Up to the previous level we rejected most video shots imported into the DB with high probability of being irrelevant to significant events. So classification of shots in this phase may be done based on the events included in them. We have listed the set of features that may be used to classify the events , features include: G, percent of pixels covering the grass field in shot keyframes, G2, percent of pixels in section E2 on the grass field in shot keyframes and the Sd (the output of fuzzy system) and Fs, Percent of Far-side view in a shot. After normalizing the above 4 features the value of each of them for each shot will range between 0 and 1, so the feature vector for each shot is shown by Fv (I,V) and expressed in the following form:

Fv(i,V)={G,G2,Fs,Sd}
Where: i is the shot number from video V.

We used SVM to classify the events. In this phase events must be associated with 5 predefined classes. All classes have their special keywords which are presented here:

EventClass = { Goal, Penalty, Kroner, Free kick, other}

After the learning phase the videos stored in the DB for making up the Meta Data are processed and then the events are classified. Afterwards the above keywords are associated with the created classes manually and then each new event automatically inherits its keyword and is recorded in the Meta Data for that event. A table is formed in the Meta Data for each single video processed (Figure 8). During implementation the name given to each table of the Meta Data is taken to be the same as the file name recorded in the database, so relations with the raw video are maintained. Also we can save the information entered into the system for each video in Title of main video file to be used in the retrieval process. Such information may include the name of competing teams, time or place of the match or other details.

Shot Index	Start of shot	End of Shot	Type of Shot	Slow-Motion	Class of Event
. . .	. .	...	. .	... ...	

Fig 8 A table is formed in the Meta Data for each single video processed (The field related to Type of Shot shows the view that has been most frequent in the shot.)

The query model we used for this project was the same proposed in [2]. The base expression used in the model included the following:

select video from search_space [where condition];
select shot from search_space [where condition];

Expression SELECT specifies the SEARCH TARGET which may be Videos or Shots. The search space comes after FROM which may be all videos available in the DB or a list of chosen videos from any given video specified with a "where" condition which may only constitute one restriction or a combination of and/or phrases used to create conditions for time dependencies, which we ignore here.The provided system will be able to answer questions such as these:

Q1: "Find all the goal shots from all the soccer videos"
Q2: "Find all the corner kick shots from all the soccer videos where the goal accurse by England team"
Remember that the prerequisite to doing the condition contained in the second question is that the required information are added to the Meta Data by the system manager while the video is being entered into the database. To find the answer it suffices to extract the defined terms from the query expression and search for them in the Meta Data.

4 Evaluation

We have used more than 5.5 hours of football Videos in the database includes: 1 match of the World Cup 2006, 2 matches from the UEFA Champions League 2005, 1 match from the FA Premier League 2004, and more than 5 clips from Euro 2004(Table 2). The file format of the input films was non-compressed avi and the size of output films is 88×79.

Table 2. Names and the length (min:sec) of the clips in the database

Euro001(46:40),Euro002(47:00),Euro003(47:30), Euro004(46:00), Euro005(46:45), FIFA-div01f(12:38), FIFA-div02f(18:23),FIFA-div03f(15:38),FIFA-div04f(17:40),FIFA-div05f(18:22),Eng1(42:7) ,Eng2(20:51)

In the training phase we used 119 shots to learning for SVM and the rate of correct class in training data is 87%. As noted earlier the output of fuzzy system is a degree for each shot and the system rejects no useful shots using a threshold(th) as system input parameter. The input margin of the system for evaluation is 0.2 and then inputs include 0.2, 0.4, 0.6, 0.8 and 1. The results of changing the input amount of the system and the accuracy of the events classification are shown in tables 3,4,5,6. In this evaluation scenario we used 187 shots includes 5 Goals, 5 Penalties, 6 Free kicks, 9 Corners and 162 shots containing no significant events. Table 3 where the input th is 0.2 then system rejected 23

ISBN: 978-989-95079-6-8

shots before classification, table 3 shows the result of classification after rejection phase with input 0.2, Table 4 where the input th is 0.4 then system rejected 86 shots. Table 5 where th is 0.6 and the system rejected 114 shots and Table 6 where th is 0.8 and the system rejected 172 shots.
When th is 0.6, 4 shots containing corner and free kicks are rejected incorrectly(see the '# of rejected' row of table 5) and When th is 0.8, 10 shots containing very important events are rejected incorrectly (see the '# of rejected row' of table 6).
In the tables accuracy formula is:
Accuracy =100* Correct/(Total + False)
The Tables indicate that the higher the threshold, the higher the number of rejected shots will be. Also, the higher the threshold, the lower the number of incorrect shot detection (see 'False' row of tables) will be. See Table 6 where th = 0.8 and False detection for all events is zero but 1 Goal, 5 Free kicks and 4 corner are rejected incorrectly.

