b\bar{y}_l^2\right)+$$

$$\frac{1}{2}\frac{\underline{f}^1\underline{g}^1}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}\left(ay_r^1+b\bar{y}_r^1\right)+\frac{1}{2}\frac{\underline{f}^1\overline{g}^2}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}\left(ay_r^1+b\bar{y}_r^2\right)+$$

$$\frac{1}{2}\frac{\overline{f}^2\underline{g}^1}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}\left(ay_r^2+b\bar{y}_r^1\right)+\frac{1}{2}\frac{\overline{f}^2\overline{g}^2}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}\left(ay_r^2+b\bar{y}_r^2\right)$$

therefore we can construct an IT2FNN that computes $az+b\bar{z}$.

3.3.2 Algebraic Closure-Multiplicative

The product $z\bar{z}$ can be expressed as

$$z\bar{z}=\frac{1}{4}\frac{\overline{f}^1\overline{g}^1}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}y_l^1\bar{y}_l^1+\frac{1}{4}\frac{\overline{f}^1\underline{g}^2}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}y_l^1\bar{y}_l^2+$$

$$\frac{1}{4}\frac{\underline{f}^2\overline{g}^1}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}y_l^2\bar{y}_l^1+\frac{1}{4}\frac{\underline{f}^2\underline{g}^2}{\left(\overline{f}^1+\underline{f}^2\right)\left(\overline{g}^1+\underline{g}^2\right)}y_l^2\bar{y}_l^2+$$

$$\frac{1}{4}\frac{\overline{f}^1\underline{g}^1}{\left(\overline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_l^1\bar{y}_r^1+\frac{1}{4}\frac{\overline{f}^1\overline{g}^2}{\left(\overline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_l^1\bar{y}_r^2+$$

$$\frac{1}{4}\frac{\underline{f}^2\underline{g}^1}{\left(\overline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_l^2\bar{y}_r^1+\frac{1}{4}\frac{\underline{f}^2\overline{g}^2}{\left(\overline{f}^1+\underline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_l^2\bar{y}_r^2+$$

$$\frac{1}{4}\frac{\underline{f}^1\overline{g}^1}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}y_r^1\bar{y}_l^1+\frac{1}{4}\frac{\underline{f}^1\underline{g}^2}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}y_r^1\bar{y}_l^2+$$

$$\frac{1}{4}\frac{\overline{f}^2\overline{g}^1}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}y_r^2\bar{y}_l^1+\frac{1}{4}\frac{\overline{f}^2\underline{g}^2}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\underline{g}^2\right)}y_r^2\bar{y}_l^2+$$

$$\frac{1}{4}\frac{\underline{f}^1\underline{g}^1}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_r^1\bar{y}_r^1+\frac{1}{4}\frac{\underline{f}^1\overline{g}^2}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_r^1\bar{y}_r^2+$$

$$\frac{1}{4}\frac{\overline{f}^2\underline{g}^1}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_r^2\bar{y}_r^1+\frac{1}{4}\frac{\overline{f}^2\overline{g}^2}{\left(\underline{f}^1+\overline{f}^2\right)\left(\underline{g}^1+\overline{g}^2\right)}y_r^2\bar{y}_r^2$$

therefore we can construct an IT2FNN that computes $z\bar{z}$.

The IT2FNN architectures that compute $az+b\bar{z}$ and $z\bar{z}$ have the same S and $\overline{S}$ if and only if the class of membership functions is invariant under multiplication. This is loosely true if the class of interval type-2 membership functions is the set of all bell-shaped functions and Gaussian-shaped (igbellmtype2, igbellstype2 and igbelltype2 for bell-shaped and igaussmtype2, igaussstype2 and igausstype2 for Gaussian-shaped, all of which can be found in the Matlab's Interval Type-2 Fuzzy Logic Toolbox [26]).

Therefore by choosing an appropriate class of membership functions, we can conclude that the IT2FNN with simplified fuzzy if-then rules satisfy the four criteria of Stone-Weierstrass theorem. Consequently, for any given $\varepsilon > 0$ and any real-valued function g, there is an IT2FNN S such that $|g(x)-S(x)|<\varepsilon$ for all x in underlying compact set. Moreover since the simplified IT2FNN is a proper subset of two types of architecture, we can conclude that the IT2FNN architecture has unlimited approximation power to match any given data set.

4 Application Examples

Two application examples are used to illustrate the proofs of universality, as follows.

Experiment 1. Identification of a one variable non-linear function.

In this experiment we approximate a non-linear function $f:\Re\to\Re$:

ISBN: 978-989-95079-6-8

$$f(u)=0.6\sin(\pi u)+0.3\sin(3\pi u)+0.1\sin(5\pi u)+\eta$$

(where η is a uniform noise component) using a one input-one output IT2FNN, 50 training data sets with 10 fold cross-validation with uniform noise levels, 6 IT2MF type igaussmtype2, 6 rules and 50 epochs. Once ANFIS and IT2FNN models are identified a comparison was made, taking into account RMSE statistic values with 10 fold cross-validation. Table 1 and Figure 3 show resulting RMSE values for ANFIS and IT2FNN, it can be seen that IT2FNN architectures [12] perform better than ANFIS.

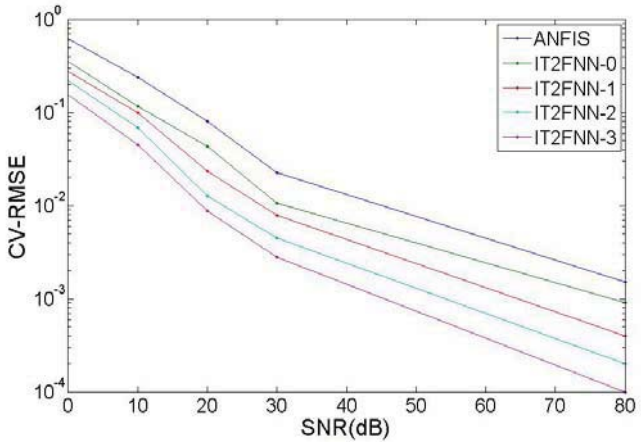

Figure 3: RMSE values of ANFIS and IT2FNN using 10-fold cross-validation for identifying non-linearity in Experiment 1.

Table 1: RMSE values of ANFIS and IT2FNN with 10-fold cross-validation for identifying non-linearity of Experiment 1.

SNR(dB)	ANFIS	IT2FNN-0	IT2FNN-1	IT2FNN-2	IT2FNN-3
0	0.6156	0.3532	0.2764	0.2197	0.1535
10	0.2375	0.1153	0.0986	0.0683	0.0453
20	0.0806	0.0435	0.0234	0.0127	0.0087
30	0.0225	0.0106	0.0079	0.0045	0.0028
free	0.0015	0.0009	0.0004	0.0002	0.0001

Experiment 2. Identification of a three variable non-linear function.

A three input – one output IT2FNN is used to approximate non-linear Sugeno [9] function $f:\Re^3\rightarrow\Re$:

$$f(x_1,x_2,x_3)=\left(1+\sqrt{x_1}+\frac{1}{x_2}+\frac{1}{\sqrt{x_3^3}}\right)^2+\eta$$

216 training data sets are generated with 10-fold cross-validation and 125 for tests; 2 igaussmtype2 IT2MF for each input, 8 rules and 50 epochs. Once the ANFIS and IT2FNN models are identified, a comparison is made with RMSE statistic values and 10-fold cross-validation. Table 2 and Figure 4 show the resultant RMSE values for ANFIS and IT2FNN. It can be seen that IT2FNN architectures [12] perform better than ANFIS.

Table 2: Resulting RMSE values in ANFIS and IT2FNN for non-linearity identification in Experiment 2 with 10-fold cross-validation.

SNR(dB)	ANFIS	IT2FNN-0	IT2FNN-1	IT2FNN-2	IT2FNN-3
0	1.0432	0.7203	0.6523	0.5512	0.5267
10	0.3096	0.2798	0.2583	0.2464	0.2344
20	0.1703	0.1637	0.1592	0.1465	0.1387
30	0.1526	0.1408	0.1368	0.1323	0.1312
free	0.1503	0.1390	0.1323	0.1304	0.1276

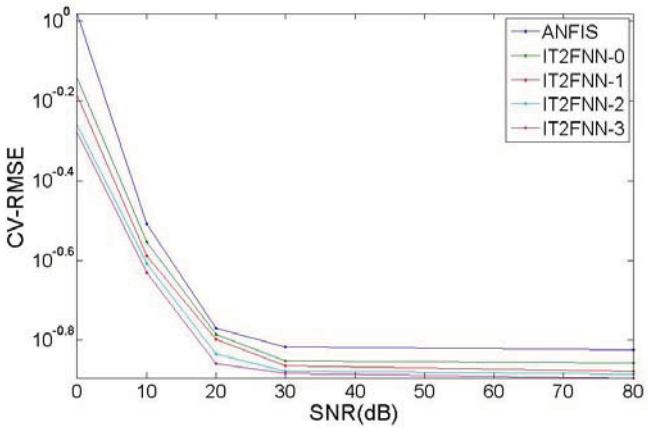

Figure 4: Resulting RMSE values obtained by ANFIS and IT2FNN for non-linearity identification in Experiment 2 with 10-fold cross-validation.

5 Conclusions

In these experiments, the estimated RMSE values for non-linear function identification with 10-fold cross-validation for the hybrid architectures IT2FNN-2:A2C0 and IT2FNN-2:A2C1 illustrate the proof based on Stone-Weierstrass theorem that they are universal approximators for efficient identification of non-linear functions. Also, it can be seen that while increasing the Signal Noise Ratio (SNR), IT2FNN architectures handle uncertainty more efficiently.

Spectral Learning with Type-2 Fuzzy Numbers for Question/Answering System

Asli Celikyilmaz[1] I. Burhan Turksen[2]

1. Computer Sciences Division, University in California, Berkeley, CA, USA
2. TOBB Economy and Technology University, Ankara, Turkey & University of Toronto, Canada

Abstract— *Graph-based semi-supervised learning has recently emerged as a promising approach to data-sparse learning problems in natural language processing. They rely on graphs that jointly represent each data point. The problem of how to best formulate the graph representation remains an open research topic. In this paper, we introduce a type-2 fuzzy arithmetic to characterize the edge weights of a formed graph as type-2 fuzzy numbers. The fuzzy numbers are identified by the changing parameters of the fuzzy kernel nearest neighbor algorithm, namely the degree of fuzziness and the hyper-parameter of the Gaussian kernel function, both of which have an effect on the uncertainty in forming the affinity matrix of the graph. We introduce a new graph-based semi-supervised learning with the type-2 arithmetic operations. We apply this technique in the framework of label propagation and evaluate on a question answering task. We demonstrate that the type-2 SSL can improve the prediction accuracy and can be considered to be the an alternative tool for text mining applications of computational linguistics.*

Keywords— Graph-based semi-supervised learning, kernel fuzzy k-nearest neighbor, type-2 fuzzy numbers.

1 Introduction and Motivation

In building reliable models for real systems, identification of exact values of variables of model equations are required. In real life practices, precise values of parameters may not be obtained due to imprecise, noisy, vague, or incomplete nature of information. Fuzzy logic provides explanatory tools for such tasks, mainly because of its capability to manage imprecise categories to represent imperfect information, by means of fuzzy sets, graduality, measures of resemblance or aggregation methods. Type-1 fuzzy sets may not be enough to explain the whole spectrum of possible results, mainly because the values used to characterize the membership functions of type-1 fuzzy numbers are usually overly precise. Usually the level of information is improperly set to define membership functions, thus it is rather necessary to use type-2 fuzzy numbers to represent uncertainties in model parameters.

In this work, we mainly focus on uncertainties in finding similarities in text mining. We consider one of the most commonly used learning methods, namely the semi-supervised learning (SSL) method [1]. It is often the case in the areas of machine learning for classification problems such as the problem of text classification on web pages, automatic translation or online question/ answering systems, etc. that one needs to deal with a very small portion of labeled data and vast amounts of unlabeled data. For such cases, graph-based SSL methods (spectral learning methods) have proved to outperform other learning methods. In graph- based methods the data is represented by the nodes of a graph (Fig. 1), the edges of which are labeled with the pairwise distance of the incident nodes. One problem with spectral learning methods is that the procedure is highly sensitive to the choice of the kernel, for example it is very sensitive to the choice of the spread (variance) of a Gaussian kernel, which naturally effects the similarity matrix defined for the given dataset.

As in the phrase of "words can mean different things to different people", an entailment relation between a candidate sentence and a question posed by the user may be evaluated differently by different people. For instance, a different degree of entailment may be assigned by different people for pairs of question "Who bought Overture?" and candidate sentences such as "Yahoo bought Overture", "Yahoo owns Overture", "Overture acquisition by Yahoo", using linguistic terms such $strict$, $loose$, or $direct$ entailment. Current methods can only use crisp values to define such relations, which cannot be explained to a full extent. Type-2 fuzzy logic is the best fit to define the entailment relations between each sentence. To our knowledge, characterization of edge weights of a graph as type-2 fuzzy numbers, as presented in this paper, is a new approach. The novel type-2 SSL defines such uncertain entailment relation between two sentences by characterizing soft linked graphs.

In this paper we concentrate on characterization of the uncertainties in similarity measure when discovering knowledge from unstructured text using graph-based SSL algorithm. A common way to construct the affinity matrix of a graph is by application of a nearest neighbor method. We use a fuzzy k-nearest neighbor (FKNN) to allow fuzzy decisions based on fuzzy labels. In addition we use its kernel extension [2] to enable solving possible non-linearly separable problems and get non-linear fuzzy boundaries instead of linear boundaries when necessary. In addition kernel methods have proven to prevent over-fitting in high dimensional feature spaces. For these reasons, we consider applying type-2 fuzzy arithmetic to situations where the similarity between two objects, i.e, two sentences, is imprecise.

Thus, the novel type-2 SSL method learns the edge link weights via kernel fuzzy k-nearest neighbor algorithm [2] (KFKNN). We use the arithmetic operations on type-2 fuzzy numbers defined in [3]. For ease of calculations, we graduate the interval valued degree of fuzziness and the kernel parameter and obtain bounded discrete valued weights (interval valued) with associated type-2 membership grades, enabling to represent each weight link with a type-2 fuzzy number. In a way each membership value is further stretched [1] based on fuzziness of the model to capture uncertainty interval of membership values (Fig. 2). Using the interval type-2 fuzzy

[1] Zadeh[4] defines the membership values as elastic constraints that has to be stretched to get their full meaning.

ISBN: 978-989-95079-6-8

weights, we construct fuzzy graph Laplacian. The novel type-2 SSL uses label propagation algorithm [1] to obtain interval valued output values. Defuzzification follows to measure the performance of the new classifier.

In this paper we mainly focus on the application of the novel spectral classification method on a specific area of natural language processing. Text-based question answering (QA) is the process of automatically finding the answers to arbitrary questions in plain English by searching collection of text files. Recently intensive research has been continuing to grow in this area fostered by evaluation-based conferences, one of which is the Text REtrieval Conference (TREC) [5]. Among different question types, most current research focuses on the $factoid$ type questions, e.g., "*How tall is Eiffel Tower*", where the answer is short string indicating a fact with a named entity. We construct a textual entailment model to find the degree of match between the question posed by the user and the candidate answers retrieved by the search engine and then rank the sentences likely to contain the correct answer at the top.

We will briefly review graph-based SSL methods, KFKNN, and type-2 fuzzy numbers. Then we will present the novel type-2 SSL method followed by the benchmark analysis on the TREC dataset. Finally conclusions are drawn.

2 Graph Based Semi-Supervised Learning

We begin with notation and a brief summary of SSL algorithms [1], [6]. Let $X = \{x_1, ..., x_n\}$ represent n data points in $\Re^d$ and $Y = \{y_1, ..., y_n\}$ be their output targets. The labeled part of X is represented with $X_l = \{x_1, ..., x_l\}$ with associated labels $Y_l = \{y_1, ..., y_l\}^T$. For ease of presentation, we concentrate on binary classification, where y_i can take on either of $\{-1, +1\}$. X has also unlabeled part, i.e., $X = X_u \cup X_l$. The aim is to predict labels for the remaining unlabeled points, $X_u = \{x_1, ..., x_u\}$.

In this section we review the most general graph-based semi-supervised learning method for binary classification problem. A graph is denoted with $g = (V, E)$, where $V = X_l \cup X_u$ is set of nodes. E represents the edges connecting two vertexes and is represented by the $n \times n$ symmetric affinity matrix W, where an edge $W(x_i, x_j) = e(i, j)$ represents the similarity between any vertexes x_i and x_j and 0 if there is no similarity between them. The most common similarity measure is the Gaussian kernel of width σ,

$$W_{ij} = K(x_i, x_j) = e^{-\|x_i - x_j\|^2/2\sigma^2} \tag{1}$$

Earlier research [1] suggests that the choice of σ can strongly influence the results (it is one of the imprecise parameters we use to characterize uncertainty interval of membership functions in our approach.) The diagonal degree matrix D is defined for g by D=$\sum_j W_{ij}$.

In graph-based SSL, a function over the graph is estimated such that it satisfies two conditions: 1) it should be close to the given labels (L), and 2) it should be smooth (S) on the whole graph. These two conditions are presented in a regularization form to minimize the following basic algorithm. Let **f**=$[f_1, ..., f_l, f_{l+1}, ..., f_n]$ denote the predicted labels of X where $f \in \Re^n$. According to the mathematical representation of graph based approach, the objective is to minimize

$$\arg min_f \; E_L(\mathbf{f}) + \lambda E_S(\mathbf{f}). \tag{2}$$

In (2) $E_L(\mathbf{f})$ is a loss function to penalize the deviation from the given labels,

$$E_L(\mathbf{f}) = \sum_{i \subset L} (f_i - y_i)^2 \tag{3}$$

and $E_S(\mathbf{f})$ is a regularizer to represent the label smoothness,

$$E_S(\mathbf{f}) = \frac{1}{2} \sum_{i,j \in L \cup U} W_{ij}(f_i - f_j)^2 = f^T \mathbf{L} f \tag{4}$$

In (4), $L = D - W$ is the graph Laplacian. To satisfy the local and global consistency [1], the normalized combinatorial Laplacian is used such that the $E_S(\mathbf{f})$ is replaced with normalized Laplacian, $\mathcal{L} = I - D^{-1/2} L D^{-1/2}$, as follows:

$$E_S(\mathbf{f}) = \sum_{i,j \in L \cup U} W_{ij}(\frac{f_i}{\sqrt{d_i}} - \frac{f_j}{\sqrt{d_j}})^2 = f^T \mathcal{L} f \tag{5}$$

The classification function **f** is learned through any of the $label\ propagation$(LP) algorithms, e.g., [1], [7] on the graph. From consistency approach [1] $f*$ can be found as :

$$f^* = (I - \lambda \left(D^{-1/2} W D^{-1/2} \right)^{-1} Y \tag{6}$$

Nearest neighbors are most commonly used method to identify the affinity matrix of the graph. In this work, we use the KFKNN method by capturing the uncertainty interval of similarities via perturbations on learning parameters.

3 Kernel Fuzzy k-Nearest Neighbor

The k-nearest neighbor approach (KNN) is commonly used in spectral learning to obtain the link weights of the graph Laplacian. It does not depend on the distribution of selected k objects, whereas fuzzy KNN [8] deals with the distribution of the selected k objects to determine the sum of similarities between labeled data points. They both use Euclidean distance function. To handle with more complex real systems, instead of Euclidean distance, we use kernel function to calculate distance between two objects. Through some non-linear mapping the input data is mapped onto a higher-dimensional feature space, i.e., $X \rightarrow \phi(X)$ to conduct the fuzzy KNN. With the kernel trick, instead of mapping the data point and calculating the distance in the feature space, we can use the kernel function and compute the dot product in some feature space, $K(x_i, x_j) = \langle \phi(x_i), \phi(x_j) \rangle$. The distances are calculated in this space as follows:

$$\|\phi(x) - \phi(x_j)\|^2 = 2 - 2K(x, x_j) \tag{7}$$

Gaussian kernel functions as in (1) is used. Let $C_i,\ i = 1, ...c$ represent each class c of distinct labels. The FKNN algorithm [8] assigns memberships as a function of vector distance from their nearest neighbors and those neighbor memberships in the possible classes. The membership values of x_i^u in each labeled class $c = 1, ..., k$ is calculated with

$$\mu_i(x^u) = \frac{\sum_{j=1}^k \mu_{ij} \left(1/\left(1 - K(x - x_j)^{1/m-1}\right) \right.}{\sum_{j=1}^k \left(1/\left(1 - K(x - x_j)^{1/m-1}\right) \right.} \tag{8}$$

    Calculate the membership values of x_j^u, $\mu_i(x_j^u)$, in each class $i = 1, ..., c$ using N_j data points via (8)
    If required, classify x_j^u into any of C_i using criteria in (9)
  end for
end procedure

The initial class memberships of labeled points are calculated using the function in [2]. Class separation criteria is based on;

$$\hat{y}^u = \arg max_{i=1...c} \ \mu_i(x) \tag{9}$$

The input parameters of KFKNN are the k-nearest neighbors, the labeled X^l data points, and unlabeled X^u data points, the degree of fuzziness parameter, m and kernel distance variance parameter σ in (1). The parameter m determines how heavily the distance is weighted when calculating each neighbor contribution to the membership value. It has been recently shown [9], [10], [11] that changing the m parameter in fuzzy clustering methods [12] such as fuzzy c-means and fuzzy c-regression have an effect on the outcome of the partition matrix, as well as the classification results. With some perturbations on the fuzziness parameter, we can identify uncertainty interval of membership values distributions. In this work, we identify the parameter m as an interval valued parameter, $m := [m^l, m^u]$, $l : lower$, $u : upper$. Next we graduate the interval manually into crisp values, $m^r = \left\{m^1, ..., m^{nr}\right\}$. We do the same discretization for the Gaussian kernel hyperparameter, $\sigma^s = \left\{\sigma^1, ..., \sigma^{ns}\right\}$. Each pair of parameter corresponds to one discrete affinity matrix obtained from KFKNN. We obtain the degree of membership values of relations, degree of similarity of an edge, via fuzzy $max - min$ rule, to be explained in section 5.

4 Type-2 Fuzzy Numbers and Operations

Before we present the novel type-2 SSL method, we give a brief review of type-2 fuzzy numbers in the next. Introduced by Zadeh [13] in the trilogy of papers, a type-2 fuzzy set $\tilde{A}$ is characterized in [14] with a type-2 membership function, $\mu_{\tilde{A}}(x, u)$, which maps elements $x \subset X$ to their membership values $u \subset J_x \subseteq [0, 1]$ as follows:

$$\tilde{A} = \left\{\left((x, u), \mu_{\tilde{A}}(x, u)\right) | \forall x \subset X, \forall u \subset J_x \subseteq [0, 1]\right\} \tag{10}$$

where J_x is a type-1 fuzzy set, i.e., primary membership value, and $0 \leq \mu_{\tilde{A}}(x, u) \leq 1$ is called secondary membership grade. Any type-2 fuzzy set can be represented as a collection of embedded type-2 fuzzy sets [14], as follows:

$$\tilde{A}_e = \sum_{i=1}^{N} \left[f_{x_i}(u_i)/u_i\right]/x_i; u_i \subset J_{x_i} \subseteq [0, 1] \tag{11}$$

where u_i is the primary and $f_{x_i}(u_i)$ is the secondary membership grade. The total number of type-2 sets embedded in $\tilde{A}$ is given by $n_e = \prod_{i=1}^{N} M_i$, where M_i is the cardinality of each primary membership grade on $x_i \in X$. When X has a numeric domain, $\tilde{A}$ can be characterized as fuzzy number. Thus for $\tilde{A}_e^j = \left\{\left(u_i^j, f_{x_i}(u_i^j)\right), j = 1..N\right\}$ and $u_i^j \in \{u_{ik}, k = 1, ..., M\}$, we can define a fuzzy number with

$$\tilde{A} = \sum_{j=1}^{n_e} A_e^j \tag{12}$$

Zadeh [13] introduced the union and intersection of type-2 fuzzy sets. Mendel and John [14] then defined the type-2 operations with embedded type-2 fuzzy sets. The union of discrete [1] type-2 fuzzy sets $\tilde{A}$ and $\tilde{B}$ is given as:

$$\tilde{A} \cup \tilde{B} = \sum_{j=1}^{n_A} \tilde{A}_e^j \sum_{i=1}^{n_B} \tilde{B}_e^i = \sum_{j=1}^{n_A} \sum_{i=1}^{n_B} \tilde{A}_e^j \cup \tilde{B}_e^i \tag{13}$$

The union of two type-2 embedded sets in (13) is defined as:

$$\tilde{A}_e^j \cup \tilde{B}_e^i = \bigcup_{k=1}^{N} \left[F_{x_k}\left(u_k^j, w_k^j\right) / \left(u_k^j \vee w_k^i\right)\right] / x_k \tag{14}$$

where $F_{x_k}\left(u_k^j, w_k^j\right)$ is the flag that is computed by the t-norm of the secondary membership grades of any kth embedded set, $\mu_{A_e^j}\left(x_k, f_{x_k}\left(u_k^j\right)\right)$ and $\mu_{B_e^i}\left(x_k, f_{x_k}\left(w_k^i\right)\right)$ [3]. When the secondary membership grades are unity, i.e., interval type-2 fuzzy sets, the union of type-2 embedded sets are defined as:

$$\tilde{A}_e^j \cup \tilde{B}_e^i = \bigcup_{k=1}^{N} \left[1 / \left(u_k^j \vee w_k^i\right)\right] / x_k \tag{15}$$

In [15] the arithmetic operations with type-2 fuzzy numbers such as addition of $\tilde{about}$ 2 and $\tilde{about}$ 5 is defined based on (14) in series of steps. Later in [3], computationally less expensive arithmetic operations, e.g., addition and multiplication with type-2 fuzzy numbers, is defined, which will be used in this paper to define the similarity between the sentences to construct the type-2 affinity matrix. with unity secondary membership grades.

Here we will only give a brief description of addition between two interval type-2 fuzzy numbers,

$$\tilde{about}\ 3 = \{0.3, 0.6, 0.7\}/2, \{1\}/3, \{0.3, 0.6, 0.7\}/4$$
$$\tilde{about}\ 5 = \{0.6, 0.7\}/4, \{1\}/5, \{0.6, 0.7\}/6$$

Since the secondary membership grades are unity, we obtain for each discrete primary membership value:

$$\mu_{about A_e^j + \tilde{about} B_e^i}(z) = sup\left(u_x^j \wedge w_y^i\right) \tag{16}$$

where $z = x \otimes y$ is performed for any discrete number defined in $\tilde{about}\ A$ and $\tilde{about}\ B$, on all embedded numbers $u_x^j = \mu_{about\ A_e^j}$, $j = 1..n_A$ and $w_x^i = \mu_{about\ B_e^i}$, $i = 1..n_B$. In (16), $\wedge$ is t-norm(minimum). Then the union of all the pairs are captured along domains of $z \in Z = X \otimes Y$. For potential duplicate values from the resultant of the $supremum$ operation in (16), the best practice is to select pair with the highest

[1] In this paper we deal with discrete fuzzy sets as naturally the fuzzy sets are discretized to do inference.

ISBN: 978-989-95079-6-8

membership value to form the resultant interval type-2 fuzzy number. From the addition operation on two type-2 fuzzy numbers, the resulting type-2 fuzzy number would yield:

$$\tilde{about}\ 8 = \{0.3, 0.6, 0.7\}/6, \{0.6, 0.7\}/7, \{1\}/8, \{0.6, 0.7\}/9, \{0.3, 0.6, 0.7\}/10$$

5 Novel Type-2 Semi-Supervised Learning

5.1 Motivation

In graph based SSL methods, one of the main problems is to construct the graph. Typically, k-nearest neighbor of each data point is identified and then each node is connected to their k nearest neighbors according to the edge weights using a Gaussian distance function as in (1). In cases where it is difficult to identify numerical characterization of similarities between two data points, one could identify imprecise similarities as type-2 fuzzy numbers (as explained in the previous section) and characterize these fuzzy numbers based on small perturbations on the learning parameters. Applications of Type-2 fuzzy modeling tools, e.g., [16], [17], [18] has shown to be effective methods for such cases.

In this work, we mainly focus on the imprecision of model parameters to define the edge weights. It is in this sense that we characterized the edge weights of a graph with type-2 fuzzy numbers, to be explained next.

5.2 The Learning Algorithm

We assume that the dataset $X = \{x_1, ..., x_n\}$ contain set of labeled and unlabeled data points which are represented as $X = \{X^u \cup X^l\}$. There are c number of classes based on the class labels of the labeled data and k represents the nearest neighbor count. For the labeled training data points the degree of memberships to any of classes is either 0 or 1 depending on the label of the class. After we obtain the partition matrix of the overall dataset X, we compute type-2 link membership values of each pair in the dataset.

We construct one KFKNN model and obtain one partition matrix $U^{sr} \subset \Re^{n \times k}$ for each pair of imprecise parameters, $\{\sigma^s, m^r\}$, $s = 1..ns$, $r = 1..nr$, where $\mu_{ij}^{sr} \in U^{sr}$ represents the degree of membership of data point x_j to any class i obtained using parameter set of $\{\sigma^s, m^r\}$. The next step is to merge all these partition matrices to construct type-2 fuzzy graph. Each vertex is connected to its k-nearest neighbor obtained from each KFKNN model. First we measure the similarities between each connected node, $w_{pq}^s \in W^s$ in each graph with Gaussian weighted distance measure as in (1). Note that the edge similarities are effected by the Gaussian variance parameter, σ^s. As a result, we characterize each edge weight, $\tilde{w}_{pq} = \{w_{pq}^1, ..., w_{pq}^{ns}\}$, $s = 1, .., ns$, with a discrete interval valued number based on σ^s.

The next step is to associate degree of similarity to each edge weight. Any vertex v_j, representing each data point x_j holds a degree of membership μ_{ij}^{sr} to each class label $i = 1...c$ (conditional degree of possibility given class labels). To construct the fuzzy graph, μ_i^{sr} we calculate the degree of relationship between each node using conditional possibilities via min-max rule. Let $\mu_{R(x_p,x_q)}$ be the degree of relationship (similarity) between paired data points, x_p and x_q, in the graph which is measured from the conditional possibility values of

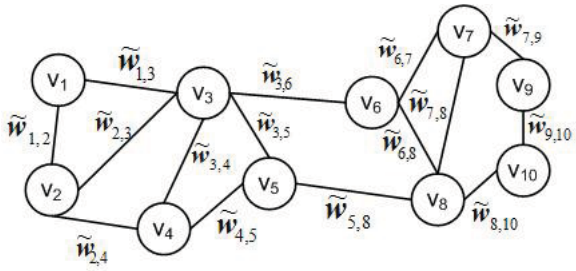

Figure 1: A type-2 fuzzy graph.

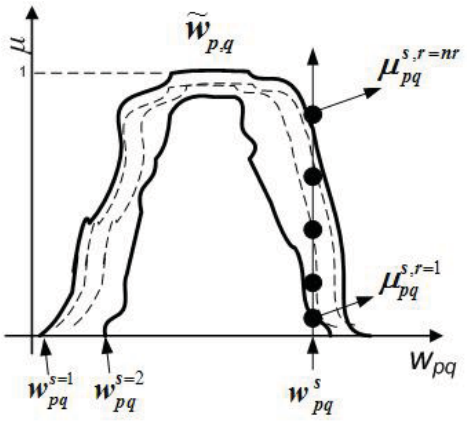

Figure 2: The interval type-2 fuzzy edge weight.

each vertex. Using the fuzzy $max-min$ rule of relations [13], we calculate the joint degree of fuzzy relations as follows:

$$\mu_{pq}(x_p, x_q) = \vee_{i=1,...,c} \left(\mu_i(x_p) \wedge \mu_i(x_q)\right) \qquad (17)$$

where $\vee$ and $\wedge$ denote max and min operations, respectively. Using (17) we define as many degree of similarity values, μ_{pq}^{sr}, as the number of discrete m^r, $r = 1..nr$, to characterize each discrete edge weight, w_{pq}^s. This would identify the edge weights as type-2 fuzzy numbers, see Figure 2.

In summary, we defined ns, $s = 1, ..., ns$ different variance values, σ^s to calculate ns different similarity values, w_{pq}^s, $s = 1.., ns.$ for any pair of connected nodes. These form the soft weight, $\tilde{w}_{pq} = w_{pq}^{s=1..ns}$ of the corresponding edge $e_{pq}, p, q = 1, ..., n$ of the graph. In addition, each discrete similarity value w_{pq}^s is represented with a degree of similarity from the $max-min$ operation, $\mu_{pq}^{sr}(x_p, x_q)$ using (17). These stretch out the degree of membership of each w_{pq}^s, and we identify discrete membership values for each weight, w_{pq}^s.

The fuzzy graph where the edges are represented with the soft type-2 weights is shown in Fig. 1, and Fig. 2 displays a sample edge weight that is in the form of type-2 fuzzy number.

The pseudo code for the type-2 fuzzy semi-supervised graph learning method is shown in Algorithm 2. Initially the partition matrix U is computed for unlabeled data points using the labeled data (Step-3). Note that the membership values of the labeled data points $\mu_i(x_j^l)$ to any of the c clusters are either 1 or 0 so they are merged to the partition matrix (Step-7).

After the conditional possibility values of each data point x_j to each class $\mu_i^{sr}(x_j)$ is obtained from every pair of parameter values, $\{\sigma^s, m^r\}$ we measure the joint possibilities of paired data points in step 9-10. We use the $max-min$ rule to obtain single degree of similarity between two nodes, x_p and x_q. In

    -Execute Algorithm 1 using $\{\sigma^s, m^r\}$ to obtain
    each partition matrix $U^{sr} \subset \Re^{n \times c}$
    -Calculate similarity matrix $W^s = \{w^s_{pq}\}$ using σ^s
  EndFor
  $\mu^{sr}_j \in U^{sr} = U^{sr} + \{\mu_{i=1..c}(x^l_{i=1..n_l})\}$ where
  For $p, q = 1, ..., n,\ p \neq q$
    -Calculate degree of fuzzy relation, $\mu^{sr}_{pq}(x_p, x_q)$
    using (17)
    -Characterize each edge weight as type-2 fuzzy
    number $\tilde{w}_{pq} = \{w^{s=1..ns}_{pq}\} \in \tilde{W} \subset \Re^{n \times n}$
    using each μ^{sr}_{pq}.
    $\tilde{d}_p \in \tilde{D} \subset \Re^{n \times n} \leftarrow \sum_{q=1}^{n} \tilde{w}_{pq}$
  EndFor
  $\tilde{Ln} \leftarrow \tilde{D}^{-1/2} \tilde{W} \tilde{D}^{-1/2}$
end procedure

this way we represent the discrete membership values of the type-2 fuzzy number of the corresponding edge similarity.

Using the type-2 fuzzy number operations from section 4 [3], we obtain the fuzzy degree of each connected edge. Note that, instead of crisp edge weights, W, and graph node degrees, D, we characterized type-2 fuzzy edge matrix $\tilde{W}$ and degrees, $\tilde{D}$. To obtain the soft normalized graph Laplace, we compute the Step-16.

5.3 Inference with Soft Graphs

In the previous section we presented the algorithm to form a soft graph Laplacian matrix $\tilde{L}_n$, the members of which are represented with interval type-2 fuzzy numbers. It has been shown in recent literature [**?**, 9, 11, 10] that some of the uncertainties in system models can be captured during learning when we define interval values for the learning parameters instead of crisp values. For instance when fuzzy clustering methods are used to construct membership functions (fuzzy sets) defining an interval valued fuzziness parameter, m, instead of crisp value, we can identify the uncertainty interval of the membership functions as well as the perturbation effects on the local functions. The same is also true for the parameters of similarity functions. The variance parameter of a Gaussian kernel has a significant effect on the outcome [7]. By the analogy of these approaches, we use the interval valued Gaussian variance distance measures and fuzziness parameter of the KFKNN for identification of the soft graph Laplacian as explained in the previous section. The classifier function is learnt using the graph Laplacian. In standard SSL methods, briefly explained in section 2, one can use a label prorogation method to find the classifier function, f^*. In Type-2 SSL algorithm of this paper, we learn classifier by first type-reducing the type-2 graph Laplacian and then defuzzifying its values to obtain a single graph Laplace.

The graph Laplacian is a sparse matrix $L := \left(l^{n \times n}_{pq}\right)$ representing the difference between the degree matrix and weight matrix. The matrix elements are zero if there is no edge link, and 1 for the diagonal elements. Hence the matrix is sparse representing the graph where there are edge

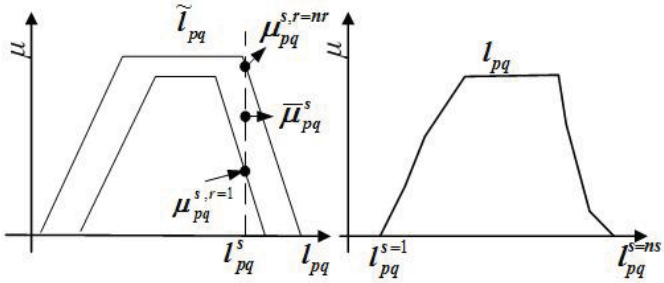

Figure 3: (Left Graph)Interval type-2 fuzzy laplace value. (Right Graph)Type-1 fuzzy laplace value.

links. We consider soft normalized graph Laplacian $\tilde{\mathcal{L}} = I - \tilde{D}^{-1/2} \tilde{W} \tilde{D}^{-1/2}$. Each matrix element $\tilde{l}_{pq}$ is an interval type-2 fuzzy number, represented as:

$$\tilde{l}_{pq} = \left\{\mu^{s=1,r=1}_{pq}, .., \mu^{s,r=nr}_{pq}\right\} / l^{s=1}_{pq} + \cdots + \left\{\mu^{s=ns,r=1}_{pq}, .., \mu^{s=ns,r=nr}_{pq}\right\} / l^{s=ns}_{pq}$$

We consider type-reducing the Laplace values via center of gravity (COG) rule as shown in Figure 3 as

$$COG(\mu^s_{pq}) = \sum_{j=1}^{nr} \mu^{s,r=j}_{pq} / nr \tag{18}$$

Then we defuzzify to obtain a single Laplace values:

$$l_{pq} = \frac{\sum_{t=1}^{ns} COG\left(\mu^s_{pq}\right) l^{s=t}_{pq}}{\sum_{i=1}^{ns} COG\left(\mu^s_{pq}\right)} \tag{19}$$

Using the defuzzified graph Laplacian, we obtain the classifier function using (6).

6 Textual Entailment Model for Question Answering

In this section we use a real question and answering (Q/A) dataset to test the performance of the type-2 SSL in comparison to the SSL method [7], and well-known SVM [19]. We used the TREC2001-2003 factoid questions for training and TREC04 questions for testing. The training and testing datasets comprise of 20 relevant sentences for each question that may or may not contain the true answer. We build the training and testing datasets using the relevant documents provided by NIST [2] and extracted 20 relevant sentences from TREC corpus using search engine [3]. We manually classified each retrieved sentence as true/false based on the provided gold-factoid-answers. In addition, we used additional question-sentence pairs from RTE-3, and RTE-4 datasets of RTE challenges [4]. We used only Q/A type sentence pairs and converted the hypothesis sentences into question forms to build the Q/A pairs. We sustained the true/false distributions in the training and testing datasets around 25% true-75% false.

Each of the Q/A pairs, i.e., from TREC and RTE, are used to extract features to indicate true/false entailment. Thus the

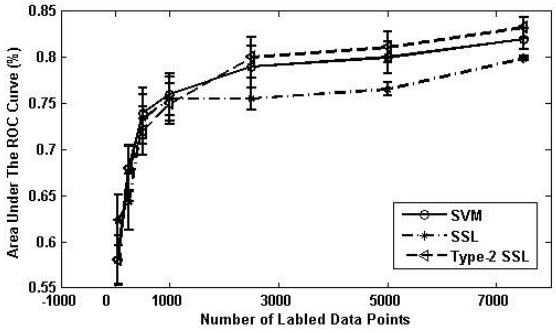

Figure 4: AUC performance on Testing Dataset.

aim of the model is to identify if the candidate sentence entails the question. To measure entailment we extracted 20 different features based on syntactic and semantic match between the question and answer sentences. Some of our features include syntactic matching (keyword and phrase match), named-entity match, headword match using hypernym, hyponym extensions of words, answer type match, which is determined from the question. An automatic hypernym relation extraction algorithm is implemented to capture semantic structures in sentences, such as 'a.k.a', 'such as', apposition relations, to list a few. In addition, we used semantic features such as sentence structure match, i.e., subject, object, headword match, named entity match based on our named entity module to match 50 fine objects in sentence pairs such as time, place, location, person, descriptions, reason, numbers, etc.

In this experiment we used around 600 training questions to compile around 7500 training data points. Similarly, using the entire 202 TREC04 factoid questions as testing, we compiled around 4000 testing data points. Among the training datasets, we used different number of labeled data points to compile series of experiments. Since the data points are randomly selected from the pool, we repeated the experiments 10 times and captured the standard errors to measure robustness. We measured the accuracy of the true/false entailments based on **A**rea **U**nder the Receiver Operating **C**urve statistic. We repeated the experiment using different training sets of different sizes. We built type-2 SSL models with parameters, i.e., $k = \{3, 5, 10, 50\}$, $m = \{1.4, 1.5, ..., 2.6\}$, $\sigma = \left\{10^{-2}, ..10^{2}\right\}$ and tested the AUC performance on the same testing dataset. We compared the performance of our models with the ones obtained from application of the same experiments using standard SSL method [20] with the same learning parameters as well as the SVM methods using learning parameters $C = \left\{2^{-1}, ..., 2^{8}\right\}$ and $\gamma = \{1 - default\}$. The AUC performance comparison with the well-known SSL and SVM method is shown Figure 4. The results of the experiment on QA datasets reveals that the new soft SSL outperforms the standard SSL method. The results are comparable with the state-of the art SVM tool. Based on the current experiment we can suggest that the presented method is an alternative method for linguistic analysis when there are not enough labeled data but more unlabeled data present.

7 Conclusions

We presented a new uncertainty modeling tool for graph-based semi-supervised learning methods using type2 fuzzy number arithmetic. We learn the interval valued degree of similarity values based on fuzzy k-nearest approach. Each edge linking weight is represented with a type-2 fuzzy number and arithmetic operations on type-2 fuzzy numbers are implemented to build the type-2 fuzzy graph Laplacian and learn a classifier function. Experiments on information extraction from unstructured text for question/answering task have shown promising results.

Can We Learn Algorithms from People Who Compute Fast: An Indirect Analysis in the Presence of Fuzzy Descriptions

Olga Kosheleva[1]

1.Department of Teacher Education
University of Texas at El Paso

El Paso, TX 79968, USA
olgak@utep.edu

Abstract— *In the past, mathematicians actively used the ability of some people to perform calculations unusually fast. With the advent of computers, there is no longer need for human calculators – even fast ones. However, recently, it was discovered that there exist, e.g., multiplication algorithms which are much faster than standard multiplication. Because of this discovery, it is possible than even faster algorithm will be discovered. It is therefore natural to ask: did fast human calculators of the past use faster algorithms – in which case we can learn from their experience – or they simply performed all operations within a standard algorithm much faster? This question is difficult to answer directly, because the fast human calculators' self-description of their algorithm is very fuzzy. In this paper, we use an indirect analysis to argue that fast human calculators most probably used the standard algorithm.*

Keywords— Fast Fourier transform, fast human calculators, fast multiplication, fuzzy description

1 People Who Computed Fast: A Historical Phenomenon

In history, several people have been known for their extraordinary ability to compute fast. Before the 20 century invention of computers, their computational abilities were actively used.

For example, in the 19 century, Johann Martin Zaharias Dase performed computations so much faster than everyone else that professional mathematicians hired him to help with their calculations; see, e.g., [1, 3]. Dase:

- computed π with a record-breaking accuracy of 200 digits,
- calculated the logarithms table with 7 digit accuracy, and
- performed many other computational tasks.

Karl Friedrich Gauss himself recommended that Dase be paid by the Academy of Science to perform the calculations.

2 People Who Computed Fast: How They Computed?

Calculations have been (and are) important in many practical problems. Because of this practical importance, people have therefore always been trying to speed up computations. One natural way to speed up computations is to learn from the people who can do computations fast.

3 People Who Computed Fast: Their Self-Explanations Were Fuzzy and Unclear

In spite of numerous attempts to interview the fast calculators and to learn from them how they compute, researchers could not extract a coherent algorithm. One of the main reasons is that most of the fast calculators were *idiots savants*: their intellectual abilities outside computations were below average. Their explanations of their algorithms were always fuzzy and imprecise, formulated in terms of words of natural language rather than in precise mathematical terms.

To us familiar with fuzzy logic and its applications this fuzziness should not be surprising. It is normal that people in general – and not necessarily idiots savants – cannot precisely describe

- how they drive,
- how they operate machines,
- how they walk,
- how they translate from one language to another,
- how they recognize faces,
- how they control different situations, etc.

– this is why fuzzy control and other fuzzy techniques, techniques for translating this fuzzy description into a precise strategy, have so many practical applications; see, e.g., [4].

What may be somewhat unusual about fast computations is that while the self-description of fast calculators was fuzzy and imprecise, the results of the computations were always correct and precise.

4 With the Appearance of Computers, the Interest in Fast Human Calculators Waned

With the appearance of computers, the need for human calculators disappeared, and the interest in their skills waned. Such such folks may provide a good entertainment, they may be of interest to psychologists who study how we reason and how we perform menial tasks – but mathematicians were no longer interested.

Yes, fast human calculators can perform calculations faster than an average human being – but electronic computers can perform the same computations much much faster. From this viewpoint, fast human calculators remained a curiosity.

ISBN: 978-989-95079-6-8

5 Why Interest Waned: Implicit Assumptions

One of the main reasons why in the 1940s and 1950s the interest in fast human calculators waned is that it was implicitly assumed that the standard techniques of addition and multiplication are the best.

For example, it was assumed that the fastest way to add the two n-digit numbers is to add them digit by digit, which requires $O(n)$ operations with digits.

It was also implicitly assumed that the fastest way to multiply two n-digit numbers is the standard way to multiply the first number by each of the digits of the second numbers, and then to add the results. Each multiplication by a digit and each addition requires $O(n)$ steps, thus multiplication by all n digits and the addition of all n results require $n \cdot O(n) = O(n^2)$ computational steps.

From this viewpoint, the only difference between a normal human calculator, a fast human calculator, and an electronic computer is in the speed with which we can perform operations with digits. From this viewpoint, the only thing we can learn from fast human calculators is how to perform operations with digits faster. Once the electronic computers became faster than fast human calculators, the need to learn from the fast human calculators disappeared.

6 A Surprising 1960s Discovery of Fast Multiplication Algorithms

The above implicit assumption about arithmetic operations was not questioned until a surprising sequence of discoveries was made in the 1960s; see, e.g., [2].

These discoveries started with the discovery of the Fast Fourier Transform algorithm, an algorithm that enables us to compute the Fourier Transform

$$\hat{f}(\omega) = \frac{1}{\sqrt{2\pi}} \cdot \int f(t) \cdot \exp(\mathrm{i} \cdot \omega \cdot t)\, dt, \tag{1}$$

where $\mathrm{i} = \sqrt{-1}$, in time $O(n \cdot \log(n))$ – instead of the $n \cdot O(n) = O(n^2)$ time needed for a straightforward computation of each of n values of $\hat{f}(\omega)$ as an integral (i.e., in effect, a sum) over n different values $f(t)$.

The ability to compute Fourier transform fast lead to the ability to speed the computation of the convolution of two functions:

$$h(t) \stackrel{\text{def}}{=} \int f(s) \cdot g(t-s)\, ds. \tag{2}$$

A straightforward computation of the convolution requires that for each of the n values $h(t)$, we compute the integral (sum) of n different products $f(s) \cdot g(t-s)$ corresponding to n different values s. Thus, the straightforward computation requires $O(n^2)$ computational steps.

Indeed, it is known that the Fourier transform of the convolution is equal to the product of Fourier transforms. Thus, to compute convolution, we can do the following:

- first, we compute Fourier transforms $\hat{f}(\omega)$ and $\hat{g}(\omega)$;
- then, we compute the Fourier transform of h as

$$\hat{h}(\omega) = \hat{f}(\omega) \cdot \hat{g}(\omega); \tag{3}$$

- finally, we apply the inverse Fourier transform to the function $\hat{h}(\omega)$ and compute the desired convolution $h(t)$.

What is the computation time of this algorithm?

- Both Fourier transform and inverse Fourier transform can be computed in time $O(n \cdot \log(n))$.
- The point-by-point multiplication $\hat{h}(\omega) = \hat{f}(\omega) \cdot \hat{g}(\omega)$ requires n computational steps.

Thus, the overall computation time requires

$$O(n \cdot \log(n)) + n + O(n \cdot \log(n)) = O(n \cdot \log(n)) \tag{4}$$

steps, which is much faster than $O(n^2)$.

V. Strassen was the first to notice, in 1968, than this idea can lead to fast multiplication of long integers. Indeed, an integer x in a number system with base b can be represented as a sum

$$x = \sum_{i=1}^{n} x_i \cdot b^i. \tag{5}$$

In these notations, the product $z = x \cdot y$ of two integers $x = \sum\limits_{i=1}^{n} x_i \cdot b^i$ and $y = \sum_{i=1}^{n} y_i \cdot b^i$ can be represented as

$$z = \left(\sum_{i=1}^{n} x_i \cdot b^i\right) \cdot \left(\sum_{j=1}^{n} y_j \cdot b^j\right) =$$

$$\sum_{i=1}^{n}\sum_{j=1}^{n} x_i \cdot y_j \cdot b^i \cdot b^j = \sum_{i=1}^{n}\sum_{j=1}^{n} x_i \cdot y_j \cdot b^{i+j}. \tag{6}$$

By combining terms at different values b^k, we conclude that

$$z = \sum_{k=1}^{n} z_k \cdot b^k, \tag{7}$$

where

$$z_k = \sum_{i} x_i \cdot y_{k-i}. \tag{8}$$

This is convolution, and we know that convolution can be computed in time $O(n \cdot \log(n))$.

The values z_k are not exactly the digits of the desired number z, since the sum (8) can exceed the base b. Thus, some further computations are needed. However, even with these further computations, we can multiply two numbers in almost the same time

$$O(n \cdot \log(n) \cdot \log(\log(n))). \tag{9}$$

The corresponding algorithm, first proposed by A. Schönhage and V. Strassen in their 1971 paper [5], remains the fastest known – and it is much faster than the standard $O(n^2)$ algorithm.

7 Fast Multiplication: Open Problems

Fast algorithms drastically reduced the computation time. Fast Fourier transform is one of the main tools for signal processing. These successes has led to the need to find faster and faster algorithms. From this viewpoint, it is is desirable to look for even faster algorithms for multiplying numbers.

The fact that researchers succeeded in discovering algorithms which are much faster than traditional multiplication gives us hope that even faster algorithms can be found.

ISBN: 978-989-95079-6-8

8 Interest in Fast Human Calculators Revived

Where to look for these algorithms? One natural source is folks who did compute fast. From this viewpoint, the fact that they were unable to clearly explain what algorithm they used becomes an advantage: maybe the algorithm that they actually used is some fast multiplication algorithm? This possibility revived an interest in fast human calculators.

So, the question is:

- did fast human calculators use fast multiplication algorithm(s), or
- they used the standard algorithm but simply performed operations with digits faster?

9 Direct Analysis Is Impossible

The most well-known fast human calculator, Johann Martin Zacharias Dase, died almost 150 years ago. Even when he was alive, his self-descriptions were not sufficient to find out how exactly he performed the computations. There might have been hope that our knowledge of fast multiplication algorithms can help in this understanding, but it did not work out. In other words, the direct analysis of Dase's behavior has been impossible – and it is still impossible. We therefore need to perform an *indirect* analysis.

10 Indirect Analysis: Main Idea

A natural way to check which algorithm is used by a computational device – be it a human calculator or an electronic computer – is to find out how the computation time changes with the size n (= number of digits) of the numbers that we are multiplying.

- If this computation time grows with n as n^2, then it is reasonable to conclude that the standard algorithm is used – since for this algorithm, the computation time grows as n^2.
- On the other hand, if the computation time grows with n as $\approx n \cdot \log(n)$ (or even slower), then it is reasonable to conclude that a fast multiplication algorithm is used.
  - It maybe a Strassen-type algorithm, for which the computation time grows as $n \cdot \log(n)$.
  - It may be a (yet unknown) faster algorithm in which case the computation time grows even slower than $n \cdot \log(n)$.

11 Data That We Can Use

Interestingly, there is a data on the time that Dase needed to perform multiplication of numbers of different size. This data comes from fact that Dase's performance was analyzed and tested by several prominent mathematicians of his time – including Gauss himself. Specifically:

- Dase multiplied two 8-digit numbers in 54 seconds;
- he multiplied two 20-digit numbers in 6 minutes;
- he multiplied two 40-digit numbers in 40 minutes; and
- he multiplied two 100-digit numbers in 8 hours and 45 minutes.

12 Analysis

For the standard multiplication algorithm, the number of computational steps grows with the numbers size n as n^2. Thus, for the standard multiplication algorithm, the computation time for performing the computation also grows as n^2:

$$t(n) = C \cdot n^2. \tag{10}$$

So, for this algorithm, two different number sizes $n_1 < n_2$, we would have $t(n_1) = C \cdot n_1^2$ and $t(n_2) = C \cdot n_2^2$ and thus,

$$\frac{t(n_2)}{t(n_1)} = \frac{n_2^2}{n_1^2} = \left(\frac{n_2}{n_1}\right)^2. \tag{11}$$

For a faster algorithm, e.g., for the algorithm that requires $O(n \cdot \log(n))$ running time, the corresponding ratio will be smaller:

$$\frac{t(n_2)}{t(n_1)} = \frac{n_2 \cdot \log(n_2)}{n_1 \cdot \log(n_1))} = \frac{n_2}{n_1} \cdot \frac{\log(n_2)}{\log(n_1)}. \tag{12}$$

Thus, to check whether a human calculators uses the standard algorithm or a faster one it is sufficient to compare the the corresponding time ratio $\frac{t(n_2)}{t(n_1)}$ with the square $\left(\frac{n_2}{n_1}\right)^2$:

- If the time ratio is smaller than the square, this means that the human calculator used an algorithm which is much faster than the standard one.
- On the other hand, if the time ratio is approximately the same as the square, thus means that the human calculators most probably used the standard algorithm – or at least some modification of it that does not drastically speed up the computations.
- If it turns out that the time ratio is larger than the square, this would mean, in effect, that a human calculator used an algorithm which is asymptotically even slower than the standard one – this can happen, e.g., if there is an overhead needed to store values etc.

According to the above data, we have:

- $t(8) = 0.9$ minutes,
- $t(20) = 6$ minutes,
- $t(40) = 40$ minutes, and
- $t(100) = 8 \cdot 60 + 45 = 525$ minutes.

Here, for $n_1 = 8$ and $n_1 = 20$, we have:

$$\frac{t(n_2)}{t(n_1)} = \frac{t(20)}{t(8)} = \frac{6}{0.9} \approx 6.7 > \left(\frac{n_2}{n_1}\right)^2 =$$

$$\left(\frac{20}{8}\right)^2 = 2.5^2 = 6.25. \tag{13}$$

For $n_1 = 8$ and $n_2 = 40$, we have

$$\frac{t(n_2)}{t(n_1)} = \frac{t(40)}{t(8)} = \frac{40}{0.9} \approx 44 > \left(\frac{n_2}{n_1}\right)^2 =$$

ISBN: 978-989-95079-6-8

$$\left(\frac{40}{8}\right)^2 = 5^2 = 25. \quad (14)$$

Finally, for $n_1 = 8$ and $n_2 = 100$, we have

$$\frac{t(n_2)}{t(n_1)} = \frac{t(100)}{t(8)} = \frac{525}{0.9} \approx 583 > \left(\frac{n_2}{n_1}\right)^2 = \left(\frac{100}{8}\right)^2 = 12.5^2 \approx 156. \quad (15)$$

In all these cases, the computation time of a human calculator grows faster then n^2 corresponding to the standard algorithm.

The same conclusion can be made if instead of comparing each value n with the smallest value n_1, we compare these values with each other. For $n_1 = 20$ and $n_2 = 40$, we have

$$\frac{t(n_2)}{t(n_1)} = \frac{t(40)}{t(20)} = \frac{40}{6} \approx 7 > \left(\frac{n_2}{n_1}\right)^2 = \left(\frac{40}{20}\right)^2 = 2^2 = 4. \quad (16)$$

For $n_1 = 20$ and $n_2 = 100$, we have

$$\frac{t(n_2)}{t(n_1)} = \frac{t(100)}{t(20)} = \frac{525}{6} \approx 88 > \left(\frac{n_2}{n_1}\right)^2 = \left(\frac{100}{20}\right)^2 = 5^2 = 25. \quad (17)$$

Finally, for $n_1 = 40$ and $n_2 = 100$, we have

$$\frac{t(n_2)}{t(n_1)} = \frac{t(100)}{t(40)} = \frac{525}{40} \approx 13 > \left(\frac{n_2}{n_1}\right)^2 = \left(\frac{100}{40}\right)^2 = 2.5^2 = 6.25. \quad (18)$$

Thus, it is reasonable to conclude that the fast human calculators did not use any algorithm which is faster than the standard one.

13 Possible Future Work

People who perform computations fast appear once in a while. It may be a good idea to record and analyze their computation time – and maybe record their fuzzy explanations and try to make sense of them.

Abstract— *This work describes a novel fuzzy-sets-based method to solve a particular class of quadratic programming problems which have vagueness coefficients in the objective function. Quadratic programming problems are of utmost importance in an increasing variety of practical fields. In addition, as the ambiguity and vagueness are natural and ever-present in real-life situations requiring solutions, it makes perfect sense to attempt to address them using fuzzy quadratic programming problems. Also, two other methods to solve this kind of problems are briefly described. The proposal uses two phases to solve fuzzy quadratic programming problems. In the first, phase we parametrize the fuzzy problem in several classical alpha-problems with different cutting levels. In the second, phase each of these alpha-problems is solved by using conventional solving techniques. The final fuzzy solution to the problem is obtained by integrating all of these particular alpha-solutions. The results obtained using these two methods are compared with the two-phased proposal outlined above.*

Keywords— Fuzzy sets, decision making, fuzzy mathematical programming, quadratic optimization.

1 Introduction

The conception of Artificial Intelligence (AI) in the early fifties was inspired by the wide variety of physical and mental tasks performed by humans without any measurements and any computations. Thus, this forward thinking described the definition of AI as it is widely known: "the study and design of intelligent agents [14]", where an intelligent agent is a system that perceives its environment and takes actions which maximize its chances of success[15]. The capability to compute and reason with perception-based information can be applied to real-world problems in which decision-relevant information is a mixture of measurements and perceptions [20], where in general, measurements are crisp, although perceptions are fuzzy.

The literature shows that the best way of modeling these types of problems is using Soft Computing methodologies. According to Verdegay et al.[17], Soft Computing is a family of problem-resolution methods headed by approximate reasoning, functional and optimization approximation methods, which now include search methods. More specifically, the search methods use thorough evaluations to find regions with approximate points of optimal solutions that are obtained by using optimization methods.

These methods, which are algorithms based on mathematical knowledge, are used to guarantee the convergence to the optimal solution. They are covered by the area of mathematical programming. This area has several sub-fields where the quadratic programming is a special type that optimizes a quadratic objective function of several variables subject to linear constraints. A precise definition of the constraints and the objective function to be optimized is necessary to obtain exact optimal solutions of quadratic programming problems.

Nevertheless, in most real practical applications (portfolio, game theory, engineering modeling, design and control, logistics, etc.) one lacks this kind of exact knowledge, and only approximate, vague and imprecise values are known. Moreover, these imprecise values can be dealt with fuzzy logic. In this case, the concept of fuzzy mathematical programming emerges when it is used.

With this in mind, the objective of this paper is to review some methods that are related to quadratic topic and to outline a soft computing model used to solve novel fuzzy quadratic programming problems.

The paper is organized as follows: Section 2 briefly introduces the different approaches to solving the quadratic programming problem with fuzzy costs. In this section, a novel approach is developed to solve quadratic programming problems with fuzzy costs where these are transformed into parametrical quadratic multiobjective programming problems. To clarify the above developments, three numerical examples are analyzed in section 3. Finally, conclusions are presented in Section 4.

2 Quadratic optimization with fuzzy costs

An optimization problem that is described with a quadratic objective function subject to linear constraints is called a "Quadratic Programming" problem. QP can be viewed both as a special case of the nonlinear programming and a generalization of the linear programming. Several applications and methods can be found in [3, 8, 9, 16, 19]. A quadratic programming problem can be formulated as

$$\begin{array}{ll} \min & \mathbf{c^t x} + \frac{1}{2}\mathbf{x^t Q x} \\ \text{s.t.} & \mathbf{A x} \leq \mathbf{b} \\ & \mathbf{x} \geq 0 \end{array} \tag{1}$$

where $\mathbf{x}$ and $\mathbf{c}$ are n vectores of real numbers, $\mathbf{Q}$ is an $n \times n$ symmetric matrix of real numbers, $\mathbf{A}$ is an $m \times n$ matrix of real numbers and $\mathbf{b}$ is an m vector of real numbers.

ISBN: 978-989-95079-6-8

In this work, quadratic programming problems with fuzzy costs are considered because there are cases of real world problems whose parameters are seldom known exactly and have to be estimated by the decision maker. Hence, the $n \times n$ symmetric matrix $\mathbf{Q}$ and the n vector $\mathbf{c}$ have fuzzy numbers in these components. The application of fuzzy logic is also a way to describe, mathematically, this vagueness as described in [2, 10, 13, 18]. The uncertainties of costs of the objective function can be dealt with by fuzzy numbers.

Thus, this set of problems with uncertain costs can be formalized in the following form:

$$\begin{array}{ll} \min & \tilde{\mathbf{c}}^{\mathbf{t}}\mathbf{x} + \frac{1}{2}\mathbf{x}^{\mathbf{t}}\tilde{\mathbf{Q}}\mathbf{x} \\ \text{s.t.} & \mathbf{A}\mathbf{x} \leq \mathbf{b} \\ & \mathbf{x} \geq 0 \end{array} \tag{2}$$

where the fuzzy numbers are characterized by membership functions that are defined by decision makers. The membership functions can be defined as

$$\mu_j, \mu_{ij} : \mathbb{R} \to [0,1], \;\; i,j \in \mathbb{J} = \{1,2,\ldots,n\}$$

In particular these membership functions will be supposed as:

$$\mu_j(y) = \begin{cases} 0 & \text{if } c_j^U \leq y \text{ or } y \leq c_j^L \\ h_j(y) & \text{if } c_j^L \leq y \leq c_j \\ g_j(y) & \text{if } c_j \leq y \leq c_j^U \end{cases} \qquad j \in \mathbb{J} \tag{3}$$

and

$$\mu_{ij}(y) = \begin{cases} 0 & \text{if } q_{ij}^U \leq y \text{ or } y \leq q_{ij}^L \\ h_{ij}(y) & \text{if } q_{ij}^L \leq y \leq q_{ij} \\ g_{ij}(y) & \text{if } q_{ij} \leq y \leq q_{ij}^U \end{cases} \qquad i,j \in \mathbb{J} \tag{4}$$

where $\mathbf{h}(\cdot)$ and $\mathbf{g}(\cdot)$ are assumed to be strictly increasing and decreasing continuous functions, respectively, $h_j(c_j) = g_j(c_j) = 1,\ j \in \mathbb{J}$ and $h_{ij}(q_{ij}) = g_{ij}(q_{ij}) = 1,\ i,j \in \mathbb{J}$.

Bellman and Zadeh describe the *fuzzy decision* in [4] as the intersection of goals and constraints which is formalized in the following definition:

Definition 1 *Assume that we are given a fuzzy goal μ_G and a fuzzy constraint μ_C in a space of alternative X. Then, μ_G and μ_C combine to form a* fuzzy decision*, μ_D, which is a fuzzy set resulting from intersection of μ_G and μ_C. In symbols*

$$\sup_{\mathbf{x} \in X} \mu_D(\mathbf{x}) = \sup_{\mathbf{x} \in X} [\mu_G(\mathbf{x}) \wedge \mu_C(\mathbf{x})]$$

Note that in Definition 1, the goals and the constraints enter into the expression for μ_D in the same way. Thus, it is able to find a maximizing decision to an extremum problem for a scalar function, as described in [13]. Let ϕ be denoted by $\phi : [0,1] \to [0,1]$ that implies $\phi(\alpha) = \sup_{\mathbf{x} \in \mathbf{X}(\alpha)} \mu_G(\mathbf{x})$ where $X(\alpha) = \{\mathbf{x} \in \mathbb{R}^n \mid \mu_X(\mathbf{x}) \geq \alpha\}$. If ϕ is continuous in [0,1] then ϕ has a *fix point* $\overline{\alpha}$ and, therefore,

$$\sup_{\mathbf{x} \in X} \mu_D(\mathbf{x}) = \sup_{\mathbf{x} \in X(\overline{\alpha})} \mu_G(\mathbf{x}) = \overline{\alpha}$$

.

A novel parametric approach to solve quadratic programming problems with fuzzy costs will be presented in the next sub-section. This approach transforms the original problem into a parametric multi-objective quadratic programming problem.

2.1 Multi-objective approach

A multi-objective approach to solve a linear programming problem with imprecise costs is described in [6, 7]. As the linear problem is a particular case of quadratic problem, this approach can be extended to solve quadratic programming problems with fuzzy costs.

The quadratic objective function can be divided into two parts, where the first one is a linear term and the second one is a quadratic term. According to this, the fuzzy costs can only be in the first part or only the second part or in both. In this section, these three ways will be presented separately.

The linear problem considered in [6] used trapezoid membership functions for the costs but here, for the sake of simplicity, they will be supposed to be like (3) and (4).

Then, by considering the $(1-\alpha)$-cut of every cost, $\alpha \in [0,1]$,

$$\begin{array}{l} \forall\, x \in \mathbb{R},\;\; \mu_j(x) \geq 1-\alpha \Leftrightarrow h_j^{-1}(1-\alpha) \leq x \leq g_j^{-1}(1-\alpha), \\ \forall\, x \in \mathbb{R},\;\; \mu_{ij}(x) \geq 1-\alpha \Leftrightarrow h_{ij}^{-1}(1-\alpha) \leq x \leq g_{ij}^{-1}(1-\alpha), \end{array}$$

where $i,j \in \mathbb{J} = \{1,2,\ldots,n\}$.

2.1.1 Quadratic programming problem with fuzzy costs vector of linear term

The approaches described in this section solve a quadratic programming problem with a vector $\tilde{\mathbf{c}}$ of fuzzy numbers. This vector describes the costs of the objective function and Problem 2 can be rewritten as follows:

$$\begin{array}{ll} \min & \tilde{\mathbf{c}}^{\mathbf{t}}\mathbf{x} + \frac{1}{2}\mathbf{x}^{\mathbf{t}}\mathbf{Q}\mathbf{x} \\ \text{s.t.} & \mathbf{A}\mathbf{x} \leq \mathbf{b} \\ & \mathbf{x} \geq \mathbf{0}. \end{array} \tag{5}$$

Thus, according to some results by Bitran [5], it has been shown that a fuzzy solution to (5) may be found from the parametric solution of the multi-objective parametric quadratic programming problem

$$\begin{array}{ll} \min & \left[(\mathbf{c^1})^{\mathbf{t}}\mathbf{x} + \frac{1}{2}\mathbf{x}^{\mathbf{t}}\mathbf{Q}\mathbf{x}, (\mathbf{c^2})^{\mathbf{t}}\mathbf{x} + \frac{1}{2}\mathbf{x}^{\mathbf{t}}\mathbf{Q}\mathbf{x}, \ldots, (\mathbf{c^{2^n}})^{\mathbf{t}}\mathbf{x} + \frac{1}{2}\mathbf{x}^{\mathbf{t}}\mathbf{Q}\mathbf{x}\right] \\ \text{s.t.} & \mathbf{A}\mathbf{x} \leq \mathbf{b},\;\; \mathbf{x} \geq \mathbf{0}, \\ & \mathbf{c^k} \in \mathbb{E}(1-\alpha),\;\; \alpha \in [0,1],\;\; k = 1,2,\ldots,2^n, \end{array} \tag{6}$$

where $\mathbb{E}(1-\alpha)$, for each $\alpha \in [0,1]$, is the set of vectors in $\mathbb{R}^n$ such that each of its components is either in the lower bound, $h_j^{-1}(1-\alpha)$, or in the upper bound, $g_j^{-1}(1-\alpha)$, of the respective $(1-\alpha)$-cut, that is, $\forall\, k = 1,2,\ldots,2^n$, and $\forall\, j \in \mathbb{J}$

$$c^k = (c_1^k, c_2^k, \ldots, c_n^k) \in \mathbb{E}(1-\alpha) \Leftrightarrow c_j^k = \begin{cases} h_j^{-1}(1-\alpha) & \text{or} \\ g_j^{-1}(1-\alpha). \end{cases}$$

Now observe that to find a parametric solution to (6), from which one can obtain a fuzzy solution to (5), one may use any classical multiobjective quadratic programming approach.

2.1.2 Quadratic programming problem with fuzzy costs matrix of quadratic term

The approach described in this section solves a quadratic programming problem with matrix $\tilde{\mathbf{Q}}$ of fuzzy numbers. This

ISBN: 978-989-95079-6-8

vector describes the costs of the objective function and Problem 2 can be rewritten as follows

$$\begin{aligned} \min \quad & \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t \tilde{Q} x} \\ \text{s.t.} \quad & \mathbf{Ax} \leq \mathbf{b} \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned} \tag{7}$$

As it was shown above, a fuzzy solution to (7) may be found from the parametric solution of the multiobjective parametric quadratic programming problem

$$\begin{aligned} \min \quad & \left[\mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q^1 x}, \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q^2 x}, \ldots, \mathbf{c^t x} + \tfrac{1}{2}\mathbf{x^t Q^{2^{n^2}} x}\right] \\ \text{s.t.} \quad & \mathbf{Ax} \leq \mathbf{b}, \ \ \mathbf{x} \geq \mathbf{0}, \\ & \mathbf{Q^k} \in \mathbb{E}(1-\alpha), \ \ \alpha \in [0,1], \ \ k = 1,2,\ldots,2^{n^2}, \end{aligned} \tag{8}$$

where $\mathbb{E}(1-\alpha)$, for each $\alpha \in [0,1]$, is the set of vectors in $\mathbb{R}^n$ such that each of its components is either in the lower bound, $h_{ij}^{-1}(1-\alpha)$, or in the upper bound, $g_{ij}^{-1}(1-\alpha)$, of the respective $(1-\alpha)$-cut, that is, $\forall\, k = 1,2,\ldots,2^{n^2}$, and $\forall\, i,j \in \mathbb{J}$

$$\mathbf{Q^k} = (q_{11}^k, \ldots, q_{1n}^k, \ldots, q_{nn}^k) \in \mathbb{E}(1-\alpha) \Leftrightarrow$$
$$\Leftrightarrow q_{ij}^k = \begin{cases} h_{ij}^{-1}(1-\alpha) & \text{or} \\ g_{ij}^{-1}(1-\alpha). \end{cases}$$

Now observe that to find a parametric solution to (8), from which one can obtain a fuzzy solution to (7), one may use any classical multiobjective quadratic programming approach.

2.1.3 *Quadratic programming problem with all fuzzy costs*

Thus, according to the parametric transformations shown above, a fuzzy solution to (2) may be found from the parametric solution of the multiobjective parametric quadratic programming problem

$$\begin{aligned} \min \quad & \left[(\mathbf{c^1})^\mathbf{t}\mathbf{x} + \tfrac{1}{2}\mathbf{x^t Q^1 x}, (\mathbf{c^2})^\mathbf{t}\mathbf{x} + \tfrac{1}{2}\mathbf{x^t Q^1 x}, \ldots,\right. \\ & \ldots, (\mathbf{c^{2^n}})^\mathbf{t}\mathbf{x} + \tfrac{1}{2}\mathbf{x^t Q^1 x}, (\mathbf{c^1})^\mathbf{t}\mathbf{x} + \tfrac{1}{2}\mathbf{x^t Q^2 x}, \ldots, \\ & \left. \ldots, (\mathbf{c^{2^n}})^\mathbf{t}\mathbf{x} + \tfrac{1}{2}\mathbf{x^t Q^2 x}, \ldots, (\mathbf{c^{2^n}})^\mathbf{t}\mathbf{x} + \tfrac{1}{2}\mathbf{x^t Q^{2^{n^2}} x}\right] \\ \text{s.t.} \quad & \mathbf{Ax} \leq \mathbf{b}, \ \ \mathbf{x} \geq \mathbf{0}, \\ & \mathbf{c^k}, \mathbf{Q^p} \in \mathbb{E}(1-\alpha), \ \ \alpha \in [0,1], \\ & k = 1,2,\ldots,2^n \text{ and } p = 1,2,\ldots,2^{n^2}, \end{aligned} \tag{9}$$

where $\mathbb{E}(1-\alpha)$, for each $\alpha \in [0,1]$, is the set of vectors in $\mathbb{R}^n$ such that each of its components is either in the lower bound, $h_j^{-1}(1-\alpha)$, or in the upper bound, $g_j^{-1}(1-\alpha)$, of the respective $(1-\alpha)$-cut, that is, $\forall\, k = 1,2,\ldots,2^n$, and $\forall\, i,j \in \mathbb{J}$

$$c^k = (c_1^k, c_2^k, \ldots, c_n^k) \in \mathbb{E}(1-\alpha) \Leftrightarrow c_j^k = \begin{cases} h_j^{-1}(1-\alpha) & \text{or} \\ g_j^{-1}(1-\alpha). \end{cases}$$

and

$$\mathbf{Q^k} = (q_{11}^k, \ldots, q_{1n}^k, \ldots, q_{nn}^k) \in \mathbb{E}(1-\alpha) \Leftrightarrow$$
$$\Leftrightarrow q_{ij}^k = \begin{cases} h_{ij}^{-1}(1-\alpha) & \text{or} \\ g_{ij}^{-1}(1-\alpha). \end{cases}$$

The obtained parametrical solutions for any of multiobjective models above, to the different α values, generate a set of solutions and then we use the Representation Theorem to integrate all of these particular alpha-solutions.

2.2 *Liu's approach*

Transforming a fuzzy quadratic programming problem into a two-level mathematical programming problem for finding the bounds of the fuzzy values in the objective function and in the set of constraints is discussed in [11, 12]. These papers describe how to transform the two-level mathematical program into the conventional one-level quadratic program. However, such a method is also valid when only the objective is fuzzy, that is, when only the vector of costs are fuzzy, and for this reason it shall be considered here. According to the goal of this work, the coefficient $\mathbf{c}$ of Problem (5) is fuzzy.

The authors derive the membership function of the goal, and then they apply Zadeh's extension principle to transform the fuzzy quadratic problem into family of classical quadratic problems that can be solved by conventional optimization techniques. Thus, the membership function of the objective function can be defined as

$$\mu_{\tilde{Z}}(z) = \sup_{\mathbf{c}} \min\{\mu_{\tilde{c}_j}(c_j), \ \forall j | z = Z(\mathbf{c})\} \tag{10}$$

where $Z(\mathbf{c})$ is the goal of the conventional quadratic problem. Membership function $\mu_{\tilde{Z}}$ can be computed by finding the functions that describe the shape of the left and right sides of the fuzzy numbers. Then, it is possible to obtain the upper bound of the objective value Z_α^U and your lower bound Z_α^L to each value α. Thus, Z_α^U is the maximum and Z_α^L is the minimum of $Z(\mathbf{c})$, respectively, that can be described as

$$Z_\alpha^U = \max_{c_j} \left\{ \begin{array}{ll} \min_{\mathbf{x}} & \sum_{j=1}^n c_j x_j + \frac{1}{2}\sum_{j=1}^n \sum_{l=1}^n q_{jl} x_j x_l \\ \text{s.a} & \sum_{j=1}^n a_{ij} x_j \leq b_i, \ \ i = 1,\ldots,m \\ & x_j \geq 0, \ \ j = 1,\ldots,n \end{array} \right. \tag{11}$$

$$Z_\alpha^L = \min_{c_j} \left\{ \begin{array}{ll} \min_{\mathbf{x}} & \sum_{j=1}^n c_j x_j + \frac{1}{2}\sum_{j=1}^n \sum_{k=1}^n q_{jk} x_j x_k \\ \text{s.a} & \sum_{j=1}^n a_{ij} x_j \leq b_i, \ \ i = 1,\ldots,m \\ & x_j \geq 0, \ \ j = 1,\ldots,n \end{array} \right. \tag{12}$$

where $c_j \in [(c_j)_\alpha^L, (c_j)_\alpha^U]$, for any $\alpha \in [0,1]$ chosen by decision maker.