Table 3. The result of proposed method with th = 0.2

	Goal	Penalties	Free kick	Corner	other	sum
Total	5	5	6	9	162	187
# of rejected	0	0	0	0	23	23
Correct	5	5	6	9	86	111
False	13	9	17	14	0	53
Accuracy	27%	36%	26%	39%	-	-

Table 4. The result of proposed method with th = 0.4

	Goal	Penalties	Free kicks	Corner	other	sum
Total	5	5	6	9	162	187
# of rejected	0	0	0	0	86	86
Correct	5	5	5	8	51	74
False	6	0	13	6	1	27
Accuracy	45%	100%	32%	53%	-	-

Table 5. The result of proposed method with th = 0.6

	Goal	Penalties	Free kicks	Corner	other	sum
Total	5	5	6	9	162	187

Accuracy	71%	100%	36%	58%	-	-

Table 6. The result of proposed method with th = 0.8

	Goal	Penalties	Free kicks	Corner	other	sum
Total	5	5	6	9	162	187
# of rejected	1	0	5	4	162	172
Correct	4	5	1	5	0	15
False	0	0	0	0	0	0
Accuracy	80%	100%	16%	55%	-	-

5 Conclusions

The proposed method uses human expert knowledge for soccer video events retrieval by fuzzy systems. After feature extraction, each shot is given a degree of significance by the fuzzy system, thereby significantly reducing time complexity of video processing. By defining a threshold on the output of the fuzzy system, the useful and none-useful shots are separated for the purpose of event classification. Support vector machines are then applied for final classification of video information.

***Abstract*— *In a rather general, essentially aggregation operator based discussion of the traditional fuzzy control strategies known as FATI and FITA strategies, a way to reduce these strategies to one another has been to define pairs of aggregation distributive aggregation operators. In this paper it is shown that for some often used special cases this reduction condition allows only the set theoretic union as aggregation operator.*

***Keywords*—** fuzzy control, FATI strategy, FITA strategy, aggregation operators, aggregation distributivity

1 Introduction

The standard paradigm behind standard approaches toward fuzzy control is that one supposes to have given, as an incomplete and fuzzy description of a control function Φ from an input space $\mathbb{X}$ to an output space $\mathbb{Y}$, a family

$$\mathcal{D} = (\langle A_i, B_i\rangle)_{1\leq i\leq n} \tag{1}$$

of (fuzzy) input-output data pairs to characterize this function Φ.

In the usual approaches such a family of input-output data pairs is provided by a finite list

$$\text{IF } x \text{ is } A_i \text{ THEN } y \text{ is } B_i, \tag{2}$$

(with $i = 1, \ldots, n$) of linguistic control rules, also called fuzzy IF-THEN rules.

The basic examples of fuzzy control approaches are Zadeh's original approach via fuzzy relations and the compositional rule of inference (CRI), as prototypically realized by the Mamdani–Assilian approach in [7], and the Holmblad–Ostergaard approach toward fuzzy control of a cement kiln as explained in [5].

Derived from these two approaches there is the well known distinction between FATI and FITA strategies to evaluate systems of linguistic control rules w.r.t. arbitrary fuzzy inputs from $\mathcal{F}(\mathbb{X})$.

2 Preliminaries

The core idea of a FITA strategy is that it is a strategy which **F**irst **I**nfers (by reference to the single rules) and **T**hen **A**ggregates starting from the actual input information A. Contrary to that, a FATI strategy is a strategy which **F**irst **A**ggregates (the information in all the rules into one fuzzy relation) and **T**hen **I**nfers starting from the actual input information A.

Both these strategies use the set theoretic union as their aggregation operator. Furthermore, both of them refer to the CRI as their core tool of inference.