These two formulations above are solved by outer-level and inner-level programs, respectively. The outer-level program obtains the values c_j that are used with parameters by inner-level program. The inner-level program solves a classical quadratic programming problem with the data obtained by outer-level program. The authors state that the formulation of two-level quadratic problems is a generalization of the conventional parametrical quadratic programming problem. Thus, the first two-level mathematical program can be transformed into the following quadratic problem by dual formulation:

$$\begin{aligned} \max \quad & \sum_{i=1}^m b_i \lambda_i - \tfrac{1}{2}\sum_{i=1}^n \sum_{j=1}^n q_{ij} x_i x_j \\ \text{s.t.} \quad & \sum_{i=1}^m a_{ij}\lambda_i + \delta_j - \sum_{i=1}^n q_{ij} x_i = c_j, \ \ j = 1,2,\ldots,n \\ & (c_j)_\alpha^L \leq c_j \leq (c_j)_\alpha^U, \ \ j = 1,2,\ldots,n \\ & \lambda_i, \delta_j \geq 0, \ \ i = 1,2,\ldots,m \text{ and } j = 1,2,\ldots,n. \end{aligned} \tag{13}$$

Since both the inner-level program and the outer-level of the second program have the same minimization operation, they can be combined into a conventional one-level program with the constraints of the two programs considered simultaneously. Consequently, some points must be analyzed which

ISBN: 978-989-95079-6-8

are shown in [11, 12]. The second program can be described as

$$\begin{array}{ll}\max & \sum_{j=1}^{n}(c_j)_{\alpha}^{L}+\frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}q_{ij}x_ix_j \\ \text{s.t.} & \sum_{i=1}^{n}a_{ij}x_i\leq b_i,\ \ i=1,2,\ldots,m \\ & x_j\geq 0,\ \ j=1,2,\ldots,n\end{array} \tag{14}$$

2.3 Ammar's approach

A method to solve a quadratic programming problem with fuzzy coefficients in the objective function and in the set of constraint is described in [1]. However, such a method is also valid when only the objective is fuzzy, that is, when only the matrix of costs are fuzzy, and for this reason it shall be considered here. This approach can be formulated in the following way:

$$\begin{array}{ll}\min & \mathbf{x^t}\tilde{\mathbf{Q}}\mathbf{x} \\ \text{s.t.} & \mathbf{Ax}\leq\mathbf{b} \\ & \mathbf{x}\geq\mathbf{0}.\end{array} \tag{15}$$

where all decision variables are non negatives and the linear term in objective function is not used. However, in this work only costs of the objective functions are imprecise.

Thus, Problem (15) can be reformulated by using α-cutting levels as

$$\begin{array}{lll}(P_\alpha): & \min & \mathbf{x^t}[\mathbf{Q}_\alpha^-,\mathbf{Q}_\alpha^+]\mathbf{x} \\ & \text{s.a} & \mathbf{Ax}\leq\mathbf{b} \\ & & \mathbf{x}\geq\mathbf{0}.\end{array} \tag{16}$$

where $\alpha\in(0,1]$. $\mathbf{Q}_\alpha^-$ represents a matrix with the lower values of the interval and $\mathbf{Q}_\alpha^+$ represents a matrix with the upper values of the interval.

[1] describes how Problem (16) can be written in two quadratic problems. Then, these problems are formulated as follows

$$\begin{array}{lll}(P_\alpha^-): & \min & \mathbf{x^t}\mathbf{Q}_\alpha^-\mathbf{x} \\ & \text{s.a} & \mathbf{Ax}\leq\mathbf{b} \\ & & \mathbf{x}\geq\mathbf{0}.\end{array} \tag{17}$$

$$\begin{array}{lll}(P_\alpha^+): & \min & \mathbf{x^t}\mathbf{Q}_\alpha^+\mathbf{x} \\ & \text{s.t.} & \mathbf{Ax}\leq\mathbf{b} \\ & & \mathbf{x}\geq\mathbf{0}.\end{array} \tag{18}$$

where the first problem uses the lower bound of the interval of the α-cutting level and the second problem uses the upper bound.

The two quadratic problems (17) and (18) can be solved by using the conditions of Karush-Kuhn-Tucker's optimality to each α value. The optimal solution of the original problem (16), (P_α), is inside the interval formed by the optimal solutions of each one problems (P_α^-) and (P_α^+).

3 Numerical example

In this section, we illustrate a quadratic programming problem that will be solved with three different way. Each way is represented by different fuzzy environment in each problem, i.e., the first problem has fuzzy costs in the linear term, while the second has fuzzy costs in the quadratic term, and the third has fuzzy costs in all coefficients in the objective function.

Example 1 *Consider the following quadratic programming problem with fuzzy coefficients in the linear term:*

$$\begin{array}{ll}\min & (-6,-5,-4)x_1+(1,1.5,2)x_2+2x_1^2-2x_1x_2+x_2^2 \\ \text{s.t.} & x_1+x_2\leq 2 \\ & 2x_1-x_2\leq 4 \\ & x_1,x_2\geq 0.\end{array} \tag{19}$$

The membership functions are:

$$\mu_{-5}(c_1)=\left\{\begin{array}{ll}c_1+6 & -6\leq c_1\leq -5\\ -c_1-4 & -5\leq c_1\leq -4\end{array}\right.$$

$$\mu_{1.5}(c_2)=\left\{\begin{array}{ll}2(c_2-1) & 1\leq c_2\leq 1.5\\ 2(2-c_2) & 1.5\leq c_2\leq 2\end{array}\right.$$

From the membership function for this costs an interval representation according to (3) can be given:

$$\begin{array}{ll}c_1^{0.2}=[-5.8,-4.2], & c_1^{0.4}=[-5.6,-4.4],\\ c_1^{0.6}=[-5.4,-4.6], & c_1^{0.8}=[-5.2,-4.8]\end{array}$$

$$\begin{array}{ll}c_2^{0.2}=[1.1,1.9], & c_2^{0.4}=[1.2,1.8],\\ c_2^{0.6}=[1.3,1.7], & c_2^{0.8}=[1.4,1.6]\end{array}$$

with $c_1^0=[-6,-4]$, $c_1^1=[-5,-5]$ *and* $c_2^0=[1,2]$, $c_2^1=[1.5,1.5]$, *and now* $\mathbb{M}=\{0,0.2,0.4,0.6,0.8,1\}$.

Thus, Problem (19) can be re-formulated as:

$$\begin{array}{ll}\min & (\alpha-6)x_1+\frac{1}{2}(\alpha+2)x_2+2x_1^2-2x_1x_2+x_2^2\\ \min & (\alpha-6)x_1+\frac{1}{2}(4-\alpha)x_2+2x_1^2-2x_1x_2+x_2^2\\ \min & (-\alpha-4)x_1+\frac{1}{2}(\alpha+2)x_2+2x_1^2-2x_1x_2+x_2^2\\ \min & (-\alpha-4)x_1+\frac{1}{2}(4-\alpha)x_2+2x_1^2-2x_1x_2+x_2^2\\ \text{s.t.} & x_1+x_2\leq 2\\ & 2x_1-x_2\leq 4\\ & x_1,x_2\geq 0.\end{array} \tag{20}$$

Problem (20) is solved by weighting objectives, with $\alpha=0.8$*, where an auxiliary problem can be obtained in the following way:*

$$\begin{array}{ll}\min & \omega_1[-5.2x_1+1.4x_2]+\omega_2[-5.2x_1+1.6x_2]+\\ & +\omega_3[-4.8x_1+1.4x_2]+\omega_4[-4.8x_1+1.6x_2]+\\ & +2x_1^2-2x_1x_2+x_2^2\\ s.t. & x_1+x_2\leq 2,\ \ 2x_1-x_2\leq 4,\ \ x_1,x_2\geq 0.\end{array} \tag{21}$$

Different optimal solutions to each of the weighting vectors is obtained by choosing the canonical base of $\mathbb{R}^4$ *as weighting vectors, as it is presented in Table 1.*

Table 1: Result of Problem 21 to each vector ω.

ω	x_1	x_2	FunObj
(1,0,0,0)	1.4600	0.5400	-3.8580
(0,1,0,0)	1.4800	0.5200	-3.7520
(0,0,1,0)	1.4200	0.5800	-3.2820
(0,0,0,1)	1.4400	0.5600	-3.1680

By taking $\omega_1=\omega_2=\omega_3=\omega_4=\frac{1}{4}$ *and solving (21) the optimal solution is* $x^*=[1.45,0.55]$ *and value of objective function is -3.5125.*

On the other hand, according to the method described in 2.2, Problem (19), which is the outer-level program, can be

ISBN: 978-989-95079-6-8

rewritten as:

$$\begin{array}{ll}\max & 2\lambda_1+4\lambda_2-\frac{1}{2}(4x_1^2-4x_1x_2+2x_2^2)\\ \text{s.t.} & \lambda_1+2\lambda_2-\delta_1-4x_1+2x_2=c_1\\ & \lambda_1-1\lambda_2-\delta_2+2x_1-2x_2=c_2\\ & -5.2\le c_1\le -4.8\\ & 1.4\le c_2\le 1.6\\ & x_1,x_2,\lambda_1,\lambda_2,\delta_1,\delta_2\ge 0.\end{array} \tag{22}$$

and the inner-level program can be written as:

$$\begin{array}{ll}\min & -5.2x_1+1.4x_2+\frac{1}{2}(4x_1^2-4x_1x_2+2x_2^2)\\ \text{s.t.} & x_1+x_2\le 2\\ & 2x_1-x_2\le 4\\ & x_1,x_2\ge 0.\end{array} \tag{23}$$

This model is a traditional quadratic program that can represent the two models described in 2.2. Hence, by solving the outer-level program the optimal solution is $x^*=[1.3,0]$ and value of objective function is -3.38. On the other hand, by solving the inner-level program the optimal solution is $x^*=[1.45,0.55]$ and value of objective function is -3.8575.

Example 2 *Consider the following quadratic programming problem with fuzzy coefficients in the quadratic term:*

$$\begin{array}{ll}\min & -5x_1+1.5x_2+(1,2,3)x_1^2+(1,2,3)x_1x_2+(0,1,2)x_2^2\\ \text{s.t.} & x_1+x_2\ge 2\\ & 2x_1-x_2\ge 4\\ & x_1,x_2\ge 0.\end{array} \tag{24}$$

The membership functions are

$$\mu_2(c_1)=\begin{cases} c_1-1 & 1\le c_1\le 2\\ 2-c_1 & 2\le c_1\le 3\end{cases}$$

$$\mu_1(c_2)=\begin{cases} c_2 & 0\le c_2\le 1\\ 2-c_2 & 1\le c_2\le 2\end{cases}$$

From the membership function for these costs an interval representation according to (4) can be given:

$$c_1^{0.2}=[1.2,2.8],\quad c_1^{0.4}=[1.4,2.6],$$
$$c_1^{0.6}=[1.6,2.4],\quad c_1^{0.8}=[1.8,2.2]$$

$$c_2^{0.2}=[0.2,1.8],\quad c_2^{0.4}=[0.4,1.6],$$
$$c_2^{0.6}=[0.6,1.4],\quad c_2^{0.8}=[0.8,1.2]$$

with $c_1^0=[1,3]$, $c_1^1=[2,2]$ and $c_2^0=[0,2]$, $c_2^1=[1,1]$, and now $\mathbb{M}=\{0,0.2,0.4,0.6,0.8,1\}$.

Thus, Problem (24) can be re-formulated as

$$\begin{array}{ll}\min & -5x_1+1.5x_2+(\alpha+1)x_1^2-(\alpha+1)x_1x_2+\alpha x_2^2\\ \min & -5x_1+1.5x_2+(\alpha+1)x_1^2-(\alpha+1)x_1x_2+(2-\alpha)x_2^2\\ \min & -5x_1+1.5x_2+(\alpha+1)x_1^2-(3-\alpha)x_1x_2+\alpha x_2^2\\ \min & -5x_1+1.5x_2+(\alpha+1)x_1^2-(3-\alpha)x_1x_2+(2-\alpha)x_2^2\\ \min & -5x_1+1.5x_2+(3-\alpha)x_1^2-(\alpha+1)x_1x_2+\alpha x_2^2\\ \min & -5x_1+1.5x_2+(3-\alpha)x_1^2-(\alpha+1)x_1x_2+(2-\alpha)x_2^2\\ \min & -5x_1+1.5x_2+(3-\alpha)x_1^2-(3-\alpha)x_1x_2+\alpha x_2^2\\ \min & -5x_1+1.5x_2+(3-\alpha)x_1^2-(3-\alpha)x_1x_2+(2-\alpha)x_2^2\\ \text{s.t.} & x_1+x_2\ge 2\\ & 2x_1-x_2\ge 4\\ & x_1,x_2\ge 0.\end{array} \tag{25}$$

Problem (25) is solved by weighting objectives, with $\alpha=0.8$, where an auxiliary problem like (21) can be obtained;

$$\begin{array}{ll}\min & -5x_1+1.5x_2+\omega 1(1.8x_1^2-1.8x_1x_2+0.8x_2^2)\\ & +\omega_2(1.8x_1^2-1.8x_1x_2+1.2x_2^2)+\omega_3(1.8x_1^2-2.2x_1x_2+0.8x_2^2)\\ & +\omega_4(1.8x_1^2-2.2x_1x_2+1.2x_2^2)+\omega_5(2.2x_1^2-1.8x_1x_2+0.8x_2^2)\\ & +\omega_6(2.2x_1^2-1.8x_1x_2+1.2x_2^2)+\omega_7(2.2x_1^2-2.2x_1x_2+0.8x_2^2)\\ & +\omega_8(2.2x_1^2-2.2x_1x_2+1.2x_2^2)\\ \text{s.t.} & x_1+x_2\ge 2,\ 2x_1-x_2\ge 4,\ x_1,x_2\ge 0.\end{array} \tag{26}$$

Different optimal solutions to each of the weighting vectors is obtained by choosing the canonical base of $\mathbb{R}^8$ as weighting vectors, as it is presented in Table 2.

Table 2: Result of Problem 21 to each vector ω.

ω	x_1	x_2	FunObj
(1,0,0,0,0,0,0,0)	1.5114	0.4886	-3.8506
(0,1,0,0,0,0,0,0)	1.5521	0.4479	-3.7630
(0,0,1,0,0,0,0,0)	1.4688	0.5312	-4.1547
(0,0,0,1,0,0,0,0)	1.5096	0.4904	-4.0505
(0,0,0,0,1,0,0,0)	1.3854	0.6146	-3.0130
(0,0,0,0,0,1,0,0)	1.2705	0.3279	-2.9303
(0,0,0,0,0,0,1,0)	1.3558	0.6442	-3.3582
(0,0,0,0,0,0,0,1)	1.4018	0.5982	-3.2040

On the other hand, the approach described in 2.3 can be obtained by using the first and last weighting vector of Table 2. Hence, by taking $\omega_L=(1,0,0,0,0,0,0,0)$ and solving (26) the optimal solution is $x^*=[1.5114,0.4886]$ and value of objective function is -3.8506. Besides, by taking $\omega_U=(0,0,0,0,0,0,0,1)$ and solving (26) the optimal solution is $x^*=[1.4018,0.5982]$ and value of objective function is -3.2040.

Example 3 *Consider the following quadratic programming problem with all fuzzy coefficients:*

$$\begin{array}{ll}\min & (-6,-5,-4)x_1+(1,1.5,2)x_2+(1,2,3)x_1^2+\\ & +(1,2,3)x_1x_2+(0,1,2)x_2^2\\ \text{s.t.} & x_1+x_2\ge 2\\ & 2x_1-x_2\ge 4\\ & x_1,x_2\ge 0.\end{array} \tag{27}$$

The membership functions are

$$\mu_{-5}(c_1)=\begin{cases} c_1+6 & -6\le c_1\le -5\\ -c_1-4 & -5\le c_1\le -4\end{cases}$$

$$\mu_{1.5}(c_2)=\begin{cases} 2(c_2-1) & 1\le c_2\le 1.5\\ 2(2-c_2) & 1.5\le c_2\le 2\end{cases}$$

$$\mu_2(c_1)=\begin{cases} c_1-1 & 1\le c_1\le 2\\ 2-c_1 & 2\le c_1\le 3\end{cases}$$

$$\mu_1(c_2)=\begin{cases} c_2 & 0\le c_2\le 1\\ 2-c_2 & 1\le c_2\le 2\end{cases}$$

From the membership function for these costs an interval

ISBN: 978-989-95079-6-8

representation according to (3) and (4) can be given:

$$c_1^{0.2} = [-5.8, -4.2], \quad c_1^{0.4} = [-5.6, -4.4],$$
$$c_1^{0.6} = [-5.4, -4.6], \quad c_1^{0.8} = [-5.2, -4.8]$$

$$c_2^{0.2} = [1.1, 1.9], \quad c_2^{0.4} = [1.2, 1.8],$$
$$c_2^{0.6} = [1.3, 1.7], \quad c_2^{0.8} = [1.4, 1.6]$$

$$c_3^{0.2} = [1.2, 2.8], \quad c_3^{0.4} = [1.4, 2.6],$$
$$c_3^{0.6} = [1.6, 2.4], \quad c_3^{0.8} = [1.8, 2.2]$$

$$c_4^{0.2} = [0.2, 1.8], \quad c_4^{0.4} = [0.4, 1.6],$$
$$c_4^{0.6} = [0.6, 1.4], \quad c_4^{0.8} = [0.8, 1.2]$$

with $c_1^0 = [-6, -4]$, $c_1^1 = [-5, -5]$, $c_2^0 = [1, 2]$, $c_2^1 = [1.5, 1.5]$, $c_3^0 = [1, 3]$, $c_1^3 = [2, 2]$ *and* $c_4^0 = [0, 2]$, $c_4^1 = [1, 1]$, *and now* $\mathbb{M} = \{0, 0.2, 0.4, 0.6, 0.8, 1\}$.

Different optimal solutions to each of the weighting vectors can be showed by the multi-objective method described choosing the canonical base of $\mathbb{R}^{32}$ *as weighting vectors. According to the previous examples, it can obtain the minimum and maximum values that form the optimal interval of this problem. The minimum value is -4.5021 where the optimal solution is* $[1.4792, 0.5208]$ *while the maximum value of this optimal interval is -2.6579 where the optimal solution is* $[1.1803, 0.2186]$.

4 Conclusions

This paper presented three approaches for solving fuzzy quadratic programming problems. A novel approach that transforms a quadratic programming problem with imprecise costs in the objective function into a parametric multiobjective quadratic programming problem. The other two approaches are methods published that are used in this work for comparison. Quadratic Programming is very important in theoretical and practical areas. When real-world applications are considered, vagueness appears in a natural way, and hence it makes perfect sense to think of fuzzy quadratic programming problems. In contrast to what happens in fuzzy linear programming problems, unfortunately until now not much research has been conducted to this important class of problems.

It was shown that the parametric multiobjective programming problem can obtain the optimal solutions of the other approaches because these solutions are a quadratic or linear combination of the optimal solutions obtained for each of weighting vectors. Hence, this shows that the parametric multiobjective approach contains the optimal solutions obtained by the others. Therefore, parametric approaches can be used as a general method to solve quadratic programming problems with uncertain costs in the objective function.

The authors aim to extend the line of investigation involving Fuzzy Quadratic Programming problems in order to try to solve practical real-life problems by facilitating the building of Decision Support Systems.

Abstract— *In this paper we investigate properties of multicriteria methods that are used for building land-use suitability assessment criteria. We identify and describe fundamental properties that are of interest in the land-use suitability analysis and the design of suitability maps. The existing multicriteria methods can be evaluated from the standpoint of their ability to support the desirable properties that affect the expressive power of evaluation methods. In this paper we investigate simple additive scoring, MAVT, MAUT, AHP, OWA, outranking methods and LSP.*

Keywords— GIS, land-use, MCDM.

1 Introduction

This paper has two main goals. The first goal is to identify properties that affect the expressive power of multicriteria decision methods (MCDM) that can be used to create suitability maps of a specific geographic region. The second goal is to investigate land-use suitability assessment methods that are based on simple additive scoring (SAS), multiattribute value technique (MAVT), multiattribute utility technique (MAUT), analytic hierarchy process (AHP), ordered weighted average (OWA), outranking methods (ELECTRE, PROMETHEE), and logic scoring of preference (LSP) in view of satisfaction of the identified properties.

We assume that the analyzed geographic region is divided into cells and that each cell with coordinates x, y is characterized by an array of suitability attribute values $a_1(x,y), \ldots, a_n(x,y)$, $n \geq 1$ [5]. The attributes are defined as quantitative parameters that affect the suitability of a cell for some specific land-use (e.g. housing, recreation, agriculture, industrial development, etc.). The set of attributes must be complete, i.e., it must include *all* relevant components. Generally, the attributes must be justifiable and not redundant with each other.

The purpose of MCDM is to provide a criterion function $\sigma : \mathbb{R}^n \rightarrow [0,1]$ for computing an overall degree of suitability $S(x,y) = \sigma(a_1(x,y), \ldots, a_n(x,y))$ that reflects the suitability of location x, y for specific land-use. The overall suitability is a matter of degree: $0 \leq S(x,y) \leq 1$. As in all soft computing models, here 0 denotes a completely unsuitable location, and 1 denotes the highest level of suitability. A suitability map is defined as a distribution of the overall suitability $S(x,y)$ for a specific geographic region [7].

Nowadays suitability maps are assumed to be dynamically created using data from GIS databases in a way illustrated in Fig. 1. The multicriteria decision model must be interfaced both with the user and with the GIS database. An attribute ETL interface is necessary to Extract, Transform, and Load the set of cell attribute values from the GIS database. The multicriteria decision model is used to implement the criterion function σ and to generate the overall suitability $S(x,y)$. The user input includes a specification of desired suitability attributes and parameters of the decision model. A suitability criterion interface is necessary for accepting user input and for rendering the resulting suitability map.

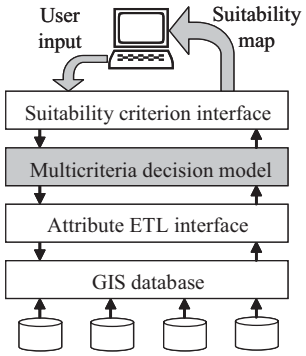

Figure 1: Dynamic generation of suitability maps using GIS.

Suitability maps introduced in GIS literature use a variety of decision models [16, 9, 11, 5, 20]. The emphasis of such efforts is primarily (and naturally) on the selection of attributes and the use of suitability maps. So far the GIS literature avoided problems of evaluating the credibility of MCDM used for the development of suitability maps.

Except for interfacing with GIS components, the land-use suitability assessment problems do not differ from evaluation problems in other areas. All multicriteria decision models are ultimately models of human decision making in the area of evaluation of complex alternatives. Therefore, the credibility of MCDM used in GIS context depends on their ability to express observable properties of human evaluation logic [4]. The primary purpose of this paper is to evaluate the expressive power of GIS-related MCDM based on the level of their ability to support the concepts of human evaluation logic.

The remainder of this paper is structured as follows. In Section 2, the logic properties of GIS-related MCDM are studied. In Section 3, the logic properties of the selected decision meth-

ISBN: 978-989-95079-6-8

ods are investigated. The major contributions of the paper are summarized and some conclusions are presented in Section 4.

2 Ten fundamental properties of MCDM

The properties of human evaluation logic are easily observable, and they are also observable in the context of land-use evaluation. Our goal is to first identify properties that are frequently encountered in all worth assessment problems. The most important properties include the following:

1. Ability to combine any number of attributes.
2. Ability to combine objective and subjective inputs.
3. Ability to combine absolute and relative criteria.
4. Flexible adjustment of relative importance of attributes.
5. Modelling of simultaneity requirements.
   (a) Modelling of soft simultaneity.
   (b) Modelling of hard simultaneity.
6. Modelling of replaceability requirements.
   (a) Modelling of soft replaceability.
   (b) Modelling of hard replaceability.
7. Modelling of balanced simultaneity/replaceability.
8. Modelling of mandatory, desired, and optional requirements.
9. Modelling of sufficient, desired, and optional requirements.
10. Ability to express suitability as an aggregate of usefulness and inexpensiveness (separation of the usefulness analysis and the cost analysis).

2.1 Ability to combine any number of attributes

We assume that the analyzed geographic region is divided into cells and that each cell is characterized by attributes $a_1, \ldots, a_n$, $n \geq 1$. In special cases $n = 1$. For example, the acoustic pollution (noise) maps presented in [11] uses in each cell a single scalar value, the level of noise. However, in all cases of more complex suitability maps we have $n > 1$. For example, the housing suitability maps discussed in [5] use $n = 11$. If we want to develop maps of complex suitability indicators that depend on variety of inputs it is reasonable to expect that the number of inputs can be large. So, in a general case, MCDM used to compute the land-use suitability must be able to support any number of inputs.

It should be noted that this requirement indirectly transforms into a requirement to use nonlinear MCDM models. Indeed, in the case of linear weighted aggregation models, the overall suitability $S(x, y)$ is a dot product of a vector of n suitability components $\mathbf{s} = [s_1(x, y), \ldots, s_n(x, y)]$ (one component for each attribute) and a corresponding vector of relative weights $\mathbf{W} = [W_1, \ldots, W_n]$: $S(x, y) = \sum_{i=1}^{n} W_i s_i(x, y)$ where $0 \leq s_i(x, y) \leq 1$, $0 < W_i < 1$, $i = 1, \ldots, n$, and $W_1 + \cdots + W_n = 1$.

Obviously, a large value of n yields a low significance of individual components. For example, if $n = 100$ the average significance (the ability to change the overall suitability S) of each input is only 1%, and in the case of unequal weights some inputs will have the significance considerably below 1% which means that such inputs may (and should) be neglected. This is not acceptable since credible decision models must be equally applicable for any number of inputs.

2.2 Ability to combine objective and subjective inputs

Some input attributes are objectively measurable values (e.g., distances, slopes, altitudes, temperatures, etc). Other inputs are subjective and must be assessed by experts (e.g., aesthetic quality of an area, the quality of educational and/or medical institutions, quality of public transportation, development costs, etc.). MCDM for GIS applications must be able to combine and aggregate objective and subjective inputs.

2.3 Ability to combine absolute and relative criteria

Each suitability attribute must satisfy specific requirements. The requirements can be defined as elementary criterion functions $g_i : \mathbb{R} \rightarrow [0, 1]$, $i = 1, 2, \ldots, n$. By definition, the attribute suitability $s_i(x, y) = g_i(a_i(x, y))$ is the degree of satisfaction of the attribute requirements. The suitability of an attribute is a component of the overall suitability of the evaluated location x, y.

Suppose that a decision maker (DM) needs a suitability map for housing in a rural area where it is possible to buy land and build a house. Let the attribute $a_i(x, y) = t$ denote the traveling time between location $L(x, y)$ and the closest elementary school (or hospital, or airport, or any other point of interest). An absolute criterion is a criterion that evaluates location L regardless of other competitive locations. E.g., a DM may specify the absolute requirements as threshold times t_{min} and t_{max} so that all times $t \geq t_{max}$ are considered unacceptable and all times $t \leq t_{min}$ are considered perfectly acceptable. Then the elementary criterion function might be defined as follows: $g_i(t) = \max(0, \min(1, (t_{max} - t)/(t_{max} - t_{min})))$. So, $g_i(t)$ specifies the attribute suitability for any value of t. If DM wants to compare locations L_1 and L_2, with respect to the access to school then the comparison can be based on $g_i(t_1)$ and $g_i(t_2)$. If t_{min} and t_{max} are well justifiable values, then $g_i(t_1)$ and $g_i(t_2)$ are very credible results.

Another approach is to define a relative criterion. In the case of k locations an example of such a criterion could be $g_i(t) = t_{min}/t$, $t_{min} = \min(t_1, \ldots, t_k)$. The relative criterion evaluates relationships between competitors regardless of DM's actual needs: the closest location is considered perfectly suitable ($g_i(t_{min}) = 1$) and a location where $t = 2t_{min}$ gets $g_i(t) = 0.5$. Obviously, the credibility of relative criteria is much less under DM's control than the credibility of corresponding absolute criteria. E.g., if only two locations are available, then the location that is 2 minutes from the closest school is likely to be equally attractive as the location that is 1 minute from the school, and locations that are 1 hour and 2 hours from the closest school might be equally unacceptable; in both cases the suitability levels of 1 and 0.5 are inappropriate. For some other values, e.g., $t_{min} = 7$ minutes, the presented relative criterion might be appropriate.

It is highly unlikely that DM knows what is better, but does not know what is good. In other words, if DM can specify a justifiable relative criterion, it is very likely that DM can also specify a justifiable absolute criterion. Absolute criteria can be used to evaluate a single alternative (e.g., a single location), while relative criteria can be applied only if we have multiple alternatives. Relative criteria are appropriate only in situations where expected values of attributes are unknown. Such situations are not frequent, but exist, and MCDM must be able to combine and aggregate absolute and relative attribute criteria.

ISBN: 978-989-95079-6-8

2.4 Flexible adjustment of the relative importance of attributes

In a general case, multiple attributes are not equally important. The relative importance of an attribute is usually expressed using multiplicative or implicative weights [3]. The relative importance has two roles in suitability criteria: it defines the level of contribution of an attribute to the overall suitability, and it defines compensatory properties between attributes. Assuming that the overall suitability is a function of attribute suitability degrees, $S = \lambda(s_1, \ldots, s_j, \ldots, s_k, \ldots, s_n)$, we expect that if the suitability s_j is more important than the suitability s_k, then $\partial S/\partial s_j \geq \partial S/\partial s_k$. Under the same assumptions, if some compensation is possible, then $\lambda(s_1, \ldots, s_j, \ldots, s_k, \ldots, s_n) = \lambda(s_1, \ldots, s_j - p, \ldots, s_k + q, \ldots, s_n)$ and $p < q$. In other words, a suitability decrement p of an attribute can be compensated by the suitability increment q of a less important attribute, but the increment q must be greater than the decrement p. These properties are essential in human reasoning and must be supported by MCDM.

2.5 Modelling of simultaneity requirements

Function $\lambda : [0,1]^n \to [0,1]$ that aggregates all attribute suitability degrees and computes the overall suitability degree is essentially a logic function. In human decision making the aggregation of suitability degrees is usually a stepwise process where small groups of related suitability degrees are aggregated and replaced by an aggregated suitability degree. The process of stepwise aggregation terminates when the suitability degrees of subsystems at the highest level are aggregated yielding the overall suitability degree S as a compound function of attribute suitability degrees.

Let us investigate an aggregation step where DM aggregates m suitability degrees using an aggregation function $\mu : [0,1]^m \to [0,1]$. In human decision making $\mu(s_1, \ldots, s_m)$ is most frequently a model of simultaneity. E.g., a homebuyer regularly prefers locations that are both close to schools for children *and* to jobs for parents. Such a simultaneity requirement can be modelled using some form of partial conjunction [3], i.e., μ is expected to have an adjustable degree of similarity with conjunction $s_1 \wedge \cdots \wedge s_m$. A normalized degree of proximity between $\mu(s_1, \ldots, s_m)$ and $s_1 \wedge \cdots \wedge s_m$ is called andness and it can be defined by: $\alpha = \frac{(s_1 \vee \cdots \vee s_m) - \mu(s_1, \ldots, s_m)}{(s_1 \vee \cdots \vee s_m) - (s_1 \wedge \cdots \wedge s_m)}$. Since $(s_1 \wedge \cdots \wedge s_m) \leq \mu(s_1, \ldots, s_m) \leq (s_1 \vee \cdots \vee s_m)$ it follows that $0 \leq \alpha \leq 1$ and $\mu(s_1, \ldots, s_m)$ is a model of simultaneity if $0.5 < \alpha \leq 1$ and $(s_1 \wedge \cdots \wedge s_m) \leq \mu(s_1, \ldots, s_m) < (s_1 + \cdots + s_m)/m$. This form of andness depends on input degrees of suitability and humans usually think globally using an average andness, e.g., $\overline{\alpha} = \int_{[0,1]^m} \alpha(s_1, \ldots, s_m) ds_1 \ldots ds_m$, $0 \leq \overline{\alpha} \leq 1$. If DM needs a high simultaneity (e.g., $\overline{\alpha} > 0.7$), that usually means that all inputs must be at least partially satisfied. In other words, $\mu(s_1, \ldots, s_m) = 0$, $s_i = 0$, $i \in \{1, \ldots, m\}$ and it is mandatory to satisfy all inputs. This kind of simultaneity is called a *hard simultaneity*. In other cases DM may need a *soft simultaneity*, where the average andness is slightly above 0.5 and $\mu(s_1, \ldots, s_m) > 0$, $s_i > 0$, $i \in \{1, \ldots, m\}$. Supporting models of simultaneity is an important requirement that MCDM must satisfy.

2.6 Modelling of replaceability requirements

Replaceability requirements are symmetrical and complementary to simultaneity requirements. Replaceability means that a high suitability in a group of attributes can be achieved using any one of the attributes (i.e., they can replace each other). E.g., a home location can be considered suitable for recreational activities if it is close to lake, *or* close to ski terrains. The intensity of replaceability can be determined using the orness indicator that is a complement of andness: $\overline{\omega} = 1 - \overline{\alpha}$. Replaceability aggregators satisfy conditions $0.5 < \overline{\omega} \leq 1$ and $(s_1 + \cdots + s_m)/m < \mu(s_1, \ldots, s_m) \leq (s_1 \vee \cdots \vee s_m)$. High orness means low andness and vice versa. Similarly to the case of simultaneity, a high level of replaceability (e.g., $\overline{\omega} > 0.7$) may be combined with the requirement for hard replaceability where $\mu(s_1, \ldots, s_m) = 1$, $s_i = 1$, $i \in \{1, \ldots, m\}$. Soft replaceability is any form of replaceability that does not satisfy the hard replaceability requirements. In the case of soft replaceability we have $\mu(s_1, \ldots, s_m) < 1$, $s_i < 1$, $i \in \{1, \ldots, m\}$.

2.7 Modelling of balanced simultaneity/replaceability

If the simultaneity and replaceability are balanced then $\alpha = \omega = 0.5$. In the case of two variables, from definition $\alpha = \frac{(s_1 \vee s_2) - \mu(s_1, s_2)}{(s_1 \vee s_2) - (s_1 \wedge s_2)} = 0.5$ it follows that $\mu(s_1, s_2) = ((s_1 \vee s_2) + (s_1 \wedge s_2))/2 = (s_1 + s_2)/2$. This result indicates that the arithmetic mean is a soft computing logic function that combines simultaneity and replaceability requirements in a balanced way: DM would like that all attributes are simultaneously satisfied, but at the same time s/he accepts that any attribute can compensate any other attribute. It is important to understand that the arithmetic mean represents a model of this specific logic condition and nothing more. MCDM that use the arithmetic mean are acceptable only in cases where DM can justify the use of this specific logic condition.

According to Malczewski [16], "GIS implementations of the weighted summation procedures are often used without full understanding of the assumptions underlying this approach."

2.8 Modelling of mandatory, desired, and optional requirements

Using models of simultaneity, replaceability and negation ($x \mapsto 1 - x$) it is possible to create a variety of compound soft computing logic functions that precisely reflect the needs of DM. A compound aggregator that is most frequent in human reasoning is used to combine mandatory and nonmandatory attributes. Most frequently there are one mandatory attribute and one or two nonmandatory attributes. E.g., a DM may reject home locations that do not have good ground transportation, but accept locations that are far from an international airport. In such cases the ground transportation is a mandatory requirement, and the vicinity of an international airport is desired, but not mandatory. Optional attributes are also nonmandatory and have lower significance than desired attributes. To model such requirements we need aggregators $\mu(s_{man}, s_{des}, s_{op})$ that satisfy the conditions $\mu(s_{man}, s_{des}, s_{op}) = 0$, $s_{man} = 0$, $s_{des} > 0$, $s_{op} > 0$ and if the compensation between s_{des} and s_{op} is possible, then $\mu(s_{man}, s_{des}, s_{op}) = \mu(s_{man}, s_{des} - p, s_{op} + q)$, $s_{man} > 0$, $p < q$. Optional attributes can be omitted, and in such cases

ISBN: 978-989-95079-6-8

we use only mandatory and desired inputs. An aggregator with these properties is a partial absorption function introduced in [2] and expanded in [19].

2.9 Modelling of sufficient, desired, and optional requirements

Sufficient, desired and optional requirements are a disjunctive counterpart of mandatory, desired and optional requirements. If the sufficient input is completely satisfied then the desired and optional inputs have no effect. If the sufficient attribute has low or even zero suitability degree, this can be partially compensated by the desired and optional attributes. The corresponding aggregator $\mu(s_{suf}, s_{des}, s_{op})$ satisfies conditions $\mu(s_{suf}, s_{des}, s_{op}) = 1, s_{suf} = 1, s_{des} < 1, s_{op} < 1$, and if the compensation between s_{des} and s_{op} is possible, then $\mu(s_{suf}, s_{des}, s_{op}) = \mu(s_{suf}, s_{des} - p, s_{op} + q)$, $s_{suf} < 1$, $p < q$.

2.10 Ability to express suitability as an aggregate of usefulness and inexpensiveness

Land-use is regularly related to a variety of costs (e.g., the cost of land, the cost of building infrastructure and objects, the cost of financing, etc.). The overall suitability depends on two simultaneous requirements: finding locations that are very useful for specific purpose and at the same time inexpensive. A convenient way to solve that problem is to define *usefulness* as a non-financial part of the overall suitability, and *inexpensiveness* as an overall result of cost analysis (an aggregate of cost components only). Then, the overall suitability can be conveniently expressed as an aggregate of usefulness and inexpensiveness. Separation of cost and usefulness attributes reflects human reasoning where the overall cost is compared with the corresponding overall satisfaction. Of course, there are cases where the overall suitability does not depend on cost. In such cases the overall suitability reduces to usefulness.

The presented list of properties is not proved to be necessary and sufficient in all cases. However, the presented conditions are relevant for many land use decision problems and show that logic aggregation of attribute suitabilities is a frequently needed property. For detailed analysis of mathematical conditions see [4], and for sample applications see [4, 5].

The necessary properties of MCDM's do not change if attributes of a cell are functions of time, or functions of the values of attributes in other cells.

3 Properties of GIS related MCDM

Several GIS related MCDM approaches have been presented in literature [15, 16]. Among the decision methods used in these approaches we selected a representative set that consists of the following techniques: *simple additive scoring* (SAS) [8, 6], *multiattribute value technique* (MAVT) [22, 13, 14], *multiattribute utility technique* (MAUT) [13, 10], *analytic hierarchy process* (AHP) [18, 1], *ordered weighted average* (OWA) [21, 17], *outranking methods* [12] and *logic scoring of preference* (LSP) [4, 5].

The ten fundamental features presented in the previous section can be used to investigate the selected decision methods in view of their appropriateness for land-use evaluation and suitability map construction.

3.1 Simple additive scoring

The SAS technique [8, 6] is based on the concept of a weighted average in which weights are used to denote relative importance of suitability attributes. A DM directly assigns a weight w_i to each suitability attribute a_i, $i = 1, \ldots, n$. These assigned weights are rescaled to normalized weights W_i, $i = 1, \ldots, n$, such that $\sum_{i=1}^{n} W_i = 1$. The overall score or overall degree of suitability $S(x, y)$ of each cell x, y is then computed by:

- Determining the n suitability components $s_1(x, y), \ldots, s_n(x, y)$ that are obtained from the evaluation of the n attributes for the cell.
- Multiplying each suitability component $s_i(x, y)$ with the normalized weight W_i of its corresponding attribute.
- Summing the products over all attributes, i.e., $S(x, y) = \sum_{i=1}^{n} W_i s_i(x, y)$.

Therefore, SAS uses a simple linear weighted aggregation model.

3.2 Multiattribute value technique

In MAVT [22, 13, 14] suitability attributes a_i, $i = 1, \ldots, n$ are evaluated using value functions that aim to mathematically represent human judgements. A single-attribute value function translates the performance of the alternative attribute values into a value score which represents the degree to which a decision objective is achieved. As such, value function v_i associates a number (or 'value') $v_i(a)$ with each alternative value a of attribute a_i in such a way that a preference order on the alternatives consistent with DM value judgements is obtained.

For aggregation, more complex value functions are used. The most commonly used function is the simple additive weighting function $S(x, y) = \sum_{i=1}^{n} W_i v_i(a_i(x, y))$ where W_i is the weight of suitability attribute a_i and $v_i(a_i(x, y))$ is the value of suitability attribute value $a_i(x, y)$ (of cell x, y). This approach is valid if suitability attributes are preferentially independent.

The weights W_i are scaling constants that have to be derived with reference to the attribute ranges. These need to be elicited through questions which capture acceptability of trade-offs (e.g., 'how many units of one suitability attribute are worth how many of units of another suitability attribute?'). Weights must sum up to 1, i.e., $\sum_{i=1}^{n} W_i = 1$.

As such, the MAVT approach is similar to the 'scoring method', except that the scores $s_i(x, y)$ are replaced by values $v_i(a_i(x, y))$ that are obtained with the value function v_i.

3.3 Multiattribute utility technique

MAUT [13, 10] is used and treated separately from MAVT when 'risks' or 'uncertainties' have a significant role in the definition and assessment of alternatives. The attitude of the DM toward risk is incorporated into the assessment of a single-attribute utility function u_i, which is obtained through utility analysis and translates the values of suitability attribute a_i into 'utility units'. A 'utility unit' is a relative value between 0 and 1 (where 0 and 1 resp. denote the worst and best values). The concept of a utility function is inherently probabilistic in nature.

ISBN: 978-989-95079-6-8

Aggregation is done by an overall utility function. A simple additive weighting function is most commonly used. In such a case $S(x,y) = \sum_{i=1}^{n} W_i u_i(a_i(x,y))$. Suitability attributes must be preferentially independent. The weights W_i, $i = 1, \ldots, n$ have to sum up to 1, i.e., $\sum_{i=1}^{n} W_i = 1$.

From aggregation point of view, the MAUT approach is similar to the MAVT and 'scoring' approaches.

3.4 Analytic hierarchy process

AHP [18, 1] uses a different approach. Cognitive psychology has found that people are poor at assimilating large quantities of information on problems. The subsequent steps in AHP can be summarized as follows:

- Model the problem as a hierarchy containing the decision goal, the alternatives for reaching it, and the suitability attributes for evaluating the alternatives.
- Establish priorities (normalized weights) among the elements of the hierarchy by making a series of judgments based on pairwise comparisons of the elements.
- Synthesize these judgments to yield a set of overall weights for the hierarchy. This is done by means of a sequence of multiplications of the matrices of relative weights at each level of the hierarchy.
- Check the consistency of the judgments.
- Come to a final decision based on the results of this process.

Suitability attributes are subdivided in subattributes and hierarchically structured. Overall suitability $s(x,y)$ for an attribute a is computed by an additive weighting function $s(x,y) = \sum_{j=1}^{m} W_{s_j(x,y)} s_j(x,y)$ where $s_j(x,y)$, $j = 1, \ldots, m$ denote the suitability components of the subattributes of a. All weights $W_{s_j(x,y)}$ must to sum up to 1, i.e., $\sum_{i=j}^{n} W_{s_j(x,y)} = 1$.

3.5 Ordered weighted averaging

In an OWA approach [17], the DM specifies the decision-relevant suitability attributes to be used as evaluation criteria; identifies preferred criteria values on a qualitative scale; and defines the relative importance of each criterion by assigning weights. The weighted criterion values are then combined using an OWA aggregation operator [21], resulting in an evaluation score for each cell. OWA allows the DM to specify a decision strategy that reflects his decision-related preferences.

The OWA operators [21], provide a parameterized class of mean type aggregation operators. Many notable mean operators such as the max, arithmetic average, median and min, are members of this class. OWA operators allow to model linguistically expressed aggregation instructions.

An OWA operator of dimension n is a mapping function $F : [0,1]^n \rightarrow [0,1]$ that has an associated collection of weights $\mathbf{W} = [W_1, \ldots, W_n] \in [0,1]^n$, for which it holds that $\sum_{i=1}^{n} W_i = 1$, and with $F(s_1, \ldots, s_n) = \sum_{i=1}^{n} W_i s'_i$ where s'_i is the ith largest value of the s_i.

By choosing different $\mathbf{W}$, different aggregation operators can be implemented. The OWA operator is a non-linear operator as a result of the process of determining the values s'_i.

3.6 Outranking methods

Outranking methods, such as variants of ELECTRE and PROMETHEE are used in the areas of GIS and environmental planning [12]. The basic idea of these methods is to use strictly relative criteria that express a range from indifference to strong preference of one alternative over another alternative separately for all individual attributes. The attribute preferences are then averaged using the arithmetic mean to generate the credibility of the outranking relation of two alternatives (PROMETHEE). In such a case no input is mandatory. The overall degree of outranking of two alternatives can also be computed using a product (ELECTRE III), making all attributes mandatory.

3.7 Logic scoring of preference

With the LSP method [4, 5] suitability maps are created with the following main steps:

1. Creation of an attribute tree. This tree contains and structures all parameters that affect the overall suitability and is build by the DM.
2. Definition of elementary criteria. The DM has to provide an elementary criterion for each attribute involved in the decision process. These criteria will be evaluated during suitability map construction. For each analyzed cell x, y, the evaluation of each attribute a_i, $i = 1, \ldots, n$ will result in an elementary satisfaction degree $s_i(x,y)$.
3. Creation of the aggregation structure. For each analyzed cell, all associated elementary satisfaction degrees must be aggregated. Therefore, the DM has to create an aggregation structure, which adequately reflects his domain knowledge and reasoning.
4. Computation of the overall suitability degree. Once the attribute tree, the elementary criteria and the aggregation structure are available, the suitability map construction can start. The elementary criteria are evaluated and their resulting elementary satisfaction degrees can be aggregated in order to compute the overall satisfaction degree of each analyzed cell.

Aggregation in LSP is done via the aggregation structure, build by the DM. The basic building blocks of the aggregation structure are the simple and compound LSP aggregators. The DM can use them to construct an easily understandable aggregation schema which is consistent with observable properties of human reasoning in the area of evaluation.

The simple LSP aggregators are all graded preference logic functions and based on a superposition of the fundamental *Generalized Conjunction/Disjunction* (GCD) function. Most frequently, GCD is implemented by the weighted power mean function $GCD(s_1, \ldots, s_n) = (W_1 s_1^r + \cdots + W_n s_n^r)^{1/r}$ where $r \in [-\infty, +\infty]$ and $0 < W_i < 1$ such that $\sum_{i=1}^{n} W_i = 1$ [5]. The parameter r determines the logical behavior of the function. As such a continuous variety of logical functions ranging from full conjunction to full disjunction can be modelled. The simple LSP aggregators can be used to construct more complex, compound operators like the conjunctive partial absorption which can be used to aggregate a mandatory and a desired criterion.

For suitability map construction, the overall suitability degree of each analyzed cell x, y must be computed. This is

ISBN: 978-989-95079-6-8

done in two steps: First, the elementary satisfaction degrees $s_1(x,y),\ldots,s_n(x,y)$ are aggregated using the logic aggregation structure. This results in the overall satisfaction degree $s(x,y)$ of the cell. Second, cost (if applicable) is taken into account. Cost is dealt with separately. This better reflects human reasoning and allows for more efficient cost/satisfaction studies. Cost is considered to be a function c of the analyzed cells. For each cell x,y the cost function returns the associated cost $c(x,y)$ of the cell. If the importance of high satisfaction of criteria is the same as the importance of low cost, then the overall suitability degree $S(x,y)$ of the cell can be computed by $S(x,y)=s(x,y)/c(x,y)$. Alternative definitions of $S(x,y)$ are possible.

4 Conclusions

All multicriteria decision methods should be models of human decision making and the only way to prove their credibility is to show their proximity to human evaluation logic. Our analysis shows that the majority of existing MCDM are not derived with an explicit goal to model observable properties of human reasoning. Indeed, human reasoning is neither restricted to the use of arithmetic mean nor restricted to relative criteria only. Humans use a spectrum of absolute and relative elementary criteria and a spectrum of soft computing logic aggregators, such as soft and hard simultaneity and replaceability with nonmandatory, mandatory and sufficient attributes, conjunctive and disjunctive partial absorption, as well as other compound aggregators.

Decision methods that are used in land-use evaluation problems cannot be randomly selected, without appropriate justification. The justification for using a specific evaluation method in a GIS environment should be based on investigating the capability of the method to support features that are proved to characterize human decision making. Many oversimplifications that are frequent in GIS literature [16] (particularly those based on simple additive models) are based on the fact that they are "easy-to-understand and intuitively appealing." Unfortunately, that is not enough. Before using mathematical models it is first necessary to prove that they are appropriate.

LSP is a method developed with the goal to support logic operators observed in human reasoning. Consequently, it is realistic to expect that the LSP method can provide highly accurate and justifiable models for GIS applications, such as land-use evaluation, suitability maps, and natural resources planning.

Abstract— *Describing and modeling a complex system is very hard and time consuming, so, we propose to use a linguistic approach introduced by Zadeh. By taking a linguistic approach we can use linguistic variables and approximate rules to characterize approximately phenomenons which are too complex or too ill-defined to be done in numerical terms.*

Starting from the results obtained in our previous works, in this paper we propose to decompose complex behaviors in simple behaviors, and context dependent rules for the behaviors coordination, which are described by set of fuzzy rules. The use of fuzzy rules for behavior coordination and behavior description has allowed us to have a shared framework that makes easy to develop and to compute with linguistic descriptions of actions.

We propose to use a mixture of competitive and cooperative co-evolutionary algorithms to manage the big search space and tackle a complex and decomposable problem.

We use the Fuzzy-IEEE 2007 Car Racing Competition as an example of a problem that allows to show the benefits of our approach. In the example presented the results obtained are better and the flexibility is increased with respect to previous works.

Keywords— Computing with Words, Computing with Actions, Fuzzy Linguistic Descriptions, Fuzzy Controllers, Co-evolutionary Algorithms, Behavior coordination.

1 Introduction

Real-life problems with solutions that are complex and unknown in advance require to build and test several prototypes before being able to build a good enough solution. Prototypes allow designers to devise what an appropriate solution might look like while they work at intermediate stages of development. In this way, designers require to test potential solutions, following a design-test-update cycle before reaching a good enough solution (as suggested in the Agile software development [1]). Computers are useful tools to develop and test these prototypes, which in turn serve designers to explore, build and test different ideas.

Describing and modeling a complex system is very hard and time consuming. So, we propose to use a linguistic approach introduced by Zadeh in [2, 3, 4, 5, 6] to deal with complex systems and complex concepts. By taking a linguistic approach we can use linguistic variables and approximate rules to characterize approximately phenomenons which are too complex or too ill-defined to be done in numerical terms [7, 8]. We use linguistic descriptions to describe the desired solution, problem decomposition techniques and fuzzy controllers to build the solution, and co-evolutionary algorithms to tune and improve the solutions.

*His work has been supported by the Spanish Department of Science and Innovation (MICINN) under program Juan de la Cierva JCI-2008-3531, and the European Social Fund.

Indeed, in this work we are introducing a tentative proposal to compute with actions by computing with linguistic descriptions of actions, paralleling Zadeh's Computational Theory of Perceptions [9], in which he proposed to compute with perceptions by means of computing with linguistic descriptions of perceptions.

To cope with these problems, we combine our previous ideas, improvements and results in the areas of computing with words [10], fuzzy controllers [11] and co-evolutionary algorithms [12].

The rest of the paper is organized as follows. In section 2, we provide details of the problem tackled, the FUZZ-IEEE 2007 Car Racing Competition. In section 3, the solution based on linguistic description of the behaviors is presented. The coordination between behaviors is presented in section 5. The mixture of co-evolutionary algorithms is presented in section 6. In section 7 we present the results and finally, we summarize our work and provide conclusions in section 8.

2 The problem: FUZZ-IEEE 2007 Car Racing Competition

Car Racing Competition is a well-known sport that gets attention from many people in a number of different scenarios, ranging from popular real-life Fomula One to virtual computer games. Particularly, we tackle the challenge of building a car pilot for the FUZZ-IEEE 2007 Car Racing Competition.

Driving is a complex problem and how to find a general solution is unknown. Everyone need a lot practice before becoming a good driver. Actually, people become driving experts by practicing in many different scenarios. So we will use the simulator provided by the FUZZ-IEEE 2007 Car Competition to simulate different races that will allow us to learn and test solutions in many different scenarios.

In this problem, the challenge was to develop the best fuzzy car driver controller for a basic form of car race. A competition in which a pair of simulated cars race through a series of waypoints within a 2d plane, and compete between them to reach the maximum number of waypoints. Basic aspects of the car race are the following:

1. A car only sees the next three waypoints at a given time.
2. Waypoints have to be visited in order and the next one to be visited is highlighted.
3. Waypoints are randomly generated on a 2d plane.
4. The car that first reaches the next waypoint scores.
5. Cars cannot collide with each other, so two cars can follow the same path at the same time.

ISBN: 978-989-95079-6-8

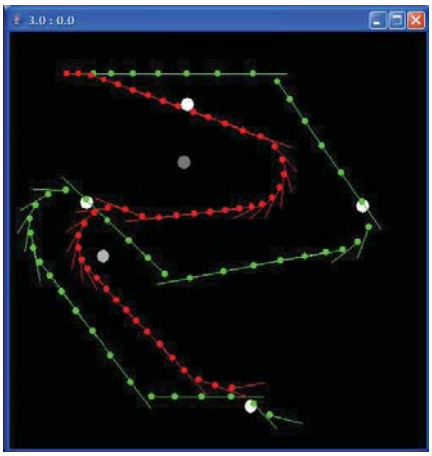

Figure 1: Car Racing Simulation on a 2d Plane.

6. Cars have imperfect sensors and actuators: gaussian noise is used to simulate the lack of perfect observations on position and velocity.

7. General driving ability rather than specialization to a particular track it is tested.

3 The solution: Behaviors described by linguistic actions

We describe a desired behavior by describing linguistically a set of actions modeled by fuzzy rules. So each behavior will be described by a set of fuzzy rules, and a solution will be composed by one or more behaviors coordinated appropriately.

Fuzzy rules are linguistically interpretable units that can serve our purposes of designing and testing prototypes easily and quickly, since they are easily human-interpretable, as well as, adjustable.

We have used fuzzy controllers [13, 14, 15] to implement individual behavior units. Fuzzy controllers incorporate heuristic control knowledge in the form of if-then rules, whose membership functions are later tuned by the co-evolutionary algorithm, similarly as it was proposed by Karr in [16].

We have used Xfuzzy 3.0, a fuzzy system development environment, to design our fuzzy inference system [17]. This system contains a set of tools that allows not only to easily describe a fuzzy inference model but also to implement it, and export it to programming languages such as JAVA, C and C++.

In this section we present the three different behaviors that we introduced in our previous paper [12]. The first behavior "Go straight to next target" was a local solution in the sense that the other targets were not considered (the other two way-points). The second behavior "Follow a spline curve" takes into account the next three way-points, thus following a more global approach. The third behavior "Avoiding ellipses around targets" cope with unwanted situation of going around a target indefinitely.

3.1 Behavior 1: Go straight to the target

Basically, this fuzzy controller takes as input variables: velocity, distance to next target and angle to next target; and has as output variables: acceleration and turn angle. The final controller is composed of two rule-bases:

- Acceleration rules:
  If Distance is Large then Acceleration is Very Positive.
  If Distance is Medium then Acceleration is Positive.
  If Distance is Small and Velocity is Very Positive then Acceleration is Very Negative.
  If Distance is Small and Velocity is Positive then Acceleration is Negative.
  If Distance is not Small and Velocity is Zero then Accelerations is Positive.

- Turn rules:
  If Angle is Zero then Turn Zero
  If Angle is Positive then Turn Positive
  If Angle is Negative then Turn Negative
  If Angle is not Zero and Distance is Very Small then Turn Zero

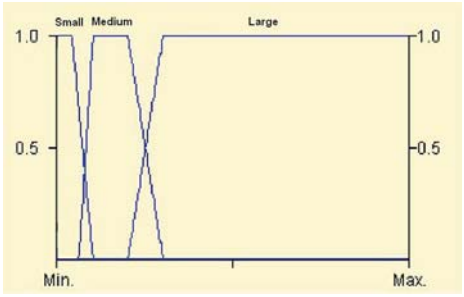

Figure 2: Distance Linguistic Variable

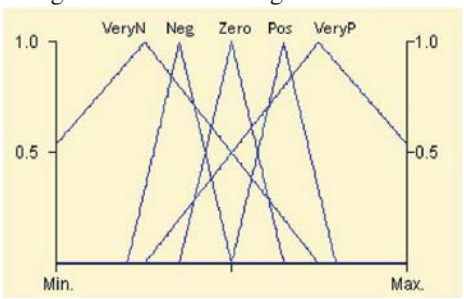

Figure 3: Acceleration Linguistic Variable

We impose the following ordering constrains [18] between the linguistic labels of the linguistic variables to maintain the interpretability of the rules, although these don't impose that they should form a partition:

- Distance = { Small $\prec$ Medium $\prec$ Large }
- Velocity = { Very Negative $\prec$ Negative $\prec$ Zero $\prec$ Positive $\prec$ Very Positive }
- Acceleration = { Very Negative $\prec$ Negative $\prec$ Zero $\prec$ Positive $\prec$ Very Positive }

After tuning parameters of the fuzzy membership functions using a genetic algorithm (see figures 2 and 3) of the fuzzy rules this behavior was able to defeat the heuristic controller in all races (see table 2 for comparison). So from now on we took it as the new baseline for comparison with the rest of the solutions.

ISBN: 978-989-95079-6-8

3.2 Behavior 2: Follow a spline curve

We observed that the previous behavior was able to align with the first target (next target) quite well, but it did not consider the positions of second and third targets. In other words, direction of the car was perfect for the next target, but it was not exploiting the knowledge about the rest other targets.

To do that, we use a spline curve instead of following straight lines, in order to follow a global strategy and gain advantage over the opponent, as soon as possible. We built a spline curve that goes through four points on a 2d plane: the position of our car, and the next three targets. We use the spline curve to calculate/approximate intermediate points between our car and the next target, and then follow them using these fuzzy rules:

- Acceleration rules:
  If Distance is Large then Acceleration is Very Positive.
  If Distance is Medium then Acceleration is Positive.
  If Distance is not Small and Velocity is Zero then Accelerations is Positive.
- Turn rules:
  If Angle is Zero then Turn Zero
  If Angle is Positive then Turn Positive
  If Angle is Negative then Turn Negative

On the negative side of this approach we can say that the distance that the car is covering is higher than in our previous behavior, that is, without using a spline curve, so when we set up a competitive co-evolutionary strategy this behavior (B2) was always loosing, unable to defeat the previous one (B1) (see table 3 for comparison).

3.3 Behavior 3: Avoid ellipses around targets

We also noticed that some races were ended when both cars were unable to reach a target. This situation occurred when a new target appeared and both cars were: 1, too close to the new target; and 2, with such a high angle to the target that it could not be corrected enough, given the short distance and the velocity of the cars. As a result, cars spent their last moments turning around the target.

To avoid that, we add this behavior (B3), that detects the unwanted situation and takes a different action. In order to detect that unwanted situation, we keep track of what happened in last n iterations. Particularly, we consider three facts during the last n iterations: 1, the target remained the same; 2, the angle to target was around 80 degrees; 3, the distance to target was small.

To address the described scenario, when the unwanted situation is detected then this new behavior is activated during a number m of iterations. This new behavior was built following the same rules that *"Go straight to the target"* with one sole difference: it did not go towards the target but in the opposite direction (it has the same rules as behavior 1 but with opposite sign).

4 Tuning Fuzzy Membership Functions by Co-evolution

Developing a good prototype from scratch is very time consuming and difficult since it involves a good understanding of the problem to do a good design, and a good understanding of the solution to adjust all its parameters. We did this initially manually and then used genetic algorithms, and co-evolutionary algorithms.

Table 1: Summary of previous results

	HC	GA	$Comp_1$	$Coop_\alpha$
HC	-	15	0	0
GA	83	-	1	5
$Comp_1$	100	99	-	47
$Coop_\alpha$	100	81	47	-

To avoid complexity and exploit the features of co-evolutionary algorithms we defined different species with different attributes to optimize. Actually, we divided our population into three species. Species number 1 consisted of individuals of behavior 1 *"Go straight to target"*, species number 2 was formed by individuals belonging to behavior 2 *"Follow a spline curve"*, and species number 3 was formed by individuals of behavior 3 *"Avoid ellipses"*.

So, we built a population with three different species with 20 individuals each, which evolve during 1000 generations. These species only met when racing (to calculate the fitness functions of individuals), while for the rest (cross, mutation, selection of individuals) were kept apart.

In [12] we compared how the use of a competitive or a cooperative co-evolutionary algorithm affects to the final solution. Obtaining that both approaches can find very good solutions, once the appropriate crossover operator is chosen. Table 6 recall the summary of results.

1. *HC*, hand coded model;
2. *GA*, complete model including three pilots, automatically tuned using a genetic algorithm;
3. $Comp_1$, complete model including three pilots, automatically tuned using a competitive coevolutionary approach, with 1-point cross operator;
4. $Coop_\alpha$, complete model including three pilots, automatically tuned using a cooperative coevolutionary approach, with BLX-alpha cross operator.

5 Behavior coordination

The main two problems of behavior coordination are:

1. Arbitration: deciding which behavior should be activated in each situation. This can be decided a priori or dynamically by establishing variable priorities. The simplest solution is a switching scheme that selects one behavior and ignores the rest. More flexible arbitration can be obtained using fuzzy context rules, that allow to activate concurrently several behaviors with different degrees of activation.
2. Command fusion: If only one behavior is active at a time, then there is not need to do it, but if there are more than

ISBN: 978-989-95079-6-8

one behavior active simultaneously, then it is needed to combine in some way the different commands generated by them. It is needed to fuse, or aggregate, properly these commands in order not to send a set of contradictory commands but to send a coherent fused command.

Context dependent blending is a flexible and general form of solving the problem of behavior coordination, since it solves both arbitration and command fusion by using a common scheme, fuzzy context rules and fuzzy aggregation. It was initially proposed by Ruspini in [19] and later expanded by Saffioti and himself in [20, 21].

5.1 Context dependent behavior coordination

In our previous work we defined a fix arbitration scheme to switch between behaviors. And compared competitive and cooperative co-evolutionary algorithms to tune the membership functions of the linguistic variables used in the fuzzy rules.

In this work we use context dependent blending, using fuzzy rules for both behavior coordination and behavior description, since that allowed us to have a shared framework that made easier to develop complex behaviors.

To address the coordination problem, we defined context rules for each behavior, so they could be activated in different situations, and serve to merge their outputs when are activated at the same time.

- Context Rule 1:
  If Distance is Small then "Go Straight to the target".
- Context Rule 2:
  If Distance is Large then "Follow a spline curve".
- Context Rule 3:
  If Distance is Small and Angle is approx. 80^o then "Avoid ellipses".

This allows to follow a local strategy when the car is near to the next target, a global strategy when the car is far to the next target, and avoiding ellipses around targets

We set up a mixture of competitive and cooperative co-evolutionary strategy, the individual behaviors cooperate to form the complex behavior (B123) while competing with the best solution obtained previously (B1). (see table 5 for comparison).

In figure 4 we can see a diagram of how the coordination of the different behaviors works. Using a weighted fusion between the commands of behaviors 1 and 2 and a switching scheme with behavior 3.

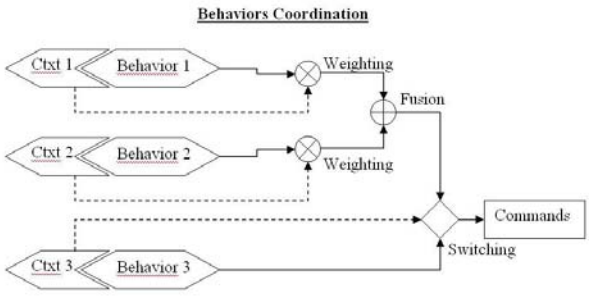

Figure 4: Behaviors Coordination

6 Mixture of Co-evolutionary algorithms

In some way, approaches pointing in the same direction that ours have already been proposed. In fact, many papers on fuzzy systems tuned with genetic algorithms have been published (for a good review see [22]).

Genetic algorithms, of single-population algorithms, are not well suited to problems which have solutions that are long, complex and interdependent [23]. In the last years, co-evolutionary algorithms have shown their ability to manage big search spaces and to tackle complex problems. Specially when the solution to the problem may be decomposable, or when there exist different competitive solutions [24, 25].

Co-evolutionary algorithms can be seen as an extension of traditional evolutionary algorithms, where there are, at least, two species that are simultaneously evolved and their fitness functions are coupled [24, 25]. Therefore, each species has its own coding scheme and reproduction scheme, but each individual is evaluated considering individuals from other species. Depending on the type of interaction between species, we can distinguish between competitive or cooperative species.

6.1 Competitive Co-evolution

In this context, each individual represents a candidate solution to the problem and competes with individuals of other species to find better solutions. Thus, if one individual increases its fitness, then fitness functions from the rest individuals decrease [24]. This may be seen as a kind of struggle between species, which presses individuals to compete between them for finding better solutions.

6.2 Cooperative Co-evolution

In this case, each individual represents a component of the solution and requires the rest components to build a complete solution. Therefore, an individual needs to cooperate with others to find a better solutions [25]. Thus, an individual fitness is linked with fitness values of its cooperative individuals. This is often seen as a kind of symbiosis between species to preserve existence, leading individuals to cooperate for finding better solutions.

6.3 Mixture of Competitive and Cooperative Co-evolution

We have different solutions that compete or cooperate to obtain better solutions. Following the two co-evolutionary approaches we have defined a mixed environment, where alternative solutions were competing to obtain better solutions, and where complementary solutions were cooperating to obtain better solutions. At the same time that the three different behaviors evolve in a cooperative way, they are competing with the best previous solutions.

The main features of the co-evolutionary algorithm used to tune the parameters of the membership functions are the following:

generations = 1000.
population size = 20.
crossover probability = 0.9.
mutation probability = 0.1.
crossover operator = BLX-α.
$\alpha = 0.7$.
species = 3.
co-evolutionary strategy = mixed.

ISBN: 978-989-95079-6-8

Each specie have its own coding as follows:

- Go Straight to Target (51 genes) + Context 1 (2 genes)
- Following a Spline Curve (39 genes) + Context 2 (2 genes)
- Avoiding Ellipses (51 genes) + Context 3 (5 genes)

7 Results

In this section it is shown the sum of the results we obtained during the development of the system and a comparative evaluation of the obtained solutions (for previous results see [12]).

Table 2:
Heuristic vs Behavior 1

6	44	3
7	43	9
8	42	8
9	42	5
10	44	5
Total	435	54

Table 2 shows the number of way-points (targets) got in 10 races by the hand coded (HC) against the behavior 1 (B1) "Go straight to the next target", in which we can see that the behavior 1 is much better than the hand coded controller, and it is wining all the races by a big difference.

Table 3 shows the number of way-points (targets) got in 10 races by the behavior 1 (B1) "Go straight to the next target" against the behavior 2 (B2) "Follow the spline curve", in which we can see that behavior 2 is performing very bad against behavior 1, loosing all the races by a huge difference of points, and performing even worse than the hand coded controller.

These results indicate that the best individual behavior is "Go straight to the next target", and that to improve these results we need to combine it with other behaviors, as we did in the next experiments.

Table 4 shows the number of way-points (targets) got in 10 races by the behavior 1 (B1) "Go straight to the next target" against the combined behavior 1 and 2 (B12) "Go straight to the next target; Follow the spline curve", in which we can see that the combined behavior 12 is much better that the behavior 1 alone, and it is wining all the races by some difference. Table 5 shows the number of way-points (targets) got in 10 races by the behavior 1 (B1) "Go straight to the next target" against the combined behavior 1, 2 and 3 (B123) "Go straight to the next target; Follow the spline curve; Avoid ellipses", in which

Race	B1	B123
1	19	35
2	18	45
3	13	43
4	22	33
5	18	32
6	20	34
7	16	37
8	26	28
9	24	32
10	20	36
Total	196	355

we can see that behavior 123 is performing very well against behavior 1 wining all the races by a big difference of points, and performing even better than the combined behavior 1 and 2 (B12).

These results indicate that the best behavior is the combined behavior 123. But after these comparisons and to evaluate the impact of the context blending behavior coordination, we compared it with the best solutions from our previous work $Comp_1$ and $Coop_\alpha$.

We set up a league competition among all of them, by playing 100 races between each pair of solutions. Table 6 shows the results of the five solutions considered: *Hand-coded*, $Comp_1$, $Coop_\alpha$ and $B123$, and their associated wins for each one in the 100 races between each pair of solutions.

Table 6: Wins Against Each Other

	HC	$Comp_1$	$Coop_\alpha$	$B123$	Total
HC	-	0	0	0	0
$Comp_1$	100	-	47	20	167
$Coop_\alpha$	100	51	-	31	182
$B123$	**100**	**74**	**63**	–	**237**

Table 6 shows the associated wins of each solution. Both behaviors, $Comp_1$ and $Coop_\alpha$, obtained good performance but the new solution $B123$ outperformed them with a greater number of wins than the other approaches, which indicates that: 1, the context dependent blending provides a great advantage compared to fixed arbitration coordination; 2, automatically tuning of fuzzy membership functions yield better results than using hand-coded solutions.

8 Conclusions

In the particular context of the FUZZ-IEEE 2007 Car Racing Competition we have introduced a tentative proposal to compute with actions by computing with linguistic descriptions of behaviors. In this context we have identified and tackled the

ISBN: 978-989-95079-6-8

following key aspects: how to define different behaviors by describing them linguistically and how to coordinate several behaviors using context dependent rules.

We have set up a mixture of competitive and cooperative co-evolutionary algorithms to model the membership functions of the linguistic variables used. On one hand, competitive co-evolution allows to find alternative solutions that compete among them to find better solutions and to avoid being trapped in local minima. On the other hand, cooperative co-evolution allows to find complementary solutions that cooperate among them to find complex and better solutions.

By following an incremental approach, we were able to decompose the solution to this problem in simple behaviors with a lower degree of complexity. The use of fuzzy rules for behavior coordination and behavior description has allowed us to have a shared framework that makes easy to develop complex behaviors and to compute with linguistic descriptions of actions. The use of co-evolutionary algorithms has allowed us to test, compare, combine and tune the different behaviors appropriately and obtain a better solution.

In general, it is not possible to predict a priori all the scenarios, problems, or solutions. So a "learning by doing" approach is a need in these cases. The know-how obtained by testing and playing with different solutions is irreplaceable in order to build systems that compute with actions described by words. This approach allows to mix designer's knowledge and knowledge learned from the data, maintaining a good interpretability of the solution. This represents a very important step-stone that would allow to change and improve the system in front of new environments and situations.

Acknowledgment

The author want to thank to Claudio Moraga, David Perez and to the anonymous reviewers for their comments and fruitful discussion about the paper.

Abstract— *We consider some existing similarity measures for Atanassov's intuitionistic fuzzy sets (A-IFSs, for short). We show that neither similarity measures treating an A-IF as a simple interval values fuzzy set, nor straightforward generalizations of the similarity measures well-known for the classic fuzzy sets work under reasonable circumstances. Next, expanding upon our previous works, we consider a family of similarity measures constructed by taking into account both all the three functions (the membership, non-membership and hesitation) describing an A-IF, and the complements of the elements we compare to each other. That is, we use all kinds and fine shades of information available. We point out their proper behavior and an intuitive appeal.*

Keywords— Atanassov's intuitionistic fuzzy sets, similarity measures.

1 Introduction

Atanassov's intuitionistic fuzzy sets (Atanassov [1], [2], [3]) – to be called A-IFSs, for short – can be viewed as a tool that may better model and process imperfect information. The use of positive and (independently) negative information that is the core of A-IFSs is natural in real life and is also well-known, advocated and studied in psychology and other social and behavioral sciences [e.g., [21], [14]]. It also attracted much attention and research interest in soft computing. It would be difficult to deal with machine learning (making use of examples and counter-examples), modeling of preferences or voting without taking into account positive and (independently) negative testimonies or opinions. Although from a mathematical point of view A-IFSs are equipotent, under some assumptions, to interval-valued fuzzy sets (cf. Atanassov and Gargov in 1989 [4]), from the point of view of solving problems (starting from the stage of collecting data), they are different as A-IFSs force the user to explicitly consider positive and negative information independently. On the other hand, while employing the interval-valued fuzzy sets, the user's attention is focused on positive information (in an interval form) only. Notably, Dubois [9] noticed recently that A-IFSs correspond to an intuition that differs from that behind the interval valued fuzzy sets.

The fact that people tend to notice and take into account only most obvious aspects (e.g. advantages only) when making decision is well known in psychology (cf. Kahneman [14]), Sutherland [21]) and may often lead to improper decisions. In this context, A-IFSs ("forcing" a decision maker to take into account both negative and positive aspects of the decisions) may be seen as belonging to modern and promising means of knowledge representation and processing.

We consider here some major similarity measures for A-IFSs. First we present a whole array of similarity measures (known from the literature) for A-IFSs viewed in terms of single intervals. Second, we consider measures that are straightforward generalization of the similarity measures for the conventional fuzzy sets. Unfortunately, both do not meet our expectations, and we provide some counter-intuitive examples. It seems to be an indirect hint that A-IFSs are not functionally equivalent to the interval valued fuzzy sets.

Next, we reconsider our (cf. Szmidt and Kacprzyk [41]) concept of a similarity measure between A-IFSs taking into account all three functions (the membership, non-membership and hesitation), and explicitly add to the above three functions the complements of the elements we compare to each other.

2 A brief introduction to A-IFSs

One of the possible generalizations of a fuzzy set in X (Zadeh [48]), given by

$$A^{'} = \{< x, \mu_{A^{'}}(x) > | x \in X\} \tag{1}$$

where $\mu_{A^{'}}(x) \in [0,1]$ is the membership function of the fuzzy set $A^{'}$, is Atanassov's intuitionistic fuzzy set (Atanassov [1], [2], [3]), A-IF, A given by

$$A = \{< x, \mu_A(x), \nu_A(x) > | x \in X\} \tag{2}$$

where: $\mu_A : X \rightarrow [0,1]$ and $\nu_A : X \rightarrow [0,1]$ such that

$$0 \leq \mu_A(x) + \nu_A(x) \leq 1 \tag{3}$$

and $\mu_A(x)$, $\nu_A(x) \in [0,1]$ denote the degree of membership and a degree of non-membership of $x \in A$, respectively.

Each fuzzy set may be represented by the following A-IF

$$A = \{< x, \mu_{A^{'}}(x), 1 - \mu_{A^{'}}(x) > | x \in X\} \tag{4}$$

For each intuitionistic fuzzy set in X, we will call

$$\pi_A(x) = 1 - \mu_A(x) - \nu_A(x) \tag{5}$$

an *intuitionistic fuzzy index* (or a *hesitation margin*) of $x \in A$ and, it expresses a lack of knowledge of whether x belongs to A or not (cf. Atanassov [3]). It is obvious that $0 \leq \pi_A(x) \leq 1$, for each $x \in X$.

The hesitation margin turns out to be important while considering the distances (Szmidt and Kacprzyk [26], [29], [39], entropy (Szmidt and Kacprzyk [31], [40]), similarity (Szmidt and Kacprzyk [41]) for the A-IFSs, etc. i.e., the measures that play a crucial role in virtually all information processing tasks.

In our further considerations we will use the following distances between fuzzy sets A, B in $X = \{x_{1,}, \ldots, x_n\}$ Szmidt

ISBN: 978-989-95079-6-8

and Baldwin [23], [24], Szmidt and Kacprzyk [29], [39]: the normalized Hamming distance

$$l_{IFS}(A,B) = \frac{1}{2n}\sum_{i=1}^{n}(|\mu_A(x_i) - \mu_B(x_i)| + |\nu_A(x_i) - \nu_B(x_i)| + |\pi_A(x_i) - \pi_B(x_i)|) \quad (6)$$

and the normalized Euclidean distance:

$$q_{IFS}(A,B) = (\frac{1}{2n}\sum_{i=1}^{n}(\mu_A(x_i) - \mu_B(x_i))^2 + (\nu_A(x_i) - \nu_B(x_i))^2 + (\pi_A(x_i) - \pi_B(x_i))^2)^{\frac{1}{2}} \quad (7)$$

For distances (6), and (7) we have $0 \leq l_{IFS}(A,B) \leq 1$, and $0 \leq q_{IFS}(A,B) \leq 1$. Clearly these distances satisfy the conditions of the metric.

In our further considerations we will use the notion of the complement elements, which definition is a simple consequence of a complement set A^C

$$A^C = \{< x, \nu_A(x), \mu_A(x) > | x \in X\} \quad (8)$$

The use of A-IFSs instead of fuzzy sets implies the introduction of another degree of freedom (non-memberships) into the set description. Such a generalization of fuzzy sets gives us an additional possibility to represent imperfect knowledge which leads to describing many real problems in a more adequate way. Applications of intuitionistic fuzzy sets to group decision making, negotiations, voting and other situations are presented in Szmidt and Kacprzyk [25], [27], [28], [30], [32], [34], [33], [35], [38], Szmidt and Kukier [42], [43].

3 Some counter-intuitive results given by the traditional similarity measures

In the literature there is a multitude of similarity measures both for A-IFSs (Atanassov [1, 2, 3], and vague sets (Gau and Buehrer [10]) which have also been proved to be equivalent to A-IFSs (Bustince and Burillo [5]). Here we adopt the notation for A-IFSs but we will consider the measures originally introduced for vague sets, too.

Chen [6, 7] considered similarity measures between two A-IFSs A and B as

$$S_C(A,B) = 1 - \frac{\sum_{i=1}^{n}|S_A(x_i) - S_B(x_i)|}{2n} \quad (9)$$

where $S_A(x_i) = \mu_A(x_i) - \nu_A(x_i)$, $S_A(x_i) \in [-1,1]$ and $S_B(x_i) = \mu_B(x_i) - \nu_B(x_i)$, $S_B(x_i) \in [-1,1]$.

But, as Hong and Kim [11] noticed

$$\mu_A(x_i) - \nu_A(x_i) = \mu_B(x_i) - \nu_B(x_i) \Rightarrow S_C(A,B) = 1 \quad (10)$$

which is counterintuitive as, e.g., for $A = (x,0,0)$ and $B = (x,0.5,0.5)$, we have $S_C(A,B) = 1$.

To overcome the problem of S_C (9), Hong and Kim [11] proposed the similarity measures S_H and S_L

$$S_H(A,B) = 1 - (\sum_{i=1}^{n}|\mu_A(x_i) - \mu_B(x_i)| + |\nu_A(x_i) - \nu_B(x_i)|)/2n \quad (11)$$

$$S_L(A,B) = 1 - \frac{1}{4n}((\sum_{i=1}^{n} S_A(x_i) - S_B(x_i)) - (\sum_{i=1}^{n}|\mu_A(x_i) - \mu_B(x_i)| + |\nu_A(x_i) - \nu_B(x_i)|)) \quad (12)$$

Since $S_H(A,B)$ takes into account the absolute values, it does not distinguish the positive from negative differences, e.g., for $A = \{(x,0.3,0.3)\}$, $B = \{(x,0.4,0.4)\}$, $C = \{(x,0.3,0.4)\}$, and $D = \{(x,0.4,0.3)\}$, we obtain from (11) that $S_H(A,B) = S_H(C,D) = 0.9$ which seems counter-intuitive.

$S_L(A,B)$ also gives counter-intuitive results, e.g. for $A = \{(x,0.4,0.2)\}$, $B = \{(x,0.5,0.3)\}$, $C = \{(x,0.5,0.2)\}$, we obtain from (12) $S_L(A,B) = S_L(A,C) = 0.95$ which seems counter-intuitive.

The same problem like with S_H occurs with the similarity measure (cf. Li et al. [16]):

$$S_O(A,B) = 1 - (1/2n)^{0.5}(\sum_{i=1}^{n}(\mu_A(x_i) - \mu_B(x_i))^2 + (\nu_A(x_i) - \nu_B(x_i))^2)^{0.5} \quad (13)$$

Dengfeng and Chuntian [15] considered the similarity measure:

$$S_{DC}(A,B) = 1 - (1/n^{1/p})(\sum_{i=1}^{n}(|m_A(x_i) - m_B(x_i)|)^p)^{1/p} \quad (14)$$

where $m_A(x_i) = (\mu_A(x_i) + 1 - \nu_A(x_i))/2$, $m_B(x_i) = (\mu_B(x_i) + 1 - \nu_B(x_i))/2$, $1 \leq p < \infty$. Unfortunately, as for (14), the medians of two intervals are compared only, it is rather easy to point out the counter-intuitive examples, e.g., $A = (x,0.4,0.2)$, $B = (x,0.5,0.3)$, then $S_{DC}(A,B) = 1$, for each p.

Mitchell [18] modified Dengfeng and Chuntian's measure S_{DC} (14) using a statistical approach by interpreting A-IFSs as families of ordered fuzzy sets. Let $\rho_\mu(A,B)$ and $\rho_\nu(A,B)$ denote a similarity measure between the "low" membership functions μ_A and μ_B, and between the "high" membership functions $1 - \nu_A$ and $1 - \nu_B$, respectively, as:

$$\rho_\mu(A,B) = S_{DC}(\mu_A, \mu_B) = 1 - (1/n^{1/p})(\sum_{i=1}^{n}(|\mu_A(x_i) - \mu_B(x_i)|)^p)^{1/p}$$

$$\rho_\nu(A,B) = S_{DC}(1 - \nu_A, 1 - \nu_B) = 1 - (1/n^{1/p})(\sum_{i=1}^{n}(|\nu_A(x_i) - \nu_B(x_i)|)^p)^{1/p}$$

Then the modified similarity measure between A and B is

$$S_{HB}(A,B) = (\rho_\mu(A,B) + \rho_\nu(A,B))/2 \quad (15)$$

Unfortunately, S_{HB} gives the same counter-intuitive results as S_H, for $p = 1$ and for one-element sets.

To overcome the drawbacks of S_{DC}, Liang and Shi [17] proposed $S_e^p(A,B)$, $S_s^p(A,B)$, $S_h^p(A,B)$ as:

ISBN: 978-989-95079-6-8

$$S_e^p(A,B) = 1 - (1/n^{1/p})(\sum_{i=1}^{n}(\phi_{\mu AB}(x_i) - \phi_{\nu AB}(x_i)|)^p)^{1/p} \quad (16)$$

where $\phi_{\mu AB}(x_i) = |\mu_A(x_i) - \mu_B(x_i)|/2$, $\phi_{\nu AB}(x_i) = |(1 - \nu_A(x_i))/2 - (1 - \nu_B(x_i))|/2$. But, for $p = 1$ and for one-element sets, $S_e^p(A,B)$=S_{HB}=S_H, which are again the same counter-intuitive results.

$$S_s^p(A,B) = 1 - (1/n^{1/p})(\sum_{i=1}^{n}(\varphi_{s1}(x_i) - \varphi_{s2}(x_i))^p)^{1/p} \quad (17)$$

where: $\varphi_{s1}(x_i) = |m_{A1}(x_i) - m_{B1}(x_i)|/2$,
$\varphi_{s2}(x_i) = |m_{A2}(x_i) - m_{B2}(x_i)|/2$,
$m_{A1}(x_i) = (\mu_A(x_i) + m_A(x_i))/2$,
$m_{A2}(x_i) = (m_A(x_i) + 1 - \nu_A(x_i))/2$,
$m_{B1}(x_i) = (\mu_B(x_i) + m_B(x_i))/2$,
$m_{B2}(x_i) = (m_B(x_i) + 1 - \nu_B(x_i))/2$,
$m_A(x_i) = (\mu_A(x_i) + 1 - \nu_A(x_i))/2$,
$m_B(x_i) = (\mu_B(x_i) + 1 - \nu_B(x_i))/2$.

S_s^p (17) avoids the problematic results obtained from S_{DC} (14) (for the intervals with equal medians) but, again, a problem of counter-intuitive results remains. For example, for $A = \{(x, 0.4, 0.2)\}$, $B = \{(x, 0.5, 0.3)\}$, $C = \{(x, 0.5, 0.2)\}$, we obtain $S_s^p(A,B) = S_s^p(A,C) = 0.95$ which seems difficult to accept.

S_h^p is given as

$$S_h^p(A,B) = 1 - (1/(3n)^{1/p})(\sum_{i=1}^{n}(\eta_1(i) + \eta_2(i) + \eta_3(i))^p)^{1/p} \quad (18)$$

where $\eta_1(i) = \phi_\mu(x_i) + \phi_\nu(x_i)$ (the same as for S_e^p),
$\eta_2(i) = m_A(x_i) - m_B(x_i))$ (the same as for S_{DC}),
$\eta_3(i) = \max(l_A(i), l_B(i)) - \min(l_A(i), l_B(i))$,
$l_A(i) = (1 - \nu_A(x_i) - \mu_A(x_i))/2$,
$l_B(i) = (1 - \nu_B(x_i) - \mu_B(x_i))/2$. But, again, there are counter-intuitive cases for this measure. For $A = (x, 0.3, 0.4)$, and $B = (x, 0.4, 0.3)$, i.e., for an element and its complement, we obtain $S_h^p(A,B) = 0.933$ (which seems to be rather too big a similarity for an element and its complement).

Hung and Yang [12] proposed the similarity measures S_{HY}^1, S_{HY}^2, S_{HY}^3 in which Hausdorff distances were employed:

$$S_{HY}^1(A,B) = 1 - d_H(A,B) \quad (19)$$

$$S_{HY}^2(A,B) = 1 - (e^{d_H(A,B)} - e^{-1})/(1 - e^{-1}) \quad (20)$$

$$S_{HY}^3(A,B) = (1 - d_H(A,B))/(1 + d_H(A,B)) \quad (21)$$

where
$d_H(A,B))$=$\sum_{i=1}^{n} \max(|\mu_A(x_i)$–$\mu_B(x_i)|, |\nu_A(x_i)$–$\nu_B(x_i)|)$
Unfortunately, (19)–(21) give counter-intuitive results (implied by the calculation of $d_H(A,B)$ - cf. Szmidt [22]). For example if $A = (x, 0.4, 0.5)$, $B = (x, 0.5, 0.4)$, $C = (x, 0.5, 0.3)$, $D = (x, 0.6, 0.4)$, $E = (x, 0.6, 0.3)$, $F = (x, 0.4, 0.3)$ then $S_{HY}^1(A,B) = 0.9$ (a counter-intuitive large similarity for A and its complement as $B = A^C$), and also $S_{HY}^1(C,D) = S_{HY}^1(C,E) = S_{HY}^1(C,F) = 0.9$. Next, $S_{HY}^2(A,B) = S_{HY}^2(C,D) = S_{HY}^2(C,E) = S_{HY}^2(C,F) = 0.85$, and also $S_{HY}^3(A,B) = S_{HY}^3(C,D) = S_{HY}^3(C,E) = S_{HY}^3(C,F) = 0.85$.

A straightforward attempt to calculate the similarity between A-IFSs just by adding the non-memberships values to the existing similarity measures for fuzzy sets is due to Hung and Yang [13]. Their measures (22) and (23) are the extension of Wang's measures [46]:

$$S_{w1}(A,B) = (1/n) \sum_{i=1}^{n} \frac{\min(\mu_A(x_i), \mu_B(x_i)) + \min(\nu_A(x_i), \nu_B(x_i))}{\max(\mu_A(x_i), \mu_B(x_i)) + \max(\nu_A(x_i), \nu_B(x_i))} \quad (22)$$

But, it is easy to give counter-examples again. For example, for $A = \{(x, 0, 0.5)\}$, $B = \{(x, 0.1, 0.5)\}$, $C = \{(x, 0, 0.6)\}$, we obtain $S_{w1}(A,B) = S_{w1}(A,C) = 0.8(3)$ (for different B and C we obtain the same result), for $A = \{(x, 0, 0.5)\}$, $B = \{(x, 0.18, 0.5)\}$, $C = \{(x, 0, 0.68)\}$, we obtain $S_{w1}(A,B) = S_{w1}(A,C) = 0.735$ (again - for different B and C the same result) etc., which seems to be difficult to accept (S_{w1} is not bijective).

$$S_{w2}(A,B) = (1/n) \sum_{i=1}^{n}(1 - 0.5(|\mu_A(x_i) - \mu_B(x_i)| + |\nu_A(x_i) - \nu_B(x_i)|)) \quad (23)$$

But for $A = \{(x, 0, 0.5)\}$, $B = \{(x, 0, 0.4)\}$, $C = \{(x, 0, 0.6)\}$, we obtain $S_{w2}(A,B) = S_{w2}(A,C) = 0.95$ (again - for different B and C the same similarity), which seems to be difficult to accept (S_{w2} is not bijective).

Another straightforward extensions of fuzzy similarity measures proposed by Hung and Yang [13] for A-IFSS are measures (24), (25) and (26) (they are extensions of Pappis and Karacapilidis' [20] measures for fuzzy sets).

$$S_{pk1}(A,B) = \frac{\sum_{i=1}^{n}(\min(\mu_A(x_i), \mu_B(x_i)) + \min(\nu_A(x_i), \nu_B(x_i)))}{\sum_{i=1}^{n}(\max(\mu_A(x_i), \mu_B(x_i)) + \max(\nu_A(x_i), \nu_B(x_i)))} \quad (24)$$

For (24) the counter-intuitive examples are like for (22).

$$S_{pk2}(A,B) = 1 - 0.5(\max_i(|\mu_A(x_i) - \mu_B(x_i)|) + \max_i(|\nu_A(x_i) - \nu_B(x_i)|)) \quad (25)$$

For (25) it is easy to give counter-examples again - especially for one-element sets. For example, for $A = \{(x, 0, 0.5)\}$, $B = \{(x, 0.1, 0.5)\}$, $C = \{(x, 0, 0.6)\}$, we obtain $S_{pk2}(A,B) = S_{pk2}(A,C) = 0.95$ (for different B and C just the same result).

$$S_{pk3}(A,B) = 1 - \frac{\sum_{i=1}^{n}(|\mu_A(x_i) - \mu_B(x_i)| + |\nu_A(x_i) - \nu_B(x_i)|)}{\sum_{i=1}^{n}(|\mu_A(x_i) + \mu_B(x_i)| + |\nu_A(x_i) + \nu_B(x_i)|)} \quad (26)$$

But for $A = \{(x, 0, 0.5)\}$, $B = \{(x, 0, 0.26)\}$, $C = \{(x, 0, 0.965)\}$, we obtain $S_{pks}(A,B) = S_{pk3}(A,C) = 0.68$ (again, for different B and C the same similarity), which seems to be difficult to accept.

ISBN: 978-989-95079-6-8

3.1 Why the measures presented may yield counter-intuitive results?

It is worth noticing that all the above measures were constructed to satisfy the following conditions:

$$S(A,B) \in [0,1] \quad (27)$$

$$S(A,B) = 1 \Longleftrightarrow A = B \quad (28)$$

$$S(A,B) = S(B,A) \quad (29)$$

$$If A \subseteq B \subseteq C, \quad then \quad S(A,C) \leq S(A,B) \; and \; S(A,C) \leq S(B,C) \quad (30)$$

Conditions (27)–(29) are obvious. The problem lies in (30) as this condition is meant as:

$$A \subset B \text{ iff } \forall x \in X, \; \mu_A(x) \leq \mu_B(x) \; and \; \nu_A(x) \geq \nu_B(x) \quad (31)$$

Unfortunately, (31) is not constructive and operational for A-IFSs as for many cases it can not be used. For example, for the elements $(x : (\mu, \nu, \pi))$: x_1: $(0.12, 0.4, 0.48)$ and x_2: $(0.1, 0.3, 0.6)$ we can not come to a conclusion. Moreover, element x: $(0, 0, 1)$ seems to be always beyond consideration in the sense of (31) which is very specific, and mostly practically irrelevant.

Furthermore, most of the similarity measures shown above are in fact similarity measures comparing just two intervals (each interval representing one of the A-IFSs under comparison). But we should bear in mind that elements of A-IF are described via the membership and non-membership function and the hesitation margin. In other words, in the terms of intervals, we have both the membership in an interval, and the non-membership in an interval so that we should represent an A-IF via two (not one) intervals.

Considering the representation of A-IFSs as single intervals implies some problems while calculating distances. Distances used in the (counter-intuitive) similarity measures mentioned in the previous section are calculated without taking into account the hesitation margins as the membership and non-membership functions only are taken into account. The counter-intuitive results obtained in such a case are in Szmidt and Kacprzyk [29], [39], Szmidt [22].

4 Some examples of intuitively justified and operational similarity measures

First we recall the measure of similarity between A-IFSs presented by Szmidt and Kacprzyk [37], [36]).

In the simplest situations we calculate the similarity of any two elements X and F belonging to an A-IF (A-IFSs). The proposed measures indicate if X is more similar to F or to F^C, where F^C is the complement of F. In other words, the proposed measures answer the question: is X more similar or more dissimilar to F?

Definition 1

$$Sim_{rule}(X,F) = \frac{l_{IF}(X,F)}{l_{IF}(X,F^C)} \quad (32)$$

where: $l_{IFS}(X,F)$ *is a distance from* $X(\mu_X, \nu_X, \pi_X)$ *to* $F(\mu_F, \nu_F, \pi_F)$*,*
$l_{IFS}(X,F^C)$ *is a distance from* $X(\mu_X, \nu_X, \pi_X)$ *to* $F^C(\nu_F, \mu_F, \pi_F)$*,*
F^C *is a complement of* F*, distances* $l_{IFS}(X,F)$ *and* $l_{IFS}(X,F^C)$ *are calculated from (6).*

For (32) we have

$$0 \leq Sim_{rule}(X,F) \leq \infty \quad (33)$$

$$Sim_{rule}(X,F) = Sim_{rule}(F,X)$$

The similarity has typically been assumed to be symmetric. Tversky [44], however, has provided some empirical evidence that the similarity should not always be treated as a symmetric relation. We stress this to show that a similarity measure (32) may have some features which can be useful in some situations but are not welcome in others (see Cross and Sudkamp [8], Wang et al. [47], Veltkamp [45]).

It is obvious (cf. Szmidt and Kacprzyk [36]) that the formula (32) can also be stated as

$$Sim_{rule}(X,F) = \frac{l_{IFS}(X,F)}{l_{IFS}(X,F^C)} = \frac{l_{IFS}(X^C,F^C)}{l_{IFS}(X,F^C)} = \frac{l_{IFS}(X,F)}{l_{IFS}(X^C,F)} = \frac{l_{IFS}(X^C,F^C)}{l_{IFS}(X^C,F)} \quad (34)$$

It is worth noticing that
– $Sim_{rule}(X,F) = 0$ means the identity of X and F.
– $Sim_{rule}(X,F) = 1$ means that X is to the same extent similar to F and F^C (i.e., values bigger than 1 mean a closer similarity of X and F^C to X and F).
– When $X = F^C$ (or $X^C = F$), i.e. $l_{IFS}(X,F^C) = l_{IFS}(X^C,F) = 0$ means the complete dissimilarity of X and F (or in other words, the identity of X and F^C), and then $Sim_{rule}(X,F) \to \infty$.
– When $X = F = F^C$ means the highest possible entropy (see [31]) for both elements F and X i.e. the highest "fuzziness" – not too constructive a case when looking for compatibility (both similarity and dissimilarity).
In other words, while applying the measure (32) to analyze the similarity of two objects, one should be interested in the values $0 \leq Sim_{rule}(X,F) < 1$.

The proposed measure (32) was constructed for selecting objects which are more similar than dissimilar [and well-defined in the sense of possessing (or not) attributes we are interested in]. In Szmidt and Kacprzyk [37] it was shown that a measure of similarity defined as above, (32), between $X(\mu_X, \nu_X, \pi_X)$ and $F(\mu_F, \nu_F, \pi_F)$ is more powerful than a simple distance between them. The following conclusion were drawn:

– when a distance between two (or more) objects/elements, or sets, is large, then it means for sure that the similarity does not occur.
– when a distance is small, we can say nothing for sure about similarity just on the basis of a distance between two objects [when not taking into account complements of the objects as in (32)]. The distance between objects can be small and the compared objects can be more dissimilar than similar.

We have shown on a simple example (cf. Szmidt and Kacprzyk [37]) that the measure (32) gives reasonable results when applied to assessing agreement in a group of experts. The only disadvantage of the proposed measure is that it does

ISBN: 978-989-95079-6-8

Table 1: Example results obtained from the similarity measures (35)–(38)

1	2	3	4	5
$X = (\mu, \nu, \pi)$	$(0.3, 0.4, 0.3)$	$(0.4, 0.2, 0.4)$	$(0.4, 0.2, 0.4)$	$(0, 0, 0)$
$F = (\mu, \nu, \pi)$	$(0.4, 0.3, 0.3)$	$(0.5, 0.3, 0.2)$	$(0.5, 0.2, 0.3)$	$(0.5, 0.5, 0)$
Sim_1	0	0.6	0.75	0.5
Sim_2	0	0.43	0.6	0.33
Sim_3	0	0.72	0.88	0.6
Sim_4	0	0.48	0.65	0.38

not follow the range of the usually assumed values for the similarity measures. But it is possible to construct a whole array of similarity measures following the philosophy, and preserving the advantages of the measure (32), and whose numerical values are consistent with the common scientific tradition (i.e. belonging to $[0, 1]$). For example:

$$Sim_1(X, F) = Sim_1(l_{IFS}(X, F), l_{IFS}(X, F^C)) = 1 - \frac{l_{IFS}(X, F)}{l_{IFS}(X, F) + l_{IFS}(X, F^C)} \quad (35)$$

$$Sim_2(X, F) = Sim_2(l_{IFS}(X, F), l_{IFS}(X, F^C)) = \frac{1 - f(l_{IFS}(X, F), l_{IFS}(X, F^C))}{1 + f(l_{IFS}(X, F), l_{IFS}(X, F^C))} \quad (36)$$

$$Sim_3(X, F) = Sim_3(l_{IFS}(X, F), l_{IFS}(X, F^C)) = \frac{1 - f(l_{IFS}(X, F), l_{IFS}(X, F^C))^2}{1 + f(l_{IFS}(X, F), l_{IFS}(X, F^C))^2} \quad (37)$$

$$Sim_4(X, F) = Sim_4(l_{IFS}(X, F), l_{IFS}(X, F^C)) = \frac{e^{-f(l_{IFS}(X,F), l_{IFS}(X,F^C))} - e^{-1}}{1 - e^{-1}} \quad (38)$$

where

$$f(l_{IFS}(X, F), l_{IFS}(X, F^C)) = = \frac{l_{IFS}(X, F)}{l_{IFS}(X, F) + l_{IFS}(X, F^C)} \quad (39)$$

and $0 \leq f(l_{IFS}(X, F), l_{IFS}(X, F^C)) \leq 1$.

The measures (35) – (38) give intuitive results. Some examples, being troublesome for other measures, are presented in Table 1. It is worth noticing that each measure assigns similarity equal 0 for an element $(0.3, 0.4, 0.3)$ and its complement $(0.4, 0.3, 0.3)$. In general, similarity measures (35) – (38) satisfy the following properties:

$$Sim_i(X, F) \in [0, 1], \quad (40)$$

$$Sim_i(X, X) = 1, \quad (41)$$

$$Sim_i(X, X^C) = 0, \quad (42)$$

$$Sim_i(X, F) = Sim_i(F, X), \quad (43)$$

for $i = 1, \ldots, 4$.

The similarity measures introduced in this section assess similarity of any two elements (X and F) belonging to an intuitionistic fuzzy set (or sets). The counterpart similarity measures for A-IFSs A and B containing n elements each, are:

$$Sim_k(A, B) = \frac{1}{n} \sum_{i=1}^{n} Sim_k(l_{IFS}(X_i, F_i), l_{IFS}(X_i, F_i^C)) \quad (44)$$

for $k = 1, \ldots, 4$.

5 Conclusions

We considered two groups of similarity measures between A-IFSs. First, we dealt with similarity measures constructed as if an A-IFSs was equal to a simple interval valued fuzzy set, or similarity measures being straightforward generalizations of those well known for the fuzzy sets. Unfortunately, in some situations, both approaches give counter-intuitive results. Second, we considered similarity measures accounting for all three functions describing an A-IF (the membership, non-membership, and hesitation margin) which is different from viewing an A-IF as a single interval. Next, we also took into account the complements of the elements compared. That is, we employed all kinds and fine shades of information available. It seems that these last measures are the most promising because, first of all, they help avoid some strong counter-intuitive results. This is crucial for both theory and applications.

Non-commutative EQ-logics and their extensions

Vilém Novák, Martin Dyba

Email: Vilem.Novak,martin.dyba@osu.cz

Abstract— *We discuss a formal many-valued logic called EQ-logic which is based on a recently introduced special class of algebras called EQ-algebras. The latter have three basic binary operations (meet, multiplication, fuzzy equality) and a top element and, in a certain sense, generalize residuated lattices. The goal of EQ-logics is to present a possible direction in the development of mathematical logics in which axioms are formed as identities. In this paper we propose a basic EQ-logic and three extensions which end up with a logic equivalent to the MTL-logic.*

Keywords— EQ-algebra, fuzzy equality, residuated lattice, MTL-logic, fuzzy logic.

1 Introduction

One of possible directions of the development of mathematical logic which can be tracked down to Leibnitz, Wittgenstein, and Ramsey (cf. [1]) is to develop it on the basis of identity (equality) as the principal connective. This direction has been crowned in a noble way by Henkin in [2] who developed the type theory (a higher order logic) using identity as a sole primitive constant. This is nice because it enables to treat equality between elements on the basis of the same principles not depending on their character. Thus, equality between truth values is, in principle, a relation of the same kind as an equality between other kinds of elements. Hence, we will speak about equality instead of equivalence even when speaking about truth values.

Note that there are works developing classical boolean logic on the basis of equivalence as the main (not sole) connective (a recent book presenting logic in this way is [3]). Moreover, the logic is developed there in the "equational style", i.e. proofs proceed as sequences of equations (in fact, equivalences).

This gives rise to an idea whether also fuzzy (many-valued) logic could be developed on the basis of fuzzy equality as the main connective where by fuzzy equality we mean, in fact, a fuzzy equivalence, i.e. a generalization of the classical logical equivalence. We will prefer the term "fuzzy equality", though. Recall that this idea is supported by the mentioned Henkin successful type theory (for a detailed development of this theory, see also [4]) as well as by the development of fuzzy type theory (see [5, 6]). On the other hand, unlike classical type theory, it seems impossible to have fuzzy equality a sole connective. At least conjunction is also necessary as follows from the considerations concerning the structure of the algebra of truth values. Namely, two approaches are apparent.

In the first approach, the structure of truth values is assumed to form a residuated lattice where the basic operations are, besides the lattice ones, the multiplication "$\otimes$" and its residuum "$\rightarrow$". The latter is in fuzzy logic a natural interpretation of implication which is a primary operation while the equivalence is interpreted by a biresiduation $a \leftrightarrow b = (a \rightarrow b) \wedge (b \rightarrow a)$ which is a derived operation. Since the basic connective, in our case, should be the fuzzy equality, it seems unnatural to interpret it by a derived operation.

The second approach follows an idea presented in [7, 8] where a specific kind of algebra called EQ-algebra is developed. Unlike the residuated lattices, the basic operation in EQ-algebras is a fuzzy equality "$\sim$" while implication is derived from it. Of course, a crucial question remains, which properties such an equality should have. At first sight it seems clear that these properties should be reflexivity, symmetry, and transitivity. We are convinced, however, that the fuzzy equality should be characterized by a deeper property reflecting some basic structure so that both symmetry as well as especially transitivity would follow. The most essential is, in our opinion, the "substitution principle" stating that if we replace an object by another one equal to the former then the result is not changed; in the case of fuzzy equality, the replacement should not make the structure in concern "worse" in some reasonable sense.

What basic structure should we consider in fuzzy logic? Clearly, this is *ordering* since the basic idea standing behind fuzziness is introducing degrees to enable measuring imprecision stemming from vagueness. Since ordering is in no way included in the equality, it must be introduced explicitly. Therefore, we will consider the basic structure to be a $\wedge$-semilattice with the greatest element $\mathbf{1}$. At the same time, we must "fuse" in some way statements about ordering and equality. The fusion is in our algebra realized by a third operation of multiplication "$\otimes$" whose properties, however, should be as weak as possible because we think that it should not participate on the ordering but enable only to "fuse things together". This is the main motivation behind axiom (E4) below. The symmetry and transitivity of $\sim$ are then consequences of it. The fusion $\otimes$ needs not be commutative and, perhaps, nor even associative.

Step by step we arrive at 8 axioms which determine the EQ-algebra. In its "crude form", there is no need to introduce the smallest element $\mathbf{0}$. Morever, the axioms make it possible to have two different truth values equivalent in the degree $\mathbf{1}$ and so, the fuzzy equality generalizes classical equivalence in an essential way. From the algebraic point of view, EQ-algebras generalize, in a certain sense, residuated lattices and so, they look as interesting class of algebraic structures.

When attempting to develop a formal logical calculus it came out, surprisingly, that the crude structure though reflecting the basic principles of fuzzy equality, is not strong enough. Namely, the logic enforced adding an axiom of "goodness" (E10) (or, as a logical formula (EQ1)) below which says that

ISBN: 978-989-95079-6-8

an element a is equal to $\mathbf{1}$ always in a degree a. This axiom implies that the algebra is separated, i.e. that two elements equal in the degree $\mathbf{1}$ must be identical in the classical sense. We conclude that the logic allows only a slight generalization of the classical equivalence. Of course, the goodness axiom has many important algebraic consequences (see [9, 8]). Among them is also the fact that each good EQ-algebra gives rise to a BCK-algebra. Putting all together we expect that EQ-algebras may put a different light on residuated lattices and on their general role in algebra and logic.

This paper is an attempt to introduce a formal logic called EQ-logic*) whose truth values are taken from a good EQ-algebra. Several basic properties of this logic demonstrating that it behaves reasonably are proved. In comparison with residuated fuzzy logics, however, our logic seems to be more limited. For example, the deduction theorem even in its weaker form probably does not hold and we guess that its validity is equivalent with residuation. Still, it is interesting to learn how far can we go with the development of EQ-logic. Besides others, it enables us to separate properties, which stem from the fuzzy equality itself, from the properties for which residuation is necessary. It may also shed light on classical logic, especially on its equational variant ([3]).

2 Definition and fundamental properties of EQ-algebras

Definition 1
A semicopula-based EQ-algebra $\mathscr{E}$ is an algebra of type (2, 2, 2, 0), i.e.

$$\mathscr{E} = \langle E, \wedge, \otimes, \sim, \mathbf{1} \rangle\,, \tag{1}$$

where for all $a, b, c, d \in E$:

(E1) $\langle E, \wedge, \mathbf{1}\rangle$ *is a commutative idempotent monoid (i.e. $\wedge$-semilattice with top element $\mathbf{1}$) where the ordering $a \le b$ is defined in standard way as $a \wedge b = a$,*

(E2) $\otimes$ *is a binary multiplication operation isotone w.r.t. $\le$, i.e. $a \le b$ implies both $a \otimes c \le b \otimes c$ as well as $c \otimes a \le c \otimes b$ and $\mathbf{1}$ is a neutral element, i.e. $a \otimes \mathbf{1} = \mathbf{1} \otimes a = a$.*

(E3) $a \sim a = \mathbf{1}$,

(E4) $((a \wedge b) \sim c) \otimes (d \sim a) \le c \sim (d \wedge b)$,

(E5) $(a \sim b) \otimes (c \sim d) \le (a \sim c) \sim (b \sim d)$,

(E6) $(a \wedge b \wedge c) \sim a \le (a \wedge b) \sim a$,

(E7) $(a \wedge b) \sim a \le (a \wedge b \wedge c) \sim (a \wedge c)$,

(E8) $a \otimes b \le a \sim b$.

The operation $\sim$ is called a fuzzy equality.

For all $a, b \in E$ we put

$$a \to b = (a \wedge b) \sim a. \tag{2}$$

This is a derived operation called *implication*†).

Note that axioms (E6) and (E7) can be rewritten as

$$a \to (b \wedge c) \le a \to b\,, \tag{E6'}$$
$$a \to b \le (a \wedge c) \to b\,. \tag{E7'}$$

The following theorem confirms that $\sim$ is indeed a fuzzy equality.

Theorem 1
Let $\mathscr{E}$ be an EQ-algebra. The following holds for all $a, b, c \in E$:

(a) Symmetry: $a \sim b = b \sim a$,

(b) Transitivity: $(a \sim b) \otimes (b \sim c) \le a \sim c$,

(c) Transitivity of implication: $(a \to b) \otimes (b \to c) \le a \to c$.

We say that the multiplication $\otimes$ is *$\to$-isotone* if

$$a \to b = \mathbf{1} \quad \text{implies} \quad a \otimes c \to b \otimes c = \mathbf{1} \tag{3}$$

for all $a, b, c \in E$. Let us remark that the $\to$-isotonicity of $\otimes$ is usually fulfilled. There exist EQ-algebras, however, which have not this property.

A semicopula-based EQ-algebra has the operation $\otimes$, in general neither commutative nor associative. If the latter is only non-commutative but associative then we will speak about a *non-commutative* EQ-algebra.

Theorem 2
Let $\mathscr{E} = \langle E, \wedge, \otimes, \sim, \mathbf{1}\rangle$ is a semicopula-based EQ-algebra and put $b \bar{\otimes} a = a \otimes b$. Then $\mathscr{E}' = \langle E, \wedge, \bar{\otimes}, \sim, \mathbf{1}\rangle$ is also a semicopula-based EQ-algebra.

The following lemmas summarizes some of the properties of EQ-algebras useful below. Its proof can be found in [9, 8].

Lemma 1
Let $\mathscr{E}$ be an EQ-algebra. For all $a, b \in E$ such that $a \le b$ it holds that

(a) $a \to b = \mathbf{1}$,

(b) $a \sim b = b \to a$,

(c) $c \to a \le c \to b$ *and* $b \to c \le a \to c$.

Lemma 2
Let $\mathscr{E}$ be an EQ-algebra. For all $a, b, c, d, a', b', c', d' \in E$ it holds that

(a) $a \otimes b \le a, a \otimes b \le a \wedge b, c \otimes (a \wedge b) \le (c \otimes a) \wedge (c \otimes b)$,

(b) $a \sim b \le a \to b, a \to a = \mathbf{1}$,

(c) $(a \to b) \otimes (b \to a) \le a \sim b$,

(d) $a = b$ *iff* $a \sim b = \mathbf{1}$,

(e) $a = \mathbf{1} \to a$ *and* $a \to \mathbf{1} = \mathbf{1}$,

(f) $a \otimes (a \sim b) \le b$,

(g) $b \le a \to b$,

(h) $((a \wedge b) \sim (c \wedge d)) \otimes (a \sim a') \otimes (b \sim b') \otimes (c \sim c') \otimes (d \sim d') \le (a' \wedge b') \sim (c' \wedge d')$.

*) This logic has been first introduced in Barcelona, October 2008 at the occasion of Prof. F. Esteva 65th birthday.

†) Note that this operation has been, in fact, introduced already by G. W. Leibnitz (cf. [10])

ISBN: 978-989-95079-6-8

Note that if $\mathscr{E}$ is separated, then $a \to b = \mathbf{1}$ implies $a \leq b$. Indeed, $a \to b = (a \wedge b) \sim a = \mathbf{1}$ implies $a \wedge b = a$, i.e. $a \leq b$.

Let $\mathscr{E}$ contain also the bottom element $\mathbf{0}$. Then we put

$$\neg a = a \sim \mathbf{0}, \qquad a \in E \tag{4}$$

and call $\neg a$ a *negation* of $a \in E$.

Definition 2
Let $\mathscr{E}$ be an EQ-algebra and $a, b, c, d \in L$. We say that $\mathscr{E}$ is:

(i) separated *if for all $a \in E$,*

(E9) $a \sim b = \mathbf{1}$ *implies* $a = b$.

(ii) good *if*

(E10) $a \sim \mathbf{1} = a$.

(iii) residuated *if for all $a, b, c \in E$,*

(E10) $(a \otimes b) \wedge c = a \otimes b$ *iff* $a \wedge ((b \wedge c) \sim b) = a$.

(iv) involutive *(IEQ-algebra) if for all $a \in E$,*

(E11) $\neg\neg a = a$.

(v) prelinear *if for all $a, b \in E$,*

(E12) $\sup\{a \to b, b \to a\} = \mathbf{1}$.

(vi) lattice EQ-algebra *(ℓEQ-algebra) if it is a lattice and*

(E13) $((a \vee b) \sim c) \otimes (d \sim a) \leq (d \vee b) \sim c$.

(vii) complete *if it's $\wedge$-semilattice reduct is complete.*

(viii) EQ(R)-algebra *if for all $a, b \in E$ there exist*

$$a/b = \max\{c \in E \mid a \otimes c \leq b\}$$
$$a\backslash b = \max\{c \in E \mid c \otimes a \leq b\}$$

(the latter equalities will be referred to as (R)-condition).

It is easy to show that good EQ-algebras are *separated*. Obviously, $\otimes$ in good EQ-algebras is $\to$-isotone. As already discussed, the "goodness property" appeared to be indispensable for logic and so, from now on, *by EQ-algebra we will always mean a good one*.

Remark 1
Let $\mathscr{E}$ be a semicopula-based EQ-algebra. A set $F \subseteq E$ is a filter if $\mathbf{1} \in F$; $a, b \in F$ implies $a \otimes b \in F$; $a, a \to b \in F$ implies $b \in F$; $a \to b \in F$ implies $(a \otimes c) \to (b \otimes c) \in F$ and $(c \otimes a) \to (c \otimes b) \in F$. Then it can be proved that a factor algebra $\mathscr{E}|F$ is a separated semicopula-based EQ-algebra. Surprizingly, there exist EQ-algebras with no proper filter and so, we cannot embed each EQ-algebra into a separated one.

The concept of EQ(R)-algebra is due to El Zekey [11]. Obviously, it inserts residuation inside EQ-algebra. In case that $E = [0, 1]$, it simply requires the operation $\otimes$ to be left-continuous.

Lemma 3
Let $\mathscr{E}$ be an IEQ-algebra. Then

(a) $\mathscr{E}$ is good ℓEQ-algebra with join defined by

$$a \vee b = \neg(\neg a \wedge \neg b).$$

(b) $a \leq b$ *iff* $\neg b \leq \neg a$.

(c) $a \sim b = \neg a \sim \neg b$.

(d) $a \otimes \neg a = \mathbf{0}$.

Theorem 3 ([11])
Let $\mathscr{E}$ be a good non-commutative EQ(R)-algebra. Then the following is equivalent:

(a) $\mathscr{E}$ is representable (i.e. subdirectly embeddable into a product of linearly ordered good EQ(R)-algebras[‡]).

(b) $\mathscr{E}$ satisfies the formula

$$(a \to b) \vee (d \to (d \otimes (c \to (b \to a) \otimes c))) = \mathbf{1}$$

for all $a, b, c, d \in E$.

3 Basic EQ-logic

In this section we introduce a propositional EQ-logic which we will call basic. This logic seems to be the simplest logic definable on the basis of EQ-algebras. Of course, we obtain more sophisticated logics when adding further axioms. From this point of view, all core (residuated) fuzzy logic in the sense of [12]) are extensions of the basic EQ-logic.

Definition 3
The language of EQ-logic consists of propositional variables $p_1, p_2, \ldots$, binary connectives $\wedge, \&, \equiv$ and a truth (logical) constant $\top$. Formulas are defined in the obvious way: each propositional variable is a formula, $\top$ is a formula and if A, B are formulas, then $A \wedge B, A \& B, A \equiv B$ are formulas. Implication is defined as a short

$$A \Rightarrow B := (A \wedge B) \equiv A. \tag{5}$$

Let J be a language of EQ-logic, F_J a set of all formulas in the language J and $\mathscr{E} = \langle E, \wedge, \otimes, \sim, \mathbf{1}\rangle$ be a good EQ-algebra. A truth evaluation $e : F_J \longrightarrow E$ is defined as usual: if $p \in J$ is a propositional variable then $e(p) \in E$. Furthermore, we put

$$e(\top) = \mathbf{1},$$
$$e(A \wedge B) = e(A) \wedge e(B)$$
$$e(A \& B) = (e(A) \otimes e(B)),$$
$$e(A \equiv B) = (e(A) \sim e(B))$$

for all formulas $A, B \in F_J$.

A formula $A \in F_J$ is a tautology if $e(A) = \mathbf{1}$ for each truth evaluation $e : F_J \longrightarrow E$.

Note that our logic has a non-commutative fusion connective $\&$ but only one implication because it is derived from equivalence (i.e. its interpretation is not residual operation adjoint with multiplication). We are convinced that this is an advantage.

[‡] A recent result of El-Zekey (personal communication) implies that the (R)-condition is unnecessary for the representability. This may lead to simplification of the structure of EQ-logics discussed below.

ISBN: 978-989-95079-6-8

3.1 Logical axioms and inference rules

The following formulas are axioms of the EQ-logic:

(EQ1) $(A \equiv \top) \equiv A$

(EQ2) $A \wedge B \equiv B \wedge A$

(EQ3) $(A \wedge B) \wedge C \equiv A \wedge (B \wedge C)$

(EQ4) $A \wedge A \equiv A$

(EQ5) $A \wedge \top \equiv A$

(EQ6) $A \,\&\, \top \equiv A$

(EQ7) $\top \,\&\, A \equiv A$

(EQ8a) $((A \wedge B) \,\&\, C) \Rightarrow (B \,\&\, C)$

(EQ8b) $(C \,\&\, (A \wedge B)) \Rightarrow (C \,\&\, B)$

(EQ9) $((A \wedge B) \equiv C) \,\&\, (D \equiv A) \Rightarrow (C \equiv (D \wedge B))$

(EQ10) $(A \equiv B) \,\&\, (C \equiv D) \Rightarrow (A \equiv C) \equiv (D \equiv B)$

(EQ11) $(A \Rightarrow (B \wedge C)) \Rightarrow (A \Rightarrow B)$

(EQ12) $(A \Rightarrow B) \Rightarrow (A \wedge C) \Rightarrow B$

Remark 2
The above axioms have been written using $\Rightarrow$ for better readability because formulas with this connective are more usual than those with $\equiv$. However, technically we apply equational-style proofs in the sense of [3], which are sequences of formulas of the form $A_1 \equiv A_2, \ldots, A_{n-1} \equiv A_n$ such that each of the individual theorems $A_i \equiv A_{i+1}$ has an independent individual proof. Therefore, a fussy presentation would require to rewrite all the axioms using $\equiv$ and the definition (5) only.

By $A[p := B]$ we denote a formula resulting from A by replacing all occurrences of a propositional variable p in A by the formula B. Then we introduce the following inference rules of EQ-logic:

$$(EA)\quad \frac{A, A \equiv B}{B} \qquad (L)\quad \frac{B \equiv C}{A[p := B] \equiv A[p := C]}$$

The rule (EA) is the *equanimity rule* and (L) is the *Leibnitz rule* for formulas (cf. [3] and elsewhere). The notion of provability is classical. A formal theory is any subset $T \subseteq F_J$. As usual, we suppose that T is defined by a set of special axioms.

3.2 Main properties

The proof of the following three lemmas is technical. They demonstrate several reasonable properties of the basic EQ-logic.

Lemma 4
The following are special derived rules:

(a) $A \equiv \top \vdash A$. *(rule (T1))*

(b) $A \vdash A \equiv \top$. *(rule (T2))*

(c) $A \wedge D \equiv C, A \equiv B \vdash B \wedge D \equiv C$. *(rule (C))*

(d) $(A \equiv D) \equiv C, A \equiv B \vdash (B \equiv D) \equiv C$. *(rule (E))*

(e) $A \,\&\, D \equiv C, A \equiv B \vdash B \,\&\, D \equiv C$. *(rule (F1))*

(f) $D \,\&\, A \equiv C, A \equiv B \vdash D \,\&\, B \equiv C$. *(rule (F2))*

Lemma 5
(a) $\vdash A \equiv A$,

(b) $A \equiv B \vdash B \equiv A$,

(c) $A \equiv B, B \equiv C \vdash A \equiv C$,

(d) $A, A \Rightarrow B \vdash B$, *(Modus Ponens)*

(e) $\vdash (\top \Rightarrow A) \equiv A$,

(f) $A \Rightarrow B, B \Rightarrow C \vdash A \Rightarrow C$,

(g) $A, B \vdash A \,\&\, B$,

(h) $\vdash (A \equiv B) \equiv (B \equiv A)$,

(i) $A \Rightarrow (B \equiv C), B \vdash A \Rightarrow C$,

(j) $\vdash (A \equiv D) \Rightarrow ((A \equiv B) \equiv (D \equiv B))$,

(k) $A \Rightarrow (B \equiv C), B \equiv D \vdash A \Rightarrow (D \equiv C)$,

(l) $A \Rightarrow (B \equiv C), C \equiv D \vdash A \Rightarrow (B \equiv D)$,

(m) $\vdash (A \equiv B) \Rightarrow (A \Rightarrow B)$,

(n) $A \equiv B, C \equiv D \vdash A \,\&\, C \equiv B \,\&\, D$,

(o) $A \Rightarrow B, C \Rightarrow D \vdash A \,\&\, C \Rightarrow B \,\&\, D$,

(p) $\vdash ((A \equiv B) \equiv C) \,\&\, (A \equiv D) \Rightarrow ((D \equiv B) \equiv C)$,

(q) $\vdash (A \equiv B) \,\&\, (C \equiv D) \Rightarrow (A \equiv C) \equiv (B \equiv D)$,

(r) $\vdash (A \Rightarrow B) \,\&\, (B \Rightarrow A) \Rightarrow (A \equiv B)$,

(s) $\vdash B \Rightarrow (A \Rightarrow B)$.

Lemma 6
(a) $\vdash (A \equiv B) \,\&\, (B \equiv C) \Rightarrow (A \equiv C)$,

(b) $\vdash (A \,\&\, (A \equiv B)) \Rightarrow B$

(c) $\vdash (A \Rightarrow B) \,\&\, (B \Rightarrow C) \Rightarrow (A \Rightarrow C)$,

(d) $\vdash (A \,\&\, (A \Rightarrow B)) \Rightarrow B$

(e) $\vdash B \Rightarrow (B \equiv \top)$,

(f) $A \Rightarrow (B \Rightarrow C) \vdash (A \,\&\, B) \Rightarrow C$,

(g) $\vdash A \,\&\, B \Rightarrow A \equiv B$,

(h) $\vdash (A \wedge B) \Rightarrow A$,

(i) $\vdash (C \Rightarrow A) \,\&\, (C \Rightarrow B) \Rightarrow (C \Rightarrow (A \wedge B))$.

By the straightforward verification we can prove the following two lemmas.

Lemma 7
All axioms of EQ-logic are tautologies.

Lemma 8
The deductive rules of EQ-logic are sound in the following sense. Let $e : F_J \longrightarrow E$ be a truth evaluation:

ISBN: 978-989-95079-6-8

(a) *If* $e(A) = \mathbf{1}$ *and* $e(A \equiv B) = \mathbf{1}$ *then* $e(B) = \mathbf{1}$.

(b) *If* $e(B \equiv C) = \mathbf{1}$ *then* $e(A[p := B] \equiv A[p := C]) = \mathbf{1}$ *for any formula* A.

The following is a standard Lindenbaum-Tarski technique. Put

$$A \approx B \quad \text{iff} \quad \vdash A \equiv B, \quad A, B \in F_J.$$

It follows from Lemmas 5(a), (h) and 6(a) that $\approx$ is an equivalence on F_J. Let us denote by $[A]$ an equivalence class of A and put $\bar{E} = \{[A] \mid A \in F_J\}$. If we define

$$\begin{aligned} \mathbf{1} &= [\top], \\ [A] \wedge [B] &= [A \wedge B], \\ [A] \otimes [B] &= [A \,\&\, B], \\ [A] \sim [B] &= [A \equiv B], \end{aligned}$$

then we obtain an algebra $\bar{\mathscr{E}} = \langle \bar{E}, \wedge, \otimes, \sim, \mathbf{1} \rangle$.

Lemma 9
The algebra $\bar{\mathscr{E}}$ *is a good semicopula-based EQ-algebra.*

Theorem 4 (Soundness)
The basic EQ-fuzzy logic is sound.

PROOF: This is a consequence of Lemmas 7 and 8. □

Theorem 5 (Completeness)
The following is equivalent for every formula A*:*

(a) $\vdash A$,

(b) $e(A) = \mathbf{1}$ *for every good semicopula-based EQ-algebra* $\mathscr{E}$ *and a truth evaluation* $e : F_J \longrightarrow E$.

PROOF: The implication (a) to (b) is soundness.

(b) to (a): By Lemma 9 the algebra $\bar{\mathscr{E}}$ of equivalence classes of formulas is a good semicopula-based EQ-algebra. Thus, if (b) holds then it holds also for $e : F_J \longrightarrow \bar{E}$. If $e(A) = \mathbf{1}$ then it means that $[A] = [\top]$, i.e. $\vdash A \equiv \top$ and so, $\vdash A$ by rule (T2). □

4 Extensions of the basic EQ-logic

In this section we will briefly discuss some extensions of the basic EQ-logic.

4.1 Involutive EQ-logic

This logic (we will speak about IEQ-logic) contains falsity and is characterized by the property of double negation which leads to some simplifications.

The language J is the same as that of basic EQ-logic with the exception that $\top$ is replaced by $\bot$. Furthermore, we introduce the following shorts of formulas:

$$\top := \bot \equiv \bot, \tag{6}$$

$$\neg A := A \equiv \bot, \tag{7}$$

$$A \vee B := \neg(\neg A \wedge \neg B). \tag{8}$$

(clearly, (7) is a *negation* and (8) a disjunction.

Axioms of IEQ-logic are (EQ2)–(EQ12) plus the following ones:

(EQ13) $(A \,\&\, B) \,\&\, C \equiv A \,\&\, (B \,\&\, C)$,

(EQ14) $(A \wedge \bot) \equiv \bot$,

(EQ15) $\neg\neg A \equiv A$.

Axiom (EQ14) characterizes the basic property of $\bot$ and it can be written as $\bot \Rightarrow A$ (ex falso quodlibet). Axiom (EQ1) is in this logic provable.

A contradiction is a formula $A \,\&\, \neg A$. Then we say that a theory T is *contradictory* if $T \vdash A \,\&\, \neg A$ for some formula $A \in F_J$.

A straightforward proof will give the following (classical) theorem:

Theorem 6
A theory T *is contradictory iff* $T \vdash A$ *for all* $A \in F_{J(T)}$.

Semantics of this logic is formed by IEQ-algebras.

Theorem 7 (Completeness)
The following is equivalent for every formula A*:*

(a) $\vdash A$,

(b) $e(A) = \mathbf{1}$ *for every IEQ-algebra* $\mathscr{E}$ *and a truth evaluation* $e : F_J \longrightarrow E$.

4.2 EQ(R)-fuzzy logic

This logic seems to be closest to the residuated fuzzy logics. In fact, it already introduces some kind of residuated structure which enables to prove a stronger variant of the completeness theorem.

The language of this logic is that of IEQ-logic extended by two binary connectives: "\" and "/" and the shorts (6) and

$$A \vee B := ((A \Rightarrow B) \Rightarrow B) \wedge ((B \Rightarrow A) \Rightarrow A).$$

Axioms are (EQ1)–(EQ14) plus the following:

(EQ16) $(A \Rightarrow B) \vee (D \Rightarrow (D \,\&\, (C \Rightarrow (B \Rightarrow A) \,\&\, C)))$

(EQ17) $C/(A \otimes B) \equiv (C/(B/A))$

(EQ18) $(A \otimes B)\backslash C \equiv ((A\backslash B)\backslash C)$

Semantics of this logic is formed by good non-commutative prelinear EQ(R)-algebras.

Using Theorem 3, the following can be proved:

Theorem 8 (Completeness)
For every formula $A \in F_J$ *the following is equivalent:*

(a) $\vdash A$.

(b) $e(A) = \mathbf{1}$ *for every truth evaluation* $e : F_J \longrightarrow E$ *and every linearly ordered good non-commutative EQ(R)-algebra* $\mathscr{E}$.

(c) $e(A) = \mathbf{1}$ *for every truth evaluation* $e : F_J \longrightarrow E$ *and every good non-commutative prelinear EQ(R)-algebra* $\mathscr{E}$.

ISBN: 978-989-95079-6-8

4.3 Residuated EQ-logic

This is stronger logic close to MTL-logic because of introducing the residuation property.

The language J is the same as that of basic EQ-logic. Its axioms are (EQ1)–(EQ12) plus the following:

(EQ19) $((A \,\&\, B) \equiv C) \,\&\, (D \equiv A) \Rightarrow (C \equiv (D \,\&\, B))$

Lemma 10
The following is provable residuated EQ-logic:

(a) $\vdash A \,\&\, B \equiv B \,\&\, A$,

(b) $(A \,\&\, B) \,\&\, C \equiv A \,\&\, (B \,\&\, C)$,

(c) $\vdash ((A \,\&\, B) \Rightarrow C) \equiv (A \Rightarrow (B \Rightarrow C))$.

By A^n we mean n-times repetition of A w.r.t. $\&$ (as usual).

Theorem 9 (Deduction)
For every theory T and formulas $A, B \in F_J$:

$T \cup \{A\} \vdash B$ *iff* *there is* $n \geq 1$ *such that* $T \vdash A^n \Rightarrow B$

Semantics for this logic is formed by residuated EQ-algebras. If we replace the constant $\top$ in the language J by $\bot$, take the definition (6) and add axiom (EQ14) and the axiom

(EQ20) $((A \Rightarrow B) \Rightarrow C) \Rightarrow (((B \Rightarrow A) \Rightarrow C) \Rightarrow C)$

then the resulting logic is equivalent with the MTL-logic.

5 Conclusion

In this paper we introduced a class of logics based on a new algebra of truth values called EQ-algebra. This algebra is specific by introducing fuzzy equality (equivalence) as the basic operation. Accordingly, the basic connective of EQ-logic is equivalence.

It is easy to show that BCK-axioms are provable in basic EQ-logic and so, basic EQ-logic is also a BCK-one (cf. [13]). However, since modus-ponens is a derived rule in the former, translation of properties of BCK-logic to EQ-logic is not straightforward. It is an open question whether there is a formal system equivalent with basic EQ-logic with modus ponens as its sole rule.

Abstract*— *This communication is concerned with the problem of supervised classification of fuzzy data obtained from a random experiment. The data generation process is modelled through fuzzy random variables which, from a formal point of view, can be identified with a kind of functional random element. We propose to adapt one of the most versatile discriminant approaches in the context of functional data analysis to the specific case we handle. The discriminant analysis is based on the kernel estimation of the nonparametric regression. The results are applied to an experiment concerning fuzzy perceptions and linguistic labels

***Keywords*—** fuzzy data, random experiments, supervised classification, kernel estimation, nonparametric regression.

1 Introduction

In many random experiments, as for instance sociological surveys, ecological studies, etc., some characteristics of interest can be assessed in a more meaningful scale if the respondents or the experts are allowed to indicate the degree of precision/imprecision of their answers/judgment/perceptions by means of fuzzy sets (see, for instance, [3] and Section 4 for more details). The results of those experiments can be soundly modelled by means of fuzzy random variables in Puri & Ralescu's sense [16]. It should be remarked that fuzzy random variables in this sense are used to model fuzzy-set-valued random elements and that our goal regards the fuzzy random variables 'per-se'. However, there are other experiments in which the quantity of interest is an underlying real-valued random variables that cannot be precisely observed. In this cases, different approaches may be considered (see, for instance, [5]).

From a formal point of view fuzzy random variables can be identified with a special case of functional random variables, although with some particular features concerning the natural arithmetic and metric structure (see [7] for a deeper discussion). Functional Data Analysis has become an important area of research in recent years (see, for instance, [12, 17, 8, 19]), and as it was suggested in [7], it is possible to take advantage of some of the results developed for those elements to analyze fuzzy data.

As a first step in classification problems concerning fuzzy random variables, some unsupervised approaches have been considered in the literature (see, for instance, [10]). In this communication we deal with the supervised classification problem. That is, given a set of possible groups and a training random sample of fuzzy data of each group, the goal is to predict the group membership of a new fuzzy datum.

As it is indicated in [6], there are different approaches to this problem in the functional context. Most of them are based on modifications of the linear discriminant analysis, however to avoid the inconveniences that frequently arises from the presence of nonlinear class boundaries, we propose a nonparametric method inspired by [6].

The rest of the paper is organized as follows. In Section 2 we introduce the notation and the basic concepts. In Section 3 the classification approach is discussed. Section 4 is devoted to the empirical results, and finally in Section 5 we conclude with some remarks and open problems.

2 Preliminaries

We will denote by $\mathcal{F}_c(\mathbb{R}^p)$ the *class of fuzzy sets* $U : \mathbb{R}^p \to [0,1]$ whose α-levels U_α are nonempty compact convex subsets of $\mathbb{R}^p$ for all $\alpha \in [0,1]$, where $U_\alpha = \{x \in \mathbb{R}^p \,|\, U(x) \geq \alpha\}$ for all $\alpha \in (0,1]$, and $U_0 = \mathrm{cl}(\{x \in \mathbb{R}^p \,|\, U(x) > 0\})$.

Recently, a new class of metrics based on the generalization of the mid-point and the spread of an interval has been defined. This class is very intuitive and versatile and has good properties for the statistical analysis (see [18]).

The generalized mid-point and spread of a fuzzy set A is a way of identifying levelwise the center (location) and the extent (imprecision) by considering each direction in the multidimensional case through the unit sphere $\mathbb{S}^{p-1}$.

Formally, let $\alpha \in [0,1]$ and $u \in \mathbb{S}^{p-1}$, and calculate the lengths $\pi_u(A_\alpha)$ of all orthogonal projections of A_α on this direction, i.e.

$$\pi_u(A_\alpha) = \big[\underline{\pi}_u(A_\alpha)\,,\, \overline{\pi}_u(A_\alpha)\big] = \big[-s_{A_\alpha}(-u)\,,\, s_{A_\alpha}(u)\big]$$

where s stands for the support function of a nonempty convex compact set, that is, $s_{A_\alpha}(u) = \sup_{a \in A_\alpha} \langle u, a\rangle$ ($\langle\cdot,\cdot\rangle$ denoting the usual inner product in $\mathbb{R}^p$). Thus, the generalized mid-point and spread of A are defined as the functions $\mathrm{mid}_A, \mathrm{spr}_A : \mathbb{S}^{p-1} \times [0,1] \to \mathbb{R}$ so that

$$\mathrm{mid}_A(u,\alpha) = \mathrm{mid}_{A_\alpha}(u) = \frac{1}{2}\big(s_{A_\alpha}(u) - s_{A_\alpha}(-u)\big),$$

$$\mathrm{spr}_A(u,\alpha) = \mathrm{spr}_{A_\alpha}(u) = \frac{1}{2}\big(s_{A_\alpha}(u) + s_{A_\alpha}(-u)\big).$$

Note that in the interval case, $\mathbb{S}^{p-1} = \{-1,1\}$ and $\mathrm{mid}_A(-1,\alpha) = -\mathrm{mid}\, A$, $\mathrm{mid}_A(1,\alpha) = \mathrm{mid}\, A$, $\mathrm{spr}_A(-1,\alpha) = \mathrm{spr}_A(1,\alpha) = \mathrm{spr}\, A$ holds for all $\alpha \in [0,1]$.

ISBN: 978-989-95079-6-8

The generalized mid-point and spread are not defined as numbers summarizing the 'central tendency' and the 'imprecision', but as functions identifying the 'central points' and the 'imprecision' in the different directions of the Euclidean space. In this way, we get a meaningful characterization of the fuzzy sets alternative to the classical support functions.

The class of distances in [18] is defined from the distances between the level sets as a meaningful generalization of the Bertoluzza et al. metric [1], by considering L_2-type distances between the mid-points and the spreads. Specifically, for each level set $\alpha \in [0,1]$, we define

$$d_\theta^2\big(A_\alpha, B_\alpha\big) = \|\mathrm{mid}\, A_\alpha - \mathrm{mid}\, B_\alpha\|^2 + \theta\|\mathrm{spr}\, A_\alpha - \mathrm{spr}\, B_\alpha\|^2$$

where $\|\cdot\|$ is the usual L_2-norm in the space of the square-integrable functions $L^2(\mathbb{S}^{p-1})$, and $0 < \theta \leq 1$ determines the relative importance of the squared distance between the spreads in relationship with the squared distance between the mids.

The metric between fuzzy sets D_θ^φ is defined as a weighting mean (w.r.t. a probability measure φ with support $[0,1]$) of the distances between the level sets by

$$D_\theta^\varphi(A,B) = \left(\int_{[0,1]} d_\theta^2(A_\alpha, B_\alpha) d\varphi(\alpha)\right)^{1/2}$$

The weight measure φ reflects the intuitive (or subjective) interpretation of fuzzy sets - for instance one may treat every α-level as equally important (and therefore use the Lebesgue measure as weight measure φ), or give more mass to α-levels close to 1 or to α-levels close to 0.

If we denote by $\|\cdot\|_{\tilde{2}}$ the usual L_2-norm on the Hilbert space $\mathcal{H} = L^2(\mathbb{S}^{p-1} \times [0,1])$, we have the following alternative intuitive expression for the metric:

$$\big(D_\theta^\varphi(A,B)\big)^2 = \big\|\mathrm{mid}_{\,A} - \mathrm{mid}_{\,B}\big\|_{\tilde{2}}^2 + \theta\big\|\mathrm{spr}_{\,A} - \mathrm{spr}_{\,B}\big\|_{\tilde{2}}^2.$$

Let $(\Omega, \mathcal{A}, P)$ be a probability space. A *Fuzzy Random Variable* (FRV) can be identified with a Borel measurable mapping $\mathcal{X} : \Omega \to \mathcal{F}_c(\mathbb{R}^p)$ (see [2, 16]). The concepts of induced probability distribution and independence are the same as for general metric-space valued random elements.

3 Nonparametric discriminant approach for fuzzy data

Assume that we have a population $(\Omega, \mathcal{A}, P)$, and for each individual we observe a fuzzy datum. In addition, each individual may belong to one of k different categories $g_1, \ldots, g_k$, and as learning sampling we have the fuzzy data and the group of n independent individuals. The goal is to find a rule that allows us to classify a new individual in one of the k groups from the fuzzy datum. For this purpose we suggest to use a nonparametric approach.

Formally, let $(\mathcal{X}, G) : \Omega \to \mathcal{F}_c(\mathbb{R}^p) \times \{g_1, \ldots, g_k\}$ be a random element in such a way that $\mathcal{X}(\omega)$ is a fuzzy datum and $G(\omega)$ is the membership group (g_1,... or g_k) of each individual $\omega \in \Omega$. Assume that we have n independent copies of $(\mathcal{X}, G)$ as training sample, that is, we have a random sample $\{\mathcal{X}_i, G_i\}_{i=1}^n$. As in a more general functional context (see [6]), we propose to estimate nonparametrically

$$P(G = g_j | \mathcal{X} = \widetilde{x})$$

for $j = 1, \ldots, k$, $\widetilde{x} \in \mathcal{F}_c(\mathbb{R}^p)$, and then to assign the new data to the class of higher estimated probability.

In order to find a reasonable estimator of the preceding probability consider first $\delta > 0$ and a closed ball $B(\widetilde{x}; \delta)$ defined in terms of the metric introduced in Section 2. From Bayes Theorem we have that

$$P(G = g_j | \mathcal{X} \in B(\widetilde{x}; \delta))$$

$$= \frac{P(X \in B(\widetilde{x}; \delta) | G = g_j) P(G = g_j)}{\sum_{l=1}^k P(X \in B(\widetilde{x}; \delta) | G = g_l) P(G = g_l)}$$

$$= \frac{P(D_\theta^\varphi(\mathcal{X}, \widetilde{x}) \leq \delta | G = g_j)) P(G = g_j)}{\sum_{l=1}^k P(D_\theta^\varphi(\mathcal{X}, \widetilde{x}) \leq \delta | G = g_l) P(G = g_l)}$$

For each $\widetilde{x}$, obviously $D_\theta^\varphi(\mathcal{X}, \widetilde{x})$ is a (real-valued) random variable. Let $F_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}$ denote the distribution function of this variable in the group g_j. Consequently,

$$P(G = g_j | \mathcal{X} \in B(\widetilde{x}; \delta))$$

$$= \frac{F_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(\delta) P(G = g_j)}{\sum_{l=1}^k F_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_l}(\delta) P(G = g_l)}$$

If we assume (as it is natural in the nonparametric setting) that $F_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}$ is uniformly continuous for all $j = 1, \ldots k$, then we have that there exists an underlying density function $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}$ and

$$\lim_{\delta \to 0} \frac{F_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(\delta)}{\delta} = f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(0)$$

As a result,

$$P(G = g_j | \mathcal{X} = \widetilde{x})$$

$$= \frac{f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(0) P(G = g_j)}{\sum_{l=1}^k f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_l}(0) P(G = g_l)}.$$

Note that the denominator is just $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})}(0)$, and for this reason according to [6] we could estimate $P(G = g_j | \mathcal{X} = \widetilde{x})$ by means of

$$\widehat{P}(G = g_j | \mathcal{X} = \widetilde{x})$$

$$\frac{\sum_{i=1}^n I_{G=g_j} K(h^{-1} D_\theta^\varphi(\mathcal{X}_i, \widetilde{x}))}{\sum_{i=1}^n K(h^{-1} D_\theta^\varphi(\mathcal{X}_i, \widetilde{x}))}$$

$$= \frac{(nh)^{-1} \sum_{i=1}^n I_{G=g_j} K(h^{-1} D_\theta^\varphi(\mathcal{X}_i, \widetilde{x}))}{(nh)^{-1} \sum_{i=1}^n K(h^{-1} D_\theta^\varphi(\mathcal{X}_i, \widetilde{x}))}$$

ISBN: 978-989-95079-6-8

$$= \frac{\left[(n_j h)^{-1} \sum_{i \in N_j} K(h^{-1} D_\theta^\varphi(\mathcal{X}_i, \widetilde{x}))\right] \cdot (n_j n^{-1})}{(nh)^{-1} \sum_{i=1}^{n} K(h^{-1} D_\theta^\varphi(\mathcal{X}_i, \widetilde{x}))}$$

where $N_j = \{i \in \{1, \ldots, n\} | G_i = g_j\}$, n_j is the cardinality of N_j, K is a kernel and h the bandwidth.

The last expression shows clearly that the estimator depends on an estimate of $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(0)$ (the densities within each group at the point 0), the empirical estimate of $P(G = g_j)$ and an estimate of $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})}(0)$ (the overall density at the point 0). In this approach the bandwidth is the same for all the estimates, and it is determined by employing the whole sample. In this way, it is verified that

$$\sum_{j=1}^{k} \widehat{P}(G = g_j | \mathcal{X} = \widetilde{x}) = 1.$$

However, since that $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})}(0)$ is composed by a mixture of the variables $\{D_\theta^\varphi(\mathcal{X}, \widetilde{x}) | G = g_j\}_{j=1}^k$ whose distributions are expected to be different (recall that the aim is to discriminate among them), it seems more convenient to estimate separately each distribution (each one of them with its own bandwidth) and then to combine them to estimate $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})}(0)$. Thus, we propose to estimate $f_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(0)$ by means of

$$\widehat{f}_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(0) = (n_j h_j)^{-1} \sum_{i \in N_j} K(h^{-1} D_\theta^\varphi(\mathcal{X}, \widetilde{x}))$$

for all $j = 1, \ldots, k$. In this way,

$$\widehat{P}(G = g_j | \mathcal{X} = \widetilde{x}) = \frac{n_j n^{-1} \widehat{f}_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_j}(0)}{\sum_{l=1}^{k} (n_j n^{-1}) \widehat{f}_{D_\theta^\varphi(\mathcal{X},\widetilde{x})|G=g_l}(0)},$$

and it is also verified that

$$\sum_{j=1}^{k} \widehat{P}(G = g_j | \mathcal{X} = \widetilde{x}) = 1.$$

The considered estimators are statistically consistent under the unique assumption that the corresponding densities exist for each $\widetilde{x} \in \mathcal{F}_c(\mathbb{R}^p)$ (and the usual regularity conditions are satisfied), however there is no assumption about the changes in the distributions as $\widetilde{x}$ varies.

4 Empirical results

In an experiment about the visual perception of the length of a rule relatively to a maximum, we have shown images like those in Figure 1 to different people. The aim has been to know the relative measure of the dark line (below)in contrast with the light line (above) for these people. They have been allowed to express the lack of precision that they may have by using a fuzzy scale. After a trial with the software, people have seen different rules with random length and they have indicated their perception about the length in the fuzzy scale and the linguistic label (very small, small, medium, large, very large) that they consider suitable for such a length.

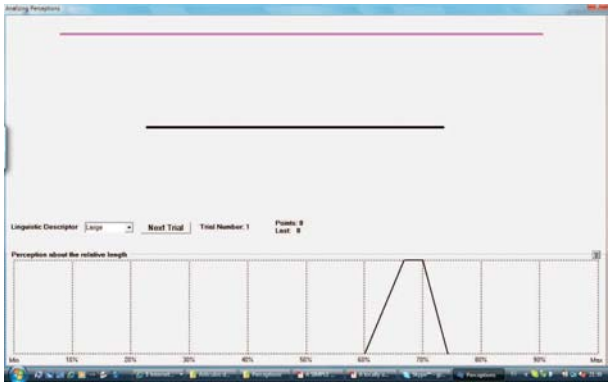

Figure 1: Software to evaluate the visual perception of a rule

The way of using fuzzy scale as explained in the software is as follows:

"*This experiment regards your perception about the relative length of different lines.*

On the top of the screen, we have plotted in light color the longest line that we could show to you. This line will remain visible in the current position during all the experiment, so that you can always have a reference of the maximum length.

At each trial of the experiment we will show you a dark line and you will be asked about its relative length (in comparison with the length of the reference light line):

- *Firstly you will be asked for a linguistic descriptor of the relative length. We have consider five descriptors (Very Small; Small; Medium; Large; Very Large). The aim is to select one of these descriptors at first sign (you can change it later if you want to).*
- *Secondly you will be asked for your own estimate or perception (without physically measuring it) of the relative length (in percentage) by means of a Fuzzy Set (the information about the design and interpretation of the Fuzzy Set will be shown to you at this time).*
- *Finally, in case your initial perception had been changed during the process you can readjust again the linguistic descriptor of its relative length.*"

Concerning the design and interpretation of the fuzzy set, when the image of Figure 1 is shown, the respondents have been asked to draw a fuzzy set representing their perceptions. In accordance with the usual interpretation, the respondents have to choose the 0-level (set of all those points with a positive degree of membership) as the set of all values that they consider compatible with the length to a greater or lesser extent. In the same way, the 1-level (set of all those points with total degree of membership) has to be fixed as the set of values that they consider completely compatible with their perception about the measure of the line. Although it is possible to change the shape of the resulting fuzzy sets, by default the trapezoidal fuzzy set formed by the interpolation of both intervals is fixed (as shown in Figure 1).

In Table 1 we show some of the data of a person who made 220 trials.

The goal here is to predict the category (very small, small, medium, large or very large) that this person would consider

9	55.17	58.40	61.79	65.75	large
10	2.26	3.63	5.57	8.08	very small

suitable from the fuzzy perception that he/she has about the length of the line. It should be remarked that the categories are treated here simply as different classes, which may be also labelled as 1, 2, 3, 4 and 5, irrespectively of the fuzzy representation that they may have. The consideration of fuzzy labels would lead to a different approach.

The line showed at each trial has been chosen at random, although to obtain also a validation sample we have proceeded as follows:

- 166 lengths were generated by means of random numbers between 0 and 100. They will be used as training sample.
- The 9 lengths in the equally spaced discrete set $\{100/27 + (i/8)100(1 - 2/27)\}_{i=0,\ldots,8}$ have been repeated 6 times. Thus, we have 54 lengths that are representative of the different situations that may arise, and that can be used as validation sample.
- The 166 random lengths of the training sample and the 54 lengths of the validation sample are interspersed and shown at random.

As it was explained in Section 3, we need to estimate the density of the random variable $D_\theta^\varphi(\mathcal{X}, \widetilde{x})$ at the point 0 for any fuzzy response $\widetilde{x}$ we obtain. The problem of estimating a density in the boundary of its support is not easy. Several approaches can be found in the literature (see for instance, [15], [13] and [11]), however none of them have solved all the inconveniences that may arise. We have considered different options to evaluate its performance in this case study:

M1: Firsty a kernel density estimation with Quartic Kernel

$$K_1(u) = \frac{15}{16}(1-u^2)^2 I_{(|u|\leq 1)}.$$

and bandwidth chosen by cross-validation were considered. It is well-known that this estimator is non consistent in the boundaries. In particular the estimation at 0 in this case is not good in general (see for instance, [15]). As we have mentioned, several boundary corrections to overcome this problem are available. Many of these corrections (basically based on Jacknife) lead to consistent estimators at the boundaries, although taking negative values in many practical situations (which makes them useless in our case). There are some exceptions in the literature that yield to both consistent and non-negative estimates.

M2: In particular, as a second scenario we have considered the proposal in [6] of using an asymmetric kernel. To be precise, we consider the absolute value of the Quartic kernel K_1, that is,

$$K_2(u) = \frac{15}{8}(1-u^2)^2 I_{(u\in[0,1])}.$$

This approach leads to consistent estimates at the boundary (but with a low convergence speed ratio). There are no studies about the optimal way of choosing the bandwidth for this asymmetric kernel, so we have used the common one provided by cross-validation techniques applied to this particular case.

M3: Finally, as a third strategy we have considered the estimator proposed by [14] which is a kernel density estimation with boundary correction that provides with non-negative estimates, that is,

$$f_P(0) = \overline{f}(0)\exp\left\{\frac{\hat{f}(0)}{\overline{f}(0)} - 1\right\}$$

where $\hat{f}(0)$ denotes the basic kernel density estimator divided by $a_0(0) = \int_{-1}^{0} K(u)du$ and $\overline{f}$ is the boundary corrected kernel density estimator based on generalised jackknifing by combining $\hat{f}$ with the analogous estimator based on the kernel $L(u) = 0.5K(2u)$. In this case and optimal (local) bandwidth is the solution of a complex variational problem (see [15] for a similar situation), that in general is not possible to obtain. For this reason we have considered the global cross-validation bandwidth for the kernel $K = K_1$.

In Table 2 we show the percentage of right classification corresponding to each one of the considered methods. We observe a better behaviour for **M2** than for **M3**. In addition **M1** is quite similar to **M3** in spite of being theoretically inconsistent. This seems to indicate that the selection of a right bandwidth is more important than the theoretical accuracy of the considered estimator (**M1** and **M2** are worse from a theoretical point of view than **M3**, provided that the optimal bandwidth is considered).

Table 2: Percentage of right classification with different methods.

	M1	**M2**	**M3**
% of right classification	75.92	83.33	77.77

5 Concluding remarks

This works is a preliminary study concerning the problem of supervised classification of fuzzy random variables. We propose to use a nonparametric approach to better capture nonlinear boundaries. However, other interesting viewpoints may be used (either by extending those in functional data analysis, as the penalized or flexible discriminant analyses, or by being developed ad-hoc for this case). Further theoretical and empirical comparative studies should be developed.

As it is mentioned in Section 4, the nonparametric estimation problem to be solved here is not easy, and there is no

ISBN: 978-989-95079-6-8

general optimal method to do it. Our empirical results seem to indicate the importance of the bandwidth selection. As it is well-known, the optimal bandwidth for the estimation of a density function is not appropriate in general for the estimation of its curvature. In the same way, the optimal bandwidth for the estimation of a density function is non necessarily appropriated for the classification problem. As an open problem, we propose to optimize the bandwidth selection for the classification problem by choosing, for instance, the values maximizing the proportion of right classifications.

On the other hand, it seems also very interesting to consider the case in which the group membership of the training data is imprecise, as it is done in [4] for real learning data.