In general, however, the interpolation operators may depend more generally upon some inference operator(s) as well as upon some aggregation operator.

2.1 Aggregation operations and fuzzy control strategies

By an *inference operator* we mean here simply a mapping from the class of fuzzy subsets of the input space to the class of fuzzy subsets of the output space.[1]

And an *aggregation operator* $\mathbf{A}$, as explained e.g. in [1, 2], is a family $(f^n)_{n\in\mathbb{N}}$ of ("aggregation") operations, each f^n an n-ary one, over some partially ordered set $\mathbf{M}$, with ordering $\leqslant$, with a bottom element $\mathbf{0}$ and a top element $\mathbf{1}$, such that each operation f^n is non-decreasing, maps the bottom to the bottom: $f^n(\mathbf{0}, \ldots, \mathbf{0}) = \mathbf{0}$, and the top to the top: $f^n(\mathbf{1}, \ldots, \mathbf{1}) = \mathbf{1}$.

Such an aggregation operator $\mathbf{A} = (f^n)_{n\in\mathbb{N}}$ is a *commutative* one iff each operation f^n is commutative. And $\mathbf{A}$ is an *associative* aggregation operator iff

$$\begin{aligned} &f^n(a_1, \ldots, a_n) = \\ &\quad f^r(f^{k_1}(a_1, \ldots, a_{k_1}), \ldots, f^{k_r}(a_{m+1}, \ldots, a_n)) \end{aligned} \tag{3}$$

for $n = \sum_{i=1}^{r} k_i$ and $m = \sum_{i=1}^{r-1} k_i$.

Our aggregation operators further on are supposed to be commutative as well as associative ones.[2]

As in [3, 4], we now consider operators Ψ of FATI-type operators Ξ of FITA-type and which have the abstract forms

$$\Psi_{\mathcal{D}}(A) = \mathbf{A}(\theta_{\langle A_1,B_1\rangle}(A), \ldots, \theta_{\langle A_n,B_n\rangle}(A)), \tag{4}$$

$$\Xi_{\mathcal{D}}(A) = \widehat{\mathbf{A}}(\theta_{\langle A_1,B_1\rangle}, \ldots, \theta_{\langle A_n,B_n\rangle})(A). \tag{5}$$

Here we assume that each one of the "local" inference operators θ_i is determined by the single input-output pair $\langle A_i, B_i\rangle$. This restriction is in general sufficient. For the present purpose we assume that our inference operators are CRI-based, i.e. we assume that $\theta_{\langle A_1,B_1\rangle}(A)$ has

[1] This terminology has its historical roots in the fuzzy control community. There is no relationship at all with the logical notion of inference intended and supposed here; but–of course–also not ruled out.

[2] It seems that this is a rather restrictive choice from a theoretical point of view. However, in all the usual cases these restrictions are satisfied.

ISBN: 978-989-95079-6-8

the form

$$\theta_{\langle A_i,B_i\rangle}(A) = R_i'' A \tag{6}$$

for some fuzzy relation R. In this case we call the inference operator $\theta_{\langle A_1,B_1\rangle}$ CRI-*based*.

Furthermore $\mathbf{A}$ has to be an aggregation operator for fuzzy subsets of the universe of discourse $\mathbb{X}$, and $\widehat{\mathbf{A}}$ has to be an aggregation operator for inference operators.

2.2 Stability conditions

If $\Theta_{\mathcal{D}}$ is a fuzzy inference operator of one of the types (4), (5), then the interpolation property one likes to have realized is that one has

$$\Theta_{\mathcal{D}}(A_i) = B_i \tag{7}$$

for all the data pairs $\langle A_i, B_i\rangle$. In the particular case that the operator $\Theta_{\mathcal{D}}$ is detrmined by the CRI-methodology, this is just the usual problem to solve a system (7) of fuzzy relation equations.

In the present generalized context the property (7) has been called the $\mathcal{D}$-*stability* of the fuzzy inference operator $\Theta_{\mathcal{D}}$.

To find $\mathcal{D}$-stability conditions on this abstract level seems to be rather difficult in general. However, the restriction to fuzzy inference operators of FITA-type makes things easier.