Abstract— *The aim of this paper is to extend the classical problem of confidence interval estimation for the mean of a random variable to the case of a fuzzy random variable. The key idea consists in considering a confidence region defined as a ball w.r.t. a given metric, which is centered in the sample mean and whose radius is determined via bootstrapping. The developed approach is illustrated both by means of simulated examples using C and R and by means of a practical example consisting of courses evaluations.*

Keywords— Fuzzy random variables, confidence interval, confidence region, expectation, bootstrap.

1 Introduction

Inferential procedures for handling fuzzy information have gained in importance in the literature during the last years. Hypothesis testing problems concerning fuzzy random variables (hereafter FRV for short) in different situations (see, for instance, [9, 13, 14, 5, 6, 3]) as well as consistency properties of the considered estimators, i.e. the associated point-wise estimation problems, have been studied extensively (see, for instance, [12, 10, 16, 7]). Nevertheless, the problem of confidence interval estimation for FRVs has not received too much attention. In this communication we will focus on the the problem of estimating by a confidence interval the expected value of an FRV in Puri & Ralescu's sense [15].

Initially, there are two main difficulties in connection with this estimation problem: the well-known lack of ordering and the lack of linearity of the space of fuzzy sets. The lack of ordering is not crucial - indeed this difficulty has been faced previously in some classical situations (as for instance in the determination of confidence bands for the linear regression). On the other hand the lack of linearity makes it senseless to attempt to express the confidence interval in the standard way (sample mean plus/minus a given quantity depending on the variability and the sample size). Consequently, we will speak about confidence regions instead of confidence intervals in the following, keeping in mind that these regions cannot be specified simply by means of an upper and lower bound.

It is well-known that if X is a real-valued random variable with mean μ and finite variance, then, based on a random sample $X_1, \ldots, X_n$ of n independent random variables having the same distribution as X, a confidence interval with confidence level $100(1-\beta)\%$ for μ, can be determined by

$$IC_n = [\overline{X} - \delta, \overline{X} + \delta],$$

whereby $\overline{X}$ is the sample mean and $\delta = \delta(X_1, \ldots, X_n)$ is so that $P(\mu \in IC_n) = 1 - \beta$. The keys are, firstly, that this confidence interval can be seen as a ball with respect to the Euclidian distance which is centered in the sample mean $\overline{X}$ and has radius δ and, secondly, that in practice δ can be computed via bootstrapping. In other words: classical confidence intervals for the mean μ can equivalently be seen as balls, having the sample mean as center and a suitable radius.

Having this is in mind, our goal is to consider a *good* metric (that is, both easy to handle and easy to interpret) on the space of all fuzzy sets and, on the basis of this metric, to define confidence regions as balls centered in the sample mean and with a given radius which is empirically determined by applying bootstrap procedures. By the comments made before this technique surely is a natural extension of the classical procedure for real random variables.

The rest of the manuscript is organized as follows. In Section 2 we will recall some preliminary concepts concerning FRVs. At the beginning of Section 3 we propose an initial algorithm to determine a confidence ball for the mean of an FRV by using bootstrap. After checking its capability by means of various simulations made in C and R we finally present an improvement of the algorithm. In Section 4 we will apply the developed procedure to a concrete fuzzy sample consisting of courses evaluations. Finally, some concluding remarks, next developments and open problems are gathered in Section 5.

2 Preliminaries

Fuzzy random variables in Puri and Ralescu's sense [15] are an extension of both random variables and random (convex compact) sets. They allow us to model situations in which an imprecise (fuzzy) value is associated with the outcome of a stochastic experiment. In order to give an exact definition of FRVs we need some preliminary notions.

$\mathcal{K}_c(\mathbb{R})$ will denote the family of all non-empty compact intervals. $\mathcal{F}_c(\mathbb{R})$ denotes the class of fuzzy numbers, i.e. functions $U : \mathbb{R} \to [0,1]$, whose α-levels U_α fulfill $U_\alpha \in \mathcal{K}_c(\mathbb{R})$ for all $\alpha \in [0,1]$ whereby, as usual, $U_\alpha := [\underline{U}_\alpha, \overline{U}_\alpha] := \{x \in \mathbb{R} | U(x) \geq \alpha\}$ for every $\alpha \in (0,1]$ and $U_0 := [\underline{U}_0, \overline{U}_0]$ is defined as the topological closure of $\cup_{\alpha \in (0,1]} U_\alpha$.

The class $\mathcal{F}_c(\mathbb{R})$ is usually endowed with a semilinear structure that is compatible with Zadeh's Extension Principle (see [17]) - i.e. with a *sum* (extending the Minkowsky addition of intervals), defined by $(U+V)_\alpha = U_\alpha + V_\alpha$ for all $\alpha \in [0,1]$, and with a *product by a scalar*, $(aU)_\alpha = aU_\alpha$ for all $\alpha \in [0,1]$ and $a \in \mathbb{R}$. For every $U \in \mathcal{F}_c(\mathbb{R})$ mid_U and spr_U are defined to be real-valued functions on $[0,1]$ such that $mid_U(\alpha) := (\underline{U}_\alpha + \overline{U}_\alpha)/2$ and $spr_U(\alpha) := (\overline{U}_\alpha - \underline{U}_\alpha)/2$

ISBN: 978-989-95079-6-8

for every $\alpha \in [0,1]$.
A very useful metric on $\mathcal{F}_c(\mathbb{R})$ from the statistical point of view is the one introduced by Bertoluzza *et al* [1]. It depends on two weighting probability measures W and φ, defined on $([0,1], \mathcal{B}_{[0,1]})$ ($\mathcal{B}_{[0,1]}$ being the Borel σ-field on $[0,1]$). For any two fuzzy numbers $U, V \in \mathcal{F}_c(\mathbb{R})$ the D_W^φ-distance is defined as:

$$\sqrt{\int_{[0,1]^2} \left[t(\underline{U}_\alpha - \underline{V}_\alpha) + (1+t)(\overline{U}_\alpha - \overline{V}_\alpha)\right]^2 \, dW(t)d\varphi(\alpha)}$$

Thereby φ is assumed to have a strictly increasing distribution function on $[0,1]$ (and therefore has the whole interval $[0,1]$ as support) and W is non-degenerate (i.e. it is not a Dirac measure). A especially useful subclass of choices for W, on that we will concentrate in the sequel is that for which $\int_0^1 t dW(t) = 1/2$ (which in fact is equivalent to assuming D_W^φ to be invariant to rigid motions on $\mathbb{R}$). In this case it is easy to see that $(D_W^\varphi(U,V))^2$ can be rewritten as follows:

$$(D_W^\varphi(U,V))^2 = \int_{[0,1]} (\mathrm{mid}_U(\alpha) - \mathrm{mid}_V(\alpha))^2 d\varphi(\alpha)$$

$$+\theta_W \int_{[0,1]} (\mathrm{spr}_U(\alpha) - \mathrm{spr}_V(\alpha)^2 d\varphi(\alpha)$$

That is, the squared D_W^φ-distance of $U, V \in \mathcal{F}_c(\mathbb{R})$ is the sum of the squared φ-weighted L_2-distances between the mids and between the spreads, where the parameter $\theta_W \in (0,1]$ allows us to weight the relative importance of the distance between mids w.r.t. the distance between spreads (in particular, when W is chosen as the Lebesgue measure λ then $\theta_W = 1/3$).

Having this, we can now return to the definition of an FRV mentioned before. Let $(\Omega, \mathcal{A}, P)$ be an arbitrary probability space. an FRV $\mathcal{X}$ is a mapping $\mathcal{X} : \Omega \to \mathcal{F}_c(\mathbb{R})$, which is Borel-measurable with respect to the D_W^φ-metric. This definition is different from the original one by Puri and Ralescu, however in many cases and in particular in the cases we will consider in the sequel coincides with the original one (see [15, 11, 2]).
The FRV $\mathcal{X}$ is said to be integrably bounded whenever $\max\{|\min X_0|, |\max X_0|\} \in L^1(\Omega, \mathcal{A}, P)$. If $\mathcal{X}$ is an integrably bounded FRV then its *expected value (or mean)* is defined as the unique fuzzy number $\mathbb{E}(\mathcal{X}) \in \mathcal{F}_c(\mathbb{R})$ such that $\big(\mathbb{E}(\mathcal{X})\big)_\alpha$ is the Aumman integral of the random set $\mathcal{X}_\alpha$ for all $\alpha \in [0,1]$ (see [15]). In particular,

$$\big(\mathbb{E}(\mathcal{X})\big)_\alpha = [\mathbb{E}(\min \mathcal{X}_\alpha), \mathbb{E}(\max \mathcal{X}_\alpha)]$$

holds for all $\alpha \in [0,1]$ if $\mathcal{X}$ is integrably bounded.
If, in addition, $\max\{|\min \mathcal{X}_0|, |\max \mathcal{X}_0|\} \in L^2(\Omega, \mathcal{A}, P)$, then the (W,φ)-*variance* of $\mathcal{X}$ (see [12, 10]) is defined as

$$\mathrm{Var}(\mathcal{X}) = \mathbb{E}([D_W^\varphi(\mathcal{X}, \mathbb{E}(\mathcal{X}))]^2). \quad (1)$$

Remark: The main reasons for using the above mentioned D_W^φ-metric are that (1) it has more good intuitive properties (see [1]) than the usual L_p metrics d_p (see [4]) do not have, and (2) it can be expressed as an inner product on the Hilbert space of all square integrable functions on $\mathcal{H} = L^2([0,1]\times\{-1,1\})$ (via using the concept of support function).

3 Confidence regions for the mean of an FRV

Let $(\Omega, \mathcal{A}, P)$ be an arbitrary probability space, and consider an FRV $\mathcal{X} : \Omega \to \mathcal{F}_c(\mathbb{R})$ verifying $\max\{|\min \mathcal{X}_0|, |\max \mathcal{X}_0|\} \in L^2(\Omega, \mathcal{A}, P)$. As mentioned in the introduction, our aim is to calculate a confidence ball for the expectation $\mu = \mathbb{E}(\mathcal{X}) \in \mathcal{F}_c(\mathbb{R})$ on the basis of n independent observations $(\mathcal{X}_1, \ldots, \mathcal{X}_n)$ of $\mathcal{X}$.
We will denote by $\overline{\mathcal{X}}$ and $\widehat{S}$ the associated sample fuzzy mean and sample (W,φ)-deviation respectively, that is,

$$\overline{\mathcal{X}} = \frac{1}{n}\sum_{i=1}^n \overline{\mathcal{X}}_i, \quad \widehat{S} = \sqrt{\frac{1}{n}\sum_{i=1}^n [D_W^\varphi(\mathcal{X}_i, \overline{\mathcal{X}})]^2}. \quad (2)$$

Following the approach mentioned in the introduction, for a given significance level $\beta \in (0,1)$ we define the confidence ball CR_β with respect to the D_W^φ-metric as

$$CR_\beta = B(\overline{\mathcal{X}}, \delta) = \{U \in \mathcal{F}_c(\mathbb{R}) | D_W^\varphi(U, \overline{\mathcal{X}}) \le \delta\}, \quad (3)$$

whereby the radius δ has to verify the coverage condition

$$P(\mu \in B(\overline{\mathcal{X}}, \delta)) = P(D_W^\varphi(\mu, \overline{\mathcal{X}}) \le \delta) = 1 - \beta. \quad (4)$$

Due to the non-existence of sufficiently general parametric models for FRVs in general it is not possible to find δ fulfilling the coverage condition. Nevertheless we may choose δ as the $(1-\beta)$-quantile of the distribution of $D_W^\varphi(\mu, \overline{\mathcal{X}})$, which in turn can be approximated by the corresponding bootstrap $(1-\beta)$-quantile. In fact, given a sample $(\mathcal{X}_1, \ldots, \mathcal{X}_n)$ of $\mathcal{X}$ we propose to proceed as follows:

Algorithm 3.1

Step 1. *Fix the significance level $\beta \in (0,1)$ and the number B of bootstrap replications.*

Step 2. *Obtain B bootstrap samples $(\mathcal{X}_1^{b\star}, \ldots, \mathcal{X}_n^{b\star})$ $(b = 1, \ldots, B)$ from $(\mathcal{X}_1, \ldots, \mathcal{X}_n)$, and for each one compute its corresponding sample mean $\overline{\mathcal{X}}^{b\star}$.*

Step 3. *Compute the distance between the sample mean and each bootstrap sample mean, $d_b^\star = D_W^\varphi(\overline{\mathcal{X}}, \overline{\mathcal{X}}^{b\star})$, for each $b = 1, \ldots, B$.*

Step 4. *Choose δ as one of the $(1-\beta)$-quantiles of the sample $(d_1^\star, \ldots, d_B^\star)$ (that is, choose δ so that at least the $100(1-\beta)\%$ of the computed distances are smaller or equal than δ and at least the $100\beta\%$ of the computed distances are greater or equal than δ).*

In order to analyze the quality and accuracy of the confidence regions obtained by means of this algorithm we have made simulations with different sample sizes n. We have chosen φ as the Lebesgue measure on $[0,1]$ and used two different weight distributions W (in fact $\theta_W = 1/3$, which corresponds to the Lebesgue measure, and $\theta_W = 9/10$ that gives more weight to the spreads, were used). Each simulation corresponds to 10000 iterations with 1000 bootstrap replications and a significance level β of 0.05.
For the simulation of general FRVs the approach introduced in [8] has been applied and $n_0 = 101$ equally spaced alpha-levels $(\alpha_i = (i-1)/(n_0-1),\ i = 1, \ldots, n_0)$ were considered. In short, this approach consists essentially of the following three steps (for more details see [8]):

ISBN: 978-989-95079-6-8

SIM1 **Decomposition:**
Fix the (future) expectation $V \in \mathcal{F}_c(\mathbb{R})$, an index $n_0 \in \mathbb{N}$ and α-levels $0 = \alpha_1 < \alpha_2 < \cdots < \alpha_{n_0} = 1$. Let V^c be the mid-point of the 1-level of V, $V^l := V^c - \min(V_0)$ the total left spread and $V^r := \max(V_0) - V^c$ the total right spread. Furthermore define

$$L_\alpha = \begin{cases} \{0\} & \text{if } V^l = 0, \\ [(\min(V_\alpha) - V^c)/V^l, 0] & \text{if } V^l \neq 0 \end{cases}$$

$$R_\alpha = \begin{cases} \{0\} & \text{if } V^r = 0, \\ [0, (\max(V_\alpha) - V^c)/V^r] & \text{if } V^r \neq 0 \end{cases}$$

for every $\alpha \in [0,1]$ and set $F^l(t) := \max(-L_{1-t})$ and $F^r(t) := \max(R_{1-t})$ for every $t \in [0,1]$ (in fact F^l and F^r are distribution function but we do not use their stochastic interpretation).

SIM 2 **Discretization:**
Define $p_1^l = F^l(\alpha_1)$ and $p_i^l = F^l(\alpha_i) - F^l(\alpha_{i-1})$ for all $i = 2, \ldots, n_0$, and $p_1^r = F^r(\alpha_1)$ and $p_i^r = F^r(\alpha_i) - F^r(\alpha_{i-1})$ for all $i = 2, \ldots, n_0$ respectively. Let $B_x \in \mathcal{F}_c(\mathbb{R})$ denote the fuzzy set fulfilling $(B_x)_\alpha = [0, \mathbf{1}_{[\alpha,1]}(x)]$ for every $\alpha \in [0,1]$ and set

$$V_{n_0} = V^c + \sum_{i=1}^{n_0} -B_{1-\alpha_i} V^l p_i^l + \sum_{i=1}^{n_0} B_{1-\alpha_i} V^r p_i^r$$

SIM 3 **Stochastic Perturbation**
Consider a $(2n_0+1)$-dimensional random vector

$$\mathcal{Y} = (C_0, C_1^l, \ldots, C_{n_0}^l, C_1^r, \ldots, C_{n_0}^r) : \Omega \to \mathbb{R} \times [0,\infty)^{2n_0}$$

of coefficients for the 'approximating' simulated FRV $\mathcal{X}^\star$ as random perturbation of $(V^c, V^l p_1^l, \ldots, V^l p_{n_0}^l, V^r p_1^r, \ldots, V^r p_{n_0}^r)$ in such a way that

$$\mathbb{E}(C_0, C_1^l, \ldots, C_{n_0}^l, C_1^r, \ldots, C_{n_0}^r) = \\ = (V^c, V^l p_1^l, \ldots, V^l p_{n_0}^l, V^r p_1^r, \ldots, V^r p_{n_0}^r)$$

holds and set

$$\mathcal{X}^\star := C^0 + \sum_{i=1}^{n_0} -B_{1-\alpha_i} C_i^l + \sum_{i=1}^{n_0} B_{1-\alpha_i} C_i^r \qquad (5)$$

This procedure generates a sample of size 1 of the FRV $\mathcal{X}$ - for a sample of size n SIM 3 simply has to be repeated n times.

Remark: To be precise, in the simulations we have made we have used perturbations from the same distributions, i.e. $C_1^l, \ldots, C_{n_0}^l$ are independent and distributed as a fixed D^l, and $C_1^r, \ldots, C_{n_0}^r$ are independent and distributed as a fixed D^r (these distributions are also mentioned in the tables below).

In particular we made simulations for three FRVs $\mathcal{X}$, $\mathcal{Y}$ and $\mathcal{Z}$ with different expectations - the above-mentioned parameters defining these FRVs are listed in Table 1. Moreover for the FRV $\mathcal{Z}$ (1) the mean, (2) examples of the simulated samples of $\mathcal{Z}$, (3) the distance between the mean V and one sample mean

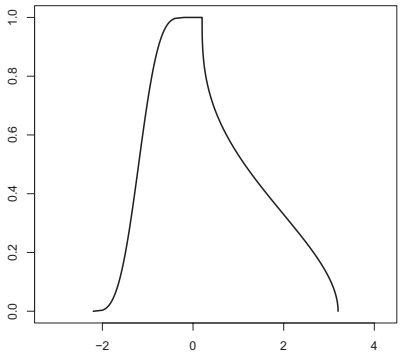

Figure 1: Expectation V of the FRV $\mathcal{Z}$

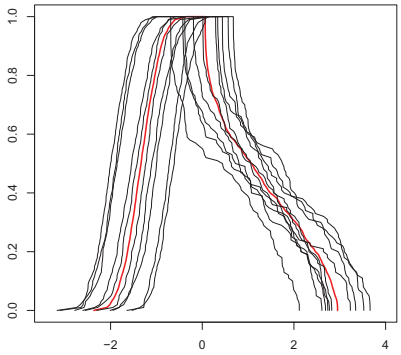

Figure 2: Simulated sample and sample mean (in red)

Table 1: Parameters defining the FRVs for the simulation

	$V = [V^c, V^l, V^r, F^l, F^r]$	$C = [C^0, D^l, D^r]$
$\mathcal{X}$	[0,1,1,Beta(1,1),Beta(1,1)]	$[U_{(-\frac{1}{2},\frac{1}{2})}, U_{(0,2)}, U_{(0,2)}]$
$\mathcal{Y}$	[4,2,2,Beta(0.5,1),Beta(3,2)]	$[U(0,8), \chi_1, \chi_2/2]$
$\mathcal{Z}$	[0,2.2,3.2,MixL,MixR)]	$[U(-1,1), U(0,2), Ex(1)]$

and (4) the empirical distribution function of the quantity $d_b^\star$ are depicted in Figure 1 - Figure 4.

Thereby MixL denotes a mixture distribution consisting of a point mass in 0 with weight 0.083 and a Beta(0.3,0.3)-distribution with weight 0.9167, and MixR denotes a mixture distribution consisting of a point mass in 0 with weight 0.067 and a Beta(3,2)-distribution with weight 0.933.

In Table 2 and Table 3 the percentage of confidence regions (among the 10,000 simulated ones) containing the populational mean in each situation is collected.

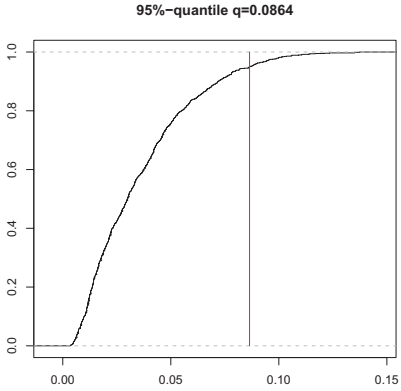

Figure 4: Empirical distribution function of $d_b^{\star}$ and 95%-quantile

Table 3: Percentage of accurate confidence regions using Algorithm 3.1 - Part 2

	$n = 100$		
θ_W	$\mathcal{X}$	$\mathcal{Y}$	$\mathcal{Z}$
$1/3$	94.51	94.83	0.00
$9/10$	94.54	94.65	0.00

Taking a look at the results in Table 2 and Table 3 it seems that (irrespective of the underlying distribution and the selected value for the parameter θ_W), the accuracy of the confidence regions generated by means of Algorithm 3.1 is sufficient for either moderate or large sample sizes (30-100 observations), whereas the results are not satisfactory for small sample sizes (10 observations). As usual, the bigger the sample size, the closer the empirical accuracy to the theoretical one.

In order to improve the results, especially for small sample sizes, we are going to modify the proposed method. The modification we make is the usual one in classical statistics - we define the radius of the confidence ball to be directly proportional to the (estimated) population variability (standardization). For this purpose, define a new confidence ball w.r.t. the D_W^{φ}-metric as follows

$$CR_\beta = B(\overline{\mathcal{X}}, \widehat{S}\delta) = \{U \in \mathcal{F}_c(\mathbb{R}) | D_W^{\varphi}(U, \overline{\mathcal{X}})/\widehat{S} \leq \delta\}, \quad (6)$$

whereby the radius δ has to verify the coverage condition

$$P(\mu \in B(\overline{\mathcal{X}}, \widehat{S}\delta)) = P(D_W^{\varphi}(\mu, \overline{\mathcal{X}})/\widehat{S} \leq \delta) = 1 - \beta. \quad (7)$$

For the same reasons mentioned in the previous case we again use bootstrapping. In this case the variability of the population, from which the bootstrap sample is taken, is completely known (denoted by $\widehat{S}$). Consequently, one possibility consists in approximating the distribution of $D_W^{\varphi}(\mu, \overline{\mathcal{X}})/\widehat{S}$ by means of $D_W^{\varphi}(\overline{\mathcal{X}}, \overline{\mathcal{X}^{\star}})/\widehat{S}$, which, however, leads exactly to the procedure proposed in Algorithm 3.1. Another possibility is to reestimate the variability of the bootstrap population instead of using the exact known value $\widehat{S}$. We will see that this alternative approach leads to better results.
In fact, the proposed procedure works as follows:

Algorithm 3.2

Step 1. *Fix the significance level $\beta \in (0, 1)$ and the number B of bootstrap replications.*

Step 2. *Obtain B bootstrap samples $(\mathcal{X}_1^{b\star}, \ldots, \mathcal{X}_n^{b\star})$ $(b = 1, \ldots, B)$ from $(\mathcal{X}_1, \ldots, \mathcal{X}_n)$, and for each one compute its corresponding sample mean $\overline{\mathcal{X}}^{b\star}$ and its sample deviation $\widehat{S}^{b\star}$.*

Step 3. *Compute the distance between the sample mean and each bootstrap sample mean, and calculate $d_b^{\star} = D_W^{\varphi}(\overline{\mathcal{X}}, \overline{\mathcal{X}}^{b\star})/\widehat{S}^{b\star}$ for each $b = 1, \ldots, B$.*

Step 4. *Choose δ as one of the $(1 - \beta)$ quantiles of the sample $(d_1^{\star}, \ldots, d_B^{\star})$.*

In Table 4 the percentage of accurate confidence regions using Algorithm 3.2 in the same situations as in the preceding simulating study is collected. As it was expected the accuracy of the confidence regions obtained by using the second approach is much better than the one of the first approach. Indeed, the procedure can be applied also for small sample sizes ($n = 10$) and seems to be a little bit conservative (with an empirical confidence level greater than the theoretical one).

4 Case Study

In this section we will apply the proposed methodology in order to obtain a confidence ball for the mean overall rating of the II Summer Course organized by the European Centre for Soft Computing in July 2008. A survey regarding different aspects of this summer course was presented to the students at the end of the course. Among other questions, the students where asked about the overall rating of the course. The answers where collected directly as fuzzy sets. In fact, a scale ranging from 0 (minimum rating) to 100 (maximum rating) was presented (see Figure 5). The students were asked to draw a trapezoidal fuzzy set R representing their rating by fixing two intervals, the 0-level and the 1-level. Firstly the 0-level was chosen in such a way that their perception about the overall rating was surely not outside of this interval. Finally the 1-level was chosen as an interval in which they thought their overall rating would be contained.

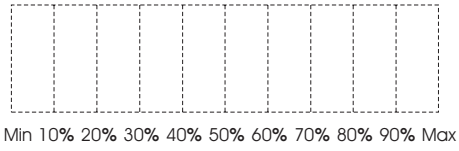

Figure 5: Scale for the made questionary

The overall rating of 33 students were collected, edited in Table 6 and the sample mean was calculated.

Applying Algorithm 3.1 and Algorithm 3.2 with $B = 10000$ bootstrap iterations and a significance level $\beta = 0.05$ we obtained the following results for the confidence balls listed in Table 7. The centre of the balls in each case is the sample mean $\overline{\mathcal{X}}$ (see Figure 6).

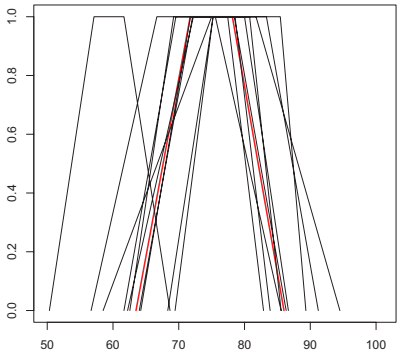

Figure 6: Thn elements of the fuzzy sample and the sample mean (red)

Figures 7 and Figures 8 depict the empirical distribution functions for the quantities $d_b^\star$ in Algorithm 3.1 and Algorithm 3.2 as well as the corresponding 95%-quantiles (for the case $\theta_W = 1/3$).

Remark: Having calculated the 95%-confidence balls for the mean overall rating, one question that naturally arises is, how this confidence balls really look like. Going back to the definition of the D_W^φ-metric it is clear that $U \in B(V, \delta)$ (ball with respect to D_W^φ), for instance, does not imply any restrictions on the support of U - in fact, the support can be arbitrarily big as long as (loosely speaking) not too many[1] α-levels are arbitrarily big. The reason for this behaviour lies in the fact that the D_W^φ-metric (because of the integration involved) averages over the distances of the α-levels (the same holds for most metrics on $\mathcal{F}_c(\mathbb{R})$). Nevertheless the condition $U \in B(V, \delta)$ (ball with respect to D_W^φ) surely implies strong restrictions on U - if for instance the spread of V is small for all α, then the spread of U can not be too big for many α's. As an example, the trapezoidal fuzzy number $(73, 73, 78, 78)$ (representation as in Table 6) is not contained in the calculated confidence Ball $B(\overline{\mathcal{X}}, 2.8239)$ since the mean spread is

5 Conclusions and open points

In this paper we have proposed two algorithms for calculating confidence balls for the mean of an FRV - we used the sample mean as centre of the ball and calculated the radius of the ball via bootstrapping. Since we already have implemented the developed procedures (and others) in C and R our aim is to write a general R-package for statistics with fuzzy data, which could then be freely used by everybody working with R.

The simulations indicate that the second method is quite accurate, in the sense of achieving the nominal significance level for moderate and even small samples. Nevertheless, it is essential to analyze theoretically this approach in order to soundly justify its usefulness.

We have focused on a kind of percentile bootstrapping for the estimations, however it can be interesting to consider other kinds of bootstrap approaches.

Finally, for a future work we propose to analyze a possible modification of the metrics to make the estimation as reasonable as possible, by avoiding to include in the confidence region fuzzy sets which are close to the sample mean, but are not too realistic.

A Fuzzy Multi-Criteria Approach to WEEE Treatment Strategy Selection*

İlke Bereketli[1] Tuncay Gürbüz[2] Müjde Erol Genevois[3]

1, 2, 3 Department of Industrial Engineering, Galatasaray University
İstanbul, Turkey
Email: ibereketli@gsu.edu.tr, tgurbuz@gsu.edu.tr, merol@gsu.edu.tr

Abstract— *Today's one of the biggest environmental problem is the alarming increase of the wastes electrical and electronic equipments (WEEE). This type of waste threats the environment and the human health by contaminating air, soil and water, because of toxic materials including in the electrical and electronic equipments (EEE). That's why we should look for exploring the environmental friendly ways to dispose of these wastes and the producers should select an appropriate strategy. Waste treatment strategies contribute also to either local or global economies by creating a new sector and employment, and by reducing use of scarce resources. In this paper, we use a fuzzy hierarchical TOPSIS method for solving multi attribute group decision making (MAGDM) problems with preference information on alternatives in fuzzy environment. Our aim is to develop a fuzzy hierarchical TOPSIS model to evaluate and to select of a waste treatment strategy for electrical and electronic equipments (EEE). In this direction, three treatment strategies alternatives and six criteria are determined. The best strategy is selected and the key criterion is found.*

Keywords— Fuzzy AHP, Fuzzy Hierarchical TOPSIS, Fuzzy TOPSIS, WEEE treatment strategies.

1 Introduction

Both technological innovation and market expansion continue to accelerate the replacement of equipment leading to a significant increase of waste electric and electronic equipment (WEEE). Hence, electrical and electronic equipments, which are a subset of technological equipments, have already begun to accumulate at the garbage dumps.

Many countries have drafted legislation to improve the reuse, recycling and other forms of recovery of such wastes so as to reduce disposal [1]. The European Commission identified the need for legislation to address the escalating problem of WEEE at the Community level, and this has taken the form of the WEEE Directive. The EU's Directive 2002/96/EC about WEEE has extended producer responsibility as its main principal and aims to increase reuse and recycling ratios [2]. This Directive obligates electronic and electrical equipment producers to take back old equipment from customers free of charge and to dispose of these wastes environmentally [3]. Turkey is also on the way to prepare a new regulation about WEEE.

In this paper, a Fuzzy multi-criteria decision making (MCDM) approach is proposed for multiple attribute group decision making (MAGDM) problems with preference information on alternatives. This approach is used to evaluate and select a waste treatment strategy for electrical and electronic equipments (EEE). In this study, Fuzzy Hierarchical Technique for Order Preference by Similarity to Ideal Solution (FH-TOPSIS) is used to reflect the decision maker's subjective preference information and to determine the weight vector of criteria, and to get the rankings of different alternatives.

In the remaining part of the paper, waste treatment strategies and the case study are mentioned. Section 2 includes some definitions, alternatives and criteria required for the evaluation of the strategies. The proposed methodology is represented in Section 3. Section 4 contains the scope of the application and the results of the study. Finally in Section 5, conclusions driven from the research are provided.

2 Selection of Waste Treatment Strategies and a Case Study

WEEE, or e-waste, can be described in general as all electrical and electronic equipments that have terminated their useful life. Widmer *et al.* defines WEEE as a generic term embracing various forms of electric and electronic equipment that have ceased to be of any value to their owners, or a waste type consisting of any broken or unwanted electrical or electronic appliance [4]. In respect of EU's Directive 2002/96/EC, WEEE's definition is as follows: WEEE means electrical or electronic equipment including all components, subassemblies and consumables which are part of the product at the time of discarding [5]. So many official and non-official foundations give its own definition, therefore there is, as yet, no standard definition.

There are generally three different ways of treating WEEE: reuse, recycling and disposal (such as incineration, landfill). The EEE producers prefer at least one of these treatment strategies in order to discard their e-wastes. In this paper, it is examined that which one should be selected considering related criteria.

A case study was already realized by Bereketli *et al.*, in a telecommunication enterprise which produces and sells cell phones in Turkey [6]. A linear programming technique for multidimensional analysis of preference (LINMAP) method for solving MAGDM problems with preference information on alternatives in fuzzy environment was proposed. The aim was to develop a fuzzy LINMAP model to evaluate and to select of a waste treatment strategy for electrical and electronic equipments (EEE). At the end of the study, The

ISBN: 978-989-95079-6-8

Fuzzy LINMAP method gave the ranking of the alternatives under the problems criteria as $A1 \phi\ A3 \phi\ A2$.

The objective of this study is to evaluate the alternatives considering all criteria with a different approach, Fuzzy Hierarchical TOPSIS method, and to observe the differences between the results. As we need the independence between the problem's criteria with the proposed method, some of the criteria between which there may be dependences are grouped under one criterion.

There are three alternatives: treating WEEE by reuse and recycling methods (2R), by insourced disposal methods, and by outsourced disposal methods. In the first alternative, the enterprise reuses or recycles its own WEEE within the facility. In the second alternative, the enterprise carries its own WEEE from its own waste collection store to an area which is purchased in order to dispose of the e-wastes by landfill or incineration. In the third and last alternative, the enterprise outsources its disposal process of its own WEEE to a specialized company. This company goes to the waste collection center periodically, gets there e-waste of the telecommunication enterprise, and brings them to its own facility. In its facility, it realizes disassembly of the e-waste and dissects some valuable integrated circuits. The telecommunication enterprise takes back these circuits periodically and reuses them in its assembly line. The outsourced company environment friendly disposes of the other parts of the e-waste.

It has been determined 6 criteria, 3 of them are quantitative (Type-1: T1) and 3 of them are qualitative (Type-2: T2). The criteria based on three alternatives are as follows:

- C1 - Waste release period: It is the period in which e-waste returns to the production line by passing reuse or recycling processes, or ends its life cycle by being disposed of. Small number of periods is preferred. Its unit is period time. (T1)
- C2 - Cost: This criterion includes the first investment, stock and process costs. It is the cost for creating new lines, implementing hardware, buying new machines, and new trucks for transporting e-waste, or purchasing an area where the telecommunication enterprise disposes of its e-waste, or contracting with the outsourced enterprise, stocking e-waste transported from waste collection center, every operation for each process during the period of e-waste treatment. Its unit is thousands of Turkish Liras (TL). (T1)
- C3 - Ratio of resource conservation: It is the ratio of the returned products (e-waste) quantity over total electrical and electronic equipment produced. Its unit is percentage. (T1)
- C4 - Capacity need: It is the need of labor-hour. (T2)
- C5 - Risk of damage for the nature and the human health: It is the potential of damaging the nature and the human health for each alternative when e-wastes are treated by their own way. (T2)
- C6 - Convenience to the possessed technology: It is the criteria about the degree of sufficiency of the technology that the telecommunication enterprise have. (T2)

3 Methodology

3.1 Basic concepts of Fuzzy Analytic Hierarchy Process (FAHP)

In this paper the FAHP approach is introduced, with the use of Triangular Fuzzy Numbers for pairwise comparison scale of FAHP according to the method of Chang's [7] fuzzy extent analysis by applying correct normalization formula given later by Wang *et al.* [8].

3.1.1 The construction of fuzzy judgment

In the conventional AHP, the pairwise comparisons for each level with respect to the goal are conducted using a nine-point scale proposed by Saaty [9]. According to Zadeh [10], it is very difficult for conventional quantification to define the complex situations, so the notion of a linguistic variable, whose values are words or sentences, is necessary. To assess the relative importance of the criteria and to evaluate the alternatives respecting the problems criteria an assumed weighting set has been developed.

The decision makers can use the linguistic rating set. The triangle fuzzy conversion scale of the linguistic values in the weighting set is shown in Table 1.

Table 1: The triangular fuzzy conversion scale

Very Low (VL)	(0, 3/6,1)
Low (L)	(2/3, 7/6, 5/3)
Medium (M)	(4/3, 11/6, 7/3)
High (H)	(2, 15/6, 3)
Very High (VH)	(8/3, 19/6, 11/3)

3.1.2 Value of fuzzy synthetic extent

The steps of Chang's extent analysis can be given as in the following [7]:

- First, by fuzzy arithmetic operations, take the sum of each row of the fuzzy comparison matrix.

$$RS_i = \sum_{j=1}^{n} \widetilde{a}_{ij} = \left(\sum_{j=1}^{n} l_{ij},\ \sum_{j=1}^{n} m_{ij},\ \sum_{j=1}^{n} u_{ij} \right),\quad i = 1,\mathrm{K}\ ,n \tag{1}$$

- Using fuzzy synthetic extent analysis, the value of fuzzy synthetic extent with respect to the ith object x_i, $i = 1,2,\mathrm{K}\ ,n$ that represents the overall performance of the object across all goals can be determined by the following normalization formula given by Wang et al. [8]:

$$\widetilde{S}_i = \frac{RS_i}{\sum_{j=1}^{n} RS_j} = \left(\frac{\sum_{j=1}^{n} l_{ij}}{\sum_{j=1}^{n} l_{ij} + \sum_{\substack{k=1 \\ k \neq i}}^{n} \sum_{j=1}^{n} u_{kj}},\ \frac{\sum_{j=1}^{n} m_{ij}}{\sum_{k=1}^{n} \sum_{j=1}^{n} m_{ij}},\ \frac{\sum_{j=1}^{n} u_{ij}}{\sum_{j=1}^{n} u_{ij} + \sum_{\substack{k=1 \\ k \neq i}}^{n} \sum_{j=1}^{n} l_{kj}} \right),\quad i = 1,\mathrm{K}\ ,n \tag{2}$$

ISBN: 978-989-95079-6-8

- Compute the degree of possibility of $\widetilde{S}_i \geq \widetilde{S}_j$ by the following equation where $\widetilde{S}_i = (l_i, m_i, u_i)$ and $\widetilde{S}_j = (l_j, m_j, u_j)$:

$$V(\widetilde{S}_i \geq \widetilde{S}_j) = \begin{cases} 1, & \text{if } m_i \geq m_j, \\ \dfrac{u_i - l_j}{(u_i - m_i) + (m_j - l_j)}, & \text{if } l_j \leq u_i, \quad i, j = 1, \ldots, n, i \neq j \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

- To compare $\widetilde{S}_i = (l_i, m_i, u_i)$ and $\widetilde{S}_j = (l_j, m_j, u_j)$, we need both the values of $V(\widetilde{S}_i \geq \widetilde{S}_j)$ and $V(\widetilde{S}_j \geq \widetilde{S}_i)$. The degree of possibility for a convex fuzzy number $\widetilde{S}$ to be greater than k convex fuzzy numbers $\widetilde{S}_i$, i=1,…,k can be defined by:

$$V(M \geq M_1, \ldots, M_k) = V[(M \geq M_1) \wedge \ldots \wedge (M \geq M_k)] = \min V(M \geq M_i) \quad (4)$$
$$\text{for } i = 1, 2, \ldots, k$$

- Assume that for the alternative Ai,

$$d'(A_i) = \min V(S_i \geq S_j), \text{ for } j = 1, 2, \ldots, n; j \neq i \quad (5)$$

- Then the weight vector is given by,

$$W' = (d'(A_1), d'(A_2), \ldots, d'(A_n))^T \quad (6)$$

- Via normalization, the normalized weight vectors are,

$$W = (d(A_1), d(A_2), \ldots, d(A_n))^T \quad (7)$$

3.2 Fuzzy TOPSIS

3.2.1 Basic concepts of Fuzzy TOPSIS

TOPSIS, developed by Yoon [11] and Hwang and Yoon [12] uses the following intuitive principle: The chosen alternative has to be the one having the smallest distance to the ideal solution and the biggest distance to the negative-ideal solution. But, the alternative which has the smallest distance to the ideal solution doesn't have necessarily the biggest distance to the nadir solution and vice versa. Hence, TOPSIS considers both distances to the ideal and nadir solutions simultaneously by measuring the relative closeness, RC, of the alternatives to the alternative called the « ideal solution ».

We can convert the decision matrix into a fuzzy decision matrix and construct a weighted normalized fuzzy decision matrix once the decision makers' fuzzy ratings have been collected. According to the TOPSIS model, we define the fuzzy ideal solution and fuzzy negative-ideal solution. And then a vertex method, proposed by Chen [13] is used in this paper to calculate the distance between two triangular fuzzy ratings.

Finally, the relative closeness of each alternative is defined to determine the final ranking of the alternatives.

3.2.2 Selection Procedure with Fuzzy TOPSIS

- Construct the Decision Matrix where all the data for the alternatives according the problems criteria is collected.
- Normalize the DM: To avoid the complicated normalization formula used in classical TOPSIS, the linear scale transformation is used here to transform the various criteria scales into a comparable scale.

$$\widetilde{x}_{ij} = \begin{cases} \left(\dfrac{a_{ij} - a_j^-}{c_j^* - a_j^-}, \dfrac{b_{ij} - a_j^-}{c_j^* - a_j^-}, \dfrac{c_{ij} - a_j^-}{c_j^* - a_j^-} \right) & \text{for j of a criteria of output nature} \\ \left(\dfrac{c_j^* - c_{ij}}{c_j^* - a_j^-}, \dfrac{c_j^* - b_{ij}}{c_j^* - a_j^-}, \dfrac{c_j^* - a_{ij}}{c_j^* - a_j^-}, \right) & \text{for j of a criteria of input nature} \end{cases} \quad (8)$$

- Find the weighted DM and define the ideal and the nadir alternatives namely A^+ and A^-. Note that after this normalization, the ideal (resp. nadir) alternative will be found by taking the maximum (resp. minimum) value for each criterion.
- Define distances of A_i from A^+ and A^- as follows:

$$d_i^+ = \sum_{j=1}^{n} d(\widetilde{x}_{ij}, \widetilde{x}_j^+) \text{ where } i = 1, 2, \ldots, M \quad (9)$$

$$d_i^- = \sum_{j=1}^{n} d(\widetilde{x}_{ij}, \widetilde{x}_j^-) \text{ where } i = 1, 2, \ldots, M \quad (10)$$

with

$$d(\widetilde{x}_i, \widetilde{x}_j) = \sqrt{\frac{1}{3}\left[(l_i - l_j)^2 + (m_i - m_j)^2 + (u_i - u_j)^2\right]} \quad (11)$$

- Rank the preference order of m alternatives by their relative closeness (RC) to the ideal alternative (the smaller the value of RC for an alternative, the more that alternative is preferred) which is given for the ith alternative as:

$$RC_i = \frac{d_i^+}{(d_i^+ + d_i^-)} \quad (12)$$

3.2.3 Proposed Method

In this study, the proposed method works as follows:

- Relative priorities for the criteria and the alternatives for the subjective criteria are obtained from the pairwise comparison matrices of the FAHP method using the extension principle.
- Subjective criteria ratings for the alternatives obtained in the previous step and objective criteria values are collected in a decision matrix.
- Finally Fuzzy TOPSIS is applied in order to find the ranking between the alternatives.

ISBN: 978-989-95079-6-8

4 Application

For the application of the proposed method, we asked their opinions to three decision makers. You can see in Table 2 one of the comparison matrices.

Table 2: Comparison matrices

C6	*A1*	*A2*	*A3*
A1	*	MH, H, H	VH, VH, VH
A2		*	MH, H, MH
A3			*

According to the ratings they have given, the pairwise comparison matrices are formed in order to weigh the problem's criteria and to obtain the relative priorities of the subjective criteria.

From these comparison matrices, using Fuzzy AHP method, the following results presented in Table 3 and Table 4 are obtained:

Table 3: Criteria weights

Criteria	C1	C2	C3	C4	C5	C6
Weights	.125	.198	.20	.11	.213	.15

Table 4: Relative priorities of the alternatives for the subjective criteria

	C4	C5	C6
A1	0.49	0.047	0.273
A2	0.415	0.735	0.281
A3	0.095	0.218	0.446

For the objective criteria, the values obtained by the alternatives are provided by the experts. For C1, the values were given by crisp values. On the other hand, for C2 and C3 they were agreed on giving by using the fuzzy values presented in Table 5.

As we defuzzified the fuzzy linguistic values given by the experts on the subjective criteria using Fuzzy AHP, while we apply Fuzzy TOPSIS in order to rank our alternatives, for these criteria, we will use the relative priorities given in Table 3 as crisp values. For example, the value obtained by A1 for the criteria C4, will be noted as (.49,.49,.49).

Therefore, we constructed the final decision matrix and normalized decision matrix as follows:

Table 5: Final decision matrix

	C1	C2	C3
A1	(4,4,4)	(887.5, 1095, 1207)	(30, 50, 80)
A2	(1,1,1)	(354.5, 460, 516)	(0,0,0)
A3	(2,2,2)	(174.5, 205, 231)	(3, 6, 10)
	C4	**C5**	**C6**
A1	(.49,.49,.49)	(.087,.087,.087)	(.273,.273,.273)
A2	(.415,.415,.415)	(.689,.689,.689)	(.281,.281,.281)
A3	(.095,.095,.095)	(.224,.224,.224)	(.446,.446,.446)

Table 6: Normalized decision matrix

	C1	C2	C3
A1	(0,0,0)	(0,.11,.31)	(.38,.63,1)
A2	(1,1,1)	(.67,.72,.83)	(0,0,0)
A3	(.67,.67,.67)	(.95,.97,1)	(.04,.08,.13)
	C4	**C5**	**C6**
A1	(0,0,0)	(1,1,1)	(0,0,0)
A2	(.19,.19,.19)	(0,0,0)	(.05,.05,.05)
A3	(1,1,1)	(.75,.75,.75)	(1,1,1)

From this matrix, using the weights given in Table 3, the weighted normalized decision matrix is calculated and ideal and nadir alternatives are deducted as follows:

$$A^{+} = [(.13,.13,.13)\ \ (.19,.19,.2)\ \ (.08,.,16,.,2)\ \ (.11,.11,.11)\ \ (.21,.21,.21)\ \ (.15,.15,.15)]$$

$$A^{+} = [(0,0,0)\ \ (0,.02,.06)\ \ (0,0,0)\ \ (0,0,0)\ \ (0,0,0)\ \ (0,0,0)]$$

Using the distance calculation formula given in (3.2.2) we calculated the distances of the alternatives from ideal and nadir alternatives and finally found the RC values as shown in the following table:

Table 6: Relative closeness values

	d^{-}	d^{+}	RC
A1	0.357	0.553	0.607
A2	0.272	0.639	0.701
A3	0.689	0.221	0.243

Hence the final ranking:

$$A3 \phi\ A1 \phi\ A2$$

5 Conclusions

Nowadays, the depletion of resources and the pollution are two serious problems in the world. WEEE, or e-waste for short, is one of the most influential factors on these problems. This type of waste threats the environment and the human health by contaminating air, soil and water, because of toxic materials including in the EEE. While the hazardous substances in e-waste pollute the environment, their shorter life cycle causes the fast consumption and the continuous overproduction; hence the depletion of resources increases. Therefore, a strong interest is arising in the field improving to recovery of e-waste. To cope with these problems, governments make laws about e-waste treatment and the producers begin to take the responsibility of their e-wastes. There are generally three different ways of treating WEEE: reuse, recycling and disposal.

In this paper, a Fuzzy MCDM approach is proposed for MAGDM problems with preference information on alternatives. This approach is used to evaluate and select a waste treatment strategy for EEE.

In this direction, three treatment alternatives are determined and six criteria based on these alternatives are also stated. The Fuzzy Hierarchical TOPSIS method gives the ranking

ISBN: 978-989-95079-6-8

of the alternatives under the problems criteria as $A3 \phi A1 \phi A2$. So, the best alternative is treating e-wastes by outsourcing its disposal process of its own WEEE to a specialized company. And the worst alternative is to carry its own WEEE from its own waste collection store to an area which is purchased in order to dispose of the e-wastes by landfill or incineration.

The difference of ranking between the LINMAP method and the method used in this paper may be due to the following reasons:

- Major difference between the first and third alternatives' cost. Relatively small difference for C5 and the difference in C3 for the advantage of the first alternative are not enough to compensate this huge difference of cost as well as capacity need and the convenience to the possessed technology.
- Assumption of independence between criteria caused us to unite some of the problem's criteria and as the LINMAP model doesn't require this assumption, this situation possibly caused a different ranking of the alternatives.
- Not enough consistency in expert judgments.

e-mail: koprow@us.edu.pl, wrobel@us.edu.pl.

Abstract *- The paper presents an algorithm designed to detect layers of eye's retina using an analysis in a hierarchic approach. This type approach has been implemented and tested in images obtained by means of Copernicus OCT (Optical Coherence Tomography). The algorithm created is an original approach to detect contours, layers and their thicknesses. The approach presented is an expansion of approaches described in [1], [2] and [4] and enables identification and recognition of external limiting membranes, retina and others in a very short time. The algorithm has been implemented in Matlab and C environment.*

Keywords - tomographic eye image, algorithm, recognition

1. Introduction

Images originating from a Copernicus tomograph due to its specific nature of operation are obtained in sequences of a few, a few dozen 2D images within approx. 1s, which provide the basis for 3D reconstruction. Because of their number, the analysis of a single 2D image should proceed within a time not exceeding 10 ms, so that the time of operator's waiting for the result would not be onerous (as it is easy to calculate for the above value, for a few dozen images of resolution usually MxN = 740x820 in a sequence, this time will be shorter than 1 s).

At the stage of image preprocessing (like in [1], [2] and [3]) the input image L_{GRAY} is initially subject to filtration using a median filter of (M_h x N_h) size of mask h equal to M_h x N_h=3x3 (in final version of the software this mask may be set also at M_h x N_h=5 x 5 so as to obtain better precision of algorithm operation for a certain specified group of images). Image L_M obtained this way is subject consecutively to decomposition to an image of lower resolution and analysed in terms of layers detection.

2. Image decomposition

It is assumed that the algorithm described should give satisfactory results considering mainly the criterion of operating speed. Although methods (algorithms) described in [1], [2] and [3] feature high precision of computations, however, they are not fast enough (it is difficult to obtain the speed of single 2D image analysis on a PII 1.33 GHz processor in a time not exceeding 10 ms). Therefore a reduction of image L_M resolution by approx. a half was proposed to such value of pixels number in lines and columns, which is a power of '2', i.e.: MxN=256x512 (L_{M2}) applying further on its decompositions to image L_{D16} (where symbol 'D' means decompositions, while '16' the size of block, for which it was obtained). Each pixel of the input image after decomposition has a value equal to a median of the area (block) of 16x16 size of the input image, acc. to Figure. 1.

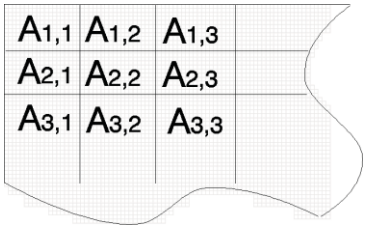

Figure. 1. Blocks arrangement in L_M image

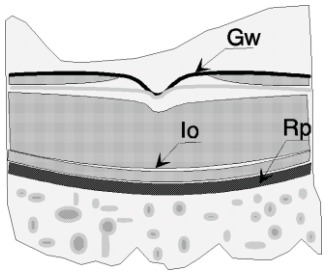

Figure. 2. Pictorial diagram of layers sought arrangement in a tomographic image

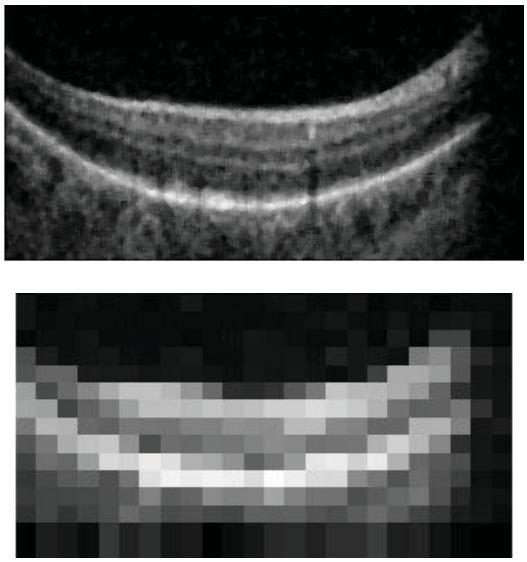

Figure. 3. Image before and after decomposition – L_{M2} and L_{D16}, respectively

ISBN: 978-989-95079-6-8

An example of L_{D16} result and the input image L_{M2} is shown in Figureure. 3. Image L_{D16} is then subject to determination of pixels position of maximum value for each column, i.e.:

$$L_{DM16}(m,n)=\begin{cases}1 & \text{if} \quad L_{D16}(m,n)=\max\limits_{m}(L_{D16}(m,n))\\ 0 & \text{others}\end{cases} \tag{1}$$

where:

m – means a line numbered from one;

n – means a column numbered from one.

Using the described method of threshold setting for the maximum value in lines, in 99 percent of cases only one maximum value in a column is obtained (Figureure. 4).

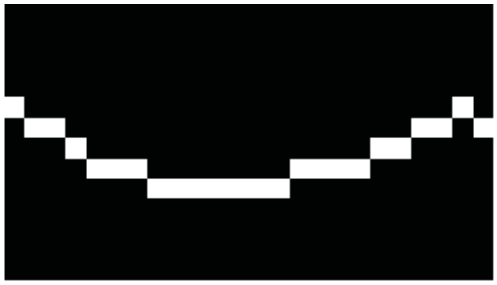

Figure. 4. Example of L_{DM16} image

Figure. 5. Example of L_{DB16} image

To determine precise position of Gw and Rp limits (Figure. 2) it turned out necessary to use one more L_{DB16} image, i.e.:

$$L_{DB16}(m,n)=\begin{cases}1 & \text{if} \quad |L_{D16}(m,n)-L_{D16}(m+1,n)|>p_r\\ 0 & \text{others}\end{cases} \tag{2}$$

for $m\in(1,M-1)$, $n\in(1,N)$,

where:

pr – threshold assumed within the range (0, 0.2).

As a result, coordinates of Gw(n) and Rp(n) limits position points are obtained as such positions of values '1' in L_{DB16} image, for which $Gw(n) \le Rp(n)$ and Rp(n) is obtained from L_{DB16} image in the same way.

This method for pr threshold selection at the level of 0.01 gives satisfactory results in around 70 percent of cases of not composed images (i.e. such, which are not images with a visible pathology). Unfortunately for the other 30 percent cases the selection of pr threshold in the adopted limits does not reduce the originated errors (Figure. 5).

The correction on this level of erroneous recognitions of Gw(n) and Rp(n) layers is that important, that for this approach these errors will not be duplicated (in the hierarchic approach presented below) for the subsequent more precise approximations.

3. Correction of erroneous recognitions

In L_{DB16} image (Figure. 5) white pixels are visible in an excess number for most columns. Two largest objects arranged along 'maxima' in columns entirely coincide with Gw and Rp limits position. Based on that and having carried out the above analysis for a few hundred images, the following limitations were adopted:

- for coordinates Rp(n) found in L_{DM16} image there must be at the same time $L_{DM16}(m,n)=1$ in other cases this point is considered as disturbance or as a point of Gw(n) layer,
- if only one pixel of value '1' occurs in image L_{DM16} and L_{DB16} for the same position, i.e. for the analysed n there is $L_{DM16}(m,n) = L_{DB16}(m,n)$ the history is analysed for $n>1$ and it is checked, whether $|Gw(n-1) - Gw(n)| > |Rp(n-1) - Rp(n)|$, i.e.:

$$Rp(n)=\begin{cases}m & \text{if} \quad L_{DB16}(m,n)=L_{DM16}(m,n)=1 \wedge \\ & \wedge |Gw(n-1)-Gw(n)|>|Rp(n-1)-Rp(n)|\\ 0 & \text{others}\end{cases} \tag{3}$$

for $m\in(1,M-1)$, $n\in(2,N)$,

- if $|Gw(n-1) - Gw(n)| \le |Rp(n-1) - Rp(n)|$, the condition $Gw(n-1) - Gw(n) = \pm 1$ is checked (giving thereby up fluctuations against history n-1 within the range ± 1 of area A (Figure. 1). If so, then this point is the next Gw(n) point. In the other cases the point is considered as a disturbance. It is assumed that lines coincide Gw(n) = Rp(n) if $Rp(n-1) - Rp(n)=\pm 1$ and only one pixel occurs of value '1' in L_{DM16} image.
- in the case of occurrence in specific column of larger number of pixels than 2, i.e. if $\operatorname{sum}_{m}(L_{DB16}(m,n))>2$ a pair is matched (if occurs) Gw(n-1), Rp(n-1) so that $|Gw(n-1) - Gw(n-1)| - |Rp(n) - Rp(n)| = \pm 1$ would occur. In this case it may happen that lines Gw(n) and Rp(n) will coincide. However, in the case of finding more than one solution, that one is adopted, for which $L_{D16}(Gw(n),n) + L_{D16}(Rp(n),n)$ assumes the maximum value (the maximum sum of weights in L_{D16} occurs).

The presented correction gives for the above class of images the effectiveness of around 99% of cases. Despite adopted limitations the method gives erroneous results for the initial value n=1, unfortunately these errors continue to be duplicated.

ISBN: 978-989-95079-6-8

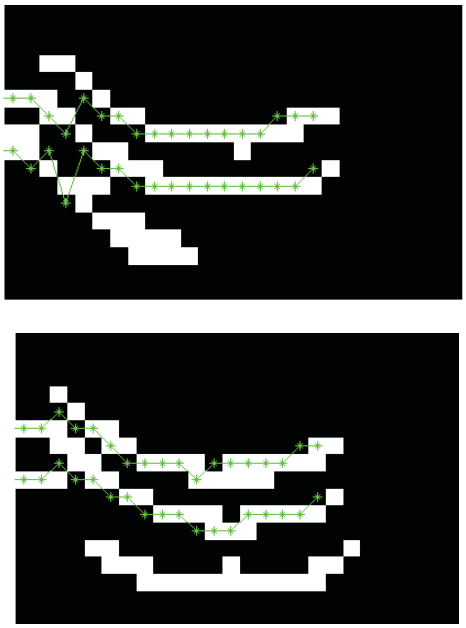

Figure. 6. Examples of L_{DB16} images for p_r=0.01 with incorrectly marked Gw(n), Rp(n) points (layers)

Unfortunately, the adopted relatively rigid conditions of acceptable difference |Gw(n-1) - Gw(n-1)| or |Rp(n)-Rp(n)| cause origination of large errors for another class of tomographic images, in which a pathology occurs in any form (Figure. 7).

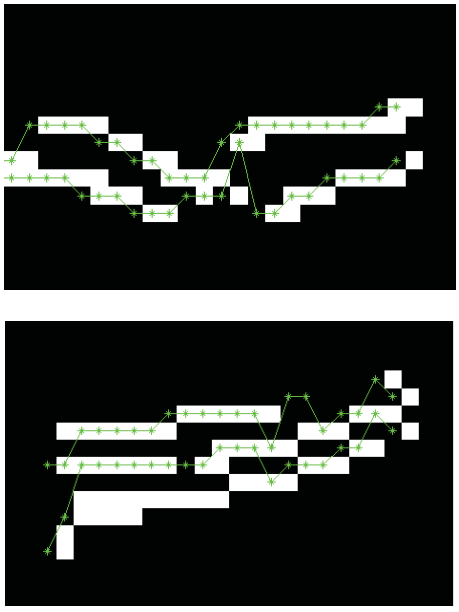

Figure. 7. Examples of L_{DB16} images for p_r=0.01 with incorrectly marked Gw(n), Rp(n) points (layers)

As it may be seen in Figure. 6 and Figure. 7 problems occur not only for the initial n values, but also for the remaining points. The reason of erroneous recognitions of layers positions consists of difficulty in distinguishing proper layers in the case of discovering three 'lines', three points in a specific column, which position changes in acceptable range for individual n.

These errors cannot be eliminated at this stage of decomposition into 16x16 pixels areas (or 16x32 image resolution). They will be the subject of further considerations in the next sections.

4. Reducing the decomposition area

The increasing of accuracy and thereby reducing the $A_{m,n}$ area size (Figure. 1) – block in L_M image – is a relatively simple stage of tomographic image processing with particular focus on the operating speed. It has been assumed that $A_{m,n}$ areas will be sequentially reducing by half in each iteration – down to 1x1 size. The reduction of $A_{m,n}$ area is equivalent to performance of the next stage of lines Gw and Rp position approximation.

The increasing of accuracy (precision) of Gw and Rp lines position determined in the previous iteration is connected with two stages:

- concentration of (m,n) coordinates in the sense of determining intermediate ((m,n) points situated exactly in the centre) values by means of linear interpolation method;
- change of concentrated points position so that they would better approximate the limits sought.

If the first part is intuitive and results only in resampling, the second requires more precise clarifications. The second stage consists in matching individual points to the layer sought. As in the ox axis the image by definition is already decomposed and pixel's brightness in the image analysed corresponds to the median value of the original image in window A (Figure. 1), the modification of points Rp and Gw position occurs only in the vertical axis. The analysis of individual Rp and Gw points is independent in the sense of dependence on n-1 point position, as was the case in the previous section.

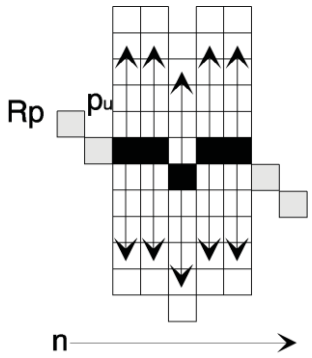

Figure. 8. Pictorial diagram of the process of Rp course matching to the edge of the layer sought. Individual pixels independent of each other may change the position within the $\pm p_u$ range

Each of Rp points, left from the previous iteration, and newly created from interpolation, in the consecutive algorithm stages is matched with increasingly high precision to the RPE layer. Point's Rp(n) position changes within the range of $\pm p_u$ (Figure. 8), where the variation range does not depend on the scale of considerations (size of A area) and strictly results from the distance between Gw and Rp (Figure. 2). For blocks A of size from 16 x 16 to 1 x 1 p_u is constant and equal 2. This value has been taken based on typical average, for analysed a few hundred L_{GRAY} images, distance between

ISBN: 978-989-95079-6-8

Gw and Rp equal to around 32 pixels, what means that after decomposition into blocks A of size 16x16 these are two pixels, i.e. p_u=2. In this ±2 range a maximum is sought in L_{DM} image and a new position of point Rp or Gw assumed for it. Thus the course of Rp or Gw is closer to the actual course of the layer analysed.

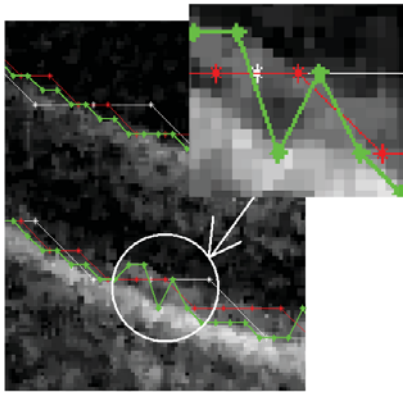

Figure. 9. Results of matching for two iterations White colour marks input Rp points and red and green – consecutive approximations

The obtained results of matching are presented in Figure. 9. White colour shows input Rp values as input data for this stage of algorithm and decomposition into A blocks of size 16 x 16 (L_{DM16} and L_{DB16} images), red colour – results of matching for A blocks of size 8 x 8 (L_{DM8} and L_{DB8} images), and green colour – results of matching for A blocks of size 4 x 4 (L_{DM4} and L_{DB4} images). As may be seen from Figure. 9 the next decompositions into consecutive smaller and smaller A areas and thus image of higher resolution, a higher precision is obtained at the cost of time (because the number of analysed Rp(n), Gw(n) points and their neighbourhoods ±p_u increases).

This method for A of 16 x 16 size has that high properties of global approach to pixels brightness that there is no need to introduce at this stage additional actions aimed at distinguishing layers situated close to each other (which have not been visible so far due to image resolution). While at A areas of 4x4 size other layers are already visible, which should be further properly analysed. At increased precision, Io layer is visible, situated close to Rp layer (Figure. 9). Thereby in the area marked with a circle there is a high position fluctuation within the oy axis of Rp layer. Because of that the next step of algorithm has been developed, taking into account separation into Rp and Io layers for appropriately high resolution.

5. Analysis of Rp and Io layers

The analysis of layers consists in separating line Io from line Rp originating from previously executed stages of the algorithm. The case is facilitated by the fact that on average around 80, 90% of pixels in each tomographic image has a maximum value in each column exactly in point Rp (this property has been already used in the first section). So the only problem is to detect the position of Io line. One of possible approaches consists of an attempt to detect the contour of the layer sought in L_{IR} image. This image originated from L_M image thanks to widening of Rp(n) layer range within oy axis within the range of ±p_I=20 pixels. L_{IR} image has been obtained with the number of columns consistent with the number of L_M image columns and with the number of lines $2 \cdot p_I+1$.

Figure. 10. Image $L_{IR} = L_M(m\text{-}R_p(n),n)$

Figure. 10 shows image $L_{IR} = L_M(m\text{-}Rp(n),n)$ originating from L_M image from Figure. 9.

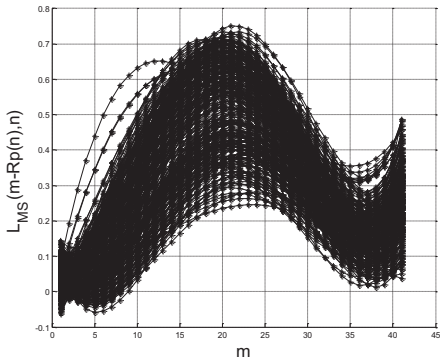

Figure. 11. Courses $L_{IRS} = L_{MS}(m\text{-}Rp(n),n)$ versus m

The upper layer visible in Figure. 10 as a pretty sharp contour is the sought course of Io. Unfortunately, because of a pretty high individual variation within the Io layer position relative to Rp the selected p_I range in further stages of the algorithm may be increased even twice (that will be described later). To determine consecutive points of Io layer position interpolations with 4th order polynomial of grey level degree for individual columns of L_{IR} image obtaining this way L_{IRS}, which changes of grey levels in individual columns are shown in Figure. 11. The position of point Io(n) occurs in the place of the highest gradient occurring within the range (Rp(n)- p_I) ÷ Rp(n) relative to L_{MS} image or 1÷ p_I relative to L_{IRS} image.

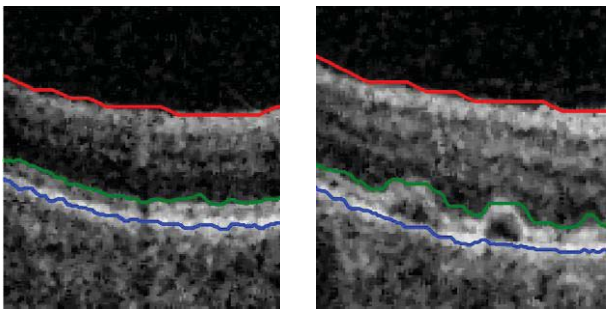

Figure. 12. Parts of L_M images with marked courses Gw – red, Rp – blue, and Io – green

As may be seen in Figure. 12, the method presented perfectly copes with detecting Gw, Rp and Io layers marked in red, blue and green, respectively.

ISBN: 978-989-95079-6-8

6. Layers thickness map and 3D reconstruction

The analysis of L_M images sequence and precisely the acquiring of Gw, Rp and Io layers allows performing 3D reconstruction and layers thickness measurement. A designation for an image sequence with an upper index (i) has been adopted, where i = {1,2,3,...,k-1,k) i.e. $L_M^{(1)}$, $L_M^{(2)}$, $L_M^{(3)}$,.., $L_M^{(k-1)}$, $L_M^{(k)}$. For a sequence of 50 images the position of Gw layers (Figure. 13), Rp (Figure. 14) and Io (Figure. 15) was measured as well as Io - Rp layer thickness (Figure. 16).

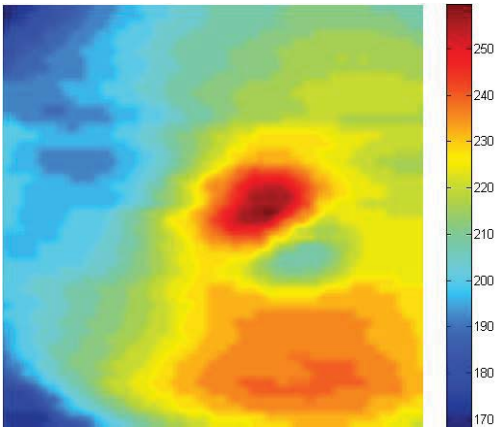

Figure. 13. Spatial position of Gw

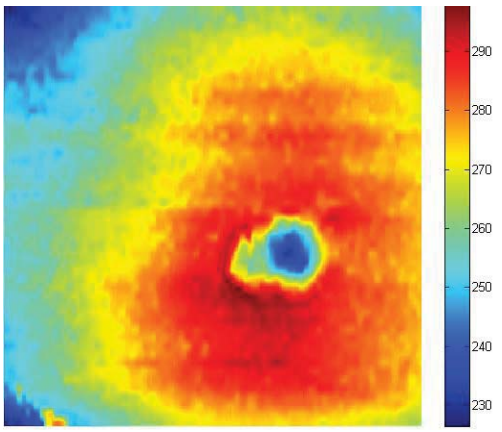

Figure. 14. Spatial position of Rp

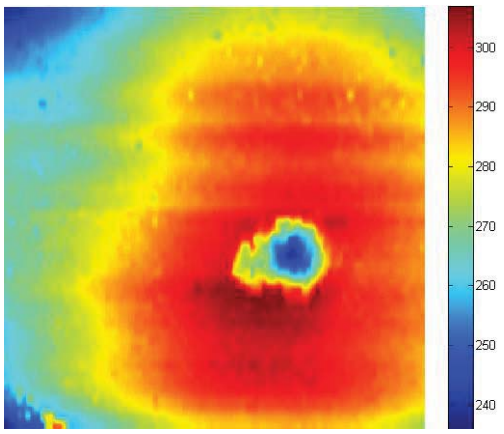

Figure. 15. Spatial position of Io

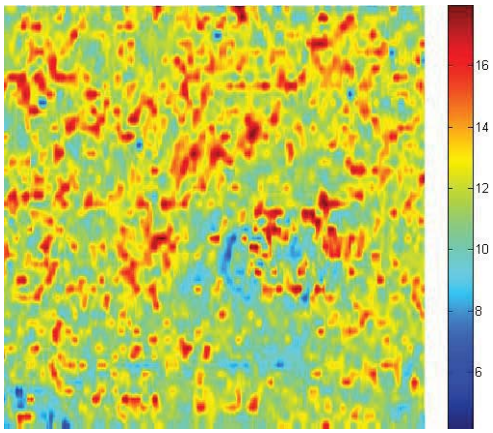

Figure. 16. Thickness of Io - Rp layer

3D reconstruction performed based on $L_M^{(i)}$ images sequence is the key element crowning the results obtained from the algorithm suggested. The sequence of images, and more precisely the sequence of $Gw^{(i)}(n)$, $Rp^{(i)}(n)$ and $Io^{(i)}(n)$ layers position provides the basis for 3D reconstruction of a tomographic image. For an example sequence of 50 images and one $L_M^{(i)}$ image resolution of MxN= 256 x 512 a 3D image is obtained, composed of three Gw, Rp and Io layers of 50 x 512 size.

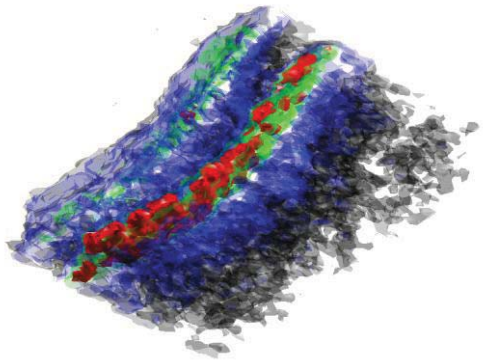

Figure. 17. Example 3D reconstruction of layers: Gw – blue, Rp – red, and Io - green

In an obvious way a possibility of automatic determination of the thickest or the thinnest places between any points results from layers presented in Figure. 18.

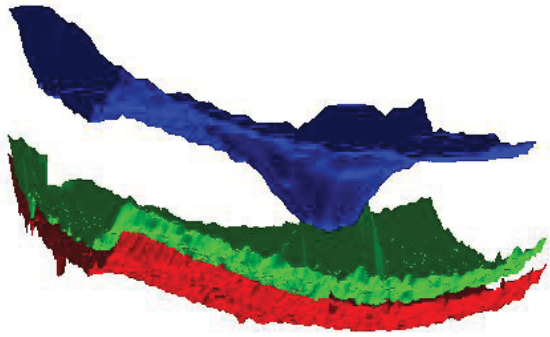

Figure. 18. Example 3D reconstruction of layers: Gw – blue, Rp – red, and Io - green

ISBN: 978-989-95079-6-8

Results are shown in Figure. 17 for an example reconstruction of original images (without processing described above) based on pixels brightness and in Figure. 18 – the reconstruction performed using the algorithm described above was carried out based on $Gw^{(i)}(n)$, $Rp^{(i)}(n)$ and $Io^{(i)}(n)$ information.

7. Summary

The algorithm presented detects Gw, Rp and Io layers within up to 50 ms time on a PC with a 2.5 GHz Intel Core 2 Quad processor. The time was measured as a mean value of 700 images analysis dividing individual images into A blocks (Figure. 1) consecutively of sizes 16 x 16, 8 x 8, 4 x 4, 2 x 2. This time may be reduced modifying the number of approximation blocks and at the same times increasing the layer position identification error – results are presented in the table below.

Table 1. Execution time of algorithm to find Gw, Rp and Io layers and 3D reconstruction

Processing stage	Total time since processing start [ms]	Time of individual stages computations [ms]
Preprocessing	10.10	10.10
Preliminary breakdown into Gw and Rp+Io	13.20	3.20
Gw and Rp+Io approximation for A – 16x16	15.90	2.74
Gw and Rp+Io approximation for A – 8x8	23.70	7.63
Precise Rp and Io breakdown	44.60	20.85

The specification of individual algorithm stages' analysis times presented in the table above clearly shows the longest execution of the first stage of image preprocessing, where filtration with a median filter is of prevailing importance (in terms of execution time) as well as of the last stage of precise determination of Rp and Io layers position. Because precise Rp and Io breakdown is related to the analysis and mainly to the correction of Rp and Io points position in all columns of the image for the most precise approximation (because of a small distance between Rp and Io it is not possible to perform this breakdown in earlier approximations). So the reduction of computation times may occur only at increasing the error of layers thickness measurement. And so for example for the analysis in the first approximation for A of 32 x 32 size and then for 16 x 16 gross errors are obtained generated in the first stage and duplicated in the next ones. For approximations for A of 16 x 16 and then 8 x 8, 4 x 4, 2 x 2 and 1 x 1 sizes the highest accuracy is obtained, however the computation time increases approximately twice.

A Two Step Solution Procedure to a Fuzzy Medical Waste Disposal Facility Location Problem

H. Ziya Ulukan Yeşim Kop

Industrial Engineering Department, Galatasaray University

Ciragan Cad. No:36 Ortakoy, Istanbul, Turkey
Email: zulukan@gsu.edu.tr, ykop@gsu.edu.tr

Abstract— *This paper handles the medical waste disposal facility location problem in Istanbul by using fuzzy TOPSIS (FETOPSIS) to select the adequate place between some candidate points that are obtained from the Ishii's undesirable facility location algorithm. Medical waste must be disposed without damaging environment and human health, complying with new regulations. The aim is to provide an alternative method to the medical waste disposal facility location problem in Istanbul, able to handle the fuzziness of the real world. People attempt to minimize the undesirable effects introduced by the new facility by maximizing its minimum Euclidean distance with respect to all demand points and also to minimize the total transportation costs. This study proposes a modified model of Ishii's algorithm to obtain a list of candidate points. Then a selection is made between these candidate points considering other criteria as earthquake risk, distance to natural water sources and level of air pollution.*

Keywords— Undesirable Facility Location, Maximin, FETOPSIS, Medical Waste, Euclidean Distances.

1 Introduction

The infectious, pathological, cutter-driller wastes emanating from medical institutions are known as medical wastes. Recently, the controlled collection and safe disposal of medical waste has become an important field of environment protection in Turkey as in whole world. The 50% of environmental pollution has occurred in the last 35 years. As a result, the scientists work on eliminating all harmful factors on air, earth, water and human life. The safe disposal and the regain of waste are some of the important fields that they work on. Even if the medical waste consist a small part of waste amount, when we consider the threat they constitute on human life, their safe disposal is vital.

The present position is that medical wastes are stored at special hazardous waste storage areas or medical waste disposal areas if they cannot be disposed by incineration. The technical criteria concerning storage are included in the By-Law on the Control of Medical Wastes (2005).

Throwing away without control or common disposal with household waste poses a serious threat for all livings. That is why medical waste must be disposed without damaging the human mental and physical health, the animal health, the flora, the water and the welfare of the society, complying with new regulations.

The aim of this study is to provide an alternative method to solve the medical facility location problem in Istanbul, able to handle the fuzziness of transportation costs and people preferences. Nuclear plant, oil refining plant, waste disposal plant must not be close to residential area. People attempt to minimize the undesirable effects introduced by the new facility by maximizing its minimum Euclidean distance with respect to all demand points and also to minimize the total transportation costs. These are semi-obnoxious facilities and to locate them, facility planners determined two objectives [1]. The first objective aims to maximize the minimum distance from the new facility to the demand points; this is the maximin problem. The second aim is to minimize the total distance from the facility to the demand points in order to minimize the transportation costs. In this study, we propose the following two-step solution procedure where we obtain all efficient solutions at the first step and then we choose the best solution at the second step. Considering the fuzzy nature of the people attitude towards the location of this kind of facilities we will try to find the site of the facility which maximizes the minimal satisfaction degree among all demand points and maximizes the preference of the site by using a method based on the Ishii's where the attitudes of people are expressed by a trapezoidal membership function [2]. The function represents the satisfaction degree of demand points with respect to the distance from these points to the facility site. We reformulate the Ishii's model to obtain a list of candidate points. Then, we make a selection between these candidate points by solving a fuzzy TOPSIS (FETOPSIS). The use of this method allows us to consider other criteria as earthquake risk, distance to natural water sources and level of air pollution. These criteria will be evaluated by experts with the first two criteria: distance to districts and transportation costs.

2 Disposal of medical waste

There are many proven techniques for the safe disposal of medical waste all around the world. Nowadays, new contagious diseases that appeared in diverse countries induced all medical authorities to take severe precautions. In 2003, with the outbreak of severe acute respiratory syndrome (SARS) the authorities take more serious steps in managing medical waste. The procedures for handling, treatment and disposal of this waste were required to comply with the most stringent standards [3, 4]. The health authority in Taiwan had to handle the current status of waste

ISBN: 978-989-95079-6-8

production for further management planning. The quantity of waste generated by hospitals varies by changes in local legislation according to the studies [5, 6, 7, 8].

In Turkey, the medical waste production increases due to the economic and social changes and the population increase. The amount of waste is too huge to dispose in the dumping ground and requires an integrated management concept involving collection, transportation and disposal. By 2005 the number of hospital in Turkey has become 1198 and due to development of medical technologies and hygienic precautions, total waste amount has been increasing. According to MEF's researches, total waste amount in Turkey is 238.26 tons per day and 86 968 tons per year. 23 000 tons of this amount is collected in Istanbul by ISTAC (sub institution of Istanbul Metropolitan Municipality) and district municipalities.

The mortal contagious diseases that appeared recently in Turkey as Avian Influenza, as well-known name bird flu, Crimean-Congo hemorrhagic fever (CCHF) and the holocausts related to these diseases, furthermore the increase of other contagious diseases as aids, hepatitis and tuberculosis accentuate the vitality of the collection and the safe disposal of medical waste.

The regulations of medical waste control inure on 20.07.2005 in Turkey. The regulations are based on the 8th article of the environment code where it is denoted that inappropriate collection, transportation and disposal are forbidden. In the 35th article of regulations there is a legal decision on the medical waste disposal facility location: The distance of disposal facility can't be closer than 1000 meters to the residential area. As it is mentioned clearly in the regulations these following criteria must be considered in the decision making process:

1. Distance between disposal facility and districts. (C_1)
2. Transportation costs. (C_2)
3. Earthquake risk. (C_3)
4. Distance to the water sources. (C_4)
5. Existing air quality. (C_5)

The first two quantitative criteria will be handled by using a fuzzy facility location method so as to obtain worthwhile candidate points. Then these points will be handled by a fuzzy TOPSIS method considering the five criteria above all together to select a single point.

3 Methodology

3.1 Fuzzy Facility Location with Preference of Candidate Sites

Facilities as power plants, chemical plants, dumping grounds, airports are undesired close to residential area but they must also be at a reasonable distance easy to reach in order to minimize transportation costs. By using different decision making methods one must compromise two objectives. People don't want to live near a dumping ground but want also to get rid of the waste they produce as fast as possible. So the facility can not be placed to an inaccessible distance.

The first step of this study is based on the [2]'s fuzzy facility location problem, where the attitudes of the demand points (people, clients) towards the location of new facility are expressed by a trapezoidal membership function. Ishii's problem is reformulated to obtain a list of candidate points. Reference 2 categorizes people attitudes in three categories. In this study we have two categories of attitude: 1. People don't want the facility near. 2. People don't want high costs of transportation. As it is mentioned in the medical waste regulations, the burning and storage facility can not be close more than 1000 meters. Anyway people prefer the facility to be more than 5000 meters far from their residential area.

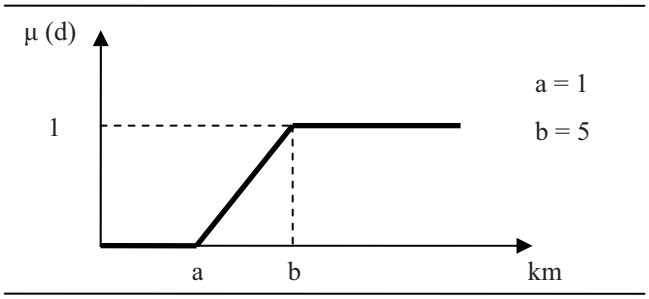

Figure 1: Membership function related to distances.

$$d_i(X) = \begin{cases} E(x-p_i)+N(y-q_i) & (x \ge p_i, y \ge q_i) \\ W(x-p_i)+N(y-q_i) & (x \le p_i, y \ge q_i) \\ E(x-p_i)+S(y-q_i) & (x \ge p_i, y \le q_i) \\ W(x-p_i)+S(y-q_i) & (x \le p_i, y \le q_i) \end{cases} \quad (1)$$

$$\mu(d_i) = \begin{cases} 0 & (d_i \le a) \\ \dfrac{d_i - a}{b-a} & (a \le d_i \le b) \\ 1 & (b \le d_i) \end{cases} \quad (2)$$

N: North = 1; *S*: South = –1; *E*: East = 1; *W*: West = –1 are constants used to provide nonnegative differences between coordinates. Let be n demand points in the rectangular area. These points are represented as (p_i, q_i), $i = 1, 2, \ldots, n$. The facility that we will build is represented as $\chi = (x, y)$ and $X = \{(x, y) | p_L \le x \le p_U,\ q_L \le y \le q_U\}$ [2]. Site $\chi \in X$.

Define α: α = $\mu(d_i)$. Then, we model the problem as [2]:

Maximize α

such that

$$\alpha \le \frac{d_i(x) - a}{b - a}$$
$$0 < \alpha \le 1$$
$$p_L \le x \le p_U$$
$$q_L \le y \le q_U \quad (3)$$

But the way that we will pursue to solve this problem is to partition the rectangular area to small rectangles by tracing the horizontal and vertical lines passing by each demand

ISBN: 978-989-95079-6-8

points. For each line intersection point called x_{jm} we will solve the sub-problem (4). The optimums of each sub problem can be handled by another decision making tool in order to select the best location for the facility.

$$\begin{aligned} Q:&\ \text{Maximize}\ \alpha \\ &\text{such that}\ \ \alpha(b-a)+a \le E(x-p_i)+N(y-q_i) \\ &\alpha(b-a)+a \le W(x-p_i)+N(y-q_i) \\ &\alpha(b-a)+a \le E(x-p_i)+S(y-q_i) \\ &\alpha(b-a)+a \le W(x-p_i)+S(y-q_i) \\ &0<\alpha\le 1 \qquad x\in X \qquad i=1,2,...,\ n \end{aligned} \tag{4}$$

3.2 Selection of the Best Candidate Site with Fuzzy TOPSIS

Method TOPSIS (Technique for Order Preference by Similarity to Ideal Solution) was developed by Hwang and Yoon (1981) as an alternative to the ELECTRE method. The basic concept of the method is that the selected alternative should have the shortest distance to the ideal solution and the farthest distance to the negative-ideal solution. The Euclidian distance approach was proposed to evaluate the relative closeness of the alternatives to the ideal solution [4]. It solves the dilemma of the choice between ideal and anti-ideal by using an idea that Dasarathy (1976) applies to the data analysis. The TOPSIS method evaluates the decision matrix which refers to m alternatives which are evaluated in terms of n criteria [9].

In real-world situation, because of incomplete or non-obtainable information, (for example, human judgments including preferences are often vague and cannot estimate his preference with an exact numerical data), the data are not deterministic; therefore they usually are fuzzy / imprecise, so, TOPSIS for fuzzy data is used [10]. The main advantage of fuzzy formulation compared to the crisp formulation is that the decision maker is not obligated to give a precise formulation, for the sake of mathematical reasons, even though he or she might be able or willing to describe the problem in fuzzy terms [11].

The extension of TOPSIS to fuzzy TOPSIS provides a new multi-criteria decision making method compatible with the real world decisions. There are diverse applications of this method in the literature as the evaluation of airline service quality of [12], selection of expatriate host country of [13], bridge risk assessment of [14], new product introduction of [15], industrial robotic system selection of [16] etc.

Let $A_1, A_2,..., A_m$ be m alternatives among which we will make the selection, $C_1, C_2,..., C_n$ be n the criteria that are under consideration during the decision making process. $\tilde{x}_{ij}$ is the fuzzy rating of alternative A_i according to the criterion C_j. Fuzzy data used here is triangular fuzzy number. We can express this fuzzy multi criteria decision making problem in matrix format [10]:

$$\begin{array}{cccccc} & C_1 & C_2 & \cdots & C_n \\ A_1 & \tilde{x}_{11} & \tilde{x}_{12} & \cdots & \tilde{x}_{1n} \\ A_2 & \tilde{x}_{21} & \tilde{x}_{22} & \cdots & \tilde{x}_{2n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ A_m & \tilde{x}_{m1} & \tilde{x}_{m2} & \ldots & \tilde{x}_{mn} \end{array} \tag{5}$$

The purpose of linear scales transformed with normalization function used in this study is to preserve the property that the ranges of normalized triangular fuzzy numbers to be included in (0,1). [17]:

$$\tilde{r}_{ij}=\left(\frac{a_{ij}}{c_j^*};\frac{b_{ij}}{c_j^*};\frac{c_{ij}}{c_j^*}\right) \tag{6}$$

Here, $c_j^*=\max_i c_{ij}$

Thereby, the normalized fuzzy decision matrix $\tilde{R}=\left[\tilde{r}_{ij}\right]_{m\times n}$ is generated. In decision making process each criterion can have a different importance for the decision maker who will assign different weights to each criterion. But in our study we assume that all criteria are equally important.

We define the positive ideal solution A^* and the negative ideal solution A^- [17]:

$$A^*=\left(\tilde{r}_1^*,\tilde{r}_2^*,\ldots,\tilde{r}_n^*\right) \tag{7}$$

$$A^-=\left(\tilde{r}_1^-,\tilde{r}_2^-,\ldots,\tilde{r}_n^-\right) \tag{8}$$

Then, we have to calculate the distance of each alternative to A^* and A^-, by using the formula of distance between two fuzzy numbers.

$$d_i^*=\sum_{j=1}^{n} d\left(\tilde{r}_{ij},\tilde{r}_j^*\right), i=1,\ldots,m \tag{9}$$

$$d_i^-=\sum_{j=1}^{n} d\left(\tilde{r}_{ij},\tilde{r}_j^-\right), i=1,\ldots,m \tag{10}$$

The distance between two fuzzy numbers is calculated as:

$$\tilde{x}=\left(a_1,b_1,c_1\right),\ \ \tilde{y}=\left(a_2,b_2,c_2\right) \tag{11}$$

$$d\left(\tilde{x},\tilde{y}\right)=\sqrt{\frac{1}{3}\left[\left(a_1-a_2\right)^2+\left(b_1-b_2\right)^2+\left(c_1-c_2\right)^2\right]} \tag{12}$$

A relative closeness index between d_i^* and d_i^- is calculated to determine the ranking order of alternatives [17,10]:

$$R_i=\frac{d_i^-}{d_i^*+d_i^-},\ \ i=1,\ldots,m \tag{13}$$

4 Application

This two-step model is applied to the medical waste facility selection for the most populated region of Istanbul including the districts Şişli, Kağıthane, Beşiktaş and Sarıyer. The figure 2 is the Google Earth map showing the application region. The distances and coordinates are provided by Google Earth.

Figure 2: Selection of a medical waste disposal facility in Istanbul.

In rectangular area there are four demand points and all lines passing through form 25 points which means that we will solve the sub problem (4) 25 times by using LINDO software. The optimum membership values and optimum candidate facility sites are in the Table 1. As our aim is to maximize membership value α, we can select the biggest α value as new facility site but there are many α values closer to each other. So, the most reasonable attitude is to handle some candidate points having big α value, considering other criteria. In this study, we handle seven points as alternatives having α value bigger than 0.600 in terms of an observation made on the map.

Table 1: Optimum α values and optimum candidate facility sites

SUB PROBLEMS	OPTIMUM POINT	OPTIMUM α VALUE
1	-	-
2	(1.790; 3.450)	0.110
3	(6.350; 0.000)	0.140
4	(5.330; 7.110)	0.167
5	(5.080; 2.160)	0.217
6	(5.080; 3.645)	0.261
7	(5.330; 3.645)	0.324
8	(4.445; 2.160)	0.376
9	(5.080; 2.795)	0.376
10	(5.080; 2.795)	0.376
11	(3.230; 0.000)	0.410
12	(6.350; 2.160)	0.410
13	(2.675; 0.540)	0.413
14	(6.350; 7.110)	0.422
15	(2.675; 0.000)	0.549
16	(0.000; 0.565)	0.565
17	(3.230; 7.110)	0.567
18	(6.350; 3.645)	0.579
19	(1.640; 5.645)	0.621
20	(6.350; 3.045)	0.631
21	(0.000; 3.100)	0.645
22	(0.000; 0.000)	0,700
23	(1.640; 7.110)	0.965
24	(0.000; 5.520)	1.000
25	(0.080; 5.690)	1.000

Seven candidate waste disposal facilities are highlighted in the Table 1. As there are several candidate points, we need a second decision process where we will introduce new decision criteria that are mentioned in the regulations to find out the best place for a medical waste disposal facility. The five criteria mentioned in the second section are evaluated for each candidate site by experts. The fuzzy TOPSIS method of [17] was used to handle these evaluations.

For the evaluation of the first criterion, the distance between the facility and the districts, experts used the α values of seven candidate points. Bigger α values improve our model.

To figure out the transportation costs, the distances between districts and candidate points are measured and given in the Table 2. The waste amount generated by each district is in the Table 3. These amounts help us to determine the weights of each district that are used in the calculation of transportation costs.

Table 2: Distances of candidate sites to each demand point

SITE	SISLI	BESIKTAS	KAGITHANE	SARIYER
1	6.680	5.870	3.800	10.770
2	3.580	7.890	2.580	7.670
3	3.525	3.525	5.595	3.915
4	5.300	10.310	5.000	5.250
5	3.785	8.795	3.485	3.485
6	5.390	10.400	5.090	5.000
7	5.250	10.260	4.950	4.860

Table 3: Waste amounts of each district and weights (Istanbul Metropolitan Municipality).

DISTRICTS	MEDİCAL WASTE AMOUNT (KG/YEAR)	WEIGHT
SISLI	87 600	0.362
BESİKTAS	64 800	0.268
KAGITHANE	64 800	0.268
SARIYER	24 600	0.102

To evaluate the earthquake risk criteria, the experts used the earthquake map of Istanbul published by earthquake observatory of Istanbul. There are five different risk levels in the map. They evaluated each candidate point according to their location on the map.

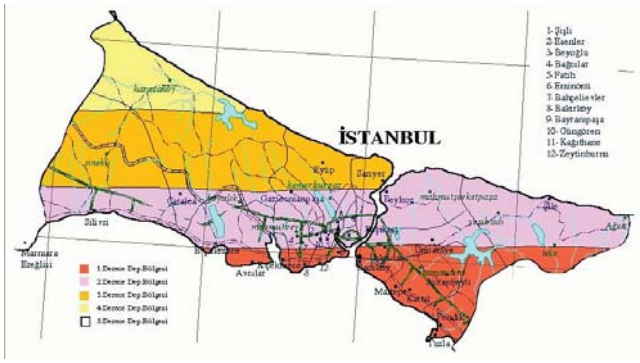

Figure 3: Earthquake Risk Map of Istanbul.

Distances of each candidate point to the water sources were measured using Google Earth. The results were evaluated by experts.

For the evaluation of air quality criterion, the experts used the data of Istanbul Technical University pollution reports.

ISBN: 978-989-95079-6-8

The figure 4 is the regional pollution map. The amount of SO_2 differs for each color in the map. It is denoted in the regulations that the waste disposal facility must be located in a region where it will not increase the pollution to high levels. So it is convenient to locate the facility in a less polluted area.

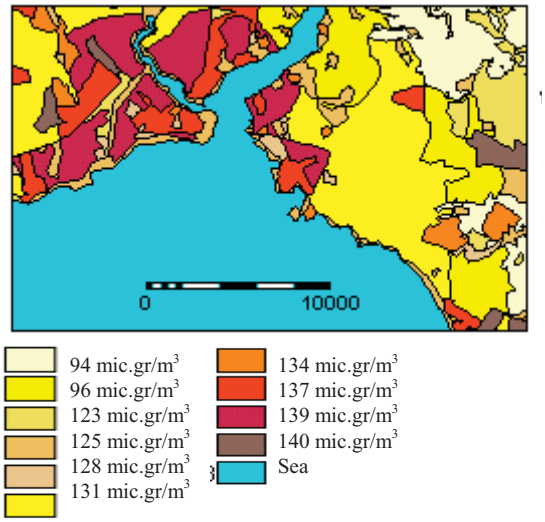

Figure 4: SO_2 amount for different places in Istanbul

The linguistic variables used by experts are in the Table 4. In our study we used a scale of [17]. The evaluation matrix and the normalized decision matrix of fuzzy TOPSIS decision process of this study are given in the Table 5 and Table 6.

Table 4: Linguistic Variables

Very poor (VP)	(0; 1; 3)
Poor (P)	(1; 3; 5)
Fair (F)	(3; 5; 7)
Good (G)	(5; 7; 9)
Very Good (VG)	(7; 9; 10)

Table 5: Expert Evaluation

	C1	C2	C3	C4	C5

A4	F	P	VP	VG	P
A5	VG	VP	F	P	VG
A6	VG	VP	F	P	VG
A7	VG	VP	F	P	VG

Table 6: Normalized Decision Matrix

	C_1	C_2	C_3	C_4	C_5
	0.00	0.50	0.43	0.00	0.70
A_1	0.10	0.70	0.71	0.10	0.90
	0.30	0.90	1.00	0.30	1.00
	0.00	0.70	0.14	0.30	0.00
A_2	0.10	0.90	0.43	0.50	0.10
	0.30	1.00	0.71	0.70	0.30
	0.10	0.50	0.14	0.50	0.30
A_3	0.30	0.70	0.43	0.70	0.50
	0.50	0.90	0.71	0.90	0.70
	0.30	0.10	0.00	0.70	0.10
A_4	0.50	0.30	0.14	0.90	0.30
	0.70	0.50	0.43	1.00	0.50
	0.70	0.00	0.43	0.10	0.70
A_5	0.90	0.10	0.71	0.30	0.90
	1.00	0.30	1.00	0.50	1.00
	0.70	0.00	0.43	0.10	0.70
A_6	0.90	0.10	0.71	0.30	0.90
	1.00	0.30	1.00	0.50	1.00
	0.70	0.00	0.43	0.10	0.70
A_7	0.90	0.10	0.71	0.30	0.90
	1.00	0.30	1.00	0.50	1.00

The results are given in the Table 7. According to these results, three areas, A_5, A_6, and A_7 are equally adequate for the medical waste disposal facility. Selected point is sufficiently far from residential area and not too far to increase the transportation costs. So one can conclude that this study is meaningful for this kind of problems. But this model does not take into account other logistical constraints.

Table 7: Range of alternatives

	d_i^*	Range	d_i^-	Range	R_i	Range
A_1	1.64	3	1.83	3	0.53	3
A_2	2.13	5	1.35	5	0.39	5
A_3	1.57	2	1.93	2	0.55	2
A_4	2.04	4	1.45	4	0.42	4
A_5	1.30	1	2.17	1	0.62	1
A_6	1.30	1	2.17	1	0.62	1
A_7	1.30	1	2.17	1	0.62	1

5 Conclusions

This paper deals with the problem of determining the undesirable facility location site in Istanbul. We tried first to find the site of the facility which maximizes the minimal satisfaction degree among all demand points and maximizes the preference of the site by using a method based on the Ishii's.

There are four drawbacks in this kind of solution procedure. The first is that this solution procedure suggests that residential areas are discrete points. This problem can be handled by revising the intervals of membership function as in this study. Second is that more than one sub-problem can have the same optimum solution. To handle this problem we use the optimum of each sub-problem having nearly same α values, bigger than a fixed value, in a new decision making process. The inaptitude to introduce qualitative criteria to the decision process is another drawback. A fuzzy TOPSIS

ISBN: 978-989-95079-6-8

method is introduced to the decision making process as a second step to improve the model. The last drawback is not handled in this study but can be subject to a further study. When the number of districts increases, the number of sub problems increases hugely and it complicates the decision making process. For a limited number of districts, the apparent advantage of our solution procedure is that all problems are converted to linear problems and we solve them easily using LINDO software.

Online Classification of Machine Operation Modes Based on Information Compression and Fuzzy Similarity Analysis

Gancho Vachkov

Faculty of Engineering, Kagawa University
Takamatsu City, Kagawa 761-0396, Japan
Email: vachkov@eng.kagawa-u.ac.jp

Abstract—*This paper proposes a computational scheme for online classification of process data sets that represent different operation modes of machines and other systems by use of fuzzy similarity analysis. The classification procedure starts with a preliminary given small number of known operation modes (data sets) which constitute the initial size of the Knowledge Base (KB). During the online classification, the dissimilarity (difference) degree between the newly submitted operation mode and each of the current modes stored in the KB is computed. As a result, depending on the preliminary given threshold for classification, the newly submitted mode is classified as belonging to a certain class (operation mode) from the KB or is considered as a new (unknown and different) mode. In the latter case, this mode is added as a new entry of the KB and used for the further online classification.*

An unsupervised learning algorithm (a modification of the Neural-Gas leaning algorithm) is used in the paper for compression of the original "raw" data from each operation mode into Compressed Information Model (CIM) with a smaller number of neurons. Then the similarity analysis is performed as a two-input fuzzy inference procedure that uses the Center-of-Gravity Distance and the Weighted Average Size Difference between two CIMs. The membership functions and the singletons of the fuzzy inference procedure are tuned in the paper by using a given set of test operation modes. The whole computational scheme is illustrated and discussed on a real example for classification of 5 main operation modes of a hydraulic excavator.

Keywords— Fuzzy Similarity, Information Compression, Online Classification, Operation Modes, Unsupervised Learning

1 Introduction

Classification of different available process data taken from the real operation of machines and other systems is a problem of utmost importance for the proper monitoring and performance evaluation of the machines. Generally speaking, the classification and pattern recognition problems, as well as various methods for their solution are very well presented and discussed in the literature [1-6]. However in the most often cases the problem is viewed as off-line classification of preliminary given set of data (patterns) with fixed size. Then the task is to classify every single data (pattern) from the given data set as belonging to one or another class.

When dealing with industrial systems and machines, the problem is sometimes different and more complicated, since one single data (i.e one measurement from a group of sensors at a given instant) is not sufficient to reveal clearly the current machine status (known as machine *operation mode*). We need a data set containing multiple measurements during a limited time of machine operation, in order to classify the current operation mode as *belonging* (or *not belonging*) to a certain operation mode.

During long time operation of the machine, *large* (or even *endless*) sequence of limited time operation data sets is obtained. Therefore a flexible *online* and *incremental classification scheme* is needed that should be able to *1)* properly classify the data sets into respective operation modes and *2)* to discover *new* operation modes that are stored in the KB in order to be used in the further online classification.

In this paper we present a special *two-stage* computation scheme for solving the problem of online classification, The *first stage* is information compression of the "raw operation data" representing a certain operation mode into a respective compressed information model (CIM), which consists of a small number of neurons. As a tool for information compression, a modified version of the off-line Neural-Gas unsupervised learning algorithm [3,4] is used in the paper. In the *second stage* a special fuzzy inference procedure for similarity analysis is proposed that uses two parameters, extracted from the CIM, namely the C*enter-of-Gravity* and the *Weighted Average Size* of the CIM. The differences between the respective parameters for a given pair of operation modes are used as two input *features* in the fuzzy inference procedure for similarity analysis.

The proposed classification scheme has the ability to perform *incremental classification*, which is very useful in the typical scenario of an unlimited sequence of operation data sets that represent different (n*ew*, unknown) *operation modes*. The flexibility and applicability of this scheme is shown in the paper on a real example for classification of five main operation modes of a hydraulic excavator.

2 The proposed unsupervised classification scheme

The Block-Diagram of the proposed scheme is shown in Fig. 1. This scheme is a further development of our previous idea for similarity analysis, discussed in [7].

The procedure starts with a small number of preliminary known *core operation modes* (core CIMs), which build the initial size of the Knowledge Base. During classification, the *difference (dissimilarity) degree* between the newly submitted (unknown) operation mode (as CIM) and all the core CIMs in the KB is computed. As a result, depending on a preliminary given *threshold Th* for classification, the new operation mode could be classified as *belonging* to a certain class (mode) from the KB or is regarded as a *quite different* (new) mode thus creating a *new class* in the KB. In such way, the proposed general concept for classification is incremental one, allowing the Knowledge Base to gradually grow, when a new operation mode with a very high dissimilarity degree to any of the core modes in the KB is discovered.

ISBN: 978-989-95079-6-8

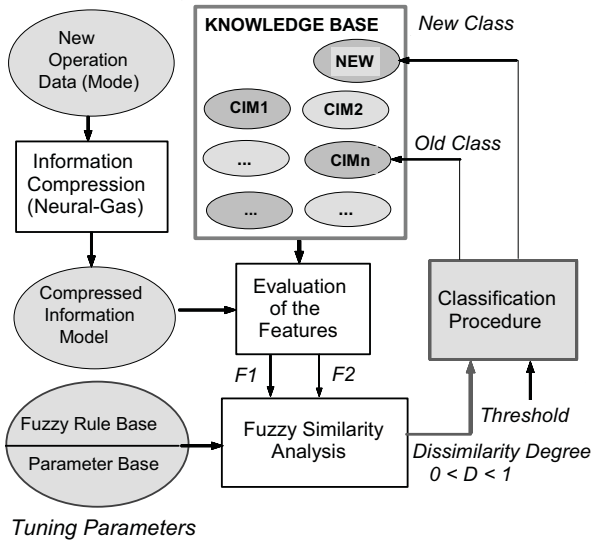

Figure 1: Block diagram of the proposed Online Classification Scheme based on fuzzy similarity analysis.

3 Unsupervised learning algorithm for information compression

The first step before the actual similarity analysis and classification of the operation modes is to find a way to reduce the large amount of the "raw data" information contained in the data set. Further on we refer to this computation step as *Information Compression*. From a computational viewpoint the information compression can be viewed as a kind of *transformation* of the original large data set: $\mathbf{x}_i = [x_{i1}, x_{i2}, ..., x_{iK}], i = 1,2,..., M$, consisting of *M* data in the *K*-dimensional input space into a respective *Neural Model* consisting of *N neurons* in the same space. Here $N << M$. and *CR = M/N* is the so called *Compression Ratio.*

The *information compression* of the original large data set (e.g. pixels or process data from sensors) can be perform by using different unsupervised competitive learning algorithms, such as clustering algorithms [1,2], Neural-Gas and its modifications [3,4,7], Support Vector Machines and Self-Organizing Maps [5,6] etc. All these algorithms try to find the most appropriate positions of the preliminary fixed number of *N* neurons (clusters) in the *K*-dimensional data space so that the resulting group of neurons resembles as much as possible the density distribution of the original data in the same space.

The essential part of any unsupervised learning algorithm is the so called *updating rule* for the neuron *centers* $\mathbf{c}_i, i = 1,2,...,N$ in the *K*-dimensional space. The algorithm updates the neuron centers iteratively with preliminary fixed number of iterations *T* (*t = 0,1,2,...,T*), as follows:

$$\mathbf{c}_i(t) = \mathbf{c}_i(t-1) + \Delta\mathbf{c}_i(t),\ i = 1,2,...,N. \qquad (1)$$

Here the computation of the update $\Delta\mathbf{c}_i(t)$ varies depending on the type of the unsupervised algorithm.

In this paper we use a modified version of the original *Neural-Gas* unsupervised learning algorithm, first presented in [3]. At every iteration the update is computed as:

$$\Delta\mathbf{c}_i(t) = R(t) H_s(t, r_i)\left[\mathbf{x}_s - \mathbf{c}_i(t-1)\right], \quad i = 1,2,...,N;\ s = 1,2,...,M \qquad (2)$$

Here $R(t),\ 0 \le R(t) \le 1,\ t = 0,1,2,...,T$ is a monotonically decreasing *Learning Rate,* which guarantees the convergence and stability of the learning process:

$$R(t) = R_0 \exp\left(-t/T_C\right),\ t = 0,1,...,T \qquad (3)$$

The so called *Neighborhood Function* in (2) $0 \le H_s(t, r_i) \le 1$ also decreases exponentially with the iterations. It computes the dynamically changing (decreasing) *activity area* for each neuron during the iterations, as follows:

$$H_s(t, r_i) = \exp\left[-(r_i - 1)/B(t)\right], \quad t = 0,1,...,T;\ s = 1,2,...,M;\ i = 1,2,...,N \qquad (4)$$

$$\text{where} \quad B(t) = \exp\left(-t/T_W\right),\ t = 0,1,...,T \qquad (5)$$

Here $r_i \in [1,2,...,N]$ is an integer number representing the so called *ranking position* of the *i*-th neuron (*i = 1,2,...,N*) to the *s*-th data point (*s = 1,2,...M*). This position is determined by the distance between the *i*-th neuron and the *s*-th data point. The closest neuron (in a sense of a minimal *Euclidean* distance) is called "winning neuron" and gets ranking position *r = 1*. The second closest neuron gets *r = 2* and so on. Example for information compression of a given data set by using the above algorithm is presented in the next Section.

4 Example of machine operation data for online classification and similarity analysis

The hydraulic excavator (HE) is a typical example of a complex machine. It is equipped with a turbo-diesel engine, which powers a special hydraulic system for performing different kinds of movements and working operations. HE normally works in a dynamical sequence of several repetitive *operation modes.* The following *five operation mode*s are typical for a normal long time operation of the excavator, when it does not move on the ground, as follows:

Mode 1. Loading the bucket with the raw material (sand, soil, stones etc);

Mode 2. Transporting the load in the bucket to the nearby truck by moving the arm (arrow) with the full bucket;

Mode 3. Unloading the bucket material into the truck;

Mode 4. Returning the arm with the empty bucket to the initial position for the next loading;

Mode 5. Short repetitive movements of the arm (*up* and *down*) for *pressing* the raw material in the truck;

All these modes differ from one to another in terms of the required engine power and the amount of the load in the bucket. Then the real practical problem is to properly *recognize* all these five operation *modes* and to *discover* possibly *new* ones (if any), by analyzing the available *online sequence* of data sets, each of them corresponding to *one operation mode*.

Such recognition and classification of the modes is important for detecting a slow trend of *deterioratio*n in the performance of the HE that needs appropriate maintenance or repair.

From an engineering viewpoint, the following six parameters are considered as important for the proper mode recognition, namely: *P1*- Engine Speed [*rpm*]; *P2* – Engine Boost Pressure; *P3* - Engine Oil Pressure; *P4* - Fuel Consumption; *P5* – Left Hydraulic Pump Pressure and *P6* – Right Hydraulic

ISBN: 978-989-95079-6-8

Pump Pressure. During the experiments, online measurements (at every second) were performed and the following Fig. 2 depicts the normalized data collected separately for each of the five typical operation modes.

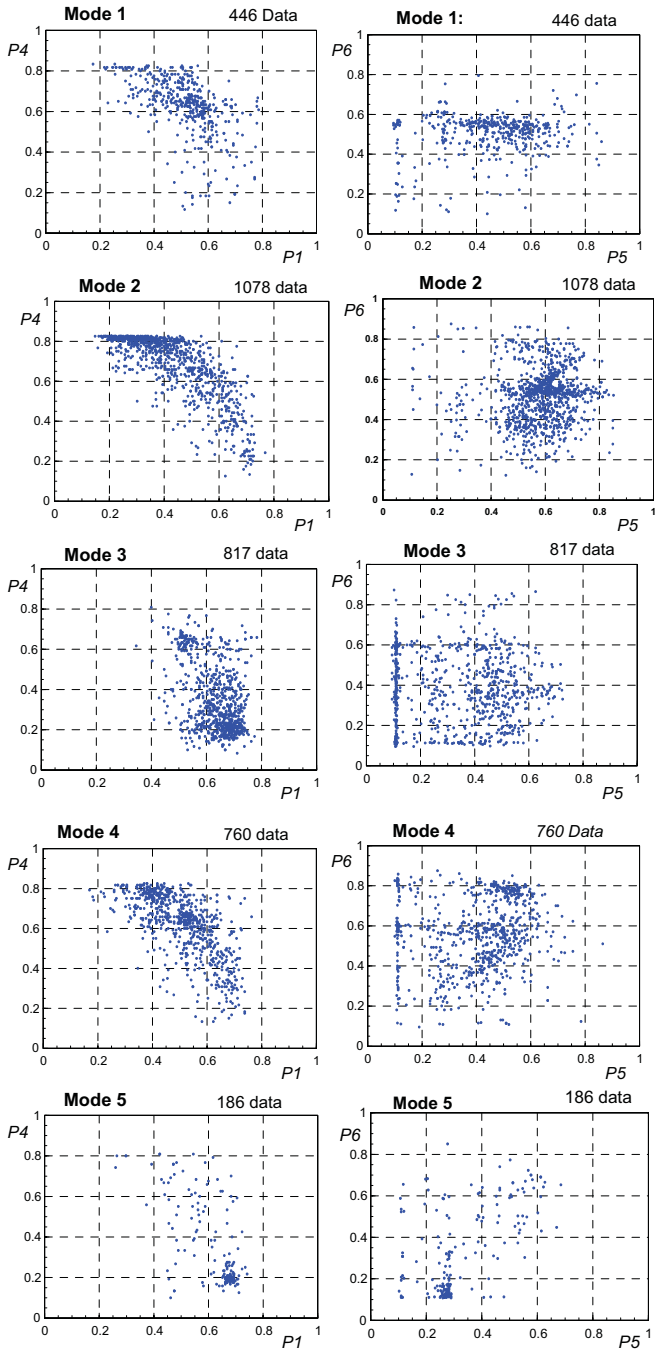

Figure 2: Plot of the normalized "raw data" representing all *5* operating modes of a hydraulic excavator.

As seen above, *two* different 2-dimensional plots are presented in Fig. 2, *P1-P4* and *P5-P6* respectively, for a better understanding of the complexity of the original *6*-dimensional problem.

Fig. 3. serves as illustration of the information compression of the "raw data" set, corresponding to operation *Mode 2*, by the Neural-Gas algorithm explained in Section 3. The following settings of the learning parameters for information compression have been used for all data sets from Fig. 2, as follows: $T = 500; R_0 = 0.16$ and $T_C = T_W = T/5$. The number of the neurons has been fixed to $N = 50$ in all simulations.

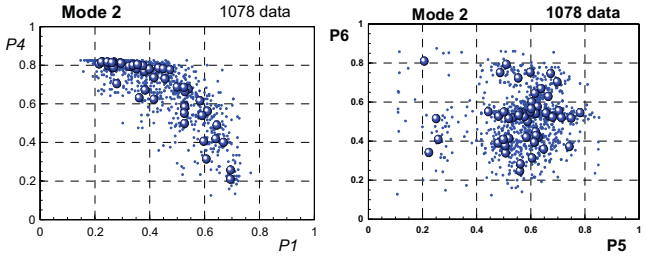

Figure 3: Results from the information compression of the "raw data" for operation *Mode 2* with $N = 50$ neurons.

5 Feature selection and computation for the fuzzy similarity analysis

As seen from Fig. 1 in Section 2, in order to evaluate the similarity between a given pair of operation modes, based on their compressed models (CIMs), we have to evaluate two important *features F1* and *F2* that characterize in an easy-to-understand numerical way the relation (similarity) between each pair of modes. For this purpose, we propose here to extract the following two distinct *parameters P1* and *P2* that characterize the *location* and the *size* of each operation mode in the *K*-dimensional input space. They are further called: *P1 - Center-of-Gravity* **CG** and *P2 - Weighted Average Size WAS* of the given operation mode.

1) The *Center-of-Gravity* $\mathbf{CG} = [CG_1, CG_2, ..., CG_K]$ of a *K*-dimensional operation mode is a *vector* that is computed directly from the respective CIM as follows:

$$CG_j = \sum_{i=1}^{N} c_{ij} g_i \Big/ \sum_{i=1}^{N} g_i, \; j = 1,2,...,K \qquad (6)$$

Here $c_{ij}, j = 1,2,...,K$ denotes the *center* (coordinates) of the *i*-th neuron in the *K*-dimensional input space and $0 < g_i \le 1, i = 1,2,...,N$ are the *normalized weights* of the neurons:

$$g_i = m_i / M; \; i = 1,2,...,N \qquad (7)$$

$m_i \le M, i = 1,2,...,N$ is the number of all data points: $\mathbf{x}_s, s = 1,2,...,m_i$, for which the *i*-th neuron is a *winning neuron* (i.e. the neuron with the shortest *Euclidean* distance to all of these data points). Obviously, the following equation holds: $\sum_{i=1}^{N} m_i = M$ and therefore $\sum_{i=1}^{N} g_i = 1$.

2) The *Weighted Average Size WAS* of the operation mode (and its respective CIM) is a *scalar* value, which takes into account the normalized weights of all neurons and the Euclidean distance ED_{pq} between all pairs of neurons, $\{p,q\}, p = 1,2,...,N; q = 1,2,...,N$, as shown in the next two equations (8) and (9):

$$WAS = \sum_{p=1}^{N-1} \sum_{q=p+1}^{N} ED_{pq} w_{pq} \Big/ \sum_{p=1}^{N-1} \sum_{q=p+1}^{N} w_{pq} \; . \qquad (8)$$

where $w_{pq} = g_p \times g_q, \quad p = 1,2,...,N; q = 1,2,...,N \qquad (9)$

Fig. 4 shows the locations of the centers-of-gravity **CG** for all *5* operation modes, computed by (6) and (7). It is seen from this figures that **CG** of some modes (such as: *Mode 1* and *Mode 4* and also *Mode 3* and *Mode 5*) are quite close to each

ISBN: 978-989-95079-6-8

other in the *K*-dimensional input space, which could result in a wrong classification.

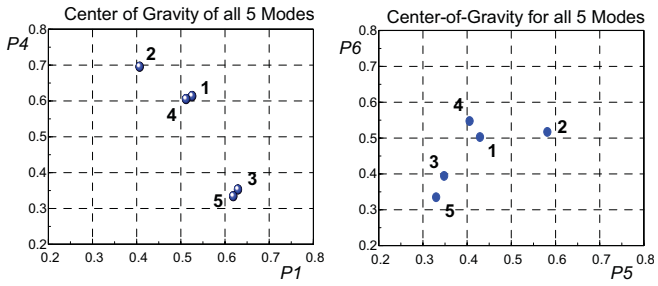

Figure 4:Center-of-Gravities **CG** for all *5* operation modes.

The following Table 1. shows the sizes *WAS* of all *5* Operation Modes, computed by (8) and (9). It also can be noticed here that some sizes are quite similar (such as *WAS* for *Mode 3* and *Mode 4*), which could also lead to wrong classification.

Table 1: Model Size *WAS* for all *5* operation modes.

Mode	Mode**1**	Mode**2**	Mode**3**	Mode**4**	Mode**5**
Model Size	*0.39538*	*0.38647*	*0.42592*	*0.42463*	*0.44486*

The above two parameters *P1* = **CG** and *P2* = *WAS* carry important information that can be used for selection of the two *features F1* and *F2* used as inputs of the Fuzzy Inference procedure for similarity analysis from Fig. 1.

We propose here an easy way to extract the features *F1* and *F2* as follows:

- The feature *F1* is a *scalar* value, computed as the *distance CGD* between the centers-of-gravities **CG** of a given pair $\{A,B\}$ of operation modes:

$$F1 = CGD_{AB} = \sqrt{\sum_{j=1}^{K} [CG_j^A - CG_j^B]^2} \qquad (10)$$

- Similarly the feature *F2* is a *scalar* value computed as the *difference WSD* between the weighted average sizes *WAS* of the same pair $\{A,B\}$ of operation modes, namely:

$$F2 = WSD_{AB} = |WAS_A - WAS_B| \qquad (11)$$

6 Structure of the block for fuzzy rule based similarity analysis

According to the block diagram shown in Fig. 1., we use the features *F1* and *F2*, computed by (10) and (11) as the inputs of the *Fuzzy Rule Based Inference Procedure* for similarity analysis of a given pair $\{A,B\}$ of operation modes.

Thus the Fuzzy Rule Based Procedure becomes a two-input / one output fuzzy system, as follows: $D = \mathbf{F}(F1,F2)$. Here $0.0 \le D \le 1.0$ is the *Difference Degree* (or *Dissimilarity Degree*). A difference degree $D = 0$ means that the operation modes *A* and *B* are *identical* (equal) and difference degree $D = 1$ means that *A* and *B* are *completely different modes*.

As well known [2], the fuzzy decision procedure consists of the following three main computation steps, as follows:

1) *Fuzzyfication* (with triangular Membership Functions);
2) *Fuzzy Inference* (with Product Operation) and
3) *Defiuzzification* (Weighted Mean Average).

For the next simulations in the paper, we assume *five triangular membership functions* that characterize linguistically the two inputs (features), namely *F1* and *F2*. They are used in the *fuzzification step* and have the following linguistic meaning: *VS = Very Small*; *SM = Small*; *MD = Medium*; *BG = Big* and *VB = Very Big*.

The Fuzzy Rule Base for the Fuzzy Inference procedure is shown in Fig. 5. It consists of *25* fuzzy rules, each of them with individual output as one of the *9 crisp* numerical values (*Singletons*): $U_1,U_2,...,U_9$, as seen in the figure. Note that the following inequality is required for achieving meaningful (plausible) results from the fuzzy similarity analysis:

$$U1 < U2 < ... < U9 \qquad (12)$$

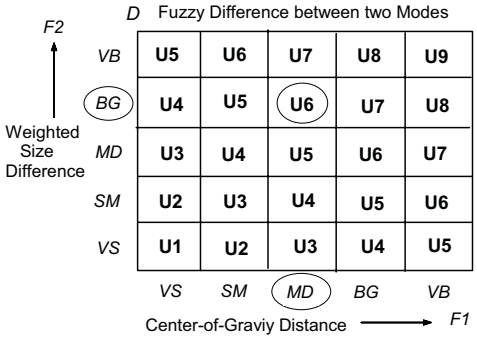

Figure 5: The Fuzzy Rule Base used for fuzzy similarity analysis.

The structure of the fuzzy rule base in Fig. 5 has been generated by using general *human logic and experience* from comparison and evaluation of data sets and other objects.

The well common weighted average method is used for the *Defuzzification* step, as follows:

$$D = \sum_{i=1}^{L} u_i v_i \Big/ \sum_{i=1}^{L} v_i \qquad (13)$$

Here $0 \le v_i \le 1, i=1,2,...,L$ is the *Firing* (*Activation*) *Degree* of the *i*-th fuzzy rule and $L = 25$ is the total number of the fuzzy rules. All rules have their individual crisp values (*Singletons*): $u_i \in [U_1,U_2,...,U_9], i=1,2,...,L$, according to the notations of the Fuzzy Rule Base in Fig. 5. For example, the *crisp* output of the Fuzzy Rule *No. 14* ($i = 14$), marked by circles in Fig. 5 is, as follows:

IF(*P1 is* MD AND *P2 is* BG) THEN $u_{14} = U6$

7 Optimization of the procedure for fuzzy similarity analysis

Once the structure of the Fuzzy Rule base is fixed, according to Fig. 5., then all the remaining parameters in the fuzzy inference procedure should be appropriately tuned. These are the parameters (*locations*) of the triangle membership functions and the *singletons* (consequents of the fuzzy rules). If successful optimization of these parameters is performed (according to a given optimization criterion), then we can expect correct (plausible) classification results.

There are two problems in connection with the optimization, namely: 1) construction of the *optimization criterion* with possible constraints and 2) selection of the *optimization method* (algorithm) to be used. As for the best selection of the

ISBN: 978-989-95079-6-8

optimization method, this is not a topic of interest in this paper, so we concentrate further on in the paper on the first problem, namely the selection of the optimization criterion.

We have collected *three groups* of data sets for all *5* operation modes of the hydraulic excavator, as well as *two* additional data sets representing two *different* (unknown) modes. One data set actually represents an *idling mode* of HE, while the other mode is not quite typical for the excavator (*moving* on the ground).

All the collected data sets have been first compressed into respective compressed information models (CIMs), according to the concept of the block diagram in Fig. 1. Then the respective CIMs have been split into the following *three* groups of models:

1) Five *training* models for each of the preliminary known operation modes, named as Mode**1**, Mode**2**,…,Mode**5**.

2) Five *test* models for the same group of five operation modes, named as: Test**1**, Test**2**, …, Test**5**;

3) A sequence of *16* operation models, used for *validation* of the classification procedure. These validation models are named as: Val**1**, Val**2**, Val**3**, …, Val**16** (or shortly: **1,2,…,16**). Then the sequence **1,2,…,16** is used to simulate the *Online Classification* process.

Table 2 shows the results from the similarity analysis between the *test modes* and the *training modes* for the initially assumed parameters (before optimization). The columns named as *Rank No.1* and *Rank No.2* refer to the *first* and *second* choice for classification (i.e the *least* difference and the *second least* difference). It is easy to notice the *contradiction* in this table arising at operation *Mode 5*. It is wrongly classified as *Mode 3* in this table.

Table 2: Similarity results before optimization.

	Training Modes: Mode **1** – Mode **5**			
Test	Rank **No.1**		Rank **No.2**	
Modes:	*No.*	*D*	*No.*	*D*
Test **1**	**1**	0.092	2	0.146
Test **2**	**2**	0.050	1	0.156
Test **3**	**3**	0.012	5	0.106
Test **4**	**4**	0.069	2	0.174
Test **5**	**3**	0.138	5	0.144

In order to correct this contradiction, we have to tune the parameters of the fuzzy inference procedure. It is done in this paper by assuming a special type of *optimization criterion,* which counts the *discrepancy DIS* between the human decision (or *human preference*) and the result from the computer-based classification. Table 3 shows example of one (plausible) human preference for classification of all *5* operation modes.

Table 3: Construction of the Optimization Criterion: *Preferred Human Decision*

Rank No. 1			**Rank No. 2**		
Test Mode	Train Mode	*D*	Test Mode	Train Mode	*D*
1	**1**	*0.10*	**1**	**4**	*0.20*
2	**2**	*0.10*	**2**	**1**	*0.20*
3	**3**	*0.10*	**3**	**5**	*0.20*
4	**4**	*0.10*	**4**	**1**	*0.20*
5	**5**	*0.10*	**5**	**3**	*0.20*

Now, by summing up the discrepancies between all *10* human preferences listed in Table 3 and the respective computer results from Table 2, we can compute the initial value of the optimization criterion as: *DIS = 0.5052.*

Further on we use a relatively simple (random search) optimization algorithm (further details omitted here) for a *two-stage* tuning of the fuzzy inference parameters:

- *Stage 1* optimizes the three intermediate locations (*SM, MD, BG*) of the membership functions for both inputs *F1* and *F2*, which means *3 + 3 = 6* optimization parameters;
- *Stage 2* optimizes the singleton values: $U_1,U_2,...,U_9$, taking into account the constraints (12).

The two stages were performed once in a consequence: *Stage1* → *Stage 2* with *30000* iteration steps for each stage. As a result the optimization criterion *DIS* was decrease to *0.3011* (after *Stage1*) and to *0.2983* (after *Stage2*). The final classification results are shown in Table 4. It is seen that all the classification results have become *correct* and with much closer degrees to the human preferences from Table 3.

Table 4: Similarity results after optimization.

	Training Modes Mode **1** – Mode **5**			
Test	Rank **No. 1**		Rank **No. 2**	
Modes:	*No.*	*D*	*No.*	*D*
Test **1**	**1**	0.123	2	0.169
Test **2**	**2**	0.096	1	0.192
Test **3**	**3**	0.016	5	0.168
Test **4**	**4**	0.114	2	0.208
Test **5**	**5**	0.141	3	0.189

The next three figures: Fig. 6., Fig. 7. and Fig. 8. are self explanatory. They show how the optimization has changed the parameters of the membership functions, the singletons and the Fuzzy Rule base response surface.

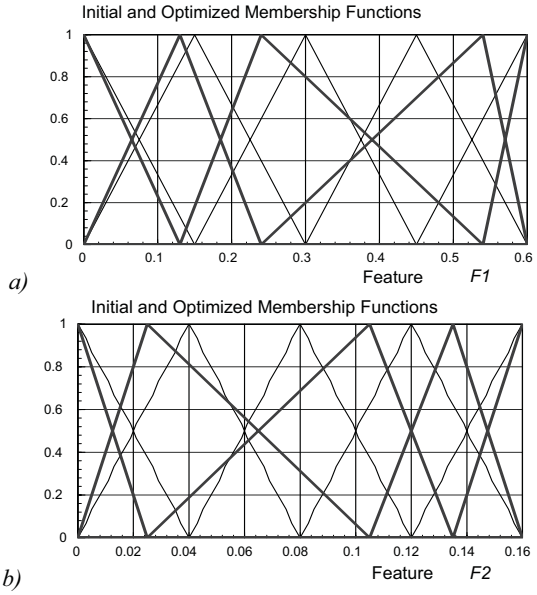

Figure 6: Results from the tuning of the membership functions. Bold lines denote the optimal positions.

8 Online classification results

After the fuzzy inference procedure has been tuned appropriately, then the whole *online classification* procedure has been tested on the sequence **1,2,…,16** of *16 validation* models Val**1**,Val**2**,…, Val**16**, according to the Block Diagram in Fig. 1. The results from the classification are shown in Fig. 9 and Fig. 10.

ISBN: 978-989-95079-6-8

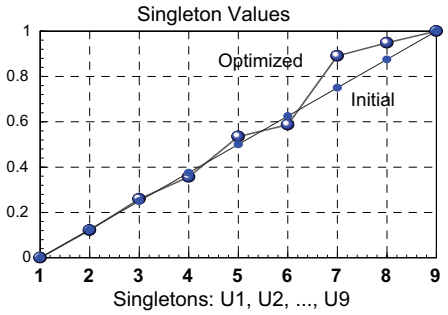

Figure 7: Results from the tuning of the singleton values.

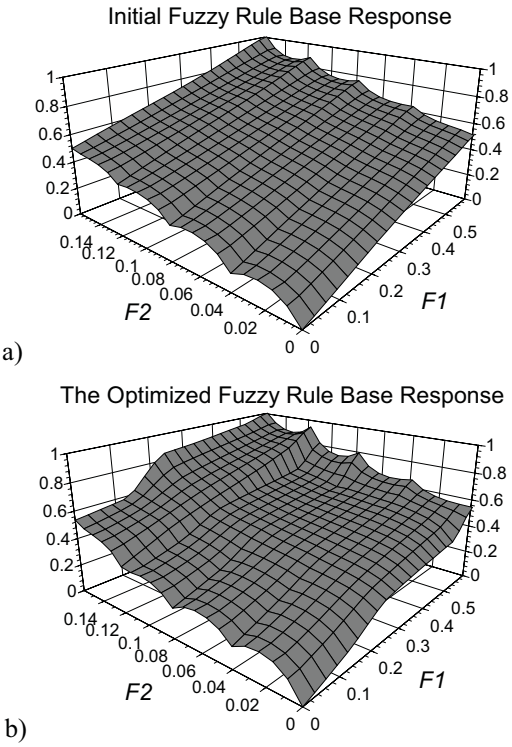

Figure 8: Response Surface of the fuzzy rule base: *a)* before optimization; *b)* after optimization.

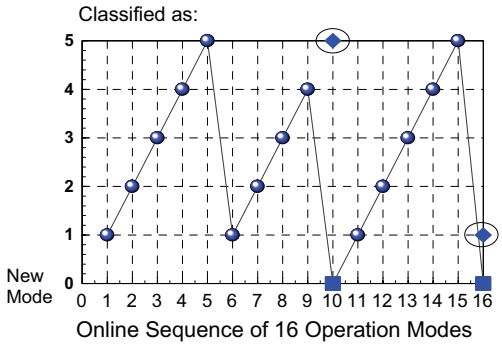

Figure 9: Classification Results for all *16* validation modes 1,2,…,16, presented as online sequence.

The "ball" symbols in Fig. 9. correspond to the correct classified modes. The two "diamond" symbols for operations *10* and *16* represent the computer classification results, while the respective two "square" symbols represent the actual "new" (unknown) operation modes.

It is seen from the similarity results in Fig. 9 that the operation sequences *10* and *16* were classified as *Mode 5* and *Mode 1* respectively. However, this decision was later *rejected,* as shown in Fig. 10, because their dissimilarity degrees exceed the predetermined threshold: *Th = 0.25*.

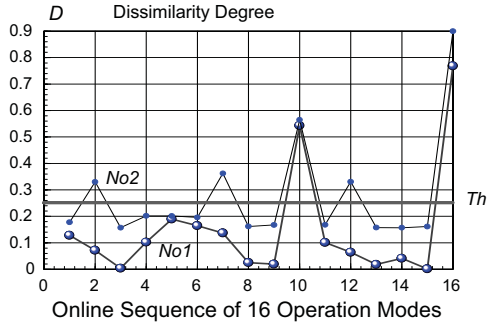

Figure 10: Confirmation results from the online classification with the predetermined threshold *Th = 0.25*.

Therefore finally the two operations *10* and *16* are assumed to correspond to *new* (*unknown*) operation modes. This result reflects the real situation.

9 Conclusions

The *Onine* classification of operation modes in continuously working machines and systems proposed in this paper uses fuzzy inference for similarity analysis. It is also suitable for possible applications in other areas of interest, such as search engines, classification and similarity analysis of images etc.

Essential feature of the whole proposed computation scheme is its *incremental* ability, in a sense that the newly detected modes could be added as new members of the current Knowledge Base and further on used for online classification.

The main originality of the proposed classification scheme is that it is a *human-assisted* classification, in which human experience and preference is taken into account and included into the optimization criterion. This criterion is further on used for tuning the parameters of the membership functions and the singletons in the fuzzy inference procedure so that to achieve the best possible matching between the computer results and human preferences.

There are several directions to improve the current status of this research. One is to investigate other optimization criterions and to select good, effective optimization method. Another direction is to solve the problem of *ever-growing* Knowledge Base during long time operation, by appropriate *pruning* and *merging* the modes in KB. In such way the whole classification system would become more flexible, *evolving classification* system.

Introducing Relation Compactness for Generating a Flexible Size of Search Results in Fuzzy Queries

Xiaohui Tang Guoqing Chen Qiang Wei

School of Economics and Management, Tsinghua University
Beijing 100084, China
Email: weiq@sem.tsinghua.edu.cn

Abstract-*Generating relevant and manageable search results is of great interest in database queries and information retrieval nowadays. This paper proposes an approach to measuring relation compactness and to generating a compact set of query outcomes under a fuzzy relational data model. The approach has desirable properties that (1) the resultant compact set is unique and contains mutually distinct tuples at the specified degree, and (2) the resultant compact set is information-equivalent to the collection of original query outcomes. Moreover, it is deemed appealing that the approach provides a way to obtain query outcomes of different size in a flexible manner according to the specified degree of compactness or the preferred number of tuples by users.*

Keywords—Tuple closeness, Fuzzy databases and queries, Relation compactness, Information equivalence, Web search

1 Introduction

The commonly used database model nowadays is the relational database (*RDB*) model initiated by Codd [1] which is generally designed under the assumption that the data/information is precise and queries are crisp. However, decision makers often face a growing need for representing and processing imprecise and uncertain information. Particularly in a web environment, approximate match is often preferred in generating search outcomes when exact match is unable to produce satisfactory results from targeted databases.

Since 1980's, a number of fuzzy relational database (*FRDB*) models and fuzzy query techniques [2-6] have been proposed to deal with imprecision and uncertainty of fuzziness type by means of fuzzy logic [7]. For instance, with the data stored in classical *RDB*, Kacprzyk and Zadrozny [8] proposed a system called *FQUERY* that could execute fuzzy queries such as "find (all) records such that most of the (important) clauses are satisfied (to a degree in [0, 1])" for crisp data stored in the Microsoft Access DBMS. In [9], a method to transform query conditions described by fuzzy numbers into the classical *SQL* queries was presented. In [10], the authors extended the *SQL* queries into *SQLf* to allow the expression of imprecise queries. Furthermore, a method was developed to transform the *FRDB* into weighted *RDB* in that a nesting mechanism was introduced to support the expression of some query results such as projection-selection-join operations [11]. In [12-13], we extended basic algebraic operators to deal with fuzzy data modeling and queries in forms of database design as well as equivalent definitions and transformation rules of the algebraic operators.

Notably, when querying databases with data of high volume, the size of the outcomes can easily be very large, even massive in a web database search context. For instance, a fuzzy query such as "*Select* Customer Name *From R Where* Age is about 25 AND Location is near B" requires an approximate match between query conditions and values of corresponding attributes. Another example is a web search, say via Google. Just click and see how many pages of outcomes to appear when keying in *"Population of Beijing"* for an exact match and *Population of Beijing* (notably without quotation marks) for an approximate match. Efforts have been made to deal with queries and web search with imprecise information and approximate match measures, so as to enrich the representation semantics and strengthen the power of search engines [5, 14-16]. Generally speaking, approximate match provides flexible queries, which is considered meaningful and useful in many cases, whereas the size of its outcomes is usually larger than that of the exact match.

Hence, the size of query outcomes becomes an issue of concern. One notable approach was to provide the users with the top-*k* results according to a ranking based on a certain evaluation function *F* between query conditions and all data records [17-18]. While sometimes the top-*k* results are sufficient for fuzzy/soft queries with approximate match, it is desirable and meaningful if a query/search could also guarantee that the selected results have no information loss as far as all the query results are concerned. The focus of this paper is then to provide the users with a compact set of query outcomes, in that the compact set (a) is smaller than and information-equivalent to the set of all query outcomes, and (b) at the same time has its size flexibly specified by users upon their need and preference.

2 Fuzzy Relational Database Model

Fuzzy logic incepted by Zadeh [7] attempts at quantifying and reasoning with imprecision and uncertainty that is common in the real world. Possibility distributions provide a graded semantics to natural language statements such as "the customer is young", which are often used in our daily communications. For example, the linguistic term "Young" can be defined as

$$\pi_{Young}(age) = \begin{cases} 1 & 0 \le age \le 30 \\ (50 - age)/20 & 30 < age \le 50 \\ 0 & age > 50 \end{cases} \quad (1)$$

ISBN: 978-989-95079-6-8

Two specific fuzzy relations are of particular interest, namely, closeness relation and similarity relation. A closeness relation c is a fuzzy relation on $X\times X$ such that $\forall x, y\in X$, $c(x, x) = 1$ (reflexive) and $c(x, y) = c(y, x)$ (symmetric). A similarity relation s is a fuzzy relation on $X\times X$ such that $\forall x, y, z\in X$, $s(x, x) =1$ (reflexive), $s(x, y) = s(y, x)$ (symmetric), and $s(x, z) \geq \sup_{y\in X} \min(s(x, y), s(y, z))$ (sup-min transitive). Apparently, similarity relation is a special case of closeness relation.

In this paper, the extended-possibility-based model is considered to be the underlying fuzzy database model since it facilitates handling both imprecision in attribute values (e.g., Age is young) and fuzziness in domain elements (e.g., between classic and gold for the domain of (customer) Class) in terms of possibility distributions (including fuzzy sets and linguistic terms) and closeness relations, respectively [4, 19]. In light of data representation, this model is deemed to be a general setting compared with two known models, namely, the so-called possibility-based model [4] where attribute values can be possibility distributions, and the so-called similarity-based model [3] where domain elements can be associated by similarity relations (reflective, symmetric and sup-min transitive). Specifically, in the extended-possibility-based model, a relation R is a subset of $\Pi(D_1) \times \Pi(D_2) \times \ldots \times \Pi(D_g)$, where $\Pi(D_i) =\{\pi_{Ai} \mid \pi_{Ai}$ is a possibility distribution of attribute A_i on domain $D_i\}$, and a closeness relation c_i is associated with domain D_i ($1 \leq i \leq g$). In addition, an g-tuple t of R is of the form: $t(\pi_{A1}, \pi_{A2}, \ldots, \pi_{Ag})$. An example tuple recording a customer's Name, Age and Class can be (Tony, {0.7/28, 1.0/33, 0.8/36}, diamond). The closeness relation c_{Class} on domain D_{Class}={classic, silver, gold, diamond} can be pre-defined by the managers as shown in Table 1.

Table 1: A closeness relation c_{Class}

c_{Class}	classic	silver	gold	diamond
classic	1.0	0.5	0.0	0.0
silver		1.0	0.75	0.25
gold			1.0	0.75
diamond				1.0

Given two g-tuples $t_p(\pi_{A1}, \pi_{A2}, \ldots, \pi_{Ag})$, $t_q(\pi'_{A1}, \pi'_{A2}, \ldots, \pi'_{Ag})$, where π_{Ai} and π'_{Ai} are normalized ($1 \leq i \leq g$), an example measure for the closeness of two values is [22]:

$$E_c(\pi_{A_i}, \pi'_{A_i}) = \sup_{\substack{x,y\in D_i \\ c_i(x,y)\geq\alpha_i}} \min(\pi_{A_i}(x), \pi'_{A_i}(y)) \qquad (2)$$

Here c_i is a closeness relation on domain D_i, $\alpha_i \in [0, 1]$ is a threshold specified by experts or the database managers. Other measures can be found in [19-21]. Then, the closeness of two tuples t_p and t_q can be considered as:

$$F_c(t_p, t_q) = \min(E_c(\pi_{A_1}, \pi'_{A_1}), E_c(\pi_{A_2}, \pi'_{A_2}), \ldots, E_c(\pi_{A_g}, \pi'_{A_g})) \qquad (3)$$

3 Tuple Extraction

Regarding tuple extraction in fuzzy relational databases, there are two issues to consider. One is to evaluate tuple closeness, the other is to extract representative tuples.

3.1 The evaluation of tuple closeness

For the fuzzy database, given an attribute A with domain D, let $\pi_1, \pi_2, \ldots, \pi_n$ be n possibility distributions as values of A, then a closeness relation on $\Pi(D)\times\Pi(D)$ is a mapping from $\Pi(D)\times\Pi(D)$ to [0,1], which can be represented by an $n\times n$ fuzzy matrix M where $e_{ij} = E_c(\pi_i, \pi_j)$, $1\leq i, j \leq n$, as follows:

$$M = \begin{pmatrix} e_{11} & e_{12} & \ldots & e_{1n} \\ e_{21} & e_{22} & \ldots & e_{2n} \\ \ldots & \ldots & \ldots & \ldots \\ e_{l1} & e_{l2} & \ldots & e_{nn} \end{pmatrix} \qquad (4)$$

Further, for $0 \leq \lambda \leq 1$, where λ is a threshold which is usually determined by users or domain experts, its λ-cut (M_λ) is a classical relation defined by:

$$(e_{ij})_\lambda = \begin{cases} 1 & e_{ij} \geq \lambda \\ 0 & e_{ij} < \lambda \end{cases} \qquad (5)$$

Moreover, it is known that if M is a closeness relation, then its transitive closure M^+ (i.e., M^+ is a series of max-min compositions onto M itself with $M^+ = M^p = M^{p+1}$, $p\geq 1$) is a similarity relation, and M^+ converges within n-1 compositions [23-25]:

$$M^+ = M^p, \ p \leq l - 1 \qquad (6)$$

Furthermore, the equivalence classes of $(M^+)_\lambda$ constitute a partition of the domain concerned [26].

Definition 1: Given a relation $R = \{t_1, t_2, \ldots, t_n\} \subseteq \Pi(D_1) \times \Pi(D_2) \times\ldots\times\Pi(D_g)$, where tuple t_i is $t_i(\pi_{i1}, \pi_{i2}, \ldots, \pi_{ig})$, and threshold $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \ldots, \lambda_g)$ with equivalence classes of $(M^+)_{\lambda i}$, $i = 1, 2, \ldots, n$, then two tuples $t_i(\pi_{i1}, \pi_{i2}, \ldots, \pi_{ig})$ and $t_j(\pi_{j1}, \pi_{j2}, \ldots, \pi_{jg})$ are called $\boldsymbol{\lambda}$-close if for all $k \in \{1, 2, \ldots, g\}$, π_{ik} and π_{jk} are in the same equivalence class. □

Example 1: Given threshold $\boldsymbol{\lambda} = (0.7, 0.8)$ and a relation $S \subseteq \Pi(D_1) \times \Pi(D_2)$ as shown in Table 2. For the sake of simplicity, assume that a_1, a_2, a_3, and a_4 are mutually distinct; so are b_1, b_2, b_3 and b_4. Then the $\boldsymbol{\lambda}$-close tuples can be generated as follows.

Table 2: A relation S with fuzziness

	A_1	A_2
t_1	$0.3/a_1, 0.7/a_2, 0.7/a_3, 0.7/a_4$	$0.53/b_1, 0.59/b_2, 0.62/b_3, 0.85/b_4$
t_2	$0.6/a_1, 0.4/a_2, 0.1/a_3, 0.8/a_4$	$0.92/b_1, 0.67/b_2, 0.09/b_3, 0.06/b_4$
t_3	$0.2/a_1, 0.6/a_2, 0.1/a_3, 1.0/a_4$	$0.45/b_1, 0.75/b_2, 0.06/b_3, 0.75/b_4$
t_4	$0.5/a_1, 0.1/a_2, 1.0/a_3, 0.9/a_4$	$0.61/b_1, 0.66/b_2, 0.35/b_3, 0.69/b_4$
t_5	$0.9/a_1, 0.6/a_2, 0.2/a_3, 0.2/a_4$	$0.56/b_1, 0.32/b_2, 0.98/b_3, 0.30/b_4$
t_6	$0.4/a_1, 0.2/a_2, 0.2/a_3, 0.4/a_4$	$0.81/b_1, 0.30/b_2, 0.93/b_3, 0.99/b_4$

First, for A_1 we can have:

$$M = \begin{pmatrix} 1 & 0.7 & 0.7 & 0.7 & 0.6 & 0.4 \\ 0.7 & 1 & 0.8 & 0.8 & 0.6 & 0.4 \\ 0.7 & 0.8 & 1 & 0.9 & 0.6 & 0.4 \\ 0.7 & 0.8 & 0.9 & 1 & 0.5 & 0.4 \\ 0.6 & 0.6 & 0.6 & 0.5 & 1 & 0.4 \\ 0.4 & 0.4 & 0.4 & 0.4 & 0.4 & 1 \end{pmatrix},$$

where each element on (i, j) in the matrix represents the closeness of t_i and t_j on A_1. Then, with $(M^+=M^3=M^2)_{0.7}$, three equivalence classes are obtained: $\{\pi_{11}, \pi_{21}, \pi_{31}, \pi_{41}\}$, $\{\pi_{51}\}$ and $\{\pi_{61}\}$. Consider attribute A_2, in the similar manner, there are three equivalence classes: $\{\pi_{12}, \pi_{22}, \pi_{52}, \pi_{62}\}$, $\{\pi_{32}\}$ and $\{\pi_{42}\}$.

ISBN: 978-989-95079-6-8

That means that values of t_1 and t_2 are in the same class for A_1 (i.e., π_{11}, π_{21}) as well as for A_2 (i.e., π_{12}, π_{22}), indicating that t_1 and t_2 are λ-close.

Finally, it is worthwhile to mention that, in case there are closeness relations on domains, the calculation of M can be readily made in consideration of c_i and α_i in E_c. For instance, suppose we have $c_1 = c_{\text{Class}}$ for A_1 with a_1 = classic, a_2 = silver, a_3 = gold and a_4 = diamond as shown in Table 1. Given α_1 = 0.7, since $c_1(a_2, a_3) = c_1(a_3, a_4) = 0.75$, we have $e'_{45} = 0.6 \neq e_{45} = 0.5$. In general, $M \subseteq M'$. □

3.2 Relation compactness

In addition to closeness of any two tuples, it is of interest to investigate the compactness of a given relation R composed of n tuples in the fuzzy relational database. Here the compactness of a relation refers to the degree of non-redundancy. For a given relation, the more redundant tuples it contains, the lower the degree of compactness. Straightforward ways of evaluating the compactness are to use the minimum closeness of any two tuples of R (*e.g.,* $1 - \min_{t,t' \in R} F_c(t, t')$) or the average closeness of any two tuples of R(*e.g.,* $1 - \sum_{t,t' \in R} F_c(t, t')/n(n-1)$) to reflect the compactness of R in whole. But it shall be noted that neither $1 - \min_{t,t' \in R} F_c(t, t')$ nor $1 - \sum_{t,t' \in R} Fc(t, t')/n(n-1)$ could describe the compactness of R in a satisfactory fashion. For example, suppose that all the n tuples in R are classical tuples for the sake of simplicity, i.e., for any $t, t' \in R$, $F_c(t, t') = 1$ or $F_c(t, t') = 0$. If there are $(n-1)$ tuples which are identical, only one tuple is not identical to them, then $1 - \min_{t,t' \in R} F_c(t, t') = 1$. But we know that there are a lot of tuples whose closeness degrees to each other are 1 in such a situation. On the other hand, if half of the tuples are identical to each other, and the other half of the tuples are also identical to each other (but different from the first half), then, $1 - \sum_{t, t' \in R} Fc(t, t')/n(n-1) = 2 \times (n/2) \times (n/2 - 1)/n(n-1) = 0.5 + 1/(2n - 2) > 0.5$. But in this situation, if n is large enough, e.g., $n = 100$, we will surely think that the compactness degree of R will be very close to 0, as 98% of the tuples can be deleted. Thus, a new measure, relation compactness, is proposed to evaluate a given relation R being compact. This measure not only works well in both of the above situations, but also possesses some good properties. Let us first consider it in classical relations, and then extend it into the relations in fuzzy databases.

In information theory [27], consider a single discrete information source, it may produce different kinds of symbol sets $A = \{a_1, a_2, \ldots, a_n\}$. For each possible symbol set A there will be a set of probabilities *pi* of producing the various possible symbols a_i ($\sum_{i=1}^{n} p_i = 1$), where these symbols are assumed successive and independent. Thus there is an entropy *Hi* for each a_i. The entropy of this given piece of information will be defined as the average of these H_i weighted in accordance with the probability of occurrence of the symbols in question,

$$H = H(p_1, p_2, \ldots, p_n) = -\sum_{i}^{n} p_i H_i = -\sum_{i}^{n} p_i \log p_i \qquad (7)$$

where the default log base is 2.

Similarly to [28], if there is a relation S with a set of classical tuples, which can be divided into m classes $C_1, C_2, \ldots, C_m$, the probability of a random tuple belonging to class C_i is n_i/n, where n_i is the number of tuples in C_i, and n is the number of tuples in S. Here, n_i/n is also called the probability of class C_i in S. The expected information for classifying this given relation S is:

$$H(n_1, n_2, \ldots, n_m) = -\sum_{i=1}^{m} p_i H_i = -\sum_{i=`}^{m} \frac{n_i}{n} \log \frac{n_i}{n} \qquad (8)$$

Definition 2: Let $R = \{t_1, t_2, \ldots, t_n\}$ be a classical relation with n tuples, R be divided into m classes $C_1, C_2, \ldots, C_m$ according to tuple identity (i.e., every tuple in C_i is identical to each other), and n_i be the number of tuples in C_i. Then the relation compactness of R is defined as

$$RC'(n_1, n_2, \ldots, n_m) = H(n_1, n_2, \ldots, n_m)/\log n$$
$$= -(\sum_{i=1}^{m} p_i H_i)/\log n = -(\sum_{i=1}^{m} \frac{n_i}{n} \log \frac{n_i}{n})/\log n \qquad (9)$$

For a relation R, its degree of compactness (RC') reflects the extent to which the tuples of R are not redundant, measured by the "amount of information" in R. In other words, the higher RC' is, the less redundant the tuples in R, meaning that the more information R contains.

Next, let us consider the fuzzy extension. Suppose there are n tuples with fuzziness involved in $R = \{t_1, t_2, \ldots, t_n\}$, where these tuples can be close to each other. To describe the degree at which a given relation with fuzziness is compact, the concept of relation compactness in the classical context could be extended to cope with the closeness of these tuples. A tuple t_k may not totally belong to class C_i, but belong to class C_i at a certain degree, e.g., $O_k^i \in [0, 1]$. Thus, we will use $\sum_{k=1}^{n_i} O_k^i$ instead of n_i in the extended relation compactness. Concretely, suppose we have n_i λ-close tuples in class $C_i = \{t_1, t_2, \ldots, t_{ni}\}$ of relation R. For each tuple t_k, $1 \le k \le n_i$, the degree of t_k belonging to C_i (or the closeness of t_k to C_i) can be defined as:

$$O_k^i = \sum_{j=1}^{n_i} F_c(t_k, t_j)/n_i \qquad (10)$$

Definition 3: Given a relation with fuzziness $R = \{t_1, t_2, \ldots, t_n\}$, where R can be divided into m classes $C_1, C_2, \ldots, C_m$ according to λ-close (i.e., every tuple in C_i is λ-close to each other), and n_i is the number of tuples in C_i. The relation compactness in R is,

$$RC(n'_1, n'_2, \ldots, n'_m) = -(\sum_{i=1}^{m} \frac{n'_i}{n} \log \frac{n'_i}{n})/\log n \qquad (11)$$

where $C_i = \{t_1, t_2, \ldots, t_{ni}\}$, $1 \le i \le m$, $1 < n_i \le n$, O_k^i is the degree of t_k belonging to C_i, and $n'_i = \sum_{k=1}^{n_i} O_k^i$ is the Σcount operation for the "effective number" of tuples in class C_i. □

As the classical relation is a special case of a relation with fuzziness, if all the tuples in $C_i = \{t_1, t_2, \ldots, t_{ni}\}$ are classical tuples, then they are equal to each other, i.e., $F_c(t_k, t_j) = 1$, $O_k^i = 1$, and $n'_i = n_i$ ($1 \le j, k \le n_i$). So $RC'(n_1, n_2, \ldots, n_m)$ is a special case of $RC(n'_1, n'_2, \ldots, n'_m)$. Note that one may also use some

ISBN: 978-989-95079-6-8

other measures (e.g., [19]) instead of O_k^i for the degree at which t_k belongs to C_i in (10). For *RC* in the fuzzy database context, the following proposition holds.

Proposition 1: Give a relation $R = \{t_1, t_2, ..., t_n\} \subseteq \Pi(D_1) \times \Pi(D_2) \times \ldots \times \Pi(D_g)$, where it is divided into m classes $C_1, C_2, ..., C_m$ according to $\boldsymbol{\lambda}$-close, $\boldsymbol{\lambda} = \{\lambda_1, \lambda_2, ..., \lambda_g\}$, and n_i is the number of tuples in C_i $(1 \le i \le m)$, then

(1) R is not $\boldsymbol{\lambda}$-close, i.e., $m = n$, $n'_1 = n'_2 = ... = n'_m = 1$, if and only if $RC(n'_1, n'_2, ..., n'_m) = 1$.

(2) Suppose $\min_{i=1}^{g} \lambda_i \ge e^{-1} \approx 0.37$, if R is totally $\boldsymbol{\lambda}$-close, i.e., $m = 1$, $n'_1 = n$, then $RC(n'_1)$ decreases when any two of the tuples's closeness $F_c(t_k, t_j)$ increases $(1 \le k, j \le n)$. Especially, if $\boldsymbol{\lambda} = \mathbf{1}$, then $RC(n'_1) = RC'(n_1) = 0$.

(3) $0 \le RC(n'_1, n'_2, ..., n'_m) \le 1$.