To explain some of the known results it is necessary to have a closer look at the aggregation operator $\mathbf{A} = (f^n)_{n\in\mathbb{N}}$ involved in (4) which operates on $\mathbb{F}(\mathbb{Y})$, of course with the inclusion relation for fuzzy sets as partial ordering.

Definition 1 *Having $B, C \in \mathbb{F}(\mathbb{Y})$ we say that C is* $\mathbf{A}$-negligible w.r.t. *B iff $f^2(B, C) = f^1(B)$ holds true.*

The core idea here is that in any aggregation by $\mathbf{A}$ the presence of the fuzzy set B among the aggregated fuzzy sets makes any presence of C superfluous.

For examples and further interesting properties of aggregation operators the interested reader may consult [3, 4].

Now we are in a position to state one of the results from [3, 4] to give an impression of what becomes of interest in the present context.

Proposition 1 *Consider a fuzzy inference operator $\Psi_{\mathcal{D}}$ of FITA-type (4). It is sufficient for the $\mathcal{D}$-stability of $\Psi_{\mathcal{D}}$, i.e. to have*

$$\Psi_{\mathcal{D}}(A_k) = B_k \qquad \text{for all } k = 1, \ldots, n \tag{8}$$

that one always has

$$\theta_{\langle A_k,B_k\rangle}(A_k) = B_k \tag{9}$$

and additionally that for each $i \neq k$ the fuzzy set

$$\theta_{\langle A_k,B_k\rangle}(A_i) \quad \text{is } \mathbf{A}\text{-negligible w.r.t.} \quad \theta_{\langle A_k,B_k\rangle}(A_k)\,. \tag{10}$$

This result has two quite interesting specializations which themselves generalize well known results about fuzzy relation equations. The interested reader may consult [3, 4].

To extend such considerations from inference operators (4) of the FITA type to those ones of the FATI type (5) let us consider the following notion.

Definition 2 *Suppose that $\widehat{\mathbf{A}}$ is an aggregation operator for inference operators, and that $\mathbf{A}$ is an aggregation operator for fuzzy sets. Then $(\widehat{\mathbf{A}}, \mathbf{A})$ is an* application distributive *pair of aggregation operators iff*

$$\widehat{\mathbf{A}}(\theta_1, \ldots, \theta_n)(X) = \mathbf{A}(\theta_1(X), \ldots, \theta_n(X)) \tag{11}$$

holds true for arbitrary inference operators $\theta_1, \ldots, \theta_n$ and fuzzy sets X.

Using this notion it is easy to see that one has on the left hand side of (11) a FATI type inference operator, and on the right hand side an associated FITA type inference operator. So one is able to give a reduction of the FATI case to the FITA case, assuming that such application distributive pairs of aggregation operators exist.

Proposition 2 *Suppose that $(\widehat{\mathbf{A}}, \mathbf{A})$ is an application distributive pair of aggregation operators. Then a fuzzy inference operator $\Xi_{\mathcal{D}}$ of FATI-type is $\mathcal{D}$-stable iff its associated fuzzy inference operator $\Psi_{\mathcal{D}}$ of FITA-type is $\mathcal{D}$-stable.*

3 Application distributivity

Based upon the notion of application distributive pair of aggregation operators the property of $\mathcal{D}$-stability can be transferred back and forth between two inference operators of FATI-type and of FITA-type if they are based upon a pair of application distributive aggregation operators.

What has not been discussed previously was the existence and the uniqueness of such pairs. Here are some results concerning these problems.

The uniqueness problem has a simple solution.

Proposition 3 *If $(\widehat{\mathbf{A}}, \mathbf{A})$ is an application distributive pair of aggregation operators then $\widehat{\mathbf{A}}$ is uniquely determined by $\mathbf{A}$, and conversely also $\mathbf{A}$ is uniquely determined by $\widehat{\mathbf{A}}$.*

And for the existence problem we have a nice reduction to the two-argument case.

Theorem 1 *Suppose that $\mathbf{A}$ is a commutative and associative aggregation operator. For the case that there exists an aggregation operator $\widehat{\mathbf{A}}$ such that $(\widehat{\mathbf{A}}, \mathbf{A})$ form an application distributive pair of aggregation operators it is necessary and sufficient that there exists some operation G for fuzzy inference operators satisfying*

$$\mathbf{A}(\theta_1(X), \theta_2(X)) = G(\theta_1, \theta_2)(X) \tag{12}$$

for all fuzzy inference operators θ_1, θ_2 and all fuzzy sets X.