(4) Suppose $(n'_p + n'_q)/n \le e^{-1} \approx 0.37$, if n is fixed, $\boldsymbol{\lambda} = \{\lambda_1, \lambda_2, ..., \lambda_g\}$, $\lambda_i = \lambda$, $i = 1, 2, ..., g$, then *RC* decreases when any two of the original classes (e.g., C_p, C_q) are merged into one class C'_p according to $\boldsymbol{\lambda}$-close.

For different n and m, the value of *RC* is different. If $m = 2$, then $RC = -((n'_1/n)\log(n'_1/n) + ((n-n'_1)/n)\log((n-n'_1)/n))/\log n$, with different n, *RC* is shown in Figure 1. If $m = 3$, then $RC = -((n'_1/n)\log(n'_1/n) + (n'_2/n)\log(n'_2/n) + ((n-n'_1-n'_2)/n)\log((n-n'_1-n'_2)/n))/\log n$, with $n = 100$, *RC* is shown in Figure 2. Figures 1 and 2 reflect that RC has a characteristic of convexity.

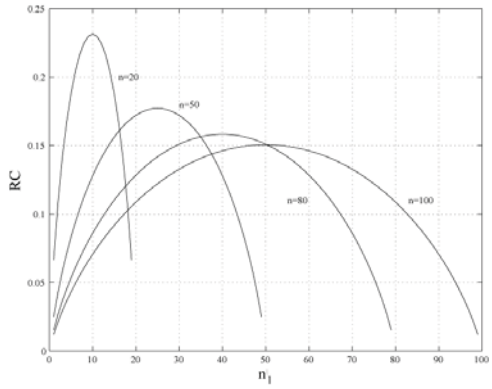

Figure 1: The value of *RC* ($m = 2$)

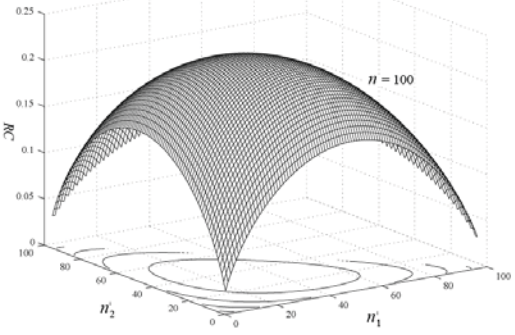

Figure 2: The value of *RC* ($m = 3$; $n = 100$)

3.3 Extraction of representative tuples

When it is known which tuples in a relation with fuzziness are $\boldsymbol{\lambda}$-close, then how to extract the representative tuples is the next problem of concern. It is considered ideal to have fewer tuples if they carry the same amount of original information. Usually, due to existence of tuple closeness, obtaining a smaller set of query outcomes becomes an effort of extracting representative tuples in light of "information equivalence".

Here we consider a center-based method for extracting the representative tuples. Conceptually, all the tuples in a same equivalence class are regarded to express approximately the same information and therefore one of them could be extracted to represent the class. Suppose we have n_i $\boldsymbol{\lambda}$-close tuples in class $C_i = \{t_1, t_2, ..., t_{ni}\}$ of a relation R. Then, we will keep the tuple whose closeness to C_i is the highest. This means, tuple t_p will be kept if $O_p^i = \max_{k=1}^{n_i} O_k^i$, $1 \le p \le n_i$.

Theorem 1: Suppose there are h $\boldsymbol{\lambda}$-close tuples in class $C = \{t_1, t_2, ..., t_h\}$ of a relation R, $C_i = C - \{t_i\}$, $1 \le i \le h$, and the relation compactness of C and C_i are *RC* and RC_i respectively. Then, tuple t_p $(1 \le p \le h)$ will be retained if and only if $RC_p = \max_{i=1}^{h} RC_i$.

Theorem 1 indicates that we can extract the representative tuples in light of relation compactness. It will keep the tuple that, without this tuple, the relation compactness of the other tuples will be the highest.

Example 2: Suppose we have had the $\boldsymbol{\lambda}$-close tuples of a fuzzy query about customers' age and salary as shown in Table 3.

Table 3: Customer's age and salary (in part)

	Age	Salary($)
t_1	0.6/25, 0.9/35, 0.6/40	0.8/4000, 0.9/5000, 0.8/6000
t_2	0.7/28, 0.8/35, 0.7/42	0.7/4500, 0.8/5000, 0.7/6000
t_3	0.6/25, 0.9/35, 0.8/42	0.9/4000, 0.7/5000, 0.6/6000

According to (2): $e_{12}(\pi_{11}, \pi_{21}) = 0.8$, $e_{13}(\pi_{11}, \pi_{31}) = 0.9$, $e_{23}(\pi_{21}, \pi_{31}) = 0.8$; $e_{12}(\pi_{12}, \pi_{22}) = 0.8$, $e_{13}(\pi_{12}, \pi_{32}) = 0.8$, $e_{23}(\pi_{22}, \pi_{32}) = 0.7$. Then, according to (3) and (10): $F_c(t_1, t_2) = 0.8$, $F_c(t_1, t_3) = 0.8$, $F_c(t_2, t_3) = 0.7$, $F_c(t_1, t_1) = F_c(t_2, t_2) = F_c(t_3, t_3) = 1$. $O_1 = 0.87$, $O_2 = 0.83$, $O_3 = 0.83$. Thus, t_2 and t_3 will be eliminated, t_1 will be kept.

Also, from the viewpoint of relation compactness, Table 3 can be considered as a class C, so, $C_1 = \{t_2, t_3\}$, $C_2 = \{t_1, t_3\}$, $C_3 = \{t_1, t_2\}$. For RC_1, $n'_1 = (F_c(t_2, t_2) + F_c(t_2, t_3))=2 + (F_c(t_3, t_3) + F_c(t_2, t_3))/2 = 1.7$. $RC_1 = -(1.7/2)\log(1.7/2)/\log 2 = 0.20$. In the same way, $RC_2 = RC_3 = 0.14$, thus, t_1 will be kept.

As far as the complexity of the tuple extraction is concerned, while introducing possibility distributions enriches the semantics that the data model represents, approximate match may lead to an increase in computational complexity. Further analysis shows that the complexity is polynomial and generally manageable. Suppose there are n tuples in relation R, the matrix M has $n \times n$ entries. For every entry, suppose there are, on average, p values in the two imprecise attribute values to compare, the cost is $O(p^2)$. The total cost to get M is then $O(p^2n^2)$. A reasonable estimate of p could be within 10. Therefore, the total cost to get M could be simplified to be $O(ln^2)$ where $l < 100$. For the transitive closure of M, the total cost is at $O(n^2)$ level for large n [24-25].

Furthermore, in consideration of generating matrix M, though detailed treatments go beyond the scope of this paper, there

ISBN: 978-989-95079-6-8

have been effective approaches in database queries, informational retrieval and web search, using a variety of measures, in respective fields, for keyword similarity, text match, semantic proximity, etc., in order to compare pair-wise closeness of data/information of interest (e.g., [30-34]).

4 Further Discussions

First, whether the extraction result is unique and representative tuples are not redundant is an interesting and important issue. Importantly, it can be proven that the result of the tuple extraction treatment in Section 3 is unique, and the resulting new relation is not $\boldsymbol{\lambda}$-close.

Second, we can also have the number of tuples in the outcome to be controlled by the setting of $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, ..., \lambda_g)$. When λ_i increases, there will be more classes, thus, after the extraction, more tuples will be kept. Especially, with $\lambda_i = 1$, the treatment turns into the classical situation, in that no tuples will be eliminated.

Third, two representations are information equivalent if the transformation from one to the other entails no loss of information, i.e., if each can be constructed from the other [35]. In other words, the information in one is also inferable from the other, and vice versa [36-37]. Here, "information equivalence" in our discussions could be described as follows. Suppose there is an original query result R_1. The classified relation is R_2 (i.e., the $\boldsymbol{\lambda}$-close tuples are in the same classes), and the resultant relation (compact set) containing representative tuples is R_3, which is not $\boldsymbol{\lambda}$-close.

Compared with original relation R_1 of the query result, R_2 and R_3 contain the classification information. We can say that, in terms of $\boldsymbol{\lambda}$-close, R_2 and R_3 are information equivalent. If we have had R_2, then R_3 could be derived (i.e., via extracting) with respect to tuple closeness/relation compactness. If we have had R_3, suppose $R_3 = \{t_u, t_w, t_x, ...\}$, then every tuple of R_3 is not $\boldsymbol{\lambda}$-close, and can be considered as a class labeled as $C_u, C_w, C_x, ...$. For every tuple t_i of R, if t_i satisfies the fuzzy query conditions, then it could be compared with the tuples in the labeled classes $C_u, C_w, C_x, ...$, if there is a tuple t in one labeled class, e.g., C_u such that t_i and t are $\boldsymbol{\lambda}$-close, then add t_i to C_u. Consequently, we will get relation R_2, as the tuples in R_3 and the equivalence classes in R_2 are bijective.

Finally, let us discuss the approach from a more applied perspective. While searching via a search engine (e.g., Google or the like) or querying available databases for some information, it would be desirable if the database/web search management systems are capable of generating outcomes that are representative and of a manageable size. Even better is to control the query/search outcomes with different compactness degrees or with different sizes. A way to view different results is to specify the degree of relation compactness. If R_C is higher, there will be fewer outcomes, otherwise, more outcomes.

Example 3: Someone uses a search engine to browse for the literature about "fuzzy queries". To help discuss the procedure and treatment details of how the search results can be shortened or extended, we hereby only chose 10 resultant items as R_1, merely for the sake of illustrative simplicity:

a_1: A Fuzzy Database Model for Supporting a Concept-Based Query ...
a_2: Fuzzy Database Query Languages and Their Relational Completeness ...
a_3: FSQL (Fuzzy SQL), a Fuzzy Query Language
a_4: Fuzzy Database Modeling with XML
a_5: Fuzzy database systems - Fuzzy Systems, 1995. International Joint ...
a_6: Amazon.com: Fuzzy Database Modeling of Imprecise and Uncertain ...
a_7: Amazon.com: Fuzzy Database Modeling with XML
a_8: Database Schema with Fuzzy Classification and Classification Query ...
a_9: Type-2 Fuzzy Logic - Publications Database
a_{10}: Fuzzy Clustering for Content-based Indexing in Multimedia Database

Suppose the threshold set by the user is $\lambda = 0.7$ and the closeness of these articles generated with a keywords match technique (e.g., [30-34]) is shown in Table 4.

Table 4: The closeness degrees among $a_1, a_2, \ldots, a_{10}$

	a_1	a_2	a_3	a_4	a_5	a_6	a_7	a_8	a_9	a_{10}
a_1	1	0.75	0.9	0.6	0.5	0.5	0.5	0.6	0.6	0.6
a_2		1	0.82	0.6	0.6	0.6	0.6	0.5	0.6	0.6
a_3			1	0.6	0.5	0.5	0.6	0.5	0.6	0.6
a_4				1	0.85	0.9	0.9	0.6	0.6	0.6
a_5					1	0.7	0.75	0.6	0.5	0.5
a_6						1	0.78	0.6	0.6	0.6
a_7							1	0.6	0.5	0.6
a_8								1	0.9	0.95
a_9									1	0.7
a_{10}										1

Now, let us consider how to obtain the outcomes with $RC|_{0.7}$ being 1 and 0.6 respectively. In doing so, the database management systems or search processing functions could execute the extracting process with $\lambda = 0.7$, $\lambda_1 = 0.8$, $\lambda_2 = 0.85$, $\lambda 3 = 0.9$ and $\lambda 4 = 1$ at the back-end as follows.

For $\lambda = 0.7$, R_1 can be classified as $\{a_1, a_2, a_3\}$, $\{a_4, a_5, a_6, a_7\}$ and $\{a_8, a_9, a_{10}\}$, extracting the representative tuples as described in Section 3.3, the final outcome is $S = \{a_3, a_4, a_8\}$, $RC(S)|_{0.7} = 1$.

For $\lambda_1 = 0.8$, R_1 can be classified as $\{a_1, a_2, a_3\}$, $\{a_4, a_5, a_6, a_7\}$ and $\{a_8, a_9, a_{10}\}$, $S_1 = \{a_3, a_4, a_8\}$, $RC(S_1)|_{0.8} = RC(S_1)|_{0.7} = 1$.

For $\lambda_2 = 0.85$, R_1 can be classified as $\{a_1\}$, $\{a_2\}$, $\{a_3\}$, $\{a_4, a_5, a_6, a_7\}$ and $\{a_8, a_9, a_{10}\}$, $S_2 = \{a_1, a_2, a_3, a_4, a_8\}$, $RC(S_2)|_{0.85} = 1$, $RC(S_2)|_{0.7} = 0.6$.

In the same manner, for $\lambda_3 = 0.9$, $S_3 = \{a_1, a_2, a_3, a_4, a_5, a_8\}$, $RC(S_3)|_{0.9} = 1$, $RC(S_3)|_{0.7} = 0.57$.

For $\lambda_4 = 1$, $S_4 = R_1 = \{a_1, a_2, a_3, a_4, a_5, a_6, a_7, a_8, a_9, a_{10}\}$, $RC(S_4)|_1 = 1$, $RC(R_1)|_{0.7} = RC(S_4)|_{0.7} = 0.47$.

Thus, if the threshold $\lambda = 0.7$, the original result of the query is compact at a degree of $RC(R_1)|_{0.7} = 0.47$. The back-end can give the user a totally compact outcome $S = \{a_3, a_4, a_8\}$ (with $RC(S)|_{0.7} = 1$) by default, which is composed of the three items:

"FSQL (Fuzzy SQL), a Fuzzy Query Language"
"Fuzzy Database Modeling with XML"

ISBN: 978-989-95079-6-8

"Database Schema with Fuzzy Classification and Classification Query ..."

If user wants to review more outcomes, e.g., $RC|_{0.7} = 0.6$, then the DBMS can generate $S_2 = \{a_1, a_2, a_3, a_4, a_8\}$, with $RC(S_2)|_{0.7} = 0.6$. Two more specific "fuzzy query" related items are listed: "A Fuzzy Database Model for Supporting a Concept-Based Query ..." and "Fuzzy Database Query Languages and Their Relational Completeness ...". In this way, the list of the literature could be shortened or extended depending upon the need and preference of the user. □

5 Conclusion

This paper has introduced a measure, namely relation compactness, to express the degree of a given relation being compact. Then an approach to evaluating and extracting representative tuples has been proposed. It has been proven that the resultant set of query outcomes is unique, smaller in size, and information equivalent to the original result. Moreover, the approach enables the query/search users to obtain various sizes of results upon their need and preference in light of compactness.

Ongoing research is centering on an application with real data on tuple extraction in both database query and web search contexts.

Abstract—*This paper presents a novel action selection method for multi robot task sharing problem. Two autonomous mobile robots try to cooperate for push a box to a goal position. Both robots equipped with object and goal sensing, but do not have explicit communication ability. We explore the use of fuzzy signatures and decision making system to intention guessing and efficient action selection. Virtual reality simulation is used to build and test our proposed algorithm.*

Keywords— Mobile robots, cooperation, fuzzy signatures, action selection, intention guessing.

1 Introduction

In this paper we focus on manipulation tasks with sufficiently challenging dynamics to require the careful cooperation of two or more robots. Sensing and actuation is noisy and uncertain in mobile robot domains, resulting in partial knowledge about the world. We explore the use of fuzzy signatures to efficient action selection and intention guessing in this environment. The intention guessing is the base of a meta-communication method between the robots. In this setup is not any explicit communication line.

We chose box-pushing as the problem domain because it has both theoretical interest and practical applications as it is an instance in large class of practical object manipulation tasks that appear to require tight feedback and control of real-world physics and dynamics [1-9]. From a theoretical standpoint, box-pushing is a variant on canonical object manipulation problem that draws on issue in fine motion as well as high level planning and control. Box-pushing is related to the well-known "piano-movers problem" [10], in that it requires the achievement of top level goal of delivering the box to a particular location, as well as the maintenance of low-level requirements including obstacle avoidance, maintaining contact with the box, and maintaining forward motion. From a practical point of view, box-pushing is a prototypical problem for studying various tasks requiring cooperation of number of smaller robots moving larger objects [6].

We use simulation in our experiments where two robots push a box to a goal position. Each robot has the own behaviour based control system thus they are fully autonomous. An action selection mechanism works in our behaviour based control in which the decision about selection is done by fuzzy signature based state describing algorithm.

2 Experimental task and environment

The actual stage of our research we use simulation of our real differential driven autonomous micro-robots (Fig. 1). The physical simulation is exact model of our robots in the case of scale, weight, mechanical systems and sensors.

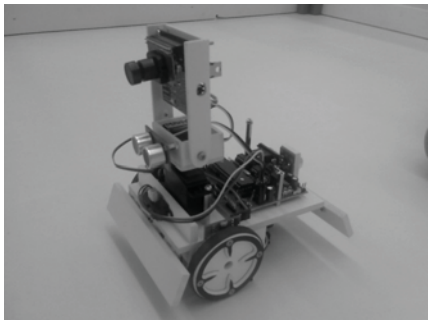

Figure 1. The real box-pushing robot

The two robots operate in a 2 x 2 m square arena. The box to be pushed is a 20 cm high and 40 cm wide and long. The

ISBN: 978-989-95079-6-8

goal region, located in one corner of the arena (Fig. 2), indicated by light sources detectable by the robot's sensor. In the experiments described here the goal location is fixed but it can be moved before and during experiments.

Each robot pushes the box with two "whiskers" which have a pair of force sensors. The left and right whiskers each provides an analog force signal which is combined to give information the relative position to the box and via the control loop keep it contact on both sides and thus perpendicular to the box.

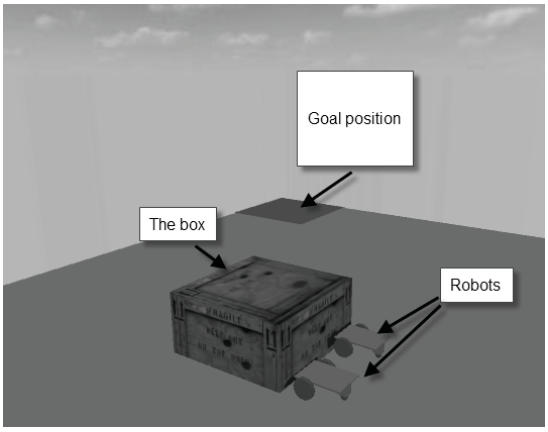

Figure 2. The simulation environment

In the description two direction sign systems are used, the absolute direction with letters N, E, S, W as in the usual sense for North, East, South and West. The second direction sign system is a box relative system where the sides of the box are N_B, E_B, S_B and W_B respectively (Fig. 3). The position of the objects (boxes and robots in this case) always can be described by the absolute course, latitude and longitude of the object. One object relative position to a box is described by the box relative system, i.e. which side of the box is touched by that object. For simplicity we assume that the sides of the box are always parallel with the N-S and E-W axes, so there is not necessary any rotation.

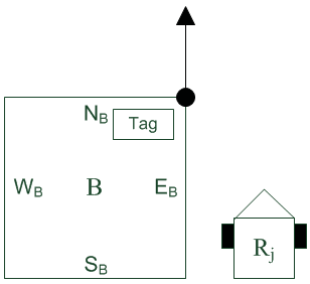

Figure 3. Symbols of boxes and robots

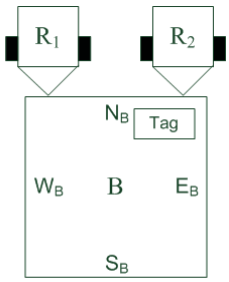
There are just a few essentially different robot positions allowed. Because two robots are needed for pushing the box, at each side of the boxes, two spaces are available for the robots manipulating them: the "counterclockwise position" and the "clockwise position" (see Fig. 4). The position is described by $P_r = [S,T]$ where r is the number of the robot, S is the side of the box where the robot touch it (N_B, E_B, S_B and W_B respectively) and the T is the turning position that means "counterclockwise position" or "clockwise position" (CC or CW).

The cooperating combination of robots is denoted by $C_{i,j}$ where i,j is the number of the robots. $C_{1,2} = P$ is the "pushing or shifting combination", when two robots (R_1 and R_2) are side by side at the same side of the box as Fig. 5 shows. In this case R_1 and R_2 are in the relative North (N_B) position. Of course, all the other three directions are similarly allowed. Any other combination of two robots is illegal, except see the next paragraph ("stopping combination").

$P_j = [N_b, CC]$ $\quad$ $P_j = [N_b, CW]$

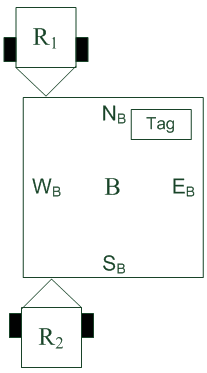
Figure 4. Robot positions at the N_B side of the box



$$\left.\begin{aligned} P_1 &= [N_B, CC] \\ P_2 &= [N_B, CW] \end{aligned}\right\} C_{1,2} = P$$

Figure 5. Allowed combinations of two robots for moving the box

Eventually, in Fig. 6, the combinations are shown where one robot intends to do a move operation, and another robot that has recognized the goal box configuration positions itself to prevent a certain move. This is an exception where a two robot combination other than the ones listed in Fig. 5 is legal as a temporary combination, clearly signalizing "stop this attempt as it is in contrary to the goal ".



$$\left.\begin{aligned} P_1 &= [N_B, CC] \\ P_2 &= [S_B, CW] \end{aligned}\right\} C_{1,2} = ST$$

Figure 6. The stopping combination

ISBN: 978-989-95079-6-8

3 Build up the codebook

After having overviewed the possible positions and combinations, let us build the part of the codebook that enables robots to recognize a situation and take action accordingly. In initial position both robots can see the goal light and know the actual position of the box. There are four good position and two pushing combination that the robots can take up.

How can take the starting position? The possible initial actions are:

1. The both robots move to reach the nearest possible good position.
2. Which reach the position first wins the temporal leader role if the other knows or guesses that this position is well for forming a useful combination. In this case the second robot turns and moves to the free position for this combination as the Fig. 7 shows. If the second robot rejects this combination then they try to take up a new form.
3. After the forming this starting combination the next is the push or shift task. We assume there are only two shifting axis, the N-S and E-S. The robots push the box a given force.

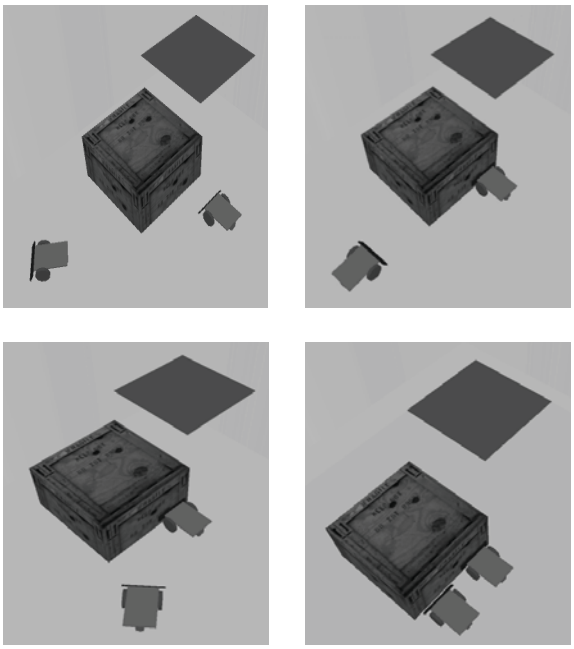


Figure 7. The robots take the starting combination

From this point a lot of scenarios are possible. Let us see some examples.

The R2 robot loses the goal sign, so it does not know the direction exactly. The R2 will slow down. The R1 robot detects the rotation of the box via its force sensors and guesses the R2 is slacken. The R1 has to make a decision, in other words it selects an action or reaction. There are two ways:

1. The R1 knows the right direction and forces to shift toward. It speeds up slightly, the R2 senses this and has to decide its reaction. The R2 makes a second self-examination and if it has not any other problem but the lost of goal sign then it switches to the *blind push* action or behavior. It means R2 pushes the box lean on R1 as follower. If R2 finds any other reason of slacken, e.g.: external obstacle or any internal error (e.g.: low battery), it keeps its own speed or decreases it. In this case the R1 gives a new reaction and so on, as long as they reach a right deal or give up the task.
2. The R1 does not sure the right direction, slow down to the speed of R2 and both robots search the goal light. If one of they find the goal takes the leader role and forces the other to push the box. If not, after a given time they stop pushing the box and move to take a new combination. After the some new unsuccessful attempt they give up.

Based on the above example and considerations it is possible to build up some elements of the action selection algorithm as a codebook. It will take the form of a decision tree, where the inputs are the direct observation, the first level outputs are intention guesses and the second level outputs the concrete actions of the corresponding robot.

Now let us see a relevant part of the codebook contains a decision tree with fuzzy elements. It is a part of the above presented example.

In R1 control system:
- Does R2 {slow down}?
  - If no then *No Action*
  - else
  - Do I know the {goal position}?
    - If no then *Goal Searching Action*
    - else
    - *Force Move Action*
  - Does R2 {accelerate}?
    - If no then *Slow Down Action*
    - else
    - *No Action*

In R2 control system:
- Can I see the {goal light}?
  - If no then *Slow Down Action*
  - .
  - .
  - .
- Does R1 {force the move}?
  - If no then *No Action* (or *Goal Searching Action*)
  - else
  - Do I have any internal or external {obstacle}?
- If no then *Blind Push Action*
- else
- *Slow Down Action* (or *Keep Move Action*)

Note that in the condition parts there are fuzzy notions which are between curly brackets. It is usually hard to judge that the R2 slows down really or the box hits an obstacle as the information come from some simple sensors that might provide only approximate results.

This simple example illustrates clearly that the meta-communication among intelligent robots by intention guessing and fuzzy evaluation of the situation might lead to effective cooperation and the achievement of task that cannot be done without collaboration and communication.

4 Fuzzy signatures and decisions

4.1 Fuzzy signatures

In 1999 Vámos, *et al.* introduced the concept of Fuzzy Signatures [11]. Some further advanced versions of the concept and it possible use for describing complex data were later proposed in [12,13,14].

The original definition of fuzzy sets was $A : X \to [0,1]$, and was soon extended to *L-fuzzy sets* by Goguen [15]

$$A_s : X \to [a_i]_{i=1}^{k}, a_i = \begin{cases} [0,1] \\ [a_{ij}]_{j=1}^{k_i} \end{cases}, a_{ij} = \begin{cases} [0,1] \\ [a_{ijl}]_{l=1}^{k_{ij}} \end{cases} \tag{1}$$

$A_L : X \to L$, L being an arbitrary algebraic lattice. A practical special case, *Vector Valued Fuzzy Sets* was introduced by Kóczy [16], where $A_{V\,k} : X \to [0,1]^k$, and the range of membership values was the lattice of k-dimensional vectors with components in the unit interval. A further generalization of this concept is the introduction of fuzzy signature and signature sets, where each vector component is possibly another nested vector (right).

Fuzzy signature can be considered as special multidimensional fuzzy data. Some of the dimensions are interrelated in the sense that they form sub-groups of variables, which jointly determine some feature on higher level. Let us consider an example. Fig. 8 shows a fuzzy signature structure.

The fuzzy signature structure shown in Fig. 8 can be represented in vector form as follow:

$$x = \begin{bmatrix} \begin{bmatrix} x_{11} \\ x_{12} \end{bmatrix} \\ \begin{bmatrix} x_{21} \\ \begin{bmatrix} x_{221} \\ x_{222} \\ x_{223} \end{bmatrix} \\ x_{23} \end{bmatrix} \\ \begin{bmatrix} x_{31} \\ x_{32} \end{bmatrix} \end{bmatrix}^T \tag{2}$$

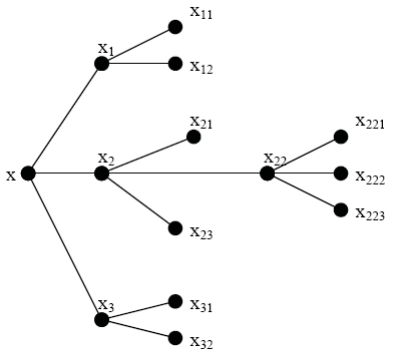

Figure 8. A Fuzzy Signature Structure

Here $[x_{11}\ x_{12}]$ from a sub-group that corresponds to a higher level compound variable of x_1. $[x_{221}\ x_{222}\ x_{223}]$ will then combine together to form x_{22} and $[x_{21}\ [x_{221}\ x_{222}\ x_{223}]\ x_{23}]$ is equivalent on higher level with $[x_{21}\ x_{22}\ x_{23}] = x_2$. Finally, the fuzzy signature structure will become $x = [x_{221}\ x_{222}\ x_{223}]$ in the example.

The relationship between higher and lower level is govern by the set of fuzzy aggregations. The results of the parent signature at each level are computed from their branches with appropriate aggregation of their child signature. Let a_1 be the aggregating associating x_{11} and x_{12} used to derive x_1, thus $x_1 = x_{11}a_1x_{12}$. By referring to Fig. 8, the aggregations for the whole signature structure would be a_1, a_2, a_{22} and a_3. The aggregations a_1, a_2, a_{22} and a_3 are not necessarily identical or different. The simplest case for a_{22} might be the min operation, the most well known t-norm. Let all aggregation be min except a_{22} be the averaging aggregation. We will show the operation based on the following fuzzy signature values for the structure in the example.

Each of these signatures contains information relevant to the particular data point x_0; by going higher in the signature structure, less information will be kept. In some operations it is necessary to reduce and aggregate information obtained from another source (some detail variables missing or simply being locally omitted). Such is when interpolation within a fuzzy signature rule base is done, where the fuzzy signature flanking an observation are not exactly of the same structure. In this case the maximal common sub-tree must be determined and all signatures must be reduced to that level in order to be able to interpolate between the corresponding branches or roots in some cases [17].

$$x = \begin{bmatrix} \begin{bmatrix} 0.3 \\ 0.4 \end{bmatrix} \\ \begin{bmatrix} 0.2 \\ \begin{bmatrix} 0.6 \\ 0.8 \\ 0.1 \end{bmatrix} \\ 0.9 \end{bmatrix} \\ \begin{bmatrix} 0.1 \\ 0.7 \end{bmatrix} \end{bmatrix}^T \tag{3}$$

After the aggregation operation is perform to the lowest branch of the structure, it will be described on higher level as:

$$x = \begin{bmatrix} 0.3 \\ \begin{bmatrix} 0.2 \\ 0.5 \\ 0.9 \end{bmatrix} \\ 0.1 \end{bmatrix}^T \tag{4}$$

Finally, the fuzzy signature structure will be:

ISBN: 978-989-95079-6-8

$$x = \begin{bmatrix} 0.3 \\ 0.2 \\ 0.1 \end{bmatrix}^T \quad (5)$$

4.2 Fuzzy signatures for box-pushing robot cooperation

Now, let us construct the fuzzy signatures for robot cooperation. The fuzzy signatures presented here are implemented in R1 robot action selection system as a part of the meta-communication codebook. Of course here is described only a slice of the whole signatures.

Fig. 9 presents the signatures which describe R2 behaviour. The information communicated to R1 is partly the observation about the last move of R2 and partly the evaluation of the situation with the box, according to those membership degrees will be attached to each leave of the actual signature.

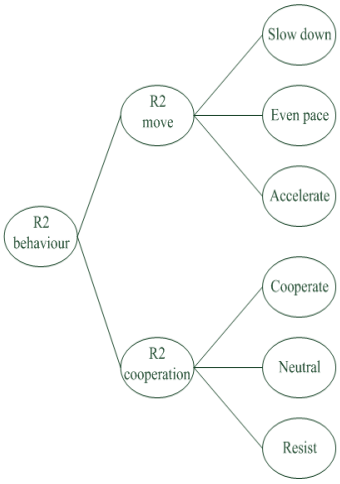

Figure 9. R2 robot's behavior fuzzy signatures

Figure 11 presents a portion of decision tree applied by R1 when it observes some action or reaction of R2 described by above mentioned behavior fuzzy signatures.

After all action selection the R1 control system reevaluates the values of the membership degrees of observed R2 behavior, environmental properties and the own state as the lines partially show in Fig. 11. After the evaluation the robot makes a decision which action is taken.

Parallel, in the R2 control system runs a similar task which reacts to the R1 decision and action. Thus, the two robots produce a circle of action and reaction (Fig. 10), where an initial action triggers the circulation of reactions and composes a meta-communication between the robots.

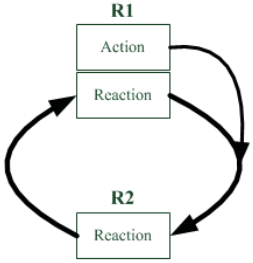

Figure 10. Action – reaction circle

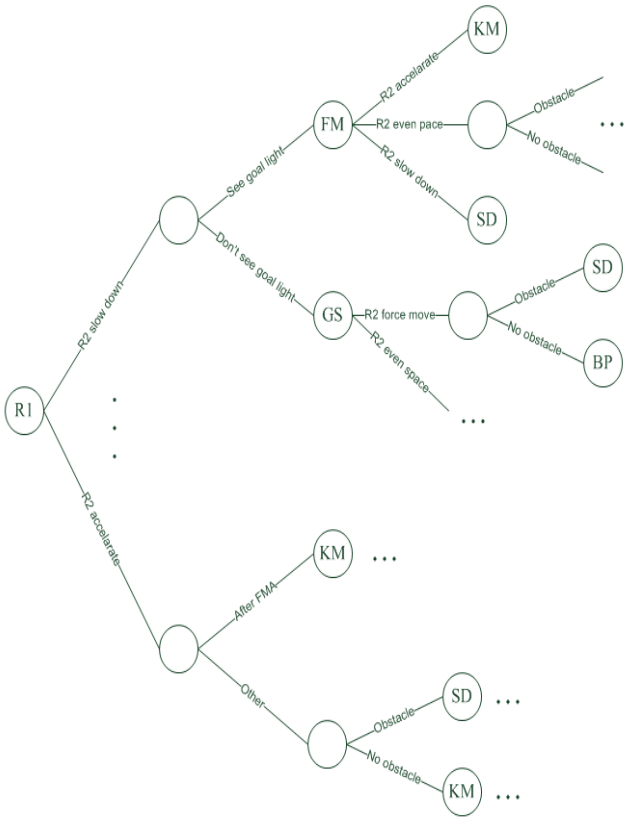
This is a type of context dependent or fuzzy communication [18, 19], which means every robot has the own codebook and communicate in a vague, compressed or quasi channel. Then the robots build up and interpret this imprecise information with their codebooks.



Where the actions are

- BP – Blind push
- FM – Force move
- GS – Goal Searching
- KM – Keep move
- SD – Slow down

Figure 11. The decision tree of R1 robot

5 Conclusions

Fuzzy communication contains vague or imprecise components and it might lack abundant information. If two robots are communicating by a fuzzy channel, it is necessary that both ends possess an identical part within the codebook. The codebook might partly consist of common knowledge but it usually requires a context dependent part that is learned by communicating. Possibly it is continuously adapting to the input information. If such a codebook is not available or it contains too imprecise information, the information to be transmitted might be too much distorted and might lead to misunderstanding, misinterpretation and serious damage. If however the quality of the available codebook is satisfactory, the communication will be efficient i.e. the original contents of the message can be reconstructed. At the same time it is cost effective, as fuzzy communication is compressed as compared to traditional communication. This advantage can be deployed in many areas of engineering, especially where the use of the communication channels is expensive in some sense, or where there is no proper communication channel available at all.

ISBN: 978-989-95079-6-8

Here we illustrate clearly that the communication among intelligent robots by intention guessing and fuzzy evaluation of the situation might lead to effective cooperation and the achievement of tasks that cannot be done without collaboration and communication.
We simulated many scenarios and almost got acceptable results, but sometimes the robots made deadlock combination and gave up the work. In future we want to work out new algorithms to solve these situations.

Abstract— *In this paper a new fuzzy filter for the removal of additive Gaussian noise in colour image sequences is presented. The proposed method, which is a colour extension of our previous work on greyscale images, consists of two subfilters. The first subfilter averages the noise in each of the colour bands separately. In this averaging, the weights of the neighbouring pixels are determined by fuzzy rules. Even though the filtering is performed in each colour band separately, information from the other colour bands is also used in the fuzzy rules. In this way, we can be more confident whether a neighbouring pixel is similar to the pixel being filtered. In order to further improve the results, a second subfilter is applied too. This colour restorating filter is based on the simplified assumption that for similar pixels the pixel value difference should be approximately the same in all colour bands. A pixel is estimated from its neighbours by estimating the differences in each colour band equal to the average over all colour bands. Experimental results show that, in terms of average PSNR and average NCD, the proposed colour extension of our previous work outperforms the usual colour extension of a greyscale filter, in which the Y component in the YUV transform is filtered with the original greyscale method and the chrominance bands U and V are averaged.*

Keywords— Video, noise filter, colour, Gaussian noise, fuzzy rule.

1 Introduction

Images sequences are among the most important information carriers in today's world. They are used in numerous applications such as broadcasting, video-phone, traffic observations, surveillance systems and autonomous navigation to name a few. The used sequences are however often affected by noise due to bad acquisition, transmission or recording. In this paper we will concentrate on image sequences corrupted with additive white Gaussian noise of zero mean and variance σ^2:

$$I_{n,i} = I_{o,i} + \epsilon_i, \qquad i = 1, \ldots, P \tag{1}$$

where $I_{n,i}$ and $I_{o,i}$ denote the i-th pixel from the noisy and the original frame respectively, $\epsilon_i \sim N(0, \sigma^2)$ and P is the number of pixels per frame.

The goal of noise filtering is not only visual improvement but also an improvement of the further analysis or coding of the sequences. During this filtering process a compromise needs to found between the removal of noise and the preservation of fine image details.

Most video filters that exist in literature are designed for greyscale sequences. Some examples are e.g. [2, 3, 4, 5]. These greyscale methods can nevertheless be extended to the RGB colour space [1] in a straightforward way by filtering each of the colour bands R, G and B separately. This might however result in the introduction of colour artefacts since the correlation between the different colour bands is neglected. Therefore, the commonly used alternative is to filter only the luminance component Y of the YUV-transform with the given greyscale method, possibly with an additional averaging of the chrominance components U and V.

The proposed filtering framework can be seen as a colour extension of our previous work presented in [4], which was inspired by the multiple class averaging filter from [5]. The presented filter consists of two separate subfilters. In the first subfilter, we add colour information to the fuzzy logic framework from our work in [4]. In this first fuzzy subfilter, each of the colour bands is denoised separately by averaging the noise. The weights assigned to the pixels considered in the averaging are determined by fuzzy rules. Even though the filtering is performed in each colour band separately, the fuzzy rules also require information from the other colour bands. Due to this increase in information, we can expect a more reliable estimation of the degree to which a neighbouring pixel is similar to the pixel that is filtered. However, especially around edges in the image, some colour artefacts might appear because sometimes not enough similar neighbours can be found to completely average the noise and it might also happen that a neighbouring pixel is wrongly considered as belonging to the same object (similar). To cope with this problem, the first subfilter is combined with an additional second subfilter, which is an extension of the second subfilter in [6]. This subfilter is based on the simplified assumption that for similar pixels the pixel value differences in the three different colour components should all three be approximately the same. The pixel being filtered is estimated from a neighbour by estimating the differences in each band equal to the average over the different colour bands.

The experimental results show that the proposed colour video denoising framework performs better than the YUV-colour extension in terms of average PSNR and NCD.

The paper is structured as follows: Section 2 gives some preliminaries about fuzzy set theory. Next, the proposed colour video denoising algorithm is explained in Section 3. Finally, experimental results are presented in Section 4.

2 Preliminaries

In this section, we will introduce some basic notions concerning fuzzy set theory and fuzzy if-then rules.

2.1 Fuzzy Sets

In classical set theory, an element x in a universe X belongs or does not belong to a certain set C, defined over the uni-

ISBN: 978-989-95079-6-8

verse X. This can be modelled by membership degrees belonging to $\{0,1\}$. In fuzzy set theory [7], there is a more gradual transition between 'belonging to' and 'not belonging to'. A fuzzy set F in the universe X is characterized by a $X \rightarrow [0,1]$ mapping μ_F, which assigns a degree of membership $\mu_F(x) \in [0,1]$ of x in the fuzzy set F, with every element x in X. This membership degree may also lie between 0 and 1, which makes fuzzy sets very useful and more natural than crisp sets to work with complex systems and human knowledge, where linguistic variables are used. In this paper, we will use a linguistic variable "large" for several parameters that will be introduced further. Using fuzzy set theory, a parameter is not necessarily large or not large, but can also be large to some degree.

2.2 Fuzzy Rules and Fuzzy Logical Operators

The general form of a fuzzy rule is "IF A THEN B", where the premise A and the consequent B are (collections of) propositions containing linguistic variables. These propositions can contain AND, OR and NOT operators, which correspond to respectively the intersection, the union and the complement of fuzzy sets.

The membership degree of an element x in the intersection (respectively union) of two fuzzy sets A and B in X is obtained through a mapping T, (respectively S) that maps the membership degrees of an element in the fuzzy sets A and B onto its membership degree in the fuzzy set $A \cap B$ (respectively $A \cup B$): $\mu_{(A \cap B)}(x) = T(\mu_A(x), \mu_B(x))$, $\forall x \in X$ (respectively $\mu_{(A \cup B)}(x) = S(\mu_A(x), \mu_B(x))$,$\forall x \in X$). In fuzzy logic for the mappings T and S, respectively a triangular norm [8] and a triangular conorm [8] are used. For the results in this paper, we have used the algebraic product and the probabilistic sum as triangular norm and conorm respectively. This norm and conorm led to the best results for our filter and are the most simple from a computational point of view.

To specify the complement of a fuzzy set A in X, we use a mapping N to derive the membership degree of an element x in the complement of the fuzzy set A from its membership degree in the fuzzy set A: $\mu_{coA}(x) = N(\mu_A(x))$, $\forall x \in X$. In fuzzy logic for the mapping N an involutive negator [8] is used. In this paper we have chosen for the well-known standard negator $N_s(x) = 1 - x, \forall x \in [0,1]$.

Let's take for example the following fuzzy rule:

Fuzzy Rule 1. `IF` (u *is* `U` `AND` v *is* V) `OR` w *is* `NOT` `W` `THEN` z *is* `Z`.

The membership degree $\mu_Z(z)$ of z in Z, which corresponds to the activation degree of the rule, i.e. the degree of thruthfulness, is then calculated as:

$$\mu_Z(z) = (\mu_U(u) \cdot \mu_V(v)) + (1 - \mu_W(w)) - (\mu_U(u) \cdot \mu_V(v)) \cdot (1 - \mu_W(w)). \quad (2)$$

3 The proposed algorithm

In this section, we will outline the proposed filtering framework. The method is a superposition of two subfilters, presented in respectively Subsection 3.1 and Subsection 3.2.

In the first subfilter a $3 \times 3 \times 2$ sliding window is used, which is moved through the frame from top left to bottom right, each time filtering the central position in the window. This window consists of 3×3 pixels in the current frame and 3×3 pixels in the previous frame as shown in Fig. 1. The central position in the window is denoted by $(\mathbf{r}, t)$, where $\mathbf{r} = (x, y)$ and t respectively stand for the spatial and temporal position in the image sequence. An arbitrary pixel position in the sliding window (which may also be the central position) is denoted by $(\mathbf{r'}, t')$, with $\mathbf{r'} = (x + k, y + l)$, $(-1 \leq k, l \leq 1)$ and $t' = t$ or $t' = t - 1$. Further, the second subfilter uses a 3×3 window in the current frame for which similar notations will be used as for the $3 \times 3 \times 2$ window.

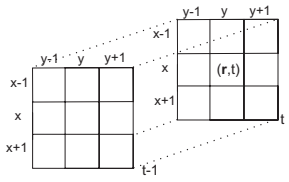

Figure 1: The $3 \times 3 \times 2$ filtering window consisting of 3×3 pixels in the current frame and 3×3 pixels in the previous frame.

3.1 First Subfilter

The subfilter explained in this subsection, can be seen as a colour extension of the filtering framework of our previous work, presented in [4]. This method was inspired by the multiple class averaging filter [5], from which we adopted the following ideas: (i) temporal blur should be avoided by taking into account only pixels from the current frame when motion is detected; (ii) image details should be preserved by filtering less when large spatial activity (details) is detected. More noise will be left, but the eye is less sensitive for the high spatial frequencies to which large spatial activity corresponds [9]. In homogeneous areas on the other hand, as much noise as possible should be removed by strong filtering.

The filtering is based on averaging the noise using the pixel values in the neighbourhood that are similar to the given pixel value and probably belong to the same object. Each colour band is filtered separately, but in the filtering of each colour band, the information from the other colour bands is used to confirm that a neighbouring pixel does indeed belong to the same object.

In the following the output of the first fuzzy subfilter is denoted by I_f, while the noisy input sequence is denoted by I_n. The output of the first subfilter for the central pixel in the window is determined as a weighted mean of the pixel values in the $3 \times 3 \times 2$ window ($i = 1, 2, 3$):

$$I_f(\mathbf{r}, t, i) = \frac{\sum_{\mathbf{r'}} \sum_{t'=t-1}^{t} W(\mathbf{r'}, t', \mathbf{r}, t, i) I_n(\mathbf{r'}, t', i)}{\sum_{\mathbf{r'}} \sum_{t'=t-1}^{t} W(\mathbf{r'}, t', \mathbf{r}, t, i)}, \quad (3)$$

The weights $W(\mathbf{r'}, t', \mathbf{r}, t, i)$ in the above weighted means are determined using fuzzy logic. The weight of a pixel is chosen equal to its membership degree in the fuzzy set "large weight". This membership degree is calculated as the activation degree of a fuzzy rule that corresponds to the ideas given at the beginning of this subsection. If large detail is detected, i.e., if a calculated detail value is large, then we should filter less by averaging only over pixels that are quite similar, i.e.,

ISBN: 978-989-95079-6-8

for which there is no large difference in the considered colour component and also in at least one of the other components. On the other hand, if there is not much detail detected, i.e., in the case that the calculated detail value is not large, strong filtering should be performed, i.e., we don't put a condition on the difference between the considered and the filtered pixel in the considered colour band (the check in the other colour bands remains for the case that the calculated detail value was not completely reliable). Further, if the pixel for which the weight is calculated belongs to the previous frame, we only want to give it a large weight if there is no motion detected in the filtering window, i.e., if a calculated motion value is not large. In the filtering of the red colour band, this results in the following two fuzzy rules, depending on whether the pixel lies in the current or the previous frame:

Fuzzy Rule 2. *Assigning the membership degree in the fuzzy set "large weight" of the weight $W(\mathbf{r'}, t', \mathbf{r}, t, 1)$ for the red value at position $\mathbf{r'}$ in the current frame ($t' = t$) of the window with central pixel position $(\mathbf{r}, t)$:*

IF $\Big($*(the detail value $d(\mathbf{r},t)$ is* LARGE AND $\Delta_1(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE AND $(\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE OR $\Delta_3(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE$)\Big)$

OR $\Big($*(the detail value $d(\mathbf{r},t)$ is* NOT LARGE$)$ AND $(\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE OR $\Delta_3(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE$)\Big)\Big)$

THEN *the red value at position $\mathbf{r'}$ has a* LARGE *weight $W(\mathbf{r'}, t', \mathbf{r}, t, 1)$ in (3).*

Fuzzy Rule 3. *Assigning the membership degree in the fuzzy set "large weight" of the weight $W(\mathbf{r'}, t', \mathbf{r}, t, 1)$ for the red value at position $\mathbf{r'}$ in the previous frame ($t' = t - 1$) of the window with central pixel position $(\mathbf{r}, t)$:*

IF $\Big($*(the detail value $d(\mathbf{r},t)$ is* LARGE AND $\Delta_1(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE AND $(\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE OR $\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE$)\Big)$

OR $\Big($*(the detail value $d(\mathbf{r},t)$ is* NOT LARGE$)$ AND $(\Delta_3(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE OR $\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ *is* NOT LARGE$)\Big)\Big)$

AND *the motion value $m(\mathbf{r},t)$ is* NOT LARGE

THEN *the red value at position $\mathbf{r'}$ has a* LARGE *weight $W(\mathbf{r'}, t', \mathbf{r}, t, 1)$ in (3).*

Similar fuzzy rules, switching the role of the red colour band and the colour band that needs to be filtered, are used to determine the weights $W(\mathbf{r'}, t', \mathbf{r}, t, 2)$ and $W(\mathbf{r'}, t', \mathbf{r}, t, 3)$ in expression (3) to filter the green and blue colour band respectively. In these fuzzy rules, a detail value $d(\mathbf{r}, t)$, three difference values $\Delta_1(\mathbf{r'}, t', \mathbf{r}, t)$, $\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ and $\Delta_3(\mathbf{r'}, t', \mathbf{r}, t)$ (one for each colour band) and a motion value $m(\mathbf{r}, t)$ are used, which we will now discuss. In our proposed method, only one detail value $d(\mathbf{r}, t)$ is used for all three colour bands. This detail value depends however on three detail values computed on each colour band separately. These three detail values are equal to the standard deviation calculated in the respective colour bands on the 3×3 pixels of the filtering window belonging to the current frame ($i = 1, 2, 3$):

$$I_{av}(\mathbf{r}, t, i) = \frac{1}{9} \sum_{\mathbf{r'}} I_n(\mathbf{r'}, t, i),$$

$$d_i(\mathbf{r}, t) = \Big(\frac{1}{9} \sum_{\mathbf{r'}} \big(I_n(\mathbf{r'}, t, i) - I_{av}(\mathbf{r}, t, i) \big)^2 \Big)^{\frac{1}{2}}.$$

We don't need to know the exact value of $d(\mathbf{r}, t)$. Only the membership degree $\mu_d\big(d(\mathbf{r}, t)\big)$ of $d(\mathbf{r}, t)$ in the fuzzy set "large detail value" is needed to calculate the activation degree of Fuzzy Rules 2 and 3 that determine the weights in the expression (3). This membership degree corresponds to the activation degree of the following fuzzy rule:

Fuzzy Rule 4. *Assigning the membership degree in the fuzzy set "large detail value" of the detail value $d(\mathbf{r}, t)$ for the pixel at the central position $(\mathbf{r}, t)$ in the filtering window of the current step:*

IF $d_1(\mathbf{r}, t)$ *is* LARGE AND $d_2(\mathbf{r}, t)$ *is* LARGE AND $d_3(\mathbf{r}, t)$ *is* LARGE

THEN $d(\mathbf{r}, t)$ *is* LARGE.

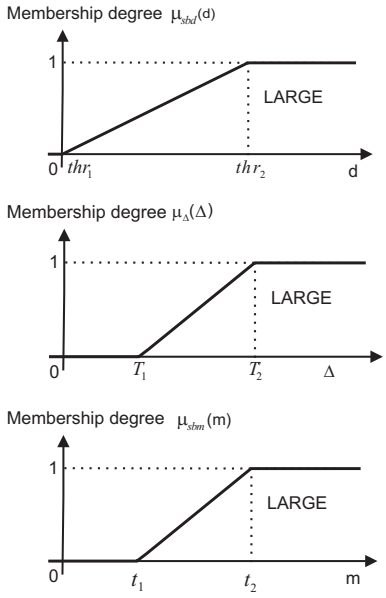

Figure 2: The respective membership functions μ_{sbd}, μ_Δ and μ_{sbm} of the respective fuzzy sets "large single band detail value", "large difference" and "large single band motion value".

The membership function μ_{sbd} of the fuzzy set "large single band detail value" is given in Fig. 2. The membership degree $\mu_d\big(d(\mathbf{r}, t)\big)$ is thus given by:

$$\mu_d\big(d(\mathbf{r}, t)\big) = \mu_{sbd}\big(d_1(\mathbf{r}, t)\big) \cdot \mu_{sbd}\big(d_2(\mathbf{r}, t)\big) \cdot \mu_{sbd}\big(d_3(\mathbf{r}, t)\big). \quad (4)$$

The three difference values $\Delta_1(\mathbf{r'}, t', \mathbf{r}, t)$, $\Delta_2(\mathbf{r'}, t', \mathbf{r}, t)$ and $\Delta_3(\mathbf{r'}, t', \mathbf{r}, t)$ that are used to determine the weights in (3) are given by ($i = 1, 2, 3$):

$$\Delta_i(\mathbf{r'}, t', \mathbf{r}, t) = |I_n(\mathbf{r'}, t', i) - I_n(\mathbf{r}, t, i)|. \quad (5)$$

The membership function μ_Δ of the fuzzy set 'large difference' is given in Fig.2.

ISBN: 978-989-95079-6-8

Analogously to the detail value $d(\mathbf{r},t)$ also only one motion value $m(\mathbf{r},t)$ is used for the filtering of all three colour bands. This value depends however again on three values computed for each of the colour bands separately. These three single band motion values are ($i=1,2,3$):

$$\begin{aligned} m_i(\mathbf{r},t) &= \Big|I_{av}(\mathbf{r},t,i) - I_{av}(\mathbf{r},t-1,i)\Big| \\ &= \Big|\frac{1}{9}\sum_{\mathbf{r'}} I_n(\mathbf{r'},t,i) - \frac{1}{9}\sum_{\mathbf{r'}} I_v(\mathbf{r'},t-1,i)\Big|. \end{aligned}$$

Just as it was the case for the detail value $d(\mathbf{r},t)$, we don't need to know the exact value of $m(\mathbf{r},t)$ either. Only its membership degree $\mu_m\big(m(\mathbf{r},t)\big)$ in the fuzzy set "large motion value" is needed for the Fuzzy Rules 2 and 3 (or thus the calculation of the weights in (3)). This membership degree is obtained from the following fuzzy rule:

Fuzzy Rule 5. *Assigning the membership degree in the fuzzy set "large motion value" of the motion value $m(\boldsymbol{r},t)$ for the pixel at the central position $(\boldsymbol{r},t)$ in the filtering window of the current step:*

IF ($m_1(\boldsymbol{r},t)$ *is* LARGE AND $m_2(\boldsymbol{r},t)$ *is* LARGE) OR
($m_1(\boldsymbol{r},t)$ *is* LARGE AND $m_3(\boldsymbol{r},t)$ *is* LARGE) OR
($m_2(\boldsymbol{r},t)$ *is* LARGE AND $m_3(\boldsymbol{r},t)$ *is* LARGE)
THEN $m(\boldsymbol{r},t)$ *is* LARGE.

The membership function μ_{sbm} of the fuzzy set "large single band motion value" is given in Fig 2. The membership degree $\mu_m\big(m(\mathbf{r},t)\big)$ is thus given by:

$$\mu_m\big(m(\mathbf{r},t)\big) = \alpha + (\beta+\gamma-\beta\cdot\gamma) - \alpha\cdot(\beta+\gamma-\beta\cdot\gamma), \quad (6)$$

with

$$\begin{aligned} \alpha &= \Big(\mu_{sbm}\big(m_1(\mathbf{r},t)\big)\cdot\mu_{sbm}\big(m_2(\mathbf{r},t)\big)\Big), \\ \beta &= \Big(\mu_{sbm}\big(m_1(\mathbf{r},t)\big)\cdot\mu_{sbm}\big(m_3(\mathbf{r},t)\big)\Big), \\ \gamma &= \Big(\mu_{sbm}\big(m_2(\mathbf{r},t)\big)\cdot\mu_{sbm}\big(m_3(\mathbf{r},t)\big)\Big). \end{aligned} \quad (7)$$

Summarized, the membership degree of the pixel at position $(\mathbf{r'},t')$ in the fuzzy set "large weight", which corresponds to the weight $W(\mathbf{r'},t',\mathbf{r},t,1)$ in (3) is thus given by

$$W(\mathbf{r'},t',\mathbf{r},t,1) = \omega\cdot\theta\cdot\phi + (1-\omega)\cdot\phi - (\omega\cdot\theta\cdot\phi)\cdot((1-\omega)\cdot\phi), \quad (8)$$

where

$$\begin{aligned} &\omega = \mu_d(d(\mathbf{r},t)) \\ &\theta = (1-\mu_\Delta(\Delta_1(\mathbf{r'},t',\mathbf{r},t))) \\ &\phi = (1-\mu_\Delta(\Delta_2(\mathbf{r'},t',\mathbf{r},t))) + (1-\mu_\Delta(\Delta_3(\mathbf{r'},t',\mathbf{r},t))) \\ &\quad - (1-\mu_\Delta(\Delta_2(\mathbf{r'},t',\mathbf{r},t)))\cdot(1-\mu_\Delta(\Delta_3(\mathbf{r'},t',\mathbf{r},t))) \end{aligned}$$

For pixel positions in the window belonging to the current frame. For pixel positions in the window belonging to the previous frame, an extra factor $1-\mu_m(m(\mathbf{r},t))$ is needed.

3.2 Second Subfilter

Because sometimes not enough similar neighbours can be found to completely average the noise in the first subfilter and because some pixels might have been wrongly considered similar in the first subfilter, some colour artefacts might still be present after applying the first subfilter. To further improve the result, the first subfilter is combined with an additional second subfilter, which is an extension of the second subfilter in [6]. Based on the simplified assumption that the difference between similar pixels is approximately the same in all three colour bands, a pixel is estimated from a neighbour by estimating a difference in a given colour component equal to the average over all three colour bands. So a difference that is larger than the average is made smaller and vice versa. The final output is a weighted average over the estimations obtained from the different neighbours, where the weight is the degree to which we believe that the neighbour belongs to the same object. The weights are introduced because for neighbours not belonging to the same object, the simplified assumption does not hold.

3.2.1 Local Differences and Correction Terms

As mentioned before, for this second subfilter, a 3×3 sliding window is used. In each step the central pixel in this window, at position $(\mathbf{r},t)$ in the image sequence, is filtered. For each pixel in the sliding window, local differences (gradients) in the three colour bands (each separately) are calculated. The differences in the red, green and blue neighbourhoods are respectively denoted by LD_1, LD_2 and LD_3 and they are calculated based on the output of the first subfilter ($i=1,2,3$):

$$LD_i(\mathbf{r'},t,\mathbf{r},t) = I_f(\mathbf{r'},t,i) \;-\; I_f(\mathbf{r},t,i). \quad (9)$$

Next, for each position in the window one correction term is determined using the calculated local differences. This correction term is defined as the average of the local difference in the red, green and blue component at the given position:

$$\epsilon(\mathbf{r'},t,\mathbf{r},t) = \frac{1}{3}\sum_{i=1}^{3} LD_i(\mathbf{r'},t,\mathbf{r},t). \quad (10)$$

3.2.2 Output of the second subfilter

In [6], the output for each component of the central pixel is an average of the corresponding components of the neighbourhood pixels, corrected with the corresponding correction term ($i=1,2,3$):

$$Out(\mathbf{r},t,i) = \frac{\sum_{\mathbf{r'}}\Big(I_f(\mathbf{r'},t,i) - \epsilon(\mathbf{r'},t,\mathbf{r},t)\Big)}{9}. \quad (11)$$

However, pixels that belong to another object and that have another colour, have a negative influence on the output. In homogeneous areas, neighbouring pixels are expected to be almost the same, and the local differences to be almost 0. So the method further averages the remaining differences caused by the noise. For a pixel belonging to another object however, the assumption that the local differences are expected to be equal in all components does not always hold. Therefore we assign weights $WT(\mathbf{r'},t,\mathbf{r},t)$ to the neighbouring pixels, based on whether they are expected to belong to the same object or not. To make this decision, we use the Euclidian distance between the central pixel and the considered neighbourhood pixel, given by

$$\delta(\mathbf{r'},t,\mathbf{r},t) = \big(\sum_{i=1}^{3} LD_i(\mathbf{r'},t,\mathbf{r},t)^2\big)^{\frac{1}{2}} \quad (12)$$

ISBN: 978-989-95079-6-8

The weights themselves are then calculated using the following fuzzy rule that expresses that the value $\delta(\mathbf{r'}, t, \mathbf{r}, t)$ should not be large. Otherwise, the considered pixel is expected to belong to another object.

Fuzzy Rule 6. *Assigning the weight in the second subfilter for the pixel at position* $(\boldsymbol{r'}, t)$ *in the filtering window:*

IF $\delta(\boldsymbol{r'}, t, \boldsymbol{r}, t)$ *is* NOT LARGE

THEN *the pixel at position* $(\boldsymbol{r'}, t)$ *has a* LARGE WEIGHT $WT(\boldsymbol{r'}, t, \boldsymbol{r}, t)$ *in the second subfilter.*

The membership function μ_δ that determines the fuzzy set "large Euclidian distance" is depicted in Fig 3. The weights in

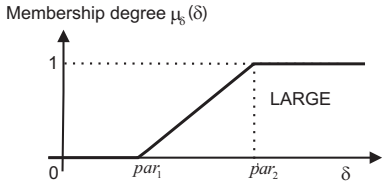

Figure 3: The membership function μ_δ of the fuzzy set "large Euclidian distance".

the filtering are again chosen equal to their membership degree in the fuzzy set "large weight", i.e., $WT(\mathbf{r'}, t, \mathbf{r}, t) = 1 - \mu_\delta(\delta(\mathbf{r'}, t, \mathbf{r}, t))$.

Finally, if not $WT(\mathbf{r'}, t', \mathbf{r}, t) = 0$ for all neighbouring pixels in the 3×3 window, the output of the second subfilter for the central pixel in the window is determined as follows ($i = 1, 2, 3$):

$$Out(\mathbf{r}, t, i) = \frac{\sum_{\mathbf{r'}} WT(\mathbf{r'}, t, \mathbf{r}, t)\Big(I_f(\mathbf{r'}, t, i) - \epsilon(\mathbf{r'}, t, \mathbf{r}, t)\Big)}{\sum_{\mathbf{r'}} WT(\mathbf{r'}, t', \mathbf{r}, t)} \tag{13}$$

where $\epsilon(\mathbf{r'}, t, \mathbf{r}, t)$ is the correction term for the components of the neighbouring pixel at position $(\mathbf{r'}, t')$. If the central pixel is so corrupt that all neighbouring pixels get a weight equal to zero, the output is calculated by giving all neigbhouring pixels in the window a weight equal to 1 and the corrupt central pixel the weight 0 ($i = 1, 2, 3$):

$$Out(\mathbf{r}, t, i) = \frac{\sum_{\mathbf{r'} \neq \mathbf{r}} \Big(I_f(\mathbf{r'}, t, i) - \epsilon(\mathbf{r'}, t, \mathbf{r}, t)\Big)}{8} \tag{14}$$

4 Experimental Results

In this section we present some experimental results obtained from the test sequences "Salesman", "Tennis", "Chair" and "Flowers", corrupted with additive Gaussian noise of zero mean and standard deviation $\sigma_n = 5, 10, 15, 20, 25$.

To draw conlusions about the proposed filtering framework, we have used the peak signal to noise ratio (PSNR) and the normalized colour difference (NCD) as measures of objective similarity and dissimilarity between the original and the filtered frames [6]. The higher the PSNR and the lower the NCD, the more similar the original and the filtered frame.

4.1 Parameter Selection

The parameters, that determine the membership functions in the above described filtering framework, have been set as follows. For the respective noise levels $\sigma_n = 5, 10, 15, 20$, the optimal parameters in terms of the mean PSNR values averaged over the sequences "Salesman", "Tennis", "Flowers" and "Chair" have been determined by letting them vary over a range of possible values. As illustrated in Fig. 4 for the parameter thr_2, this led to a linear relationship between these optimal values and the noise level. Hence, the parameters are set as the best fitting line through the observations, as shown in Fig. 4. The equations of those straight lines are given in Table 1, where σ_n stands for the standard deviation of the Gaussian noise. If this standard deviation is not known, it can be estimated by e.g. the method from [10].

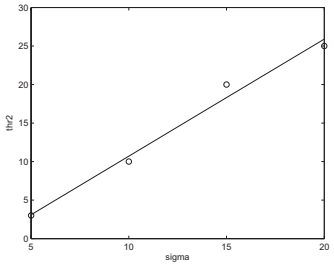

Figure 4: Optimal parameter values in terms of the PSNR.

T_2	$3.14\sigma_n - 1.0$	par_2	$6\sigma_n + 35$

4.2 Experiments

In the experiments, we have compared the proposed filter (denoted by FMDAF-CR) to the filtering scheme in which a wavelet extension of the original pixel domain greyscale method [4], which outperforms both the pixel domain filter and other state-of-the-art greyscale methods of a similar complexity (as shown in [4]), is applied on the Y component of the YUV transform, followed by an averaging (3×3 window) of the chrominance components U and V (denoted by FMDAF-YUV). The average PSNR and NCD values found for the test sequences corrupted with different noise levels and processed by these two above approaches are given in Tables 2 and 3 respectively. From these tables, we can conclude that the proposed colour extension performs better in terms of average PSNR and average NCD than the commonly used YUV-filtering. For a visual comparison, we have made the original and noisy ($\sigma_n = 15$) "Salesman" sequence and the results after applying respectively the FMDAF-CR and the FMDAF-YUV filter available on `http://users.ugent.be/~tmelange/colourrule`. we concentrate on the side of the phone, we see that for the FMDAF-YUV method more colour artefacts (green and red spots) are visible than for the FMDAF-CR filter, which might be an explanation for the better PSNR and NCD values. Further, we also see that the wavelet domain method FMDAF-YUV has removed more noise and produces a smoother result. This smoother result can however be attributed to the use of a wavelet domain filter. If the original pixel domain greyscale method would have been used, we would also have had a little more noise remaining. Remark also that the smoother result also has as a result that the details have been smoothed a little more. This trade-off between noise removal and detail preservation is one of the main challenges in the development of a noise filter.

Abstract *— A lot of disciplines (e.g. archaeology) have to process imprecise temporal information. There are different possibilities to handle this kind of information, amongst them e.g. fuzzy set theory and rough set theory. In this paper, due to its capability in the context of many data acquisition applications, the focus has been set on rough set theory. To illustrate temporal information, an interval is often visualised by means of a one-dimensional segment in a one-dimensional space. An alternative representation of time intervals is called the Triangular Model (TM) by which a time interval is represented by a point in a two-dimensional space. In this paper, rough set theory is applied into TM, which gets extended to the Rough Triangular Model (RTM). In RTM, Rough Time Intervals (RTI) and their mutual relations can be visualised diagrammatically, which offers opportunities to visualise and analyse imprecise temporal information. Aerial photos, taken during World War I, containing imprecise temporal information with archaeological background, are used to illustrate the potentials of the model in processing RTI.*

Keywords — Imprecise temporal information, rough set theory, temporal reasoning, temporal relation, time interval, triangular model.

1 Introduction

For time intervals, the most widely adopted representation is the linear model where time intervals are modelled as finite linear segments in a one-dimensional space. Much research has been carried out on representing and reasoning about time intervals, most of which is based on this linear concept and simple temporal relations [1] [3] [6] [7] [10]. Though Rough Time Intervals (RTI), i.e. intervals starting and/or ending at uncertain time stamp are also frequently used in many disciplines, there is still a shortage of methods and tools to visualise them. An alternative temporal model, the Triangular Model (TM), has been proposed in [11] [12] [2]. This model is based on the W-diagram introduced in [4] [5]. Up till now, TM has remained mainly a theoretical concept. However, it seems to offer a promising design for several applications.

A lot of disciplines (e.g. archaeology, geography, psychology, and philosophy) are faced by the problem of having imprecise temporal information. To handle this information it can be reverted to different approaches, for instance to fuzzy set theory [13]. This theory aims to formalise inherently fuzzy concepts by permitting the gradual assessment of the membership of an element in relation to a set. Another way to deal with imprecise temporal information can be found in rough set theory [8] [9]. This theory introduces a concept of lower and upper approximation and a boundary region, describing a set where elements can or can not be decisively classified into a set X. In contrast to fuzzy set theory, rough set theory is particularly useful in the context of many data acquisition applications. Therefore, in this paper the rough set theory has been chosen to be applied into the TM.

This paper extends TM to RTM in order to visualise and analyse RTIs. First, the basics of TM are introduced in section two. The remainder of this section describes RTIs and their visualisation in the RTM. In section three, we illustrate how to visualise rough time relations of RTIs by means of the RTM. This section is followed by a description of an application of the RTM to incomplete temporal data which is deriving from an archaeological background. Finally, conclusions are drawn and future work is pointed out.

2 The Triangular Model

2.1 Representing time intervals with TM

Time is usually conceptualised as a linear, one-dimensional time line (Fig. 1). In this classical concept, a temporal interval I is visualised by a segment that is bounded by a begin point I^- and end point I^+. In the linear model, the vertical dimension is only used to differentiate multiple overlapping intervals, if used at all. An interval without duration is visualised as a point (zero dimension). The basic concept of TM is the construction of two lines through the extremes of a linear time interval (Fig. 2). For each time interval I, two straight lines (L_1 and L_2) are constructed, with L_1 going through I^-; L_2 going through I^+, and where the angle $\alpha_1 = \alpha_2$. The intersection of L_1 and L_2 is called the interval point I. The position of I in the two-dimensional space completely determines both, the beginning and end point of the interval (Fig. 3).

ISBN: 978-989-95079-6-8

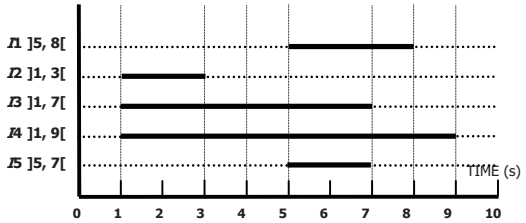

Figure 1: Linear representation of time intervals.

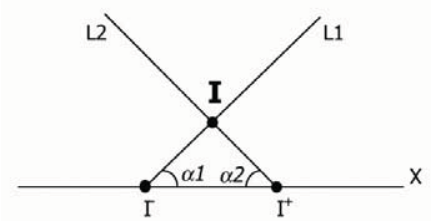

Figure 2: Construction of a simple interval point.

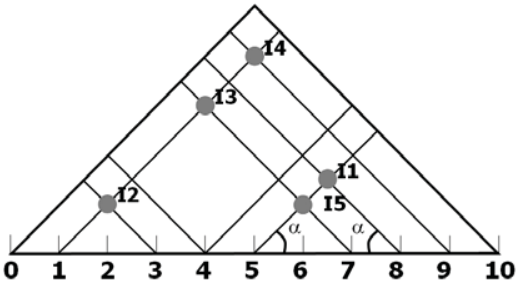

Figure 3: Time intervals in TM.

2.2 Representing RTIs with TM

It is often difficult for scientists to obtain precise temporal information about events or processes. Geological periods, for example, are always associated with uncertain starting and ending times. In history and archaeology as well, many events are lacking precise temporal demarcation. For instance, consider the impreciseness coming along with radiocarbon dating.

Scientifically underpinned treatments for imprecise information handling are already existing. For instance, fuzzy set theory [13] aims to formalize inherently fuzzy concepts by permitting the gradual assessment of the membership of an element in relation to a set. It extends conventional (crisp) set theory and handles the concept of partial truth, i.e. truth values between 0 (complete false) and 1 (complete true).

Another way to deal with imprecise information can be found in rough set theory [8] [9]. The main purpose of rough set theory is the induction of approximations of concepts, which are represented by the upper approximation $\overline{B}$ and the lower approximation $\underline{B}$. Within $\underline{B}$, elements can be decisively classified into a set X; outside $\overline{B}$, elements are not members of X. The difference between $\overline{B}$ and $\underline{B}$ forms a boundary region. If the boundary region is nonempty, a set is said to be rough; otherwise the set is crisp. In the boundary region, elements can not be decisively classified as members or not members of X.

Rough set theory is particularly useful in the context of temporal information, due to the nature of data acquisition in many scientific applications. Remote sensing, for instance, is a world-wide applied tool that relies on images taken at discrete time stamps. One can determine the state of a feature on these snapshots, whereas this state is uncertain in between two time stamps. However, we rely on the very natural assumption that this state does not change in between two snapshots which show similar states, i.e. the uncertain parts only remain in between two snapshots showing different states. Hence, we might consider a period of snapshots showing similar states (closed time interval) as a lower approximation for this state and its neighbouring periods of uncertainty (two open time intervals) as boundary region; both then cumulate into the state's upper approximation (open time interval) (Fig. 4). Thus, a feature's state can be considered as a rough set or more specifically a RTI. Next to remote sensing, this idea applies to numerous other fields, such as, soil core sampling, socio-economical census and surveys, and opinion polls.

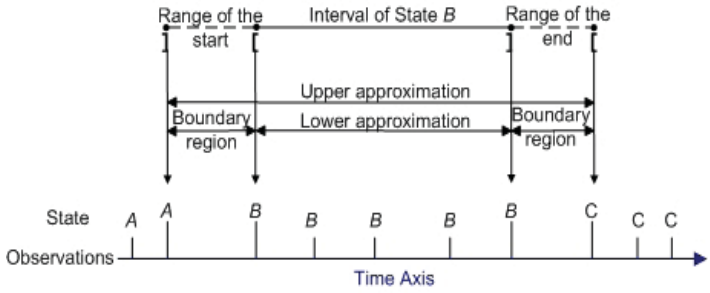

Figure 4: Rough set interval in remote sensing.

In the classical linear model, RTIs are represented as linear segments with an uncertain beginning range and an uncertain end range (Fig. 5). If there is a huge amount of rough intervals, it is quite difficult for humans to abstract information from this representation. Therefore the analyse capacities of the linear model are quite limited. For an advanced temporal analysis based on visualisation an alternative is needed.

In TM, a RTI is represented by a polygon. Four lines are constructed respectively from the earliest/latest beginning and the earliest/ latest end, forming a diamond (Fig. 6). This polygon indicates a zone within which the uncertain interval can be found. We call this representation the Rough Triangular Model (RTM).

In some cases, the beginning and end range have intersections. Take I_5 in Fig. 6 for example, we only know that it starts between 3 and 5, and ends between 3 and 5. In this case, the interval is represented as a triangle incumbent on the x-axis in RTM. In some other cases, intervals are partially rough: they have a precise beginning/end, but an imprecise end/beginning. These semi-rough intervals can be represented by lines (e.g. I_2 in Fig. 6). There are still other possibilities such as semi-open intervals, two-sided open intervals and totally indefinable intervals. In this paper, we are focussing on the

ISBN: 978-989-95079-6-8

first type of RTIs which are having a twofold, non-overlapping boundary region.

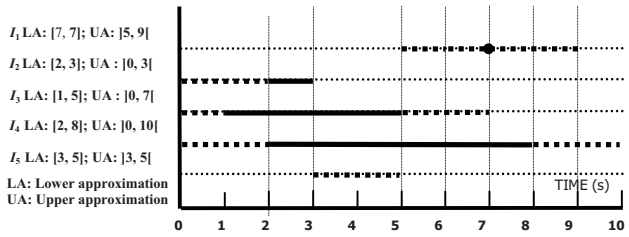

Figure 5: Linear representation of RTIs[1].

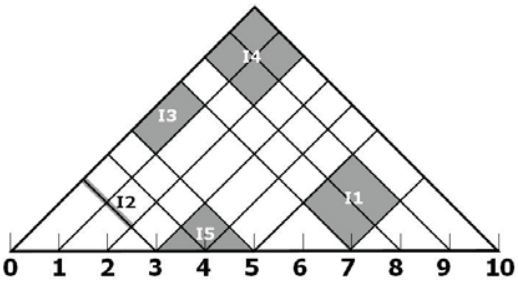

Figure 6: Visualising RTIs in RTM.

3 Rough temporal relations

When time intervals are rough, the relations between them also become rough. RTM provides the possibility of visualising and analysing temporal relations in a two-dimensional space

3.1 Representing fine temporal relations in TM

Based on the basic work of Allen [1], an interval I is represented as a pair (I^- ; I^+) with real numbers I^- and I^+, denoting respectively the beginning and end points of the interval. This means that Allen only deals with simple intervals having a specified duration. Let the beginning I^- and end point I^+ of two simple intervals have the following three possible relations: smaller than (<), equal (=) and larger than (>). Then, thirteen possible fine relationships between two intervals can be defined (see Tab. 1).

Table 1: Thirteen Allen relations [1].

Allen's temporal relations			
I_1 *equal* I_2	if $I_1^- = I_2^-$	^ $I_1^+ = I_2^+$	
I_1 *starts* I_2	if $I_1^- = I_2^-$	^ $I_1^+ < I_2^+$	
I_1 *started-by* I_2	if $I_1^- = I_2^-$	^ $I_2^+ < I_1^+$	
I_1 *finishes* I_2	if $I_1^+ = I_2^+$	^ $I_1^- > I_2^-$	
I_1 *finished-by* I_2	if $I_1^+ = I_2^+$	^ $I_2^- > I_1^-$	
I_1 *meets* I_2	if $I_1^+ = I_2^-$		
I_1 *met-by* I_2	if $I_2^+ = I_1^-$		
I_1 *overlaps* I_2	if $I_2^- > I_1^-$	^ $I_1^+ < I_2^+$	^ $I_1^+ > I_2^-$
I_1 *overlapped-by* I_2	if $I_1^- > I_2^-$	^ $I_1^- < I_2^+$	^ $I_2^+ < I_1^+$
I_1 *during* I_2	if $I_1^- > I_2^-$	^ $I_1^+ < I_2^+$	
I_1 *contains* I_2	if $I_2^- > I_1^-$	^ $I_2^+ < I_1^+$	
I_1 *before* I_2	if $I_1^+ < I_2^-$		
I_1 *after* I_2	if $I_2^+ < I_1^-$		

[1] In this paper, we use ISO standard notation to distinguish open intervals and close intervals. In this notation,]a, b[denotes open interval, [a, b] denotes close interval and]a, b] denotes left-open but right-close intervals. Since Allen's intervals are open, we use]a,b[here to denotes Allen's intervals.

Using TM [12], these relations can be visualised. Each relation thereby corresponds to a specific Fine Relation Zone (FRZ) within TM. Given a study period beginning at 0 and ending at 100, all examined intervals are located within the isosceles triangular of I]0, 100[. To obtain the best visualisation, the reference interval I_2]33,66[is chosen to be located in the centre of TM. As shown in Fig. 7b several intervals (I_{1a}, I_{1b}, I_{1c}, I_2) may exist *before* interval I_2]33,66[. All possible intervals for which $I_1^+ < I_2^-$ applies are generalised, with respect to interval I_2, into the FRZ *before,* displayed by the black triangle in Fig. 7c. Note that as Allen worked with open intervals, also the interval zone corresponding to I]0,33[is open. The right boundary of FRZ *before* represents all intervals for which applies $I_1^+ = I_2^-$. Therefore, the intervals have their end point at 33, resulting in the *meets* relationship.

Comparing the visualisations of TM with the linear model, both visualise the same fine interval relations, as displayed in Fig. 7a and Fig. 7c. The benefit of TM in visualising time relations gets spontaneously definite. The time intervals in Fig. 7c is faster to capture than the one in Fig. 7a. An overview of positions and names of the thirteen FRZs is given in Fig. 8.

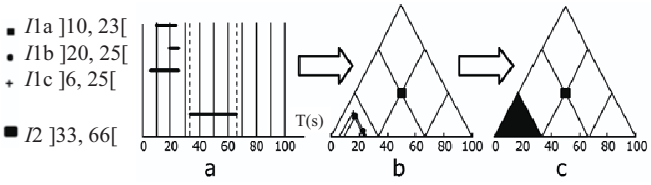

Figure 7: Visualisation of fine intervals by means of the linear model a) and TM b). FRZ *before* within TM c).

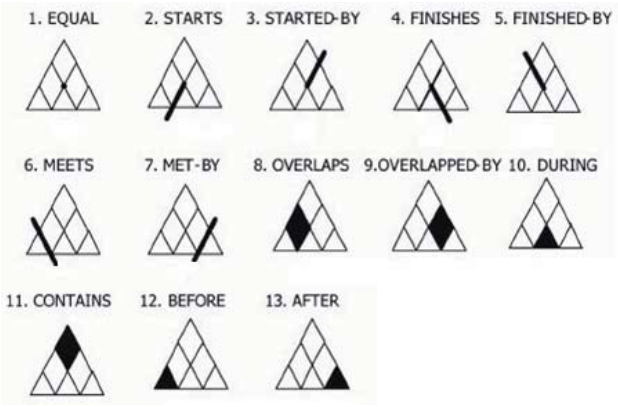

Figure 8: Thirteen FRZs in TM.

3.2 Relation zones in RTM

While TM represents fine intervals and fine interval relations, RTM represents rough intervals and its relation zones are Rough Relation Zones (RRZs).

To transform FRZs into RRZs, all point and line zones of TM (*equal, starts, started-by, finish, finished-by, meets,* and *met-*

ISBN: 978-989-95079-6-8

by) are expanded according to the duration of the boundary regions of the reference interval I_2. Hence, two polygon zones arise from the intersections of the expanded line zones *starts* and *meets* as well as from the intersections of the expanded line zones *finishes* and *met-by* (Fig. 9). Note that the absolute position of these zones may change according to the used data, while the relative position always remains.

Transforming the TM to RTM, fifteen relation zones are generated; nine of these are expanded zones (Fig. 9 and Tab. 2). The names of the expanded zones are based on the names of FRZs, but preceded by 'maybe'. Therefore these expanded relation zones are named *maybe* zones.

In TM, only one specific fine relation is possible within a FRZ (Tab. 2). Different from that, in RTM *maybe* zones represent zones where several fine relations are possible (Tab. 2). This is caused by the fact that a RRZ consists of parts of corresponding neighbouring FRZs in TM. The dashed lines in Fig. 9 represent the borders of original FRZs. In RTM, the positions of these dashed lines are uncertain and can be anywhere within the corresponding *maybe* zone. This is different from fuzzy set interval where the dashed lines have gradually-changing probability of appearance. Thus, we only use flat colour (white) to mark the interior of *maybe* zones. Note that each maybe zone contains the relations of its neighbouring zones in RTM (Fig. 9).

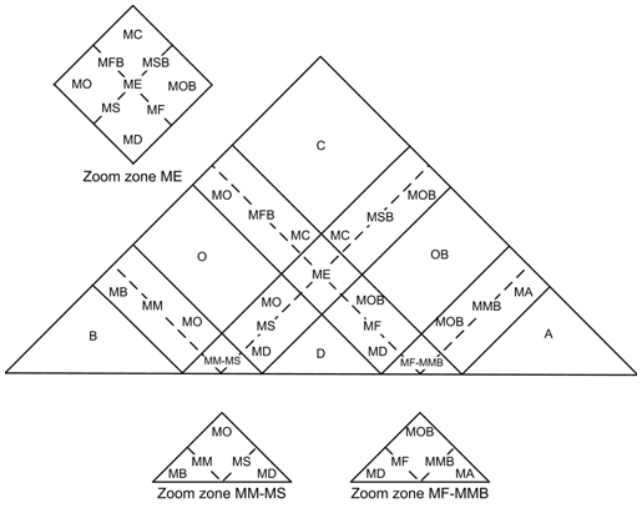

Figure 9: RRZs in RTM.

Table 2: Thirteen FRZs in TM and fifteen RRZs in RTM

FRZ		RRZ		
Name	**Abbr.**	**Name**	**possible relations**	**Abbr.**
equal	E	*maybe equal*	*contains, started-by, overlapped-by, finishes, during, starts, overlaps, finished-by, equal*	ME

/	/	*maybe meets or maybe starts*	*before, meet, overlaps, during, starts*	MM-MS
/	/	*maybe finishes or maybe met-by*	*during, finishes, overlapped-by, met-by, after*	MF-MMB

Unlike with FRZs, the border lines of RRZs do not make up separate relation zones but belong to one of their neighbouring RRZs. Due to their definition, the boundary regions in the beginning and the end of RTIs are open intervals (Fig. 4). The corresponding assignments are illustrated in Fig. 10, where the arrows are pointing into the zone to which the respective border line is assigned.

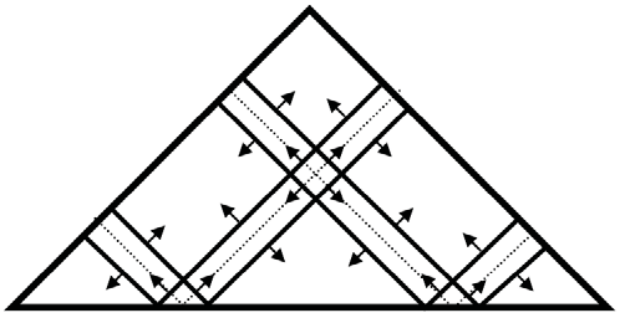

Figure 10: Assignment of the borders of RRZs.

3.3 Applying RTM

In order to evaluate whether RTM is helpful for the analysis of imprecise temporal information; we tested RTM with data deriving from an archaeological context. During World War I, aerial photos covering the Belgian-German front line in West-Flanders (Belgium) have been taken. From these aerial photos, we can observe whether a feature such as a fire trench, a gun position or a barrack, was not yet present, was present or was destroyed. For each feature, several photos with according date of acquisition exist. Hence, if we can find (1)

ISBN: 978-989-95079-6-8

the last photo where the feature is not yet found, (2) the first photo where the feature is found, (3) the last photo where the feature is found, and (4) the first photo where the feature is destroyed, we can derive a RTI representing the feature's uncertain lifetime (Fig. 4).

In RTM, fifteen RRZs can be created for one feature (Fig. 9). Lots of similar intervals will yield overlapped RRZs. If different grey shades are added to denote the number of overlaps in the concerning area, there will appear some patterns which reflect characteristics of the underlying data.

Fig. 11 and Fig. 12 visualise the overlaps of *maybe equal* zones of gun positions and breastworks respectively. More overlapped areas are marked with dark grey, and vice versa. Comparing these two visualisations, we can have a direct overview about how the two types of features are temporally distributed. As in the model most polygons of gun positions are distributed right of the breastworks zones, comparing Fig. 11 with Fig. 12, we may observe that gun positions exist relatively later than breastworks. It also can be observed that breastworks generally exist longer than gun positions because most of the breastworks zones are higher on the *y*-axis than the zones of the gun positions.

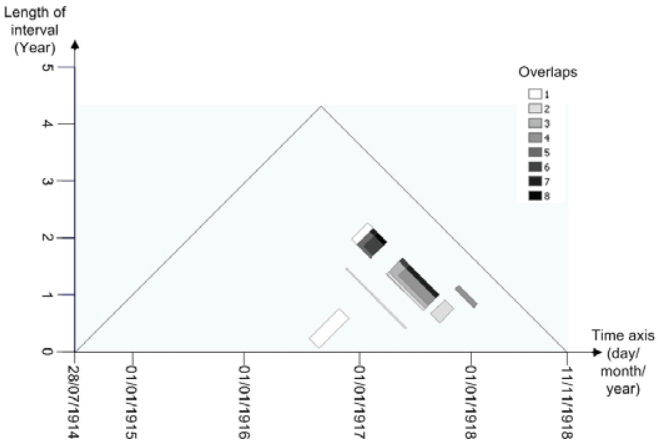

Figure 11: Overlaps of maybe equal zones of gun positions.

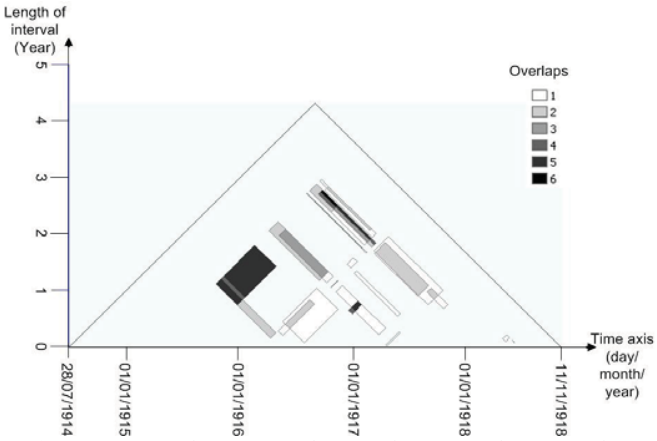

Figure 12: Overlaps of maybe equal zones of breastworks.

If we select *contain* interval zones of gun positions (Fig. 13), the display of the model can be divided into several zones according to the colour grade. If an interval point is in the dark zone, it contains intervals of most features. In other words, in the dark zone, all intervals contain most features lifetime intervals. In natural language, we could say: if an interval is in a dark zone, it witnesses the lifetime of most features. This approach can be applied to other RRZs and even to combinations of relation zones.

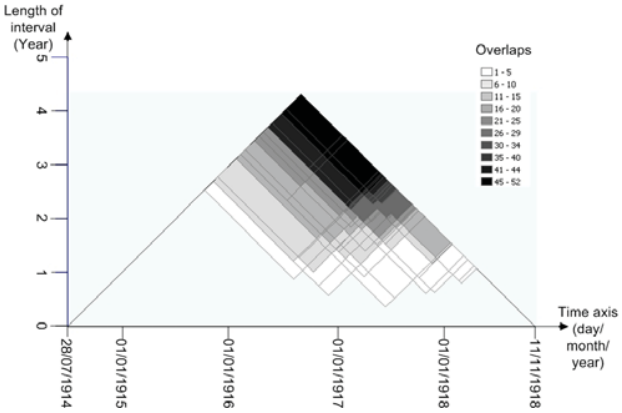

Figure 13: The overlaps of the *contain* zone of gun positions.

4 Conclusions and future work

Since a lot of disciplines (e.g. archaeology, geography, psychology, and philosophy) are faced by the problem of having imprecise temporal information we extended TM into RTM in order to visualise RTIs and temporal relations between them. We do not intend to create a new or extend an existing temporal calculus or temporal logic. Our approach takes special care for the intuitive and visualization aspects. In RTM, RTIs are represented by simple geometries (e.g. lines and polygons) in a two-dimensional space. Compared to the classical linear model, which has limited analytical capacities, RTM gives people a direct overview of the temporal distribution of RTIs. When handling a huge amount of rough intervals, RTM provides a compact visualisation pattern, which helps in further exploratory analysis. Furthermore, the temporal relations between RTIs can be visualised as zones, i.e. RRZs, in the two-dimensional space, which gives potentials in visual queries of rough temporal relations.

In this paper, we described the basics of RTM and RRZs. However, further research needs to be done.

First, as explained in 2.2; also other types of RTIs should be considered, e.g. partially rough intervals, one-sided open intervals and intervals with overlapped begin and end boundary regions. This would imply a wide modification of the RRZs. This major change in the division of the RRZ consequently has to be followed by an adaptation of visualisation and interpretation. Whether these visualisation and analyses are delivering feasible results has to be tested in further research.

ISBN: 978-989-95079-6-8

Second, the idea of conceptual neighbourhood has proved its importance in qualitative reasoning about time and space. When temporal relations become rough, there are more possibilities that one relation continuously changes to another relation without passing through other relations. Thus, the conceptual neighbourhood diagram of rough temporal relations will change accordingly. Also, the practical use of conceptual neighbourhood of temporal relations of rough intervals has to be studied in detail.

Third, so far we dedicated the borders of the RRZs of the RTM to one of the RRZs. But following the example of the TM, these lines could be relation zones by themselves. That would mean that additionally to the fifteen RRZ we would have nineteen line zones and probably six point zones. In total RTM would be build up out of forty zones. The additional line zones would include, for example, line zones of TM like *starts*, *started-by*, *finishes*, *finished-by, meets* and *met-by*. But also new line zones would be created like the line zones which are located between the zones *maybe starts or maybe meets* and *maybe meets*. Within this line zone a wide range of relations are possible. Whether this great number of RRZ provides useful visualisations and if the interpretation could be aided by a computer still needs to be determined. Also whether this interpretation would deliver helpful information still needs to be investigated.

Finally, this model can be more useful if it is implemented as an interactive tool. More flexible and interactive visualisation tools can help to better analyse complex temporal data.

Abstract*—The problem of solving a multi-objective programming problem, by assuming that the decision maker has fuzzy goals for each of the objectives, is addressed. In this case a fuzzy goal programming problem has to be solved. But when we have several objectives it can be a difficult task for the decision maker to determine coherent aspiration levels, so it is possible that the tolerance thresholds be inconsistent with each other, therefore obtaining an infeasible problem. We present a procedure in order to repair the infeasibility. We rebuild the unattainable fuzzy goals keeping their relaxation levels as small as possible while maintaining, at the same time, a good balance vis-à-vis the degree of achievement of the others goals.*

***Keywords*—**, Fuzzy goal programming, Goal programming, Infeasibility, Multi-objective programming.

1 Introduction

Let a multi-objective programming (MOP) problem with k objective functions $z_i(x) = c_i x$, $i = 1,...,k$ be

$$\text{(MOP)} \quad \text{Min} \quad z(x) = (z_1(x), z_2(x), ..., z_k(x))$$
$$\text{S. t.} \quad x \in X$$

Where $X = \{x \in \mathbb{R}^n \mid Ax \geq b, x \geq 0\}$, $c_i = (c_{i1}, ..., c_{in}) \in \mathbb{R}^n$, $i = 1,...,k$; $b = (b_1, ..., b_m) \in \mathbb{R}^m$ and A is a $\mathbb{R}^{m \times n}$ matrix.

For the sake of simplicity we suppose that all the objectives should be minimized. However, the procedure demonstrated is easily extendable were the case to include some maximizing objectives.

In (MOP) it is unlikely that all objectives will simultaneously achieve their optimal value. Therefore in practice the decision maker (DM) chooses a satisfying solution, according to the aspiration level fixed for each objective.

Assuming that the DM proposes imprecise aspiration levels such as, "$z_i(x)$ should be essentially less than or equal to some value g_i", model (MOP) can be written as

$$\text{(FGP)} \quad \text{Find } x$$
$$\text{Such that} \quad z_i(x) \lesssim g_i \quad i = 1,2,...,k$$
$$x \in \text{X}$$

Each expression $c_i x \lesssim g_i$ is represented by a fuzzy set called fuzzy goal, whose membership function, $\mu_i(z_i)$, $\mu_i : \mathbb{R} \to [0,1]$, provides the satisfaction degree λ_i to which the i^{th} fuzzy inequality is satisfied. In order to define the membership function $\mu_i(z_i)$ the DM has to provide the tolerance margins g_i+t_i that she/he is willing to accept. So $\mu_i(z_i)$ should be equal to 1 if $z_i \leq g_i$, strictly monotone decreasing from 1 to 0 over the interval $(g_i, g_i + t_i)$ and equal to 0 if $z_i \geq g_i + t_i$.

Models like this are named fuzzy goal programming (FGP) problems. (FGP) should be considered as an auxiliary model in order to solve (MOP).

As it has been widely seen, a FGP problem, using the fuzzy decision max-min of Bellman and Zadeh [1] and introducing the auxiliary variable λ, adopts the following formulation [2]

$$\text{(B-Z)} \quad \text{Max } \lambda$$
$$\text{S.t.} \quad 0 \leq \lambda \leq \mu_i(z_i(x)) \quad i = 1,\ldots,k$$
$$x \in X, \ \lambda \leq 1$$

But when there are several objective functions it can be a difficult task for the DM to determine coherent aspiration levels. Therefore it is possible that some tolerance thresholds will be inconsistent with each other or with the crisp constraints, some of them being unattainable (membership degree=0). In this case (B-Z) is infeasible. Chinneck [3] summarizes the state of the art in algorithms related to infeasibility in optimization. Most published research has been focused on the diagnosis of infeasibility. Little investigation has been made in infeasibility resolution and very limited literature can be found in infeasibility resolution using fuzzy approach. León and Liern [5] use a fuzzy sets approach to relax constraints to repair infeasibility in crisp mathematical programming problems. Gupta et al. [6] take a similar fuzzy approach to finding a best approximate solution to an infeasible mathematical programming problem. In this paper we propose a procedure in order to solve a FGP should the above described drawback occur. We demonstrate the

ISBN: 978-989-95079-6-8

operativeness of our approach by means of a numerical example.

2 Repairing infeasibility

Let us assume that (B-Z) is infeasible because the tolerance thresholds of some goals are unattainable. The first step (M.I) is to identify one minimum-cardinality subset of {1, 2,…, k}, that will be denoted *CS*, so that the goals {1, 2,…, k}−*CS* provide a feasible (B-Z) problem. This procedure is related to the minimum cardinality irreducible infeasible subsystem (IIS) set-covering problem (MIN IIS COVER) (see [3, 4]). Hence the Chinneck's algorithm [4] will be applied to the following sets of linear constraints

$$z_i(x) \le g_i + t_i \qquad i = 1,2,...,k$$
$$x \in \mathrm{X}$$

where only the k -first constraints (the goals) are elasticized. So we will work with the model

$$\text{(M.I)} \quad \text{Min} \sum_{i=1}^{k} p_i$$
$$\text{S.t.} \quad z_i - p_i \le g_i + t_i \quad i = 1,\ldots,k$$
$$x \in X$$

Next, in order to repair infeasibility, we have to shift the unattainable goals, i.e. the *CS*-goals, as low as possible without penalizing excessively the achievement degree of other goals. Taking this into account we consider the following two positions: 1) we allow the feasible goals to deteriorate to their corresponding tolerance threshold 2) we aim to attain a satisfactory solution for the feasible goals. Obviously the relaxation of the unattainable goals will be smaller in the first position than in the second. Therefore we assign a satisfaction degree equal to 1 to the relaxed values obtained in the first position and a satisfaction degree equal to 0 to that obtained in the second position, decreasing monotonously between these values. This way, we obtain the membership functions $\mu_i^*\left(z_i(x)\right)$ that rebuild the new fuzzy goals corresponding to the, previously, unattainable goals.

Assuming, for the sake of simplicity, that the unattainable goals are the first *r*. Consider the aforementioned position 1, that is to say, we allow the feasible goals to deteriorate until their tolerance threshold and, being an inclusive condition, we look for the lowest relaxation levels for the unattainable goals by conventional goal programming approach [7]. Thus we propose to solve the following model

$$\text{(M.II)} \quad \text{Min} \sum_{i=1}^{r} w_i p_i$$
$$\text{S.t.} \quad z_i(x) - p_i \le g_i + t_i, \quad i = 1,...,r$$
$$z_i(x) \le g_i + t_i, \qquad i = r+1,...,k$$
$$x \in X, p_i \ge 0$$

where $\sum_{i=1}^{r} w_i = 1$ and $w_i \ge 0$ for all i=1,…,r. The variables p_i have the same significance as the positive deviation in goal programming (GP). (M.II) searches for a solution with the smallest weighted average relaxation levels in order to achieve feasibility, considering that the other goals could reach their corresponding tolerance threshold. Weight w_i represents the priority or importance of the relaxation levels of tolerance threshold g_i+t_i. It is well known that when $w_i>0$ for all i=1,…,r, any optimal solution of (M.II) is efficient [8], which give us a large set of possible goal shifts that provide a feasible solution.

Let x^{II} be an optimal solution of (M.II). In line with what we have said before, the values $z_i^{\mathrm{II}} = z_i\left(x^{\mathrm{II}}\right), i = 1,...,r$, have membership degree equal to 1 in the new (repaired) fuzzy goals that we are constructing.

Now let us consider the aforementioned position 2, that is to say we are looking for a good degree of satisfaction of the goals that are attainable in (M.I). In order to achieve this we solve the following max-min model in which only the feasible goals are included

$$\text{(M.III)} \quad \text{Max } \lambda$$
$$\text{S. t. } z_i(x) \ge z_i^{\mathrm{II}}, \ i = 1,...,r$$
$$0 \le \lambda \le \mu_i\left(z_i(x)\right) \quad i = r+1,\ldots,k$$
$$x \in X \text{ , } \lambda \le 1$$

Let x^{III} be an optimal solution of (M.III) and $z_i^{\mathrm{III}} = z_i\left(x^{\mathrm{III}}\right)$, i=r+1,…,k. We can consider the values $\max\left\{z_i^{\mathrm{III}}, g_i\right\}$, i=r+1,…,k as sufficiently satisfactory. In the process of searching for the lowest relaxation levels of the infeasible goals, maintaining the values of the feasible goals sufficiently satisfactory, we solve the following GP model

$$\text{(M.IV)} \quad \text{Min} \sum_{i=1}^{r} w_i p_i$$
$$\text{S.t.} \quad z_i(x) - p_i \le g_i + t_i, \quad i = 1,...,r$$
$$z_i(x) \ge z_i^{\mathrm{II}}, \qquad i = 1,...,r$$
$$z_i(x) \le \max\left\{z_i^{\mathrm{III}}, g_i\right\}, \qquad i = r+1,...,k$$
$$x \in X, p_i \ge 0$$

Let x^{IV} be an optimal solution of (M.IV). The values $z_i^{\mathrm{IV}} = z_i\left(x^{\mathrm{IV}}\right), i = 1,...r$, achieved by the unattainable goals, have membership degree equal to 0 in the new (repaired) fuzzy goals that we are constructing.

We write $z_i^{\mathrm{II}} \equiv g_i^*$ and $z_i^{\mathrm{IV}} \equiv g_i^* + t_i^*$.

This way we have obtained the new fuzzy aspiration levels $\mu_i^*\left(z_i(x)\right)$ which restore feasibility with the lowest relaxation levels (see figure 1).

Finally we solve the following max-min model, by replacing the unattainable aspiration levels substituted with the new aspiration levels, which restores feasibility.

$$\text{(B-Z*)} \quad \text{Max } \lambda$$
$$\text{S.t.} \quad \mu_i^*\left(z_i(x)\right) \ge \lambda \ge 0, i = 1,...,r$$
$$\mu_i\left(z_i(x)\right) \ge \lambda \ge 0, i = r+1,...,k$$
$$x \in X, \quad \lambda \le 1$$

ISBN: 978-989-95079-6-8

The optimal solutions of (B-Z*) can be considered as solutions of (B-Z) well balanced between attainable fuzzy goals an unattainable fuzzy goals. Moreover, if the solution of this problem is not fuzzy-efficient of (FGP) and/or not Pareto optimal of (MOP), the solution can be improved following a procedure showed in [9].

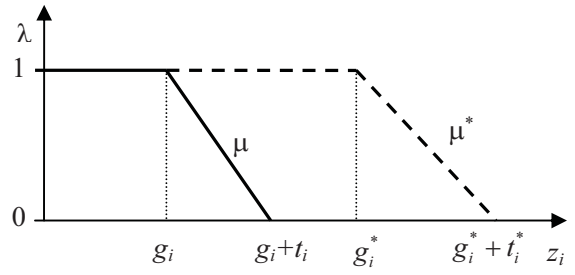

Figure1: Relaxation of an unattainable fuzzy aspiration level.

3 Example

To check the usefulness of our approach we consider the following numerical example.
Let a MOLP problem be

$$\begin{aligned}
&\text{Min } z_1=3x_1+3x_2+3x_3+2x_4+3x_5\\
&\text{Min } z_2=2x_1+x_2+2x_3+x_4+3x_5\\
&\text{Min } z_3=4x_1+4x_2+2x_3+3x_4+x_5\\
&\text{Max } z_4=x_1+6x_2+5x_3+7x_4+6x_5\\
&\text{Min } z_5= 5x_1+5x_2+4x_3+7x_4+5x_5\\
&\text{S.t. } 4x_1+2x_2+4x_3+2x_4+3x_5 \geq 18\\
&\quad x_1 \geq 1,\ 0 \leq x_3 \leq 3\\
&\quad x_2 \geq 0,\ x_4 \geq 0,\ x_5 \geq 0
\end{aligned}$$

Assume the DM proposes the following imprecise aspiration levels: "z_1 should be essentially less than or equal to 18", "z_2 should be essentially less than or equal to 6", "z_3 should be essentially less than or equal to 13", "z_4 should be essentially greater than or equal to 24" and "z_5 should be essentially less than or equal to 17", the respective tolerance threshold being 21, 8, 15, 21 and 20.

Step 1. We solve the (B-Z) problem

$$\begin{aligned}
&\text{Max } \lambda\\
&\text{S.t.}\\
&\lambda \leq \frac{1}{3}\left(21-\left(3x_1+3x_2+3x_3+2x_4+3x_5\right)\right)\\
&\lambda \leq \frac{1}{2}\left(8-\left(2x_1+x_2+2x_3+x_4+3x_5\right)\right)\\
&\lambda \leq \frac{1}{2}\left(15-\left(4x_1+4x_2+2x_3+3x_4+x_5\right)\right)\\
&\lambda \leq \frac{1}{3}\left(\left(x_1+6x_2+5x_3+7x_4+6x_5\right)-21\right)\\
&\lambda \leq \frac{1}{3}\left(20-\left(5x_1+5x_2+4x_3+7x_4+5x_5\right)\right)\\
&4x_1+2x_2+4x_3+2x_4+3x_5 \geq 18\\
&x_1 \geq 1,\ 0 \leq x_3 \leq 3\\
&x_2 \geq 0,\ x_4 \geq 0,\ x_5 \geq 0,\ 0 \leq \lambda \leq 1
\end{aligned}$$

This problem is infeasible because the tolerance thresholds of some goals are unattainable.

Step 2. We will identify one minimum-cardinality irreducible infeasible subsystem of goals by applying the Chinneck's algorithm to the following system of linear constraints where only the five first constraints (the goals) are elasticized:

$$\begin{aligned}
&3x_1+3x_2+3x_3+2x_4+3x_5 \leq 21\\
&2x_1+x_2+2x_3+x_4+3x_5 \leq 8\\
&4x_1+4x_2+2x_3+3x_4+x_5 \leq 15\\
&x_1+6x_2+5x_3+7x_4+6x_5 \geq 21\\
&5x_1+5x_2+4x_3+7x_4+5x_5 \leq 20\\
&4x_1+2x_2+4x_3+2x_4+3x_5 \geq 18\\
&x_1 \geq 1,\ 0 \leq x_3 \leq 3\\
&x_2 \geq 0,\ x_4 \geq 0,\ x_5 \geq 0
\end{aligned}$$

We obtain $CS=\{2, 5\}$.

Step 3. In order to repair infeasibility we propose to solve the following model (see M.II)

$$\begin{aligned}
&\text{Min } p_2 + p_5\\
&\text{S.t.}\\
&2x_1+x_2+2x_3+x_4+3x_5-p_2 \leq 8\\
&5x_1+5x_2+4x_3+7x_4+5x_5-p_5 \leq 20\\
&3x_1+3x_2+3x_3+2x_4+3x_5 \leq 21\\
&4x_1+4x_2+2x_3+3x_4+x_5 \leq 15\\
&x_1+6x_2+5x_3+7x_4+6x_5 \geq 21\\
&4x_1+2x_2+4x_3+2x_4+3x_5 \geq 18\\
&x_1 \geq 1,\ 0 \leq x_3 \leq 3\\
&x_2 \geq 0,\ x_4 \geq 0,\ x_5 \geq 0\\
&p_2 \geq 0,\ p_5 \geq 0
\end{aligned}$$

We get $z_2^{II}=9$ and $z_5^{II}=21.5$. These values have membership degree equal to 1 in the new (repaired) fuzzy goals that we are constructing.
In order to look for the balanced relaxation levels of the infeasible goal we need to find the values sufficiently satisfactory for the feasible goals.

Step 4. We solve the following model (M. III)

$$\begin{aligned}
&\text{Max } \lambda\\
&\text{S.t.}\\
&\lambda \leq \frac{1}{3}\left(21-\left(3x_1+3x_2+3x_3+2x_4+3x_5\right)\right)\\
&\lambda \leq \frac{1}{2}\left(15-\left(4x_1+4x_2+2x_3+3x_4+x_5\right)\right)\\
&\lambda \leq \frac{1}{3}\left(\left(x_1+6x_2+5x_3+7x_4+6x_5\right)-21\right)\\
&2x_1+x_2+2x_3+x_4+3x_5 \geq 9\\
&5x_1+5x_2+4x_3+7x_4+5x_5 \geq 21.5\\
&4x_1+2x_2+4x_3+2x_4+3x_5 \geq 18\\
&x_1 \geq 1,\ 0 \leq x_3 \leq 3\\
&x_2 \geq 0,\ x_4 \geq 0,\ x_5 \geq 0\\
&0 \leq \lambda \leq 1
\end{aligned}$$

As $z_i^{III}=15.48$, $z_3^{III}=11.32$, $z_4^{III}=26.52$ then in the process of searching for the lowest relaxation levels of the infeasible

ISBN: 978-989-95079-6-8

goals, maintaining the values of the feasible goals sufficiently satisfactory, we solve the following GP model:

Step 5. (see M.IV)

$$\begin{aligned}
&\text{Min } p_2 + p_5\\
&\text{S.t.}\\
&2x_1+x_2+2x_3+x_4+3x_5 - p_2 \le 8\\
&5x_1+5x_2+4x_3+7x_4+5x_5 - p_5 \le 20\\
&3x_1+3x_2+3x_3+2x_4+3x_5 \le 18\\
&2x_1+x_2+2x_3+x_4+3x_5 \ge 9\\
&4x_1+4x_2+2x_3+3x_4+x_5 \le 13\\
&x_1+6x_2+5x_3+7x_4+6x_5 \ge 24\\
&5x_1+5x_2+4x_3+7x_4+5x_5 \ge 21.5\\
&4x_1+2x_2+4x_3+2x_4+3x_5 \ge 18\\
&x_1 \ge 1,\ 0 \le x_3 \le 3\\
&x_2 \ge 0,\ x_4 \ge 0,\ x_5 \ge 0\\
&p_2 \ge 0,\ p_5 \ge 0
\end{aligned}$$

We get $z_2^{IV} = 9.5,\ z_5^{IV} = 24.96$. These values achieved by the unattainable goals, have membership degree equal to 0 in the new (repaired) fuzzy goals that we are constructing.

This way we have obtained the new fuzzy aspiration levels which restore the feasibility with the lowest relaxation levels: "z_2 should be essentially greater than 9" and "z_5 should be essentially greater than 21.5" with tolerance threshold equal to 9.5 and 25, respectively. Finally we solve the following (B-Z*) model

$$\begin{aligned}
&\text{Max } \lambda\\
&\text{s.t.}\\
&\lambda \le \frac{1}{3}\left(21-\left(3x_1+3x_2+3x_3+2x_4+3x_5\right)\right)\\
&\lambda \le \frac{1}{0.5}\left(9.5-\left(2x_1+x_2+2x_3+x_4+3x_5\right)\right)\\
&\lambda \le \frac{1}{2}\left(15-\left(4x_1+4x_2+2x_3+3x_4+x_5\right)\right)\\
&\lambda \le \frac{1}{3}\left(\left(x_1+6x_2+5x_3+7x_4+6x_5\right)-21\right)\\
&\lambda \le \frac{1}{3.5}\left(25-\left(5x_1+5x_2+4x_3+7x_4+5x_5\right)\right)\\
&4x_1+2x_2+4x_3+2x_4+3x_5 \ge 18\\
&x_1 \ge 1,\ 0 \le x_3 \le 3\\
&x_2 \ge 0,\ x_4 \ge 0,\ x_5 \ge 0\\
&0 \le \lambda \le 1
\end{aligned}$$

We get $x_1^* = 1,\ x_2^* = 0.79,\ x_3^* = 2.86,\ x_4^* = 0.25,\ x_5^* = 0.13$; $z_1\left(x^*\right) = 14.92,\ z_2\left(x^*\right) = 9.2,\ z_3\left(x^*\right) = 13.83,\ z_4\left(x^*\right) = 22.75$ and $z_5\left(x^*\right) = 22.95$. This can be considered as a solution of model (B-Z) well balanced between attainable fuzzy goals and unattainable fuzzy goals.

4 Conclusions

This paper describes a method to deal with infeasibility in fuzzy goal programming problems in case of the DM proposes unattainable tolerance thresholds for some goals. Considering the inherent flexibility of fuzzy approach we restore the feasibility by shifting the unattainable goals as low as possible but, at the same time, taking care not to penalize excessively the degree of achievement of the others goals. This way we rebuilt the unattainable goals obtaining a new feasible fuzzy goal programming problem whose solution is well balanced between attainable and unattainable fuzzy goals.

Abstract—*Two basic issues for data analysis and kernel-machines design are approached in this paper: determining the number of partitions of a clustering task and the parameters of kernels. A distance metric is presented to determine the similarity between kernels and FCM proximity matrices. It is shown that this measure is maximized, as a function of kernel and FCM parameters, when there is coherence with embedded structural information. We show that the alignment function can be maximized according FCM and kernel parameters. The results presented shed some light on the general problem of setting up the number of partitions in a clustering task and in the proper setting of kernel parameters according to structural information.*

Keywords— Affinity matrix, Clustering, Fuzzy C-Means (FCM), Kernel matrix, Reordering, Sorting.

1 Introduction

The importance of kernels has been much emphasized in the literature as the basic construct of learning machines like SVMs [6]. Kernel parameters play, therefore, a major role in achieving good performance of these classifiers. Setting up kernel parameters is usually accomplished by an exhaustive search carried out in the space of parameters. Quite often this search is completed without a full understanding of how kernels represent relations in the input space. The proper set-up of kernels is only expected to capture the input to feature space mapping that results on an acceptable overall machine performance, without any direct constraints imposed on the internal representation of relationships between patterns.

However, like Fuzzy C-Means (FCM) [7] proximity matrices (FPM) [8], kernels may incorporate important structural information about the data. In fact, data clustering can be accomplished by using information already contained in kernels, by finding the proper order of columns and rows of the kernel matrix [2, 3, 4, 5]. A similar affinity matrix [1] representation can also be obtained for FPMs, which may suggest that kernels and FPMs embody similar information about the data if their parameters are set accordingly. This observation also suggests that supervised and unsupervised learning may exhibit a closer relationship by the exchange of information between kernels and FPMs.

The problem of approximating kernels and FPMs relies, therefore, on setting their parameters so that they yield matrices that are close to each other or, in other words, that represent the same structural information. The parameters to be set are basically the width *r* of the Gaussian functions, for RBF kernels, and the number of partitions c, the basic parameter of FPMs. In this paper, we investigate how these two parameters are related to the alignment between RBF kernels and FPMs.

Experimental results on synthetic data yielded maximum alignment on values of *c* that coincide with the number of clusters of the data generator functions. This suggests that, for a given kernel matrix, the proper number of clusters can be induced by maximizing the similarity of FPM and the kernel matrix. In addition, it is also shown that, for the same problems, SVMs [6] can also be designed by setting the kernel parameter to the corresponding value of *r* that maximizes the similarity.

The paper is organized as follows. We start with a general overview of the main concepts including kernels and FPM. The concept of affinity matrix representation of kernels and FPMs is then described. Another important link between these two representations of data is presented in section 5 where kernels are shown to incorporate the same structural information the FPMs. The metric for similarity measure is then presented, which is followed by the description of the optimization algorithm, the main results, discussions and conclusions.

2 Mercer Kernels

The main characteristic of (Mercer) kernels [9] in the supervised learning context is that they allow implicit mapping of input data into feature space without actually computing the mapping itself. Instead, the mapping is accomplished by computing the internal product located in the input space. The kernel matrix $\mathbf{K}=[k(x_i,x_j]$ is regarded as a Mercer kernel if it is symmetric and positive semi-definite. In general, the kernel matrix can be considered as a matrix capturing similarity between all pairs of points of a data set. Kernels can be implemented by polynomials, linear and sigmoidal functions as well as Gaussian functions. A Gaussian, or RBF, kernel is described as follows

$$k(x_i, x_j) = e^{\frac{-(x_i - x_j)^2}{2r^2}} \quad (1)$$

where *r* is the radius of the Gaussian function.

ISBN: 978-989-95079-6-8

As an example, let us consider Fig. 1, where data were sampled from two Gaussian distributions. The corresponding RBF kernel where *r=0.25* is shown in Fig. 2. As patterns are not ordered according to the generator functions, no structural information can be directly visualized in the kernel matrix. In order to observe pattern relation properties directly from the kernel matrix, it is necessary to order the patterns accordingly, as it will be described in the next sections.

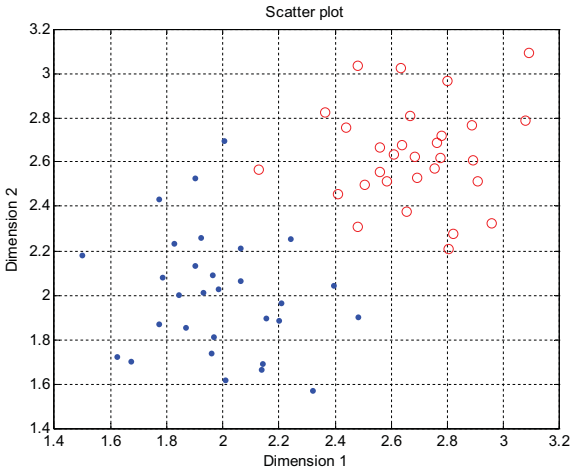

Figure 1: Data sample from two Gaussian distributions.

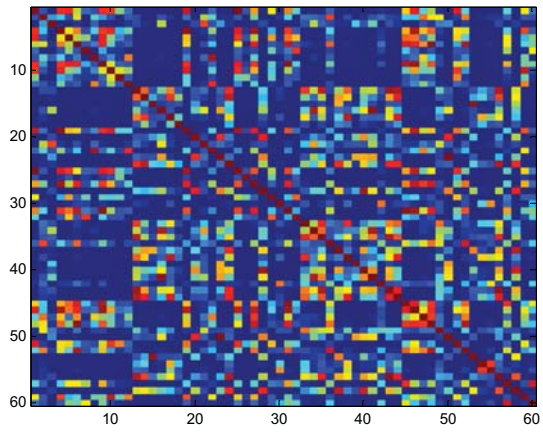

Figure 2: Unordered RBF kernel matrix (r=0.25) for the data of Fig. 1.

3 FCM Proximity Matrix

Fuzzy clustering realized by the well-known FCM algorithm [7] is formulated as a constrained optimization problem, where the partition matrix $\mathbf{U}=[u_{ik}]$ satisfies the constraint $\sum_{i=1}^{c} u_{ik} = 1$, while the objective function to be minimized reads as follows

$$J = \sum_{i=1}^{c}\sum_{k=1}^{N} u_{ik}^{m} \| \mathbf{x}_k - \mathbf{v}_i \|^2 \qquad (2)$$

where c is the number of partitions (clusters) in the data set, N is the data set size, m is the fuzziness coefficient (fuzziness factor) and $\mathbf{v}_i$ is the prototype of cluster i.

The obtained partition matrix $\mathbf{U}=[u_{ij}]$ can be used to generate the *NxN* proximity matrix $\mathbf{P}=[p_{kl}]$, according to the known relationship available in the literature [8] that is presented in (3). Likewise kernels, the proximity matrix **P** embodies relationships between patterns according to the clusters represented in the partition matrix **U**.

$$p_{kl} = \sum_{i=1}^{c} \min(u_{ik}, u_{il}) \qquad (3)$$

4 Affinity matrices

Given a data set $\Gamma_u = \{x_k\}_{k=1}^{N}$, where N is the number of patterns, the elements s_{ij} of the Affinity Matrix $\mathbf{S}=[s_{ij}]$ contain a measurement or estimation of the affinity of the pair of patterns $(\mathbf{x}_i, \mathbf{x}_j)$, where affinity is defined as a likeness based on relationship or causal connection [1]. For reflexive affinities, **S** is symmetrical, what implies on $s_{ij}=s_{ji}$. In general, the Affinity Matrix can be represented as a block diagonal symmetrical matrix as the one of (4).

$$S = \begin{bmatrix} S_{11} & S_{12} & \cdots & S_{1k} \\ S_{21} & S_{22} & \cdots & S_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ S_{k1} & S_{k2} & \cdots & S_{kk} \end{bmatrix} \qquad (4)$$

where $\boldsymbol{S}_{ij}=\boldsymbol{S}_{ji}$ are sub-matrices of **S** and k is the total number of sub-groups of **S**.

For ordered data sets, kernels and proximity matrices can be represented in the form of (4), where sub-matrix $\mathbf{S}_{ii}$ represents within-cluster affinities and $\mathbf{S}_{ij}$ represents inter-cluster affinities, for $i \neq j$. Consider, for instance, the data set of Fig. 1 and the corresponding kernel presented in Fig. 2, which is now ordered according to the generator distributions and presented in Fig. 3. The block-diagonal affinity matrix form of the kernel presented in Fig. 3 shows clearly the structure of the data set. The block-diagonal matrices $\mathbf{S}_{11}$ and $\mathbf{S}_{22}$ represent the two clusters of Fig. 1 with 30 elements each, whereas the matrices $\mathbf{S}_{21}$ and $\mathbf{S}_{12}$ represent the relationships between data of matrices $\mathbf{S}_{11}$ and $\mathbf{S}_{22}$. Matrices $\mathbf{S}_{21}$ and $\mathbf{S}_{12}$ have in fact very small values, indicating that the two clusters are not quite related to each other, as can be confirmed in Fig. 1. A similar result to the one presented in Fig. 3 would have been obtained if the proximity matrix **P** were obtained and ordered according to the partition matrix **U** for c=2.

5 Clustering by Sorting Kernels

In the previous section we have pointed out to the close relationship between kernels and proximity matrices as represented by affinities of the data. Clustering algorithms can be described with the objective of sorting kernel matrices. There are in fact clustering algorithms in the literature that work by sorting rows and columns of the kernel matrix [2, 3, 4, 5] in order to obtain affinity matrices like the one presented in Fig. 3. Once the affinity matrix has been formed, embedded cluster information can be directly extracted from the kernels.

The eigenvector ordering method [1, 2] was applied to the data set presented in Fig. 4, which was generated from 6 Gaussian generator functions. The corresponding ordered RBF kernel is presented in Fig. 5. As it can be observed, the ordered kernel shows clearly the presence of 6 groups of data in the input space. The affinity matrix representation of kernels simply reveal the information that is already present in the kernel, since only permutation operations were accomplished in the rows and columns of the original matrix. This indicates that (properly set) kernels already contain information about data structure that is equivalent to that obtained by clustering methods.

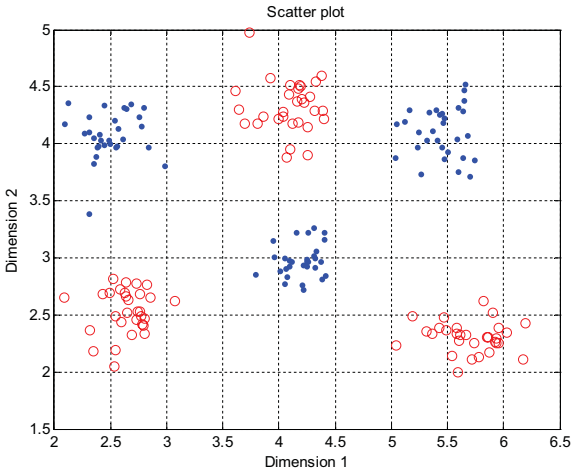

Figure 4: Data set obtained from 6 Gaussian functions.

6 Alignment of Kernels and FPMs

In order to quantify the similarity between kernels and proximity matrices, the Empirical Alignment described in [2] was adopted. The alignment quantity A is described in the form

$$A(K,P) = \frac{\langle K,P\rangle_F}{\sqrt{\langle K,K\rangle_F \langle P,P\rangle_F}} \tag{3}$$

where K and P, respectively, are the kernel and proximity matrices and $\langle .,. \rangle_F$ is the Frobenius inner product [2],

$$\langle K,P\rangle_F = \sum_{i=1}^{N}\sum_{j=1}^{N} K(i,j)P(i,j) \tag{4}$$

7 Alignment as an Optimization Problem

As discussed in the previous sections, depending on their parameters, kernels and FPM may incorporate analogous information about patterns and cluster relationships which hold in the input space. For the RBF kernels, structural information may be revealed by the proper setting of the width r, whereas FPM ability to describe pattern relations depends on the previously set number of clusters c. Nevertheless, these parameters are usually blindly configured in advance by the user. In the SVM design, the value of r can be fine-tuned according to the overall learning machine performance, while further cluster analysis can also give a hint for fine tuning of the value of c. When the setting of (c, r) results on affinity matrices that are coherent with the actual data structure, the corresponding kernel and FPM will be aligned to each other, according to the metric presented in (3). These arguments suggest that A(K,P) has a maximum on (c^*, r^*), where c^* and r^* are, respectively, the number of partitions and RBF width that best describe the original data structure. This characterizes the optimization problem presented in (5). The objective is therefore to obtain the values of the parameters c and r that maximize the alignment, which are expected to be the ones that describe better the data set for both kernel and proximity matrix.

$$\arg \max_{(c,r)} A(K,P) \tag{5}$$

ISBN: 978-989-95079-6-8

In order to demonstrate the arguments above, the values of A(K,P) were computed as a function of *c* and *r* for the data sets coming from Fig. 1 and 4, respectively. The obtained results are shown in Fig. 6 and 7. The same calculations were also completed for another data set with 4 original Gaussian generator functions. The obtained graph is presented in Fig. 8. As can be observed in Fig. 6, 7 and 8, the maximum occurs for *c=2*, *c=6* and *c=4*, respectively, which correspond to the original number of generator functions used in each data set. These results confirm the principle that the alignment function (3) has a maximum corresponding to the number of generator functions and that (5) could be optimized in order to obtain the values of *c* and *r* that result on the best representation of the data set. In the next section, the optimization of (5) will be implemented with a simple Genetic Algorithm (GA) [10] approach.

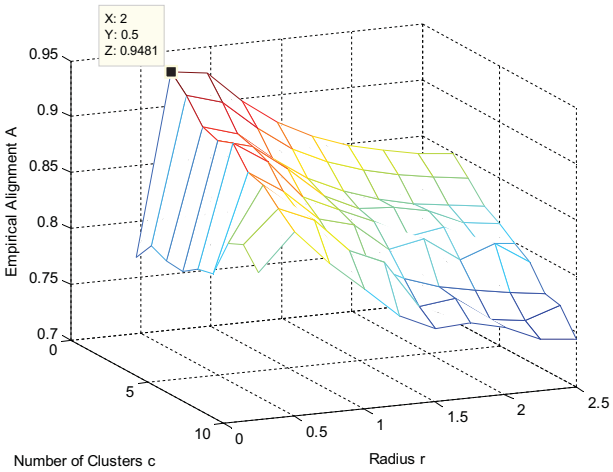

Figure 6: Alignment A(K,P) as a function of c and r for the data set of Fig. 1.

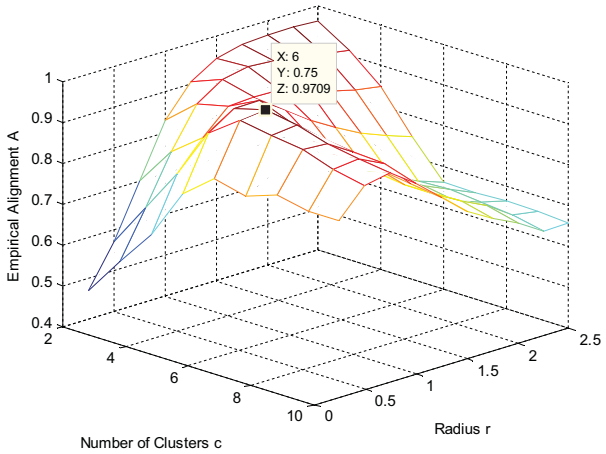

Figure 7: Alignment A(K,P) as a function of c and r for the data set of Fig. 4.

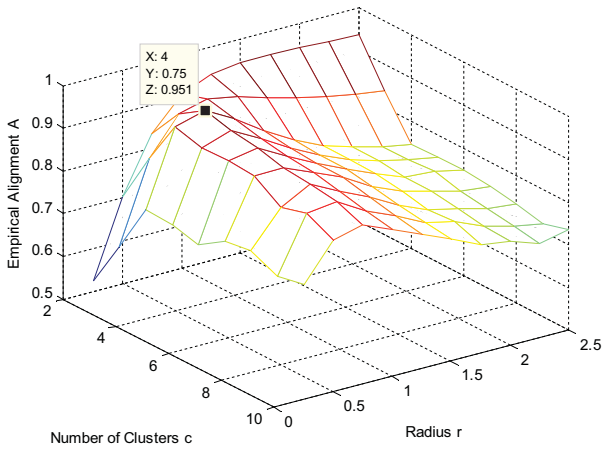

Figure 8: Alignment A(K,P) as a function of c and r for a data set with 4 Gaussian generator functions.

8 Evolutionary Optimization

A simple Genetic Algorithm (SGA) [10] was implemented in order to optimize (5) for the three problems represented by the objective functions of Fig. 6, 7, and 8. GA parameters are presented in Table 1 and the obtained results in Table 2. As can be observed, the maximum obtained for the three objective functions are quite close to the ones observed in the figures. As for the number of clusters, the optimization yielded exactly the same number of generator functions.

Table 1: Parameters of the SGA for optimization of the objective functions of Fig. 6, 7 and 8.

Number of variables in search space	2
Population size	50
Maximum number of generations	65
Crossover rate	0.6
Mutation rate	0.03
Biased linear cross-over coefficient	0.9
Linear cross-over coefficient	0.5

Table 2: SGA solutions for the objective functions of Fig. 6, 7 and 8.

Number of generator functions	***Number of iterations***	***r***	***c***	**A**
Two	52	0.5894	2	0.9540
Four	19	0.6808	4	0.9537
Six	63	0.6551	6	0.9758

The SGA was also applied to the data set of Fig. 9, represented as a binary classification problem. In order to distinguish between structural information and data set labels for classification problems, one of the classes was sampled from two Gaussian distributions, as can be observed in Fig. 9. In such a situation, there are three generator functions and two classes. This can be visualized by the ordered kernel of Fig. 10, which suggests the existence of the three clusters, in spite of the number of labels. The SGA optimization resulted on *r=0.66959*, *c=3* and *A=0.92225*,

ISBN: 978-989-95079-6-8

what is consistent with the number of clusters of the original distribution.

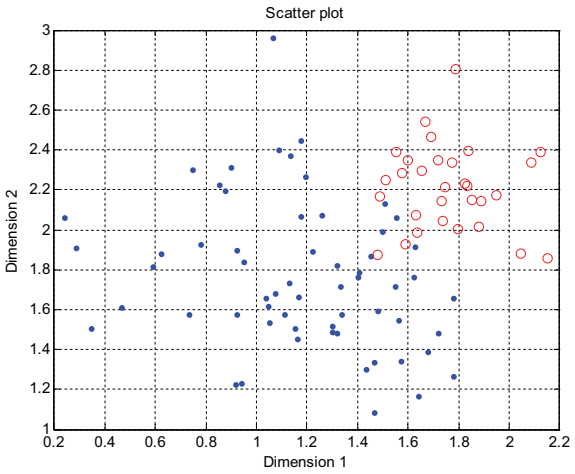

Figure 9: Binary classification problem sampled from three generator functions.

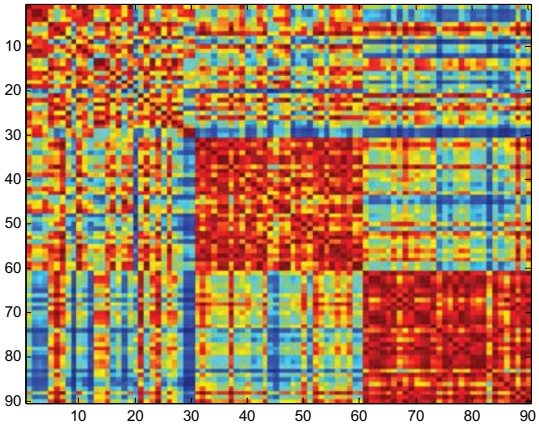

Figure 10: Affinity matrix representation of the ordered RBF kernel matrix of the data set of Fig. 9.

In order to show the consistency of the RBF width resulted from SGA optimization for classification purposes, a SVM was designed with the obtained value of $r=0.66959$. The corresponding separating surface is presented in Fig. 11 and, as can be observed, the resulting surface is coherent with the classification problem (the margin parameter was set to $C=2$). This suggests that the maximum obtained from (5) also points out to a proper tuning of kernel parameters for SVM design. Similar procedures were applied to the Iris data set [12], which resulted on $c=2$ in the maximum alignment. This result is consistent with the literature and with statistical analysis of the data set [13].

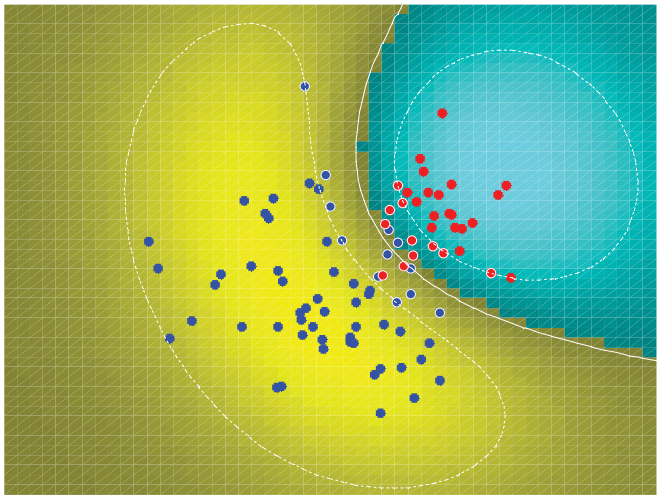

Figure 11: SVM separation surface for Fig. 9. RBF kernel was selected with and $r=0.66959$ obtained from SGA optimization.

9 Discussions and conclusions

Kernel and clustering design was presented in this paper in the perspective of function optimization. Our main argument to support this principle is that when both kernel and FPM are coherent with the embedded structural information contained in the data set, they should be aligned to each other. Alignment is measured in this paper according to the Frobenius inner product [2] between kernel and FPM, computed as a function of the parameters c and r. Therefore, we argue that maximum alignment should result on a proper setting of the parameters c and r. This approach differs from other kernel FCM algorithms [11], since the original objective functions are used.

This principle sheds some light on the discussion of determining the number of partitions of a clustering task. It has been shown throughout the paper that coherent partitions can be inferred according to the maximum alignment principle. Likewise, proper kernel design can also be obtained from the alignment. This suggests that kernel can be designed by exploring the structural data properties instead of performing an exhaustive blind search in the space of parameters with the aim of solely accomplishing the input-output mapping. According to these arguments, kernels should be more representative of the underlying data instead of serving uniquely as a mapping engine. This also suggests that kernels and FCM clustering should be co-designed and not described independently. According to the same principle, supervised and unsupervised learning may exhibit a closer relationship by collaborative interaction between kernels and FPMs.

Abstract— *Multi-source information fusion usually deals with redundant sources; the goal is to aggregate decisions, or evidence which supports one or another class. Many frameworks are then available: OWA, fuzzy integrals, etc. In this paper we are interested in managing complementary information sources. The integration is done using a fuzzy rule base. The rules are generated using a fuzzy decision tree algorithm. The application consists in the design of a crop harvest monitoring system. The three information sources are a time series of satellite images, a crop growth model and expert knowledge. The results show that the system is ready to use in an operational way.*

Keywords— Crop growth modeling, Decision, Expert knowledge, Fuzzy rules, Learning, Remote sensing.

1 Introduction

Over the past decade, time series of satellite images acquired at high spatial resolution have proven to be an important source of information for different agricultural applications. Several authors have recognized the benefits of this kind of data for monitoring agricultural lands [1], classifying land cover [2-4], mapping seasonal patterns and crop rotations [5, 6], and for many other uses (see papers collected in [7, 8]).

Nevertheless, the quantity of information extracted from time series of optical images is often restricted by several factors: acquisition gaps, atmospheric conditions, imperfect radiometric normalization, radiometric confusion, etc. Therefore, to make credible decisions, this information needs to be supplemented with data from other sources.

Let us focus on the sugarcane industry. One of its principal needs is to have continuous information about the harvest progress throughout the season. Such information helps increasing the effectiveness in fields and factory. The main method reported in the literature, to monitor the sugarcane harvest is based on a multispectral classification [9-11]. The major limitations of this method are the subjectivity and the considerable time to invest in the photo-interpretation phase and the confusion between the various states of a sugarcane field when the gap between two released images is important (more than 2 months). Since the harvest campaign extends over several months, it is difficult in some cases to distinguish between a standing crop and the regrowth in a field harvested at the beginning of the season.

In order to improve and automate the monitoring of sugarcane harvest using time series of high spatial resolution satellite images, it is necessary to develop a new method that process the time series in co-operation with other sources. This co-operation allows compensating for the possible lack of data in the time series of images by the integration of temporal and environmental constraints.

As the sources are complementary and of different nature, usual frameworks of fusion information cannot be used. In this paper we propose to make the source integration within a fuzzy inference system. Next section introduces the study site and the data used. The characteristics of the three information sources are presented in section 3. Section 4 describes the fuzzy inference system and section 5 goes into detail of the experiments. The last section deals with concluding remarks.

2 Study site and data sets

The study site consists of two sugarcane farms located in the north-east part of Reunion Island, which is a small territory of ~2,500 km² in the Indian Ocean (21°7' to 19°40' S, 55°13' to 61°13' E), where sugarcane is the main crop. The first farm is at an average altitude of 70 m and includes 33 fields with an average size of 5.4 ha. The second farm is at an altitude ranging from 400 to 700 m, and has 46 fields with an average size of 3.5 ha. As the study area is located in a tropical zone, the year is divided into two seasons: a hot rainy season from November to April, and a cool dry season from May to October.

The satellite data set used in this study consists of 18 SPOT5 images acquired over Reunion Island between January 10th, 2003 and December 7th, 2004. Both SPOT5 instruments (HRG1 and HRG2) acquire radiation in four spectral bands[1] with high spatial resolution: 10 m for the Green, Red, and Near Infra-Red (NIR) bands, and 20 m for the Short Wave Infra-Red (SWIR) band. The images belong to the Kalideos-ISLE REUNION database

[1] Green (0.50 - 0.59 µm), Red (0.61 - 0.68 µm), Near Infra-Red (0.78 - 0.89 µm), Short Wave Infra-Red (1.58 - 1.75 µm).

ISBN: 978-989-95079-6-8

set up by the CNES[2] [12, 13]. All images were ortho-rectified and co-registered to the UTM coordinate system (zone 40 South) with a root mean square error of less than 0.5 pixel per image.

The radiometry of the images was corrected so that pixel values represent the top of canopy reflectances in the four spectral bands [14, 15]. Cloud mask was available for each image.

Block field boundaries for all Reunion Island were provided by the DDAF[3] and were refined by the CIRAD[4] to define the boundaries of each field in the study site.

Daily climatic data recorded at La Mare meteorological station near the two sugarcane farms were collected for the period covered by the satellite time series. These data are daily estimations of rainfall (mm), potential evapo-transpiration (mm), global radiation (J/m^2), and minimum, maximum and mean temperature values (°C). Climatic data were required to run the crop growth model.

A ground truth database was built by using harvest dates reported by farmers for each field during the 2003 and 2004 harvest campaigns. This database indicates the status of each field (whether it was harvested or not) between each pair of consecutive satellite acquisition dates in the time series.

3 Three information sources

3.1 SPOT5 time series

The time series of SPOT5 images are the principal source of information. By using field boundaries, the temporal profiles of reflectances in the four spectral bands, Green, Red, NIR and SWIR, were extracted from the images for each field in the study site. This extraction was carried out by calculating the average value of field pixels in each spectral band. The calculation was done after discarding cloud pixels using the cloud masks. Temporal profiles of NDVI (Normalized Difference Vegetation Index) where then calculated for each field using reflectance values in the Red, ρ_{Red}, and NIR, ρ_{NIR}, bands:

$$NDVI = \frac{\rho_{NIR} - \rho_{Red}}{\rho_{NIR} + \rho_{Red}} \quad (1)$$

The temporal profile of NDVI provides useful information about the actual field status, and about its different historical stages. In general, this profile can be divided into two periods: a period in which NDVI values increase, corresponding to the vegetative development of the field crop, and another period with steady or decreasing values, corresponding to the maturation phase. Fig.1 shows an example of the temporal profile of a sugarcane field NDVI, extracted from a time series of SPOT5 images acquired with high temporal repeatability.

3.2 Sugarcane growth model

To cope with missing data or cloudy images, the sugarcane growth model MOSICAS [16] was used. It provides information on the field harvest possibility that is independent of the satellite images and based essentially on climatic data. This information is particularly interesting when the gap between two cloud-free satellite images is more than two months.

MOSICAS is a dynamic model that estimates the growth of the sugarcane on a daily time scale by using climatic and biophysical data of the environment of the sugarcane field. It allows the simulation of LAI (Leaf Area Index) profiles (Fig.1) that can be converted into NDVI profiles using a linear model [17]. An illustration of such a simulated profile is plotted in Fig.1. From the simulated NDVI temporal profiles, we build a helpful indicator for harvest detection: this indicator represents the nominal time required (in days) to reach a given threshold of NDVI starting with a given harvest date.

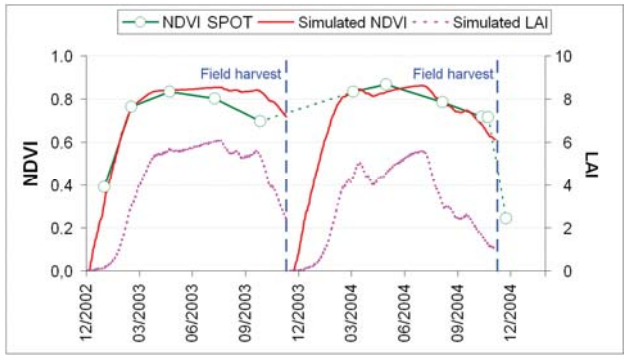

Figure 1: Example of temporal profiles of a sugarcane field NDVI extracted from SPOT5 time series, as well as NDVI and LAI temporal profiles simulated using the sugarcane growth model MOSICAS.

3.3 Expert Knowledge

The third source of information is the knowledge about phenological stages of the sugarcane, as well as its cropping system. This knowledge allows a better understanding of the relationship between the dynamics of the signals extracted from the satellite image time series and the sugarcane field status; it offers also very useful temporal constraints that particularly help in making decisions when there is a lack of satellite data. Examples of parameters defining these temporal constraints are the nominal length of the sugarcane cycle and the dates of opening and closing of the sugar factories which determine the harvest campaigns, as illustrated in Fig.2.

Various variables are built from the three information sources and used as inputs of the decision system. The inputs are divided into three main groups:

- The first group (4 inputs) is based on the NDVI and SWIR values calculated at field scale using each satellite image.
- The second group (5 inputs) relates to the dynamics in the temporal profiles of NDVI and SWIR.
- The third group (5 inputs) represents the temporal constraints resulting from the sugarcane growth model and the expert knowledge.

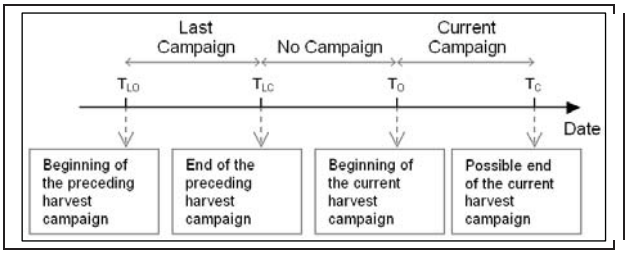

Figure 2: Temporal intervals used for the classification of image acquisition dates. T_{LO}, T_{LC}, T_O and T_C are opening and closure dates of the preceding and the current campaign respectively.

A thorough description of the inputs can be found in [18].

4 Decision system

The information coming from the three sources (SPOT5 time series, sugarcane growth model and expert knowledge) is heterogeneous and of different nature. The information extracted from the SPOT5 images is based on reflectance "measurements". The sugarcane model provides "estimates" using parameters that are not directly connected to the studied phenomenon (*i.e.* the field harvest). Expert knowledge contribution is neither "measurements" nor "estimates". Another important characteristic to highlight is that the sources are not redundant but complementary. That means that none of them is able to make a decision on its own; the cooperation is needed within the decision process. This discards usual aggregation techniques such as votes, OWA or fuzzy integrals. The general framework used to combine the different and complementary information sources is a fuzzy inference system.

The rules are of the following form: "*if X Then Y*", e.g.

$$\begin{aligned}
&\text{Rule}_1\text{: if } x_1 \text{ is } A_1^1 \text{ and } x_2 \text{ is } A_2^1 \ldots \text{ and } x_n \text{ is } A_n^1 \text{ then } y \text{ is } B^1\\
&\text{Rule}_2\text{: if } x_1 \text{ is } A_1^2 \text{ and } x_2 \text{ is } A_2^2 \ldots \text{ and } x_n \text{ is } A_n^2 \text{ then } y \text{ is } B^2\\
&\quad\vdots\\
&\text{Rule}_r\text{: if } x_1 \text{ is } A_1^r \text{ and } x_2 \text{ is } A_2^r \ldots \text{ and } x_n \text{ is } A_n^r \text{ then } y \text{ is } B^r
\end{aligned} \quad (2)$$

where A_k^r is the fuzzy set of the k^{th} input variable involved in the rule r, and B^r is the conclusion of the r^{th} rule.

The rule conclusion is a symbolic label, related to the field status. Two are possible: H (harvested) or NH (not harvested).

For each input universe a partition is defined. Some of the input partitions are crisps (see Fig.2), the other are fuzzy. In this case, we built standardized partitions according to expert knowledge. Fig.3 illustrates the fuzzy sets of NDVI and an example of NDVI profiles plotted according to thermal time for several sugarcane fields. NDVI fuzzy sets were designed according to expert knowledge about the phenology and field status of sugarcane as well as about its NDVI temporal profiles.
Linguistic labels are related to the NDVI:

- "Low" NDVI values (< 0.30) generally correspond to residues and bare soil after field harvesting.
- "Medium" NDVI values (between 0.30 and 0.75) are observed in the growth and senescence phases. The growth phase is characterized by an accumulation of biomass and an increasing length of the stems. The senescence is caused by the sugarcane ageing, the reduction in the temperature and the lack of water.
- "High" NDVI values (>0.75) are obtained at the end of the growth stage and before senescence. In this phase sugarcane fields are well developed and green covered.

The inference technique used in our system is based on Mamdani's method [19]. The weight attributed to the conclusion of an activated rule is calculated by combining the membership degrees of rule premises in a conjunctive way using the *min* operator. The aggregation of the distinct conclusions of the activated rules is done in a disjunctive way using the *max* operator.
Once system inputs and output as well as inference parameters are defined, the last step is reasoning rule description. In a previous version [18], the rules were defined according to expert knowledge. 116 rules were needed to cover all possible situations. The system proved to be accurate. A comparison between fuzzy and crisp partitions showed that the former ones increase a 15% the overall accuracy. The rules can also be generated by an automatic procedure. A fuzzy decision tree induction algorithm, which is a fuzzy extension of the well known ID3 algorithm [20], is used. The main advantage of the decision trees is to generate incomplete rules, only defined by a subset of the available input variables. The generated rules are informative for experts to the condition that the partitioning is carefully defined. The Fispro [21] implementation is used with the partitions proposed by the experts, those which proved efficient in the expert fuzzy system.

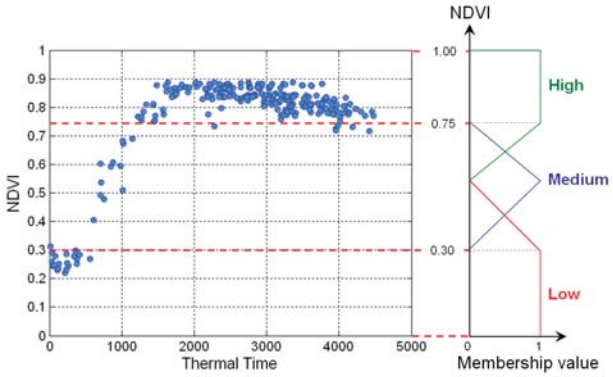

Figure 3: NDVI profiles plotted according to thermal time for several sugarcane fields. On the right are the fuzzy sets of NDVI-defined inputs.

5 Results and discussion

The learning process includes a cross validation. It has been carried out with various configurations to assess the system sensitivity to important parameters: the size of the training set and the number of satellite images per year. Finally, the contribution of each of the information sources is evaluated.
The data set has been randomly split to build training and test sets. For each proportion, the given result is the

ISBN: 978-989-95079-6-8

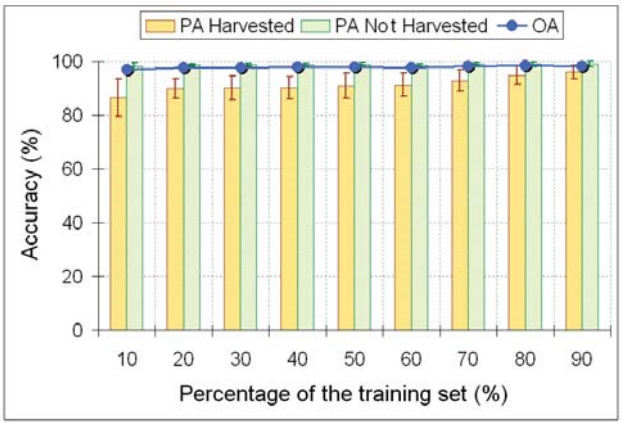

Figure 4: System performances using different percentages of training set (OA: overall accuracy; PA Harvested and PA Not Harvested: producer's accuracy for the two classes "Harvested" and "Not Harvested" respectively). These performances are obtained from confusion matrices.

average of ten runs. Nine percentages have been tested for the training set: 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80% and 90%. The performance is measured over the test set.

Fig.4 shows the average values and the standard deviations (for ten iterations) of the overall accuracy (OA) of the system and the producer's accuracy for the classes "Harvested" and "Not Harvested" (PA Harvested and PA Not Harvested, respectively). Let's notice that the performance for the Not Harvested decision is quite independent from the size of the training set, while the Harvested one increases with the sample size. This is due to the respective proportions of both cases in a given image: the not harvested fields are much more numerous than the harvested ones. So, only a small number of images is needed to learn the not harvested case.

The other key parameter related to system robustness, is the number of available images. It is likely to vary from a year to another because of the lack of acquisition or cloudy weather which makes unusable the satellite images.

Fig.5 shows the selected images for each of the studied years. The selection takes into account the campaign organisation. For instance, in the case of 3 images per year, one is chosen before, the other between and the last one after the harvest campaign.

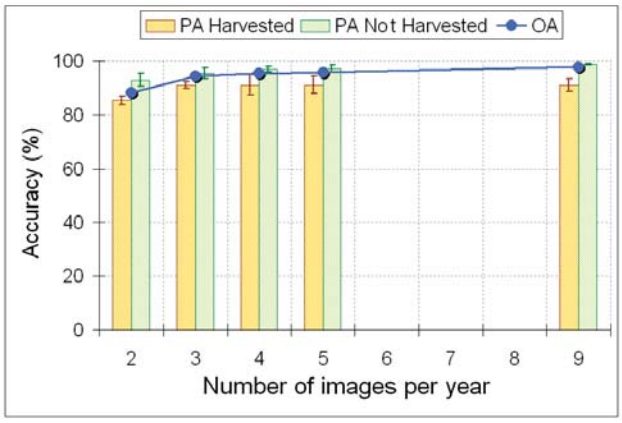

Figure 6: System performances according to the number of satellite images per year. (OA: overall accuracy; PA Harvested and PA Not Harvested: producer's accuracy for the two classes "Harvested" and "Not Harvested" respectively).

Fig.6 shows that the system performance is still acceptable even when the number of images per year drops to 3.

The number of generated rules also evolves with the number of images per year. It reaches an average of 38 for the 5 image configuration as shown in Fig.7.

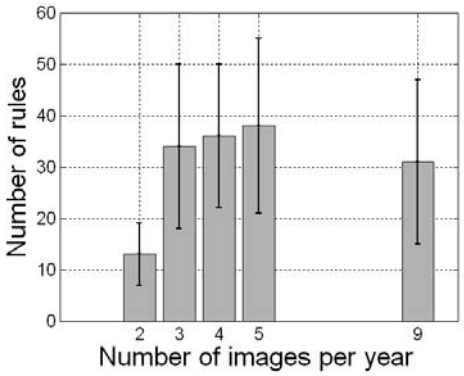

Figure 7: Number of induced rules according to the number of satellite images per year. Histogram bars represent the average values for the different training sets, and error bars the standard deviation.

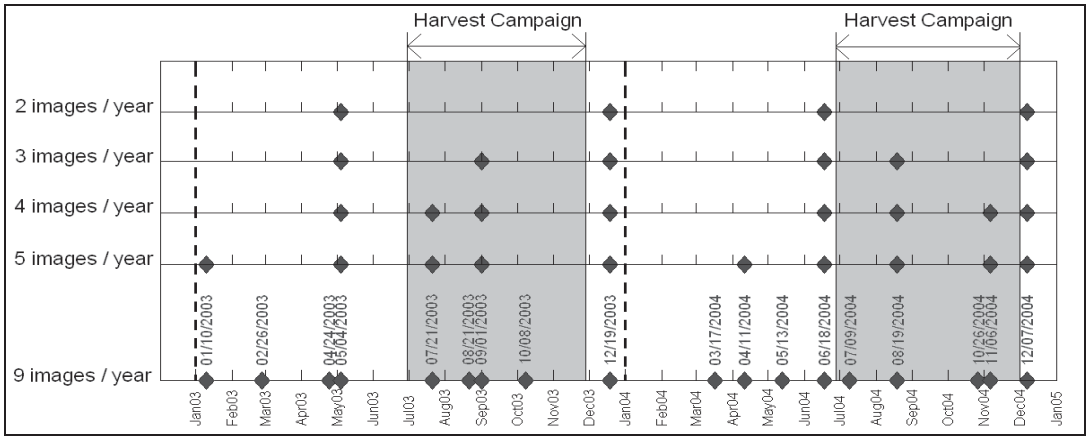

Figure 5: Acquisition dates selected at different stages of the assessment of system robustness with respect to the number of images per year.

ISBN: 978-989-95079-6-8

To assess the information source contribution three sets of input variables have been considered:

- SAT: the set of input variables that are related to the information extracted from the satellite images;
- MOD: the set of input variables built using the sugarcane growth model;
- EXP: the set of some input variables dealing with expert knowledge. Although the expert knowledge is difficult to isolate since it contributes to the design of the whole system, some variables are only related to this sources. They are encoding agronomic knowledge such as the nominal cycle length.

Four combinations have been tested and the results are reported in Fig.8. The best ones are the closest to the origin. As expected, all of them include SAT and MOD, and in most cases, the best one is SAT+MOD+EXP.

The sugarcane growth model contribution is interesting to analyze for each of the two classes "Harvested" and "Not Harvested". Fig.9 shows that it is higher in the harvested case. This result was expected: there is no need of a growth model to label a field as not harvested. The essential role of the model is to remove potential ambiguity concerning harvested fields.

6 Conclusions

This paper presented a novel approach for dealing with time series of optical satellite images used for crop monitoring. Data extracted from time series were combined with information from crop model output and expert knowledge, in order to make credible decisions. The description of the approach was done using an application example of sugarcane harvest monitoring with a SPOT5 time series. A decision system designed and implemented for automatic harvest detection was described.

Results obtained when evaluating the system were in substantial agreement with ground truth data; the overall accuracy reached 96.07%. The next step concerning the sugarcane application consists in examining the robustness of the automatically generated rules by testing the system at other sites and in other years.

The approach outlined in this paper is generic and very promising. Many models that simulate the growth of the main annual crops exist (e.g., STICS [22]), and expert knowledge about these crops could be obtained easily either from farmers or from agronomic knowledge bases [23].

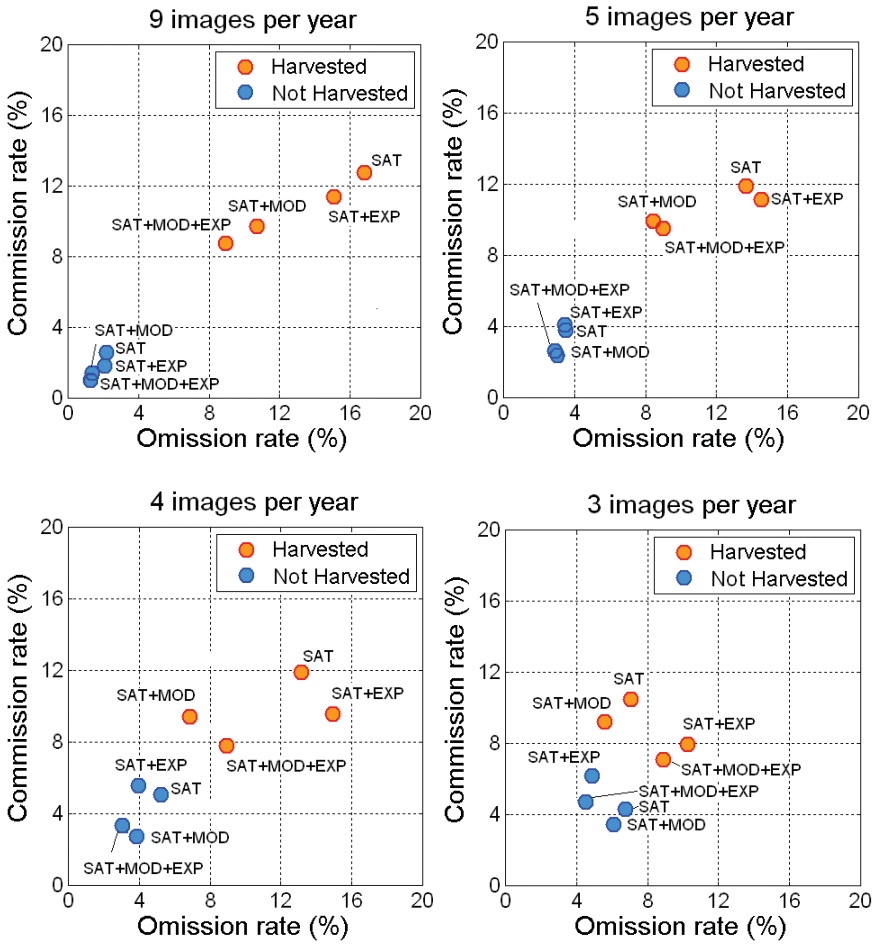

Figure 8: System performances obtained for different image frequencies by using different combinations of information sources.

ISBN: 978-989-95079-6-8

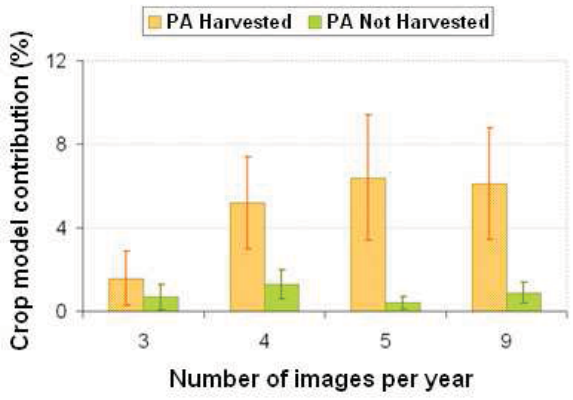

Figure 9: Crop growth model contribution in the system performances (PA Harvested and PA Not Harvested: producer's accuracy for the two classes "Harvested" and "Not Harvested" respectively). Histogram bars represent the average values for the different training sets, and error bars the standard deviation.

The combination of crop model outputs and expert knowledge with time series of high spatial-resolution satellite-images seems to be an excellent tool for crop monitoring.

Acknowledgment

We would like to thank Hélène de Boissezon and Sébastien Garrigues (CNES) for their help and support. We would also like to thank the CNES for funding the Kalideos database (http://kalideos.cnes.fr) and for generously providing the SPOT5 images.

E-mail: veronica.sanz@softcomputing.es

Abstract— *Artificial Intelligence has been one of the fields within Computer Science that has generated more interest and debates among philosophers. Later on, the most recent field of Science and Technology Studies (STS) also has shown some interest in AI. In both cases most of the authors have been quite critical about the promises, the practices and particularly the epistemological basis of Classical AI. The first part of the paper consists on an enumeration of the most important authors and their critiques to AI in Philosophy and STS studies. Since Soft Computing implies important changes with respect to traditional AI approaches like Symbolic AI, the second part of the paper will be devoted to confront Soft Computing with the critiques and challenges and to weight up to what extent Soft Computing could (or could not) answer differently than other AI approaches regarding the critiques received.*

Keywords— Epistemology, Philosophical critiques to AI, Science and Technology Studies (STS), Soft Computing.

1 Introduction

Since its origins Artificial Intelligence has been one of the fields within Computer Science that has generated more interest and debates among philosophers and cognitive scientists. Not in vain, Artificial Intelligence deals with some of the traditionally most debated issues in philosophy such as knowledge and reasoning. In concrete, some of the ambitious statements of the first AI researchers touch very sensitive "fibers" of philosophers. Authors like John Searle, Daniel Dennett, Hubert Dreyfus or Roger Penrose were among the first ones to cope with these issues [1, 2, 3, 4, 5].

The philosophical debate during the 1970s and 80s focused on Artificial Intelligence via Symbolic AI (the branch of artificial intelligence research that concerns itself with attempting to explicitly represent human knowledge in a declarative form -i.e. facts and rules-), since this was the approach followed by the main scientists in the field from the early days on. The main interest of philosophers has been traditionally centred in the question about whether computers can or cannot think, which generally implies doing it "in the sense humans do". There was an assumption among philosophers (though induced by claims made by some of the first AI researches) that the aim of AI is to create "an artificial mind". Despite the successes of some AI symbolic systems during the 60s, the enormous promises of early AI texts posed the debate in terms of the possible success or failure of the whole enterprise of creating an artificial mind.

Because of that the discussion was pursued in a very bi-polar manner with some philosophers (like Dennett) clearly optimistic about the question and others (like Searle and Dreyfus) very critical about it. The philosophical critique was in tune with a significant resistance in general culture, which tried to assure the specificity of human nature with regard to computational artifacts, often appealing to non-cognitive aspects of the mind (intentionality, emotion, perception, etc).

2 Philosophical Critiques

2.1 Turing

The British mathematician Alan Turing was not only the one who set the basic elements of computation, but also the one who posed the first stone of this debate about the possibility of "thinking machines", proposing a mental experiment known, since then, as the "Turing test" [6]. It consists on an interrogator asking questions (through a separating barrier) to a machine and a human, trying to guess who (which) is answering. If the interrogator cannot tell whether the responder is the human or the machine, then the intelligence of the machine would be proved.

The interest of Turing's idea lies on the practical way he is proposing the test as an "imitation game". He is not defining, at least *a priori*, what intelligence *is* but establishing a practice were the performance of human intelligence is showed. Whether the machine thinks "in the way humans do" or not is not addressed by the Turing's test. In fact, it is precisely this kind of philosophical question what he tries to avoid.

2.2 Searle

In his famous paper from 1980 [1] the American philosopher John Searle argued against the strong claim that computers can be intelligent *in the same way* humans are, which for him implies having cognitive or psychological states (i.e. conscious understanding and intentionality). He distinguishes two strands of AI. The former claim is called "Strong AI": intelligent machines would replicate not only intelligent *products,* but the intelligent *process*[1]. By contrast, "Weak AI" is the perspective that understand computers as useful tools that mimic some of the abilities and tasks of humans (included those that are considered intelligent), in part because they can simulate "smart actions"[2]. Weak AI does not make the claim that computers *actually understand* or *have* mental states.

Searle's critique is directed to Strong AI. To do that, he proposes a thought experiment known as "The Chinese room" in response to Alan Turing's suggestion to replace the question "Can machines think?" with the question of whether

ISBN: 978-989-95079-6-8

they can succeed in an "imitation game". In short, Searle's conclusion is that a native English speaker who knows no Chinese together with a book of instructions for manipulating the symbols would able to pass out Chinese symbols which are correct answers to the questions. The instructions enable him/her to pass the Turing Test but he does not understand a word of Chinese[3].

The axis of the argument relies also on the idea that *syntactic manipulation* (formal symbol manipulation or computation) does not imply understanding *semantics* (understanding of meanings). For Searle, we can not attribute intelligence to such a system since "real intelligence" is related with understanding. The background argument of the Chinese room is that one of the main features of human minds is intentionality (which is a mental state) and that is something that computers do not (and can not) have.

2.3 Dennet

Though many of the philosophers of AI have been very critical, Daniel Dennett is an exception [2]. He shared with Symbolic AI researchers what in philosophy of mind and cognitive sciences is called the "Computational (and Representational) Theory of Mind". Dennett has been positively linked to AI and he has participated in some AI projects. He disagrees with Searle in two important points:

a) The way that Searle understands intentionality is already assumed from the beginning as limited to humans. Against that, Dennett affirms that human consciousness and intentionality are not as specific as we use to think, which is showed in the way we use a "mentalist language" when describing the actions of animals, machines and so on.

b) The Chinese Room thought experiment is very ingenious but is very far from actual practices in everyday life. It involves a number of things that are quite impossible to do so it is very doubtful to be used as a proof of something[4].

2.4 Dreyfus

However, the philosopher who most energy and time has devoted to the critique of AI during the past 30 years has been the phenomenologist Hubert Dreyfus [3, 4]. Drawing upon Heidegger and existential phenomenology, his arguments are quite different from Searle's (though he also affirms that neither current machines nor future ones would be intelligent).

Dreyfus criticizes the epistemological assumption of Symbolic AI that all activity can be formalized in the form of propositional knowledge (which would allow computation in the form of "rule-based symbol manipulation") as it is done in many Symbolic AI based expert systems. For Dreyfus, many parts of human knowledge and competences cannot be reduced to an algorithmic procedure, i.e. the kind of knowledge one might employ when learning a skill like walking, riding a bike or ice skating. This learning is done through practice with our bodies: to learn how to do it one must get on and try it, it's not enough to follow written rules. This requires having a body and experimenting with it in a changing environment.

Though Dreyfus concedes that certain well-circumscribed experts systems for particular domains have succeeded, he predicts that many others will never fulfil the expectations (i.e. Lenat y Guha's "Cyc" [7]). This is not because of technical shortages (that could be overcome in the future) but because symbolic type of artificial systems are incapable of representing bodily-skills knowledge, which can not be captured in an algorithm.

3 Soft Computing confronting Philosophical Critiques

3.1 Not related to Strong AI

The problem with Searle's thought experiment is that most of practitioners in AI do not take issue with intentionality or creating an artificial mind. This debate is in fact a philosophical one (the old debate between Behaviorism and Mentalism[5]) and is far from the interests of Soft Computing (SC) practitioners, as far as I could observe. Although this debate was in part provoked by the excessively optimistic predictions of some of the founding fathers of AI, it can be said that the SC community is more focused on solving concrete problems by constructing machines that can perform "intelligent" tasks, which is more in tone with what Searle called "Weak AI". Because of that, these kind philosophical critiques do not apply to Soft Computing.

However in one of his last articles, Zadeh says that there is a possibility of achieving "human-level machine intelligence", though for that there is needed a paradigm shift [8].

3.2 Necesity of Semantics

The other axis of Searle's critique relied on the idea that *syntax* (formal symbol manipulation or computation) does not imply *semantics* (understand meanings). Searle applied it to say that, to have "real intelligence", syntax is not enough. One of the fundaments of Fuzzy Logic is precisely to deal with meaning in natural language. Fuzzy Logic agrees with Wittgenstein's definition of meaning as its use in language [9], that is, as used by concrete people in concrete contexts.

To model and operate with natural language and its non-static meanings would require tools which can deal with imprecision and uncertainty, which is precisely the main characteristic of Fuzzy Logic. The enormous importance of natural language for SC is shown in the turn Zadeh proposed in 1996 saying that Fuzzy Logic was equivalent to "Computing with Words*"* [10]. Computing with words (CW), Zadeh says, is a methodology in which words are used in place of numbers for computing and reasoning. As fuzzy sets are able to model some natural language's concepts, it would be possible to use these models to compute directly with them.

3.3 The "Bodily-skills knowledge" Problem

Dreyfus's main critique to symbolic type of artificial systems is its incapability of representing bodily-skills knowledge. Other types of AI systems have tried to avoid this problem, like Rodney Brooks' "bottom-up" strategies in *embedded* or *situated robotics* [11]. The work of Brooks and his colleagues focus on *embodiment,* the idea that intelligent behaviour is an *emergent* phenomenon resulting from the

ISBN: 978-989-95079-6-8

individual's interactions with its environment, which are more related to action than to representation.
What Soft Computing has to say about this debate? In general we could say not much. The problem of embodiment is typical in Robotics (where there are "embodied machines", not only software) but not necessarily in most of the branches of AI. Fuzzy Logic indeed deals with language and representation of meanings and not so much with actions. However, applications of Fuzzy Logic to concrete systems (fuzzy control) do actually deal with systems-in-action. One clear example is the "inverted pendulum" solved by Yamakawa [12] using a small set of simple fuzzy rules. Fuzzy control system design is based on empirical methods, basically an approach of trial-and-error, which is quite related to the way humans learn bodily-skills knowledge.

4 STS Critiques

Among the different non-technical disciplines not only philosophy has been interested in the study of AI. Within the so-called area of STS, at least some practitioners have turn around to Artificial Intelligence.
An STS methodology implies the analysis of the social and cultural contexts where all scientific and technological developments take part. This model resists classical accounts that science and technology are totally objective and neutral with respect to the context where they are made.
Regarding AI, STS takes a different stand on that philosophical critique. They don't take part in abstract discussions about the ultimate goal of AI. Their methodology consists on looking at real practices, including ethnographic observation of AI practitioners. From the STS view, the important thing is the way these engineers understand and use (or model) concepts such as knowledge and reasoning in their daily practice.

4.1 Harry Collins

Harry Collins' study of AI [13] is the most important contribution from part of STS to the study of AI. The field of Experts Systems has attracted the most attention from part of social scientists. His critique is in a way quite similar to Dreyfus' regarding the impossibility of formalizing certain types of knowledge.
Based on recent Sociology of Scientific Knowledge [14] and Laboratory Studies [15], in which is shown how experimenters need to share a culture in order to produce science, Collins maintains that skills (know-how knowledge) are principally acquired through enculturation and the acquisition of tacit capacities whose transmission is implicit (and cannot, therefore, fully be spelt out in formal algorithms). This kind of knowledge it is commonly known in STS as "tacit knowledge", which can be also understood as the "common knowledge" of a particular community (what is taken for granted within it)[6].
However, Collins understands "tacit knowledge" more widely than Dreyfus' embodied knowledge. Acquisition of skills-type knowledge in his view is related to socialization rather than embodiment. The underlying argument of Collins against Dreyfus is the importance of natural language. Collins affirms that one can learn to speak fluently about the world without being bodily involved in it. This model assumes that socialization (in a certain group) is necessary to communicate knowledge. In this way, Collins brings the discussion to the cultural arena
Another of the issues addressed by Collins is his focus on AI systems that are already being used and seem like functioning, not in possible future ones. The challenge is, then, to explain that "success". On the contrary of philosopher's understanding of computers as artificial brains, to him the role (and success) of AI is to create "social prostheses". And it is the ability of humans to interpret their actions and repairing their deficiencies which makes them successful. In a way, humans interpret machines actions as one kind of actions humans can perform (what Collins calls "machine-like action"), but this is only a little part of the whole kind of humans' actions. This human ability to interpret and repair normally remains invisible, but, for Collins, is here where the intelligence attributed to machines rests on.

4.2 Diana Forshyte

The work of Diana Forsythe [16] belongs to the field of Anthropology of Science[7] rooted in cultural anthropology's tradition. This normally implies a more or less long-term field research using the ethnographic method of participant observation. In her ethnographic study of an Expert Systems community in the US, she investigated what she called the "Culture of the Experts Systems Engineers", defined as the values and assumptions (explicit but mostly implicit) that constitute what they take for granted. Forshyte also refers to this as "common sense truths", which are those things 'everybody knows' within a given setting (this shared and tacit knowledge is indeed the main criterion to be considered a member of the community). The importance of the ethnographic method relies on the main thesis of cultural anthropology about the complex relation between beliefs and practices: usually what people do, what they think they do, and what they report they do are someway different.
Investigating the culture of the Expert Systems practitioners she found they share a particular notion of knowledge (a very restricted one), that has important implications for the products they make. Their epistemological stances are very important because they are going to be incorporated (encoded) into the expert systems produced. To prove this she focused on the first step of the process of building an expert system: 'knowledge acquisition' (also known as elicitation process), consisting in the "extraction" of the knowledge from human experts. The very use of the terms "extraction" and others such "store" (knowledge is presumed to be "stored" in the head of the experts) are metaphors which implies an understanding of knowledge as objective and susceptible of being formally transferred into a machine.
Despite that, the elicitation process is considered by knowledge engineers themselves a very persistent problem and is thought to be the cause of failures in the systems when encountering 'real-world situations' (situations that the systems builders did not anticipate). Knowledge engineers blame human experts interviewed for not being able to explicit clearly their expert knowledge, that is, in the way they can encode it (it is not casual that the kind of expert

ISBN: 978-989-95079-6-8

knowledge they prefer to work with are already those very formalized in well-defined narrow domains).
They would never think about the possibility that their implicit assumptions about knowledge can be the cause of their problems. Forshyte affirms that the knowledge encoded in experts systems is static, brittle and narrow, while in real life knowledge is continuously modified in relation to contextual factors and trough negotiations between different actors, and that is the real cause of the 'brittleness' of the systems[8].
In general terms, the kind of expert systems studied by Forshyte are included in the more general approach of Symbolic AI, since, in the end, knowledge "extracted" from human experts has to be written-down in rules-type propositional knowledge. With respect to this, the same critique from Dreyfus and Collins about the inability to model other types of knowledge (particularly social knowledge) is applicable relating Forshyte's work.

4.3 Alison Adam

One tradition within STS studies are those investigating the relations of gender factors with science and technology[9]. Notions of gender are constructed not only in relation to economy or moral values but also science and technology became in our culture more associated with the masculine than the feminine, reflecting cultural's view of what constitutes masculine or feminine. However this is not a fixed but a historical process[10].
Alison Adam is a British computer scientist and feminist who has pursued the most extended study about gender and Artificial Intelligence [17]. She accurately applies the insights of feminist epistemology (an alternative kind of epistemology which criticizes the classical conservative epistemologically) to the main traditions in AI as Symbolic AI, Expert Systems, and also more recent approaches such as Artificial Life and Situated Robotics. Adam's work is devoted to "uncover" the implicit (gendered) epistemological assumptions in AI, because on them depend how AI researchers understand some key concepts which very much influence their work such 'intelligence', 'knowledge', 'reasoning' and 'efficiency'. The idea, then, is not to look for the contributions of individual women in the history of AI, but rather to look if there can be gendered models of knowledge implicit in AI systems.
One of Adam's theses is that traditional AI systems are based on the Cartesian ideal of a disembodied mind and the over-valuation of mental (abstract) knowledge over corporeal (concrete) knowledge; the former has been historically associated with masculine realm while the latter has been largely associated with the feminine. For Adam as for other feminist epistemologists [18, 19], this is very much related to the "mathematization" of the Western Culture (started in ancient Greece and increased in the Modern Age) and the idea that the entire universe was governed by numbers. Although there was already among the Greeks a plea for other ways of knowing it, was this Platonic and then Aristotelian conception of the world which finally succeeded. Aristotle is considered "the father of Logic", and defines the correct way of reasoning in terms of a dichotomous logic (there are only true or false statements which imply only valid or invalid inferences). As we know, the rejection of this thesis was the starting point of Zadeh's Fuzzy Logic.
Following the work of the philosopher Lorrain Code [20], Adam shows that traditional AI is based on the rationalistic epistemological model of "S knows that p". 'S' refers to the knowledge subject (*who knows*), and 'p' the object of that knowledge (w*hat can be known*).
Regarding 'p', as we already said, propositional knowing (or *knowing that)* is considered to be superior knowledge while others (skill-knowledge or *knowing how*) are less important. Feminist epistemologies consider this stratification as an *epistemic discrimination* (which they affirm is not innocent of gender factors).
Regarding 'S', the ideal knower of Classical AI is an anonymous, universal and "knowing from nowhere" subject[11]. On the contrary, Adam emphasizes the "situatedness" of the knower. For example, who are the "knowledge subjects" of systems like "Cyc"? This project leaded by Douglas Lenat [7] tries to build a vast knowledge base which will include most of human common-sense knowledge. Above all, Lenat assumes that there is one *and only one* consensus reality available common to all humans. The development of STS and Anthropology is the last decades have shown that it is quite problematic to assume that hypothesis. We "see" the world according to our theories of the world, and these theories depend on our cultural location. At bottom, what CYC knowledge base would consist on is what Adam's calls "*The-World-As-The-Builders-Of-Cyc-Believe-It-To-Be",* who are a group of predominantly middle-class male US university professors, that, without realizing it or intending it, are privileging their "consensus reality" over other groups' [17].
As a way of summarizing the differences between the two kind of epistemologies we can make the following table:

Table 1: Contrasting Epistemologies

Symbolic AI Epistemology	**STS Epistemology**
Objective Knowledge *(context free, universal)*	Situated Knowledge *(contextual, local)*
Propositional knowing (*knowing that*)	Skills-type and Common-sense Knowledge
Abstract reasoning	Concrete reasoning
Epistemological Monism	Epistemological Pluralism
Lack of Reflexivity	Accountability and Responsibility

5 Soft Computing confronting STS Critiques

5.1 Contextualism

As we said before, workers in the field of Symbolic AI claim that cognition is the manipulation of internal symbols by logical rules, so, therefore, human knowledge is, to a large extent, *context free*. We have explained how this idea has been criticized by authors like Dreyfus or Collins.
Wittgenstein's pragmatist turn in *The Philosophical Investigations*, which is assumed by SC, implies that meaning can only be grasped when used by concrete people

ISBN: 978-989-95079-6-8

in concrete contexts. The philosopher, Wittgenstein says, must "look and see" the variety of uses to which the word is put in particular cases. In this way, previous empirical analysis of the context of use it is an obligatory step for SC developments.
This obligates SC to be an e*mpirically-based research,* not only a theoretical approach (this is also because the ultimate goal of SC is engineering, that is, constructing machines, which in the end has to be used by users).
In spite that the idea of contextualism may be implicit in SC practitioners, the problem about the "situatedness" of the knowledge subject regarding the difference or culture, class, nation, race or gender has not been addressed as such neither in theory nor in specific projects, as far as I know.

5.2 The "Common-sense knowledge" Problem

As we have seen, the apelation to the inability of Classical AI to deal with common-sense knowledge is an important part of STS critiques. Their argument is that this kind of knowledge is mostly tacit and took for granted, and, because of that, it can not be formalized.
On the contrary, many SC articles contain the affirmation that fuzzy logic could represent common-sense knowledge. The most explicit article from Zadeh about the topic [21] explain that common-sense knowledge is expressed in *dispositions*, as opposed to propositions. A disposition in philosophy is a kind of belief that is stored in the mind but is not currently being considered (in a way we can say is a kind of tacit knowledge). For the purpose of representation Zadeh defines a disposition as a proposition with implicit fuzzy quantifiers, so in that way fuzzy logic can be used to deal with that kind of knowledge.
Although this strategy is only in its first steps, I think is a very promising way of dealing with common-sense knowledge, at least much better than Guha and Leant kind of propositional knowledge data base. However, there are many issues that are not addressed or solved yet in SC. A very important one has to do with the very definition of "common-sense knowledge" and its interrelations with concepts as "tacit knowledge", "skill-knowledge", "situated knowledge" and so on. Is it all common-sense knowledge tacit or just "taken for granted"? The difference between common-sense and skill-knowledge is that one can be formulated in *dispositions* and the other one not? What Zadeh exactly means when he talks about "world knowledge" –defined as "the knowledge humans acquire though experience, communication and education"?

5.3 Pluralism and Hybridization

Though we have not explicitly say it before, one of the main proposals from STS and feminist epistemologies is the appeal to alternative ways of knowing and doing science. Lucy Suchman, regarding computer science, talks about **"**expanding the frame of basic modeling assumptions" [22], which means expanding the very foundational paradigms of the discipline (particularly its assumptions about knowledge) and introduce alternative paradigms. This, regarding theory of knowledge, is what is called *Epistemological Pluralism*.
I think SC can be a little bit closer to these suggestions than other approaches. On one hand the basic characteristic of SC is precisely the combination of methods. Quoting Zadeh: *"SC is not a single methodology; rather is a consortium of methodologies which are aimed at exploiting the tolerance for imprecision (...) The constituent methodologies in SC are for the most part complementary and synergistic rather than competitive* [22]*".* So we can say pluralism and hybridization are at the very core of what SC is, but… do they mean with that the same as STS scholars when they mention it?
This question leads us to the following point.

5.4 Issues of Accountability and Responsibility

Pluralism in STS and feminist epistemology is related to issues of accountability and responsibility, which means that the ultimate goal is to introduce (some) changes in science and technology to make them more inclusive and socially just. Authors as Lucy Suchman [23] and Philip Agre [24] whose work is devoted to Artificial Intelligence, appeal to epistemological and methodological pluralism as a way of accommodating diversity. Agre calls this possible way of doing technology a *critical technical practice*, which consists on identifying core metaphors of the field, noticing what (when working with these metaphors) is marginalized, and inverting dominant metaphors bringing alternative perspectives from the margins of the discipline to the center.
As far as I could observe, Soft Computing practitioners have not introduce the issues of accountability and responsibility explicitly in their practice (on the other hand like most part of computer science and technology except but some particular approaches in software engineering like participatory design or user-centred design). However my suggestion is that, because of some particular characteristics (that we already pointed out), Soft Computing is more suitable to include this issues than other more abstract approaches such, for example, Symbolic AI.

6 Conclusion Remarks

Along the article I have enumerated various critiques made to traditional approaches in Artificial Intelligence from part of Philosophy and, later, from Science and Technology Studies. Soft Computing distinguishes itself very much from traditional AI approaches. Because of that, it appears to me as a very interesting topic to question how Soft Computing could cope with these critiques and challenges.
Although this research is still in a preliminary state, I think the issues treated in this article can provide a good frame for future work in the new field of Soft Computing in Humanities and Social Sciences. In addition to that, it could be also of some use for Soft Computing itself. Soft Computing have to face many challenges in order to improve other AI methodologies and try to achieve what they weren't able to. Having a clear picture of these challenges will be very useful. Philosophical and sociological studies of science could help to identify problems and challenges, and, although far from engineering practice, can inspire and suggest new ways of facing the most durable challenges.

In addition, I want to thank the Foundation for the Advancement of Soft Computing for providing me the best place and environment to proceed with my research in this topic.

[1] Strong AI is would be, then, the materialization of the "Computational Theory of Mind" (the philosophical view that holds that the mind is *literally* a digital computer and reasoning consists on formal manipulations of symbolic representations of the world). Through this thesis the debate became not only a philosophical one but also a psychological one: it provides a working model of human intelligence.

[2] In fact this is in tune with the most quoted definition of AI: *"AI is the ability of a computer or other machine to perform those activities that are normally thought to require intelligence"* [25]

[3] For a detailed description see *Stanford Encyclopedia of Philosophy's* entry "The Chinese Room Argument".

[4] Actually Dennett elaborated this critique in general against all kind of "thought experiments".

[5] That is, whether or not there are "internal mental states" in the mind that can be studied by psychologists, or only observable behavior.

[6] Very much related with a very important concept in STS known as "epistemic cultures"

[7] The pioneers of the application of Anthropology to the study of science are the so-called laboratory studies of Latour and Woolgar [15], Karin Knorr-Cetina, and Michael Lynch.

[8] As an anthropologist whose background understanding about knowledge is precisely the opposite (in Social Sciences knowledge is a highly problematic issue, mostly tacit and unconscious and whose "locus" is the a social group or community) is very shocking to confront herself with such a different approach.

[9] We should explain here what we mean with "gender" in gender studies. It is not about the gender of the particular individuals involved in science and technology (particular men or women) not even men and women in general, but the gender systems (defined as gender structures, gender identities and gender symbolisms) in which these science and technology is developed (in our case Western gender system), and how this system influence its process, for example gendered models of knowledge, which is the main topic of the so-called Feminist Epistemology.

[10] However there is no intrinsic reason why a technology may become associated with the masculine or the feminine gender, this may change over time. It is precisely in the contingence of this process where feminism locates its hope in change towards a more egalitarian relation between women and technology.

[11] This epistemology considers logic as the paradigm of valid knowledge. Logic characterizes precisely by depersonalizing the subject and being the paradigm of context-free knowledge.

Abstract—In our previous work we proposed a Multilayer Perceptron Neural Networks (MLP NN) consisting of fuzzy flip-flops (F^3) based on various operations. We showed that such kind of fuzzy-neural network had good learning properties. In this paper we propose an evolutionary approach for optimizing fuzzy flip-flop networks (FNN). Various popular fuzzy operation and three different fuzzy flip-flop types will be compared from the point of view of the respective fuzzy-neural networks' approximation capability.

Keywords— Bacterial Memetic Algorithm, feedbacked fuzzy J-K and fuzzy D flip-flops, Multilayer Perceptron Neural Networks

1 Introduction

Fuzzy set theory, artificial neural networks, bacterial evolutionary algorithms and their hybrid combination have been the subject of intense study and application, especially in the last decades. These were developed with the aim to deal with problems which were hard to solve using traditional techniques. Fuzzy systems are transparent and interpretable, neural networks possess the property of auto-adaptability, while evolutionary, especially bacterial algorithms have been used for the approximation of the optimal structure. To approximate various test functions we use a combination of the above mentioned three main branches of Computational Intelligence. Although some paper report about Support Vector Machines (SVM) outperforming traditional Multilayer Perceptron (MLP) in classification task, but in prediction and regression problems the MLP gives smaller errors with lower network complexity [12]. The paper is organized as follows. After the Introduction Section 2 defines triangular norms and co-norms; and then highlight the five well known fuzzy operations (algebraic, Yager, Dombi, Hamacher and Frank). Section 3 presents the concept of a single fuzzy J-K and D flip-flop, using the fundamental equation as it was proposed in [13]. A comparative study of several types of fuzzy J-K flip-flops based on the five fuzzy operations is made. Comparisons of fuzzy J-K flip-flops with feedback and of two different interpretations of fuzzy D flip-flops are presented. Section 4 is devoted to the investigation of the F^3 based neurons and the MLP [11] constructed from them. We proposed the Fuzzy Flip-Flop Neural Network (FNN) architecture that can be used for learning and approximating various simple transcendental functions. In Section 5 we present Bacterial Memetic Algorithm with Modified Operator Execution Order (BMAM) [5] for FNN variables optimization. Experimental results and comparison between different types of FNNs trained with Levenberg-Marquardt (LM) method and the BMAM are discussed in Section 6, followed by a brief conclusion in the last Section.

2 Fuzzy operations

Klement, Mesiar and Pap enumerate and give the basic definitions and properties of the most general triangular norms in [8], including also graphical illustrations, comparisons. In general a triangular norm [8] (t-norm) is a binary operation T on the unit interval [0, 1], i.e., a function $T:[0,1]^2 \rightarrow [0,1]$, such that for all $a, b \in [0,1]$ the commutativity, associativity, monotonicity and boundary conditions are satisfied. Triangular co-norms (s-norm) were introduced [8] as dual operations of t-norms.

Table 1 shows various t-norms and s-norms selected by us, (as possible bases of the FNN), all five can be used as basic operators in the definition of the fundamental formulas of the fuzzy flip-flop introduced in the next Section. (Many other did not produce good enough neural network properties, cf. [10].) For simplicity we denote the t-norm with i, and the s-norm with u, where the subscripts refer to the initial of the name of the norm: e.g., in case of Yager norms: $i_Y(a,b) = a\ i_Y\ b$ and $u_Y(a,b) = a\ u_Y\ b$.

3 Fuzzy flip-flops

3.1 Fuzzy J-K Flip-Flops

The fuzzy J-K flip-flop is an extended form of the binary J-K flip-flop. In this approach the truth table for the J-K flip-flop is fuzzified, where the binary NOT, AND and OR operations are substituted by their respective fuzzy counterparts, i.e. fuzzy negation, t-norm, and co-norm respectively.

ISBN: 978-989-95079-6-8

Table 1: Some t-norms and co-norms.

Fuzzy operation	t-norm; i (a, b)	s-norm; u (a, b)
Algebraic (A)	ab	$a+b-ab$
Yager (Y)	$1-\min\left[1,((1-a)^w+(1-b)^w)^{1/w}\right]$	$\min\left[1,(a^w+b^w)^{1/w}\right]$
Dombi (D)	$\frac{1}{1+\left[(1/a-1)^\alpha+(1/b-1)^\alpha\right]^{1/\alpha}}$	$\frac{1}{1+\left[(1/a-1)^{-\alpha}+(1/b-1)^{-\alpha}\right]^{-1/\alpha}}$
Hamacher (H)	$\frac{ab}{\gamma+(1-\gamma)(a+b-ab)}$	$\frac{a+b-(2-\gamma)ab}{1-(1-\gamma)ab}$
Frank (F)	$\log_s\left[1+\frac{(s^a-1)(s^b-1)}{s-1}\right]$	$1-\log_s\left[1+\frac{(s^{1-a}-1)(s^{1-b}-1)}{s-1}\right]$

Parameters w, α, γ and s lie within the open interval $(0, \infty)$. The next state $Q(t+1)$ of a J-K flip-flop is characterized as a function of both the present state $Q(t)$ and the two present inputs $J(t)$ and $K(t)$. (For simplicity (t) will be omitted in the next.) The so called fundamental equation of the J-K type fuzzy flip-flop [13] is

$$Q(t+1) = (J \vee \neg K) \wedge (J \vee Q) \wedge (\neg K \vee \neg Q) \quad (1)$$

where $\neg, \wedge, \vee$ denote fuzzy operations (e.g. $\neg K = 1-K$). As a matter of course, it is possible to substitute the standard operations by any other reasonable fuzzy operation triplet (e.g. De-Morgan triplet), thus obtaining a multitude of various fuzzy flip-flop pairs.

In [9] we studied the behavior of fuzzy J-K flip-flops based on various fuzzy operations, and illustrated their behavior by the graphs belonging to the next states of fuzzy flip-flops for typical values of Q, J and K.

3.2 Fuzzy D Flip-Flops

Connecting the inputs of the fuzzy J-K flip-flop in a particular way, namely, by applying an inverter in the connection of the input J to K, case of $K = 1-J$, a fuzzy D flip-flop is obtained. Substituting $D = \neg K = J$ in equation (1), the fundamental equation of fuzzy D flip-flop will be

$$Q(t+1) = (D \vee D) \wedge (D \vee Q) \wedge (D \vee \neg Q) \quad (2)$$

As an alternative approach, Choi and Tipnis [4] proposed an equation which also exhibits the characteristics of a fuzzy D flip-flop, as follows

$$Q(t+1) = D \wedge (D \vee Q) \wedge (\neg Q \vee D) \quad (3)$$

We will refer to this type of fuzzy D flip-flop as Choi (type fuzzy) D flip-flop (because of the first author). Comparing the characteristical equation of the fuzzy D flip-flop (2), with expression (3), there is essential difference between the two fuzzy flip-flops.

As $D = D \wedge D$, and $D = D \vee D$ i.e. the t-norm (T) and co-norm (S) are idempotent [1], hold only in the exceptional case ($T(x, x) = x$ and $S(x, x) = x$ for all $x \in [0,1]$); when

T = min, and S = max.

For example, using the algebraic norm

$$u_A(a,a) = a + a - a \cdot a = 2 \cdot a - a^2 = a \quad (4)$$

is satisfied only in the two borderline cases, when $a = 0$, or $a = 1$. It is surprising how much the satisfaction of idempotence influences the behavior of the fuzzy D flip-flops, as it will be shown.

In the next Section we will give an overview of the different type fuzzy J-K, D and Choi D F^{3}s, based on familiar norms listed in Table 1.

3.3 Fuzzy Flip-Flops Based on Various Fuzzy Operations

The behavior of fuzzy flip-flops based on algebraic, Yager, Dombi, Hamacher and Frank t-norms, combined with the standard negation $c(a)$=1-a in every case has been analyzed and compared [9] , in order to investigate, whether and to what degree they present more or less sigmoidal (S-shaped) $J \to Q(t+1)$ transfer characteristics in the particular cases, when K=1-Q, K=1-J, with a fixed value of Q. F^3 based algebraic type t-norm presents non-sigmoidal behavior, with piecewise linear characteristics and several breakpoints, but having the advantage of the hardware implementation of F^3 [14], this type was also studied for comparison.

3.4 Fuzzy J-K, D and Choi D Flip-Flops Based on Some Classes of Fuzzy Set Unions and Intersections

Using a triplet consisting of the standard negation, and a dual pair of fuzzy operations, i.e., using Yager t-norm and s-norm, the maxterm form in the unified equation (1) can be rewritten as:

$$Q_Y(t+1) = \left(J \; u_Y \left(1-K\right)\right) \; i_Y \; \left(J \; u_Y \; Q\right) \; i_Y \; \left(\left(1-K\right) \; u_Y \left(1-Q\right)\right) \quad (5)$$

This is the fundamental equation of the Yager type fuzzy J-K flip-flop.

By substituting the above mentioned triplet into equations (2) and (3) we defined the fundamental equations of the Yager type fuzzy D (6) and Yager type Choi D (7) flip-flops.

$$Q_Y(t+1) = (D \; u_Y \; D) \; i_Y (D \; u_Y \; Q) \; i_Y \; (D \; u_Y \; (1-Q)) \quad (6)$$

$$Q_Y(t+1) = D \; i_Y (D \; u_Y \; Q) \; i_Y \; ((1-Q) \; u_Y \; D) \quad (7)$$

In a very similar way, in the cases of algebraic, Dombi, Hamacher and Frank operation triplets we defined the corresponding fundamental equations of the respective fuzzy J-K, D and Choi D flip-flops.

ISBN: 978-989-95079-6-8

The parameter values in the Yager, Dombi, Hamacher and Frank norms strongly influence the $J \to Q(t+1)$ characteristics curvature. We have compared the characteristics for various typical parameter values and choose w=2, α=2, γ=10 and s=100, where we obtained more or less S-shaped $J \to Q(t+1)$ characteristics. A change of the t-norms in the characteristical equations of fuzzy J-K, D and Choi D flip-flops leads to the modification of the slope of the transfer function, which will affect the learning rate in the implementation of neural networks.

4 Fuzzy flip-flop based neurons

In this section we propose the use of the fuzzy flip-flops discussed above as neurons in a MLP. In the next, we study the effect of applying the mentioned five t-norms and co-norms in the investigation of the F^3 based neurons and the MLPs constructed from them. An important aspect of these F^3s is that they all have a certain convergent behavior when their input J is excited repeatedly. This convergent behavior guarantees the learning property of the networks constructed this way.

4.1 Function Approximation by Fuzzy Flip-Flop Network Trained with Levenberg – Marquardt Algorithm

A fuzzy flip-flop based supervised feedfordward backpropagation network is applied in order to approximate test functions. This function is represented by a set of 100 input/output data sets. All the input and output signals are distributed in the unit interval. In general, two trainable layer networks with sigmoid transfer functions in the hidden layer and linear transfer functions in the output layer have good approximation and interpolation properties [7], analogously the neural system model proposed is based on two hidden layers constituted from fuzzy flip-flop neurons.

The nonlinear characteristics exhibited by fuzzy neurons are represented by quasi sigmoid transfer functions given by fuzzy J-K, D and Choi D flip-flops based on algebraic, Yager, Dombi, Hamacher and Frank operations. The proposed network activation function is the same at each hidden layer, from unit to unit. For simplicity we did not apply activation function or threshold to the output layer, and considered our model with only one output. The number of neurons was chosen after experimenting with different size hidden layers. Smaller neuron numbers in the hidden layer result in worse approximation properties, while increasing the neuron number results in better performance, but longer simulation time. In our approach the weighted input values are connected to input J of the fuzzy flip-flop based on a pair of t-norm and t-conorm, having quasi sigmoid transfer characteristics. The output signal is then computed as the weighted sum of the input signals, transformed by the transfer function.

During network training, the weights and thresholds are first initialized to small, random values and the network was trained with Levenberg-Marquardt algorithm with 100 maximum numbers of epochs as more or less sufficient. First we fixed the activation function, the number of layers and the number of units in each layer. The chosen target activation function was the *tansig* (hyperbolic tangent sigmoid transfer function). This function is well suited to the demands of backpropagation.

5 Bacterial Memetic Algorithm with Modified Operator Execution Order (BMAM)

The Bacterial Memetic Algorithm with Modified Operator Execution Order (BMAM) [5] is a very recent soft computing tool. It combines a special kind of Genetic Algorithm [6] - Pseudo-Bacterial Genetic Algorithm (PBGA) - and the Levenberg-Marquardt (LM) method. We use this algorithm for training fuzzy flip-flop based neural network (FNN) to improve function approximation performance. The Bacterial Memetic Algorithm (BMA) resulted in better approximation properties in fuzzy modeling problems than the Bacterial Evolutionary Algorithm (BEA) (which outperformed the traditional Genetic Algorithms [2], [3]).

The core of BMAM contains the bacterial mutation, which is inspired by the biological bacterial cell model. Its basic idea is to improve the parts of chromosomes contained in each bacterium. The bacterial mutation mechanism is used by the bacteria which can transfer genes to other bacteria. To find the optimal approximation for our network we encoded our FNN weighs, biases, Q and fuzzy operation parameter values in a bacterium (chromosome). Therefore a procedure is working on changing the variables, testing the model obtained in this way and selecting the best models.

5.1 Function Approximation by Fuzzy Flip-Flop Network Trained with BMAM

The learning of the FNN is formulated as a parameter optimization problem, using the mean square error as the fitness evaluation set-up. The basic steps followed by the algorithm embrace the bacterial mutation operation and the LM method.

In the initial population a number of individuals are randomly created and evaluated. Next, an evolutionary cycle is started by applying the bacterial mutation operation for each individual. A number of copies (clones) of the bacterium are generated. Then the same part or parts of the chromosome is choose and mutate randomly, except one single clone that remains unchanged during this mutation cycle. The LM method nested into evolutionary algorithm is applied for a few times for each individual. The selection of the best clone is made and transfers its parts to the other clones. The part choosing-mutation-LM method-selection-transfer cycle is repeated until all the parts are mutated, improved and tested. The best individual is remaining in the population, and all other clones are deleted. This process is repeated until all the individuals have gone through the modified bacterial mutation.

6 Simulation results

The combination of two sine wave forms with different period lengths as test function was,

$y = \sin(c_1 * x) * \sin(c_2 * x)/2+0.5$,

ISBN: 978-989-95079-6-8

where the input vector x generated a sinusoidal output y. The values of constants c_1 and c_2 were selected to produce a frequency proportion of the two components 1:0.35.
The function approximation goodness depended on the flexible Q and fuzzy operation parameter values, on the fuzzy flip-flop types, hidden layer neuron numbers and in addition on the fuzzy operations themselves. To check the goodness of training, we used the Mean Squared Error (MSE) as a measure of the error made by the FNN. The simulation results are summarized in the next two tests.

6.1 Test 1

In one of our earlier paper [9] we optimized the value of Q, for every combination of J-K, D and Choi D type F^3s with all five fuzzy operation pairs, the parameters of the norms chosen for suitable values, solving the problem of the selection of the value of Q with the fine tuning of FNN.
The fuzzy flip-flop based FNNs are based on algebraic, further parametric Yager, Dombi, Hamacher and Frank norms. Table 2 shows the experimental results obtained with LM optimization [9].

Table 2: Q optimums obtained with LM algorithm.

	Fuzzy neuron type		
Fuzzy operation	J-K	D	Choi D
Algebraic (A)	**0.21**	**0.15; 0.91**	**0.09; 0.81**
Yager (Y)	0.06	0.20	0.17
Dombi (D)	**0.11**	0.92	0.06
Hamacher (H)	0.32	0.57	0.38
Frank (F)	0.31	0.45	0.55

The $J \to Q(t+1)$ fuzzy D and Choi D flip-flop characteristics based on algebraic norm present about the same sigmoidal character in multiple points of the domain [7], which fact can leads to rather different optimum results, corresponding to minimal median MSE values. In Test 1 we propose a new method to find the optimal Q – fuzzy operation parameter pair for every combination of J-K, D and Choi D type F^3s by training a 1-8-8-1 FNN with bacterial memetic algorithm. The advantage of this network size lies in good learning capability. In our application a population with 29 parameters - according to the network size - was initialized. During simulations 20 generations of 5 individuals with 5 clones were chosen to obtain the best fitting variables. Table 3 shows the unique optimal Q values found by BMAM algorithm, which are approximately equal to the respective optimum values listed in Table 2. We obtained almost the same results after every run, although in short term the training is not always successful.

Table 3: Q optimums obtained with BMAM algorithm.

	J-K	D	Choi D
Algebraic	0.25	0.12	0.13

The experimental results in case of J-K F^3 type FNN based on Dombi norm further indicated that the proposed network had multiple optimal Q – α parameter pairs. The test revealed, for example, the Q = 0.12, α = 2.9 values as a result that was close to the optimum solution mentioned above.

6.2 Test 2

In the next we will compare the function approximation performance of FNN trained in two different ways. In the first one the network training function updates weight and bias values according to Levenberg-Marquardt optimization (section 4.1). In the second approach the FNN variables - weights, bias, for fixed Q and fuzzy operation parameter values - optimization was made by the bacterial memetic algorithm with the modified operation execution order (section 5.1). During the simulations we covered all 15 possible combinations of fuzzy J-K, D and Choi D type FNNs with all five fuzzy operation pairs to approximate the above mentioned test function.
By changing the number of the layers, we used a 1-4-3-1 FNN in order to have a network that approximated accurately and also fast enough the sine waves, to emphasize the difference between various FNNs.
The parameter of Dombi, Yager, Hamacher and Frank norms were fixed α=2, w=2, γ=10 and s=100, which values provided good learning and convergence properties.
In our approach we fixed the value of Q, the present state value belonging to each fuzzy flip-flop, according to the values in Table 2. Tables 4, 5 and 6 present the 30 runs average approximation goodness, by indicating the minimum, median, mean and maximum mean squared error of the training values for each of the *tansig*, algebraic, Yager, Dombi, Hamacher and Frank types of FNNs.
Figures 1 and 2 present the graphs of the simulations in case of fuzzy J-K flip-flop with feedback based neural network trained with LM and respectively BMAM algorithms. In both of cases the algebraic F^3 provides a fuzzy neuron with rather bad learning ability. Comparing the median MSE values, considering them as the most important indicators of trainability, the Yager and Dombi types FNNs performed best, they can be considered as rather good function approximators. Our simulations have shown that BMAM performs better in every case than the original LM technique.
Figures 3, 4 and 5, 6 compare the behavior of fuzzy D flip-flop and Choi type fuzzy D flip-flop based NNs. It is interesting that according to the numerical illustrations (Tables 5 and 6) the average of 30 run mean squared errors in these cases the best results after the idealistic *tansig* function are given by the Hamacher and Yager F^3, which are followed by the Dombi and finally by the algebraic one. The Hamacher and Yager types FNNs have excellent approximation properties. It is surprising how much the satisfaction of idempotence influences the behavior of the fuzzy D flip-flop based NN. Comparing the simulation results belonging to the two types of fuzzy D flip-flop with the same norms, it can be seen that, for the same value of Q, the value of the MSE differs, which fact leads to a rather different behavior in the applications.
Using BMAM algorithm in the FNN variable optimization task, we obtained better function approximation capability with lower error than in case of FNNs trained with LM method.

7 Conclusions

In this paper we proposed the use of BMAM to optimizing fuzzy flip-flop based neural network (FNN). We compared the function approximation performance of five different types of FNNs, which depends from the choice of different fuzzy flip-flop types and from the training algorithm. The result of learning as well as its performance might differ quite significant under these two learning modes. The simulations have shown that the bacterial memetic algorithm can improve the function approximation capability by optimizing the FNN variables values.

Bi-criteria Genetic Selection of Bagging Fuzzy Rule-based Multiclassification Systems

Abstract— *Previously we proposed a scheme to generate fuzzy rule-based multiclassification systems by means of bagging, mutual information-based feature selection, and a multicriteria genetic algorithm (GA) for static component classifier selection guided by the ensemble training error. In the current contribution we extend the latter component by the use of two bi-criteria fitness functions, combining the latter error measure with the selected ensemble likelihood. A study on four popular UCI datasets with different dimensionalities is conducted in order to analyze the accuracy-complexity trade-off obtained by the two GAs, the initial fuzzy ensemble and a single fuzzy classifier.*

Keywords— Bagging, feature selection, fuzzy rule-based multiclassification systems, genetic selection of individual classifiers, multicriteria genetic algorithm.

1 Introduction

Multiclassification systems (MCSs) are promising data mining tools dealing with complex classification problems, especially when the number of dimensions or the size of the data are really large [1]. They usually combine decision trees [2] or neural networks [3], but also more recently fuzzy classifiers [4, 5, 6].

In a previous study [7], we described a methodology in which classical MCS design approaches such as bagging [8] and random subspace [2] are used to generate fuzzy rule-based multiclassification systems (FRBMCSs) using a basic heuristic fuzzy classification rule generation method [9], as well as a classifier selection technique based on a GA driven by a multicriteria fitness function [10]. Later, we improved our methodology in [10] using a feature selection approach based on the Battiti's method [11] and the GRASP procedure [12]. Finally, in [13], we extended the genetic selection method by considering additional error measures.

We drew the conclusion that a feature and instance selection procedure combined with a simple grid partitioning FRBS is a good approach to overcome the curse of dimensionality problem in large datasets while using FRBMCS, mainly due to the fact that these kind of classifiers are instable enough. Nevertheless, once a set of classifiers has been trained, we still need to deal with the high number of rules and the correlations between individual classifiers. This is why a selection of the classifiers is so crucial. As said before, we already proposed a GA guided by several single-criteria fitness functions, based on the training error [10], the likelihood [7], or the Out-Of-Bag error [13]. This methodology, quite novel in this topic, lead us to the generation of a compact sets of rules, while still preserving its accuracy, in a single GA run, without resorting on a Pareto-based multi-objective optimization technique. However, many experimentations suggested the choice of the fitness function is very dependent of the problem being solved. For instance, when using the training error, the accuracies of two FRBMCSs can be similar or even null, making difficult for the GA to discriminate between them in order to improve the generalization ability. On the contrary, using the likelihood alone seems to give bad results on many datasets. This suggests the fact that a combination of some criteria could be a good idea to overcome this issue, producing better results than any criterion in isolation.

The aim of the current contribution is to propose a solution by exploring two new fitness functions based on a combination of the training error and the likelihood measures. By doing so, we will try to combine them using the two most simple ways: weighted average and lexicographic order (i.e. considering the optimization of a single criterion, and using the second in case of tie). Introducing such elaborated method we hope that it will allow the FRBMCS to deal with high dimensional data.

We aim to check if the new GA fitness functions will perform better in terms of accuracy than the previous ones for some datasets, while still being competitive for the others datasets. A preliminary study will be conducted on small and medium size datasets from the UCI machine learning repository to test the two new fitness functions in comparison to a single classifier, the original FRBMCS, and the GA-selected FRBMCSs using the said fitness functions. Several parameter settings for the global approach (e.g. different granularity levels as well as different feature selection methods) will be tested and compared regarding the accuracy and the size of the rule base obtained by a single classifier and the original FRBCS ensemble.

This paper is set up as follows. In the next section, existing GA-based methods to select MCSs are reviewed. Sec. 3 recalls our approach for designing FRBMCSs considering bagging and feature selection, while Sec. 4 describes the proposed multicriteria GA for component classifier selection. The experiments developed and their analysis are shown in Sec. 5. Finally, Sec. 6 collects some concluding remarks and future research lines.

2 Related work on genetic selection of MCSs

In general, the selection of a subset of classifiers is done using the *overproduce-and-choose strategy* (OCS) [14], in which a large set of classifiers is produced and then selected to extract the best performing subset. GAs are a popular technique within this strategy. In the literature, performance, complexity and diversity measures are usually considered as search criteria. Complexity measures are employed to increase the interpretability of the system whereas diversity measures are used to avoid overfitting.

ISBN: 978-989-95079-6-8

Among the different genetic OCS proposals, we can remark the following ones. In [15], a hierarchical multi-objective GA (MOGA) algorithm, performing feature selection at the first level and classifier selection at the second level, is presented which outperforms classical methods for two handwritten recognition problems. The MOGA allows both performance and diversity to be considered for MCS selection. In [16] a GA is used to select from seven diversity heuristics for k-means cluster-based ensembles and the ensemble size is also encoded in the genome. In the study of Martínez-Munoz et al. [17], a GA is compared to five other techniques for ensemble selection. Even if the performance of the GA was the worst obtained, they showed that while selecting a small subset of classifiers, the generalization error was significantly decreased. In [18], the authors developed a multidimensional GA to optimize two weight-based models, in which the weights are assigned to each classifier or to each class. They applied their system to 6 different classifiers (only linear and quadratic classifiers are explored), but on only two small datasets and without comparing to the results obtained on a single classifier. Finally, our own previous studies [10, 7] also consider a multicriteria GA for the ensemble selection in an OCS fashion, with performance (training error) and complexity as criteria to guide the GA.

In general, the performance obtained with the initial MCS is outperformed by the ensemble selected by the GA, while simplifying the system. In our current contribution, we will confirm this conclusion by the study of two improved fitness functions mixing the two most used criteria: the accuracy and the complexity of the classifiers. The fitness function will directly incorporate one or two accuracy criteria (i.e., the training error and the likelihood), while the MCS complexity will be implicitly optimized by the considered coding scheme.

3 Bagging and feature selection-based FRBMCSs

In this section we will both detail how the individual classifiers and the FRBMCSs are designed. A normalized dataset is split into two parts, a training set and a test set. The training set is submitted to an instance selection and a feature selection procedure in order to provide individual training sets (the so-called *bags*) to train simple FRBCSs (through the method described in section 3.1). The instance selection and the feature selection procedures are described in section 3.2. After the training, we got an initial FRBMCS, which is validated using the training and the test errors (*Ensemble Training Error* and *Ensemble Test Error*), as well as a measure of complexity based on the total number of rules in the FRBCSs. This ensemble is selected using a multicriteria GA (described in the next section) guided by two accuracy-based fitness functions. The final FRBMCS is validated using different accuracy (Training Error, Test Error) and complexity measures (number of classifiers, total number of rules).

3.1 Individual FRBCS composition and design method

The FRBCSs considered in the ensemble will be based on fuzzy rules R_j with a class C_j and a certainty degree CF_j in the consequent: If x_1 is A_{j1} and ... and x_n is A_{jn} then Class C_j with CF_j, $j = 1, 2, \ldots, N$, and they will take their decisions by means of the single-winner method [9]. This fuzzy reasoning method has been selected due to its high simplicity and interpretability. The use of other more advanced ones [19] is left for future works.

To derive the fuzzy knowledge bases, one of the heuristic methods proposed by Ishibuchi et al. in [9] is considered. The consequent class C_j and certainty degree CF_j are statistically computed from all the examples located in a specific fuzzy subspace $D(A_j)$. C_j is computed as the class h with maximum confidence according to the rule compatible training examples $D(A_j) = \{x_1, \ldots, x_m\}$: $c(A_j \Rightarrow Class\ h)$ = $|D(A_j) \bigcap D(Class\ h)|/|D(A_j)|$. CF_j is obtained as the difference between the confidence of the consequent class and the sum of the confidences of the remainder (called CF_j^{IV} in [9]).

This method is good for our aim of designing FRBCS ensembles since it is simple and quick. However, it carries two drawbacks: its low accuracy and the generation of large fuzzy rule bases. We aim to consider more advanced techniques in the future.

3.2 FRBMCS design approaches

The generation of the FRBMCSs is performed by means of a bagging approach combined with a feature selection method [10]. Three different feature selection methods, random subspace and two variants of Battiti's MIFS, greedy and GRASP, are considered.

As said before, *random subspace* [2] is a method in which we select randomly a set of features from the original dataset. The greedy Battiti's MIFS method [11] is based on a forward greedy search using the Mutual Information measure [20], with regard to the class. This method selects the set S of the most informative features about the output class which cannot be predicted with the already selected features. It uses a coefficient, β, to set up the penalization on the information brought by the already selected features.

The MIFS-GRASP variant is an approach where the set is generated by iteratively adding features randomly chosen from a Restricted Candidate List (RCL) composed of the best τ percent decisions according to the Battiti's quality measure. Parameter τ is used to control the amount of randomness injected in the MIFS selection. With $\tau = 0.5$, we get an average amount of randomness, while still preserving the quality-based ordering of the features.

For the bagging approach, the bags are generated with the same size as the original training set, as commonly done. In every case, all the classifiers will consider the same fixed number of features.

Finally, no weights will be considered to combine the outputs of the component classifiers to take the final FRBMCS decision, but a pure voting approach will be applied: the ensemble class prediction will directly be the most voted class in the component classifiers output set.

4 A multicriteria GA-based MCS selection method

In our previous studies, we used a multicriteria GA, which is able to obtain a list of possible MCS designs ranked by their quality *from a single chromosome* thanks to its novel coding scheme. However, the fitness function considered was based on a single criterion, either the likelihood (L) [7], the *training*

ISBN: 978-989-95079-6-8

error (TE) [10, 13], or the out-of-bag error [13]. Although the TE-based GA provided better overall results, the L-based GA outperformed it in some of the cases. That led us to the idea of combining the both measures, which moreover show complementary characteristics.

4.1 Multicriteria genetic optimization

The GA searches for an optimal sequence of the classifiers, in the way that the most significant classifiers have the lowest indexes, while those redundant members, which can be safely excluded, are in the last positions. The coding scheme is thus based on an order-based representation, a permutation $\Pi = \{j_1, j_2, \ldots, j_l\}$ of the l originally generated individual classifiers. In this way, each chromosome encodes l different solutions to the problem, based on considering a "basic" MCS comprised by a single classifier, that one stored in the first gene, then another one composed of two classifiers, those in the first and the second genes, and so on.

So, the computation of the evaluation criteria for the whole ensemble is obtained in a *cumulative* way, defined as a vector containing the measured values of the first classifier; the subset formed by the first and the second; and so on. The fitness function is thus using the values of a multicriteria vector, being composed of an array of l values, $L^i = L'_{\{j_1,j_2,\ldots,j_i\}}$, corresponding to the cumulative measure-value of the l mentioned MCS designs.

At the end of the GA, the best chromosome is that member in the population overcoming the others using the considered criterion. Then, the final design encoded in this chromosome is the MCS comprising the classifiers from the first one to the one having the the best cumulative measured value (although any other design not having the optimal accuracy but, for example, showing a lowest complexity can also be directly extracted). In this way, an implicit use of a complexity criterion is also made.

To increase its convergence rate, the GA works following a steady-state approach. The initial population is composed of randomly generated permutations. In each generation, a tournament selection of size 3 is performed, and the two winners are crossed over to obtain a single offspring that directly substitutes the loser. In this study, we have considered OX crossover and the usual exchange mutation [21].

4.2 The two used evaluation criteria

For the definition of the fitness functions, we use TE and L as the evaluation criteria.

The TE is computed as follows. Let $h_1(\mathbf{x}), \ldots, h_l(\mathbf{x})$ be the outputs of the component classifiers of the selected ensemble for an input value $\mathbf{x} = (x_1, \ldots, x_n)$. For a given sample $\{(\mathbf{x}^k, C^k)\}_{k\in\{1\ldots m\}}$, the TE of that MCS is:

$$TE = \frac{1}{m} \cdot \#\{k \mid C^k \neq \arg\max_{j\in\{1\ldots M\}} h_j(\mathbf{x}^k)\} \qquad (1)$$

Fitness evaluation using TE alone was already studied in one of our previous publications [10]. We will call it *Training Error-based Fitness Function* (TEFF).

The L is computed as follows. Let the classes $h_1(\mathbf{x}), h_2(\mathbf{x}), \ldots, h_l(\mathbf{x})$ be the decisions of the component classifiers of the selected ensemble S for an input value $\mathbf{x} = (x_1, \ldots, x_n)$. We will assume that the fraction of the members of S that agree on the class of $\mathbf{x}$ is an estimate of the conditional probability of that class:

$$P_S(C|\mathbf{x}) = \frac{1}{|S|} \cdot \#\{i \in S \mid h_i(\mathbf{x}) = C\}.$$

The L of the subset S, to be maximized, is:

$$L_S = \prod_k P_S(C^k|\mathbf{x}^k).$$

As the small values of L_S may produce numerical instabilities, we use instead a bounded log-likelihood:

$$L'_S = \sum_k \log(P_S(C^k|\mathbf{x}^k) + \epsilon),$$

where the value ϵ foresees that case for which none of the members of the subset has found the true class of the pattern. In [7], we endowed the fitness function with the L, as it allows us to discern differences between ensembles with the same TE (specifically, between those with null error!). A learning process using only the TEFF will automatically end up with the learning, while L will go on improving the estimations of the probability distributions for each class, thus reducing the chances of overfitting the training data.

4.3 The two new bi-criteria fi tness functions

In this contribution we propose two approaches for the fitness function combining the L with the TE measure, the *Lexicographical Order-based Fitness Function* (LOFF) and the *Weighted Combination Fitness Function* (WCFF).

Notice that, working in this way, we are introducing a second multi-criteria optimization level in our algorithm. On the one hand, a multi-criteria optimization is made by means of the considered coding scheme and the cumulative evaluation of the possible MCS designs (see Sect. 4.1). On the other hand, a higher level is introduced when evaluating the latter possible designs by means of a bi-criteria fitness function.

In the first one, the LOFF, we use the lexicographical order to deal with the multicriteria optimization. When comparing two chromosomes, one is better than the other if it takes a better (lower) minimum value of the TE. In case of tie, the L measure is considered. The ordering scheme gives priority to TE, as it provided better results in our previous study, while taking the L only in the last resort in the case of the frequent ties encountered by the system.

In the second approach, the WCFF, we propose objective function scalarization by a weighted combination of both measures:

$$WC = factor_0 * \alpha * TE + (1 - \alpha) * L \qquad (2)$$

where α is a weight in [0,1] and $factor_0 = L_0/TE_0$ is a first evaluation-based normalization using L_0 and TE_0, the L and the TE from the initial FRBMCS. The fitness function is to be minimized.

5 Experiments and analysis of results

In this section, we discuss the performance obtained by a single FRBCS, the initial FRBMCS, and three different GA-selected FRBMCSs including our two new fitness functions on four chosen datasets.

ISBN: 978-989-95079-6-8

5.1 Experimental setup

To evaluate the performance of the generated FRBMCSs, we have selected four datasets from the UCI machine learning repository (see Table 1). In order to compare the accuracy of the considered classifiers, we used Dietterichs 5×2-fold cross-validation (5×2-cv), which is considered to be superior to paired k-fold cross validation in classification problems [22].

Table 1: Data sets considered

Data set	#attr.	#examples	#classes
Pima	8	768	2
Glass	9	214	7
Vehicle	18	846	4
Sonar	60	208	2

Three different granularities, 3, 5 and 7, are tested for the single FRBCS derivation method, for feature sets of size 5 selected by means of three approaches: the greedy Battiti's MIFS filter feature selection method [11], the Battiti's method with GRASP (with τ equal to 0.5, see section 3.2), and random subspace [2]. Battiti's method has been run by considering a discretization of the real-valued attribute domains in ten parts and setting the β coefficient to 0.1.

The FRBMCSs generated are initially comprised by 50 classifiers. The GA for the component classifier selection works with a population of 50 individuals and runs during 50 generations. The mutation probability considered is 0.05. The weights of WCFF were set to 0.8 for TE and 0.2 for L as our aim was to allow a small influence of the L in the cases in which the TE gives similar values. The other values for the weights will not improve the results significantly.

All the experiments have been run in a cluster at the University of Granada on Intel quadri-core Pentium 2.4 GHz nodes with 2 GBytes of memory, under the Linux operating system.

5.2 Comparison of the three fi tness functions

The statistics (5×2-cv error, number of rules, and run time required for each run, expressed in seconds) for the genetically selected FRBCS ensembles using LOFF, WCFF and TEFF are collected in Tables 2, 3 and 4 respectively. There are three subtables for each of the feature selection method considered. The best results for a given feature selection method are shown in bold and the best values overall are outlined.

Comparing the three fitness functions, we can see how the WCFF approach is able to outperform the TEFF and LOFF considering the individual test error 9 times (+2 draw). The best individual improvement was observed on the sonar dataset (-8% regarding LOFF, -4% regarding TEFF) with greedy and 5 labels. We observed that in 4 out of 9 cases, WCFF outperforms other approaches on the sonar and pima datasets. The best overall result was obtained on the pima dataset with GRASP and 5 labels (draw with LOFF).

The FRBMCSs based on LOFF are better than TEFF and WCFF in 12 of the 36 cases (+2 draw). The best individual improvement was observed on the sonar dataset with random subspace and 5 labels (-9% regarding WCFF, -12% regarding TEFF). The best overall result was obtained on the pima dataset with greedy and 5 labels (draw with WCFF) and on the glass dataset with GRASP and 5 labels. We can observe that in 5 out of 9 cases, LOFF outperforms the other genetic approaches on the glass dataset.

Comparing the two new fitness functions, the LOFF provides better results than WCFF considering individual test error in 21 cases (+ 2 draw). We can also observe that LOFF outperforms the other approach on the glass dataset in 7 out 9 cases (+1 draw) giving a good performance for the vehicle (7 out 9 cases) datasets. However, the WCFF is better in 6 out of 9 cases on the pima dataset and in 5 out of 9 cases (+1 draw) on the sonar dataset. In general, LOFF is better than WCFF since it gives a lower influence to L, whereas the weighted combination is better on the sonar dataset due to the many ties with the TE on this dataset, making the use of the L more likely.

The TEFF-based FRBMCSs outperforms the LOFF and the WCFF considering individual test error for 13 of the 36 times. The best overall result was obtained on the sonar dataset with random subspace and 3 labels, and on the vehicle with random subspace and 7 labels. We may conclude that the LOFF and WTEL are competitive with TEFF. The LOFF got best results 12 times (+2 draw), WTEL 9 (+2 draw) and TEFF 13 times. However, in the direct comparison, the use of LOFF improves the single TEFF performance in 18 out of 36 cases (+3 draw) and the WTEL improves the single TEFF performance in 19 out of 36 cases, which indicates that L does not produce overfitting. Thus, the use of L as a secondary criterion is only useful in some of the cases.

On 36 cases, the number of classifiers is lower in 12 cases (+1 draw) with the LOFF, in 9 cases with the WCFF and in 15 cases (+1 draw) with the TEFF. The two new fitness functions generate a higher number of classifier, since they are more conservative due to the use of L. Such fitness functions could be viewed as a proper way to improve performance of the datasets having the larger size.

5.3 Genetically selected FRBMCSs vs. single FRBCS/original FRBMCSs

The results of the single FRBCSs are presented in Table 5 while those of the original FRBMCSs are presented in Table 6. In all the 36 cases, the generated FRBMCSs improve the performance of the single FRBCS.

Although the main goal of the genetic selection is to reduce the complexity of the generated FRBMCS, the accuracy results obtained from that process are also improved in most of the cases, showing the potential of the approach. In only 10 of the 36 cases (+1 draw) the original FRBMCS outperforms the best genetically designed one in terms of accuracy. Comparing the best overall TE values of genetically selected FRBMCSs with those of the original FRBMCSs, the GA improves the results on the sonar dataset (-2% regarding TEFF) and glass (-10% regarding LOFF), showing a slight increase for the other problems (+2% for pima regarding LOFF/WTEL, +2% for vehicle regarding TEFF).

5.4 Statistical signifi cance of the results

Table 7 shows the results of the statistical tests performed to check if the performance of the initial FRBMCSs and the performance of the GA selected FRBMCSs outperform significantly the performance of the single classifier. The Wilcoxon signed-rank test [23] has been used for this purpose. The best

result for each dataset is marked with a star '*'.

The best results (in average) are always obtained by the initial or the selected ensembles. Even if they are only significant for two datasets, they correspond to those with the largest dimension. Notice that, on sonar, the GA outperforms significantly the single classifier. The initial ensemble outperforms the best genetically selected FRBMCSs in one of the four cases (vehicle), whereas TEFF achieves the best result for the sonar dataset and WCFF for the sonar.

In the direct comparison, TEFF is the best choice two times for the vehicle and sonar dataset. The new fitness functions outperforms one of the four cases for pima with LOFF and glass dataset with WCFF.

Thus, combining bagging and the GA selection process to design FRBMCSs performs better for high dimensional problems with a large number of attributes, producing a smaller rule base while reducing the test errors in some cases, which was our original goal. When combining these two techniques with an advanced feature selection process we also get an improvement of the accuracy for datasets with higher dimensions (glass, vehicle and sonar, see Table 7).

6 Conclusions and future works

In this study, we extended our previously developed methodology in which a bagging approach together with a feature selection technique are used to train FRBMCSs, at a later stage selected by a multicriteria GA. Two new fitness functions were tested, the LOFF and the WCFF, based on one or two accuracy criteria (i.e., the training error and the likelihood). The generated selected FRBCS ensembles are performing correctly on classification problems with a significant number of features. By using abovementioned techniques, we would like to obtain FRCMCS dealing with high dimensional data.

One of the next steps we will consider in the future line is the design of a generic framework to define the multicriteria fitness function. At least two different information levels will be studied: the chromosome and the objective level. Furthermore, we would like to extend this study on larger data sets (more than 1,000 examples), to study the influence of other parameters (the GA parameters, the weighting coefficient in the WCFF, etc.), and to design more advanced genetic MCS selection techniques (e.g. the use of Pareto-based algorithms). Analysis of the different fuzzy rule genreation techniques and introduction a diversity criterion in the algorithm are another important points for future research.

Abstract—*Fuzzy C-Means (FCM) and hard clustering are the most common tools for data partitioning. However, the presence of noisy observations in the data may cause generation of completely unreliable partitions from these clustering algorithms. Also, application of the Euclidean distance in FCM only produces spherical clusters. In this paper, a new noise-rejection clustering algorithm based on Mahalanobis distance is presented which is able to detect the noise and outlier data and also ellipsoidal clusters. Unlike the traditional FCM, the proposed clustering tool provides much efficient data partitioning capabilities in the presence of noise and outliers. For validation of the proposed model, the model is applied to different noisy data sets.*

Keywords— Cluster Validity Index (CVI), Fuzzy C-Means (FCM), Possibilistic C-means (PCM), Revised Gustafson-Kessel (GK), Revised Mahalanobis Distance.

1 Introduction

Clustering methods have been extensively used in computer vision and pattern recognition. Fuzzy clustering methods have shown spectacular ability to detect not only volume clusters, but also clusters which are actually thin shells, i.e. curves and surfaces.

Most analytic fuzzy clustering approaches are derived from the fuzzy C-means (FCM) algorithm. FCM uses the probabilistic constraint that the membership of a data point across classes sums to 1. The constraint is used to generate the memberships update equations for an iterative algorithm. The memberships resulting from FCM and its derivative however, do not always correspond to the intuitive concept of belonging or compatibility. Moreover, the algorithms have considerable trouble in noisy environments. Reference [1] summarizes the main problems of classic FCM as follows:

- In order to get the optimal partition, initial locations of the cluster centers should be assigned. The FCM algorithm always converges to a local extreme. Different choices of initial cluster centers may lead to a different extrema.
- The scientific basis for the choice of m, the weighting exponent, is still not clear.
- The optimum number of clusters in the data is assigned a priori. There should be a criterion to assign the optimal number of clusters.

To overcome these problems and drawbacks, first, [2] introduces a new method for fuzzy clustering called possibilistic fuzzy clustering. Their approach differs from the previous clustering methods in that the resulting partition of the data can be interpreted as a possibilistic partition, and the membership values may be interpreted as degrees of possibility of the points belonging to the classes, i.e., the compatibilities of the points with the class prototypes. They construct an appropriate objective function whose minimum will characterize a good possibilistic partition of the data, and derive the membership and prototype update equations from necessary conditions for minimization of the related criterion function. Next nominated work is [1]. Melek et al. in [1] show how their PCM addresses the mentioned problems of the FCM for some example cases. However, their method has some limitations which are the concentration of this paper.

The Rest of the paper is organized as follows: Section 2 discusses the drawbacks of the previous PCM's. Then, in section 3 the proposed method is presented in order to overcome these limitations. Section 4 applies the method for different data sets to verify and validate the proposed method.

2 Limitations of the traditional PCM's

Reference [1] uses Euclidean distance in all data partitioning steps. However, clearly, Euclidean distance usually fails to recognize the appropriate shape of the clusters in complex data sets. Especially, when data include ellipsoidal shapes, Euclidean distance loses sight to those data which should be considered in a cluster from data which should not be included in that cluster.

Moreover, the cluster validity index (*CVI*) applied in [1], suffers from linear behaviour of the Euclidean distance. There are many samples of data sets which the applied *CVI* is not able to recognize the number of clusters correctly.

Another limitation is about noise identification procedure. Application of Euclidean distance can mislead the noise rejection procedure. This problem is discussed in the related section of the proposed algorithm.

While Euclidean distance implies the above mentioned limitations, Mahalanobis distance can mitigate or in some cases can overcome the cited limitations completely. Another advantage of the Mahalanobis distance is that the

Mahalanobis distance can identify both spherical and ellipsoidal clusters correctly.

3 Improvements to the traditional PCM's

As quoted in introduction, the proposed method applies the Mahalanobis distance for noise rejection problem. However, when applying mahalanobis distance, some difficulties may occur with covariance matrix.