However, there is an important restriction concerning the existence of such pairs of application distributive aggregation operators, at least for the interesting particular case that the application operation is determined by the compositional rule of inference (CRI). And this means simply that the inference operations θ_i are determined via suitable fuzzy relations R_i.

ISBN: 978-989-95079-6-8

Definition 3 *An aggregation operator* $\mathbf{A} = (f^n)_{n\in\mathbb{N}}$ *for fuzzy subsets of a universe of discourse* $\mathbb{X}$ *is* pointwise defined *iff for each* $n \in \mathbb{N}$ *there exists a function* $g_n : [0,1]^n \to [0,1]$ *such that for all* $A_1, \ldots, A_n \in \mathcal{F}(\mathbb{X})$ *and all* $x \in \mathbb{X}$ *there hold*

$$f^n(A_1, \ldots, A_n)(x) = g_n(A_1(x), \ldots, A_n(x)) \,. \tag{13}$$

And an aggregation operator $\widehat{\mathbf{A}}$ *for inference operators is* pointwise defined *iff it can be reduced to a pointwise defined aggregation operator for fuzzy relations.*

From the isotonicity behavior of the aggregation operator $\mathbf{A}$ it follows that also these characterizing functions g_n are isotonic, and similarly in the case of $\widehat{\mathbf{A}}$.

The restrictive result, first proved in [6], now reads as follows.

Theorem 2 *Suppose that all inference operators are CRI-based. Then the pair* $(\bigcup, \bigcup)$ *is the only application distributive pair among the commutative, associative, and pointwise defined aggregation operators.*

Proof: Obviously the considerations can restricted to the binary case $n = 2$. So let us start in this CRI-based case with an aggregation operator $\widehat{\mathbf{A}}$, which has to give a fuzzy relation $\widehat{\mathbf{A}}(R_1, R_2)$ for any two inference operators θ_1, θ_2 determined by the fuzzy relations R_1, R_2, respectively. Because $\widehat{\mathbf{A}}$ has to be pointwise defined, according to Definition 3 there has to be a function $\widehat{g} : [0,1] \times [0,1] \to [0,1]$ such that one has for the membership degrees of the corresponding fuzzy relations

$$\widehat{\mathbf{A}}(R_1, R_2)(x, y) = \widehat{g}(R_1(x, y), R_2(x, y)) \,. \tag{14}$$

In a similar way, again by Definition 3, a corresponding aggregation operator $\mathbf{A}$ has to be determined by a function $g : [0,1] \times [0,1] \to [0,1]$. Assuming that these aggregation operators $(\mathbf{A}, \widehat{\mathbf{A}})$ form an aggregation distributive pair, gives for arbitrary fuzzy inputs A the condition

$$\begin{aligned}
&\widehat{\mathbf{A}}(R_1, R_2)''(A)(y) \\
&= \bigvee_x T\Big(A(x), \widehat{\mathbf{A}}(R_1, R_2)(x, y)\Big) \\
&= \bigvee_x T\Big(A(x), \widehat{g}(R_1(x, y), R_2(x, y))\Big) \qquad (15) \\
&= g\Big(\bigvee_x T(A(x), R_1(x, y)), \bigvee_x T(A(x), R_2(x, y))\Big) \\
&= \mathbf{A}(R_1'' A, R_2'' A)(y) \,,
\end{aligned}$$

which has to be satisfied for arbitrary fuzzy sets A and fuzzy relations R_1, R_2. Of course, T here is the t-norm involved in the CRI application process.

So let be always $A(x) = 1$ and furthermore $R_1(x, y) = a, R_2(x, y) = b$ for some $a, b \in [0,1]$. Now routine calculations yield $\widehat{g}(a, b) = g(a, b)$, which means equality of the functions $\widehat{g} = g$ which determine the aggregation operators $\widehat{\mathbf{A}}, \mathbf{A}$, respectively.

So application distributivity of the pair $(\mathbf{A}, \widehat{\mathbf{A}})$ becomes a condition which has to be satisfied by the characterizing function g, and this condition reads

$$\begin{aligned}
&\bigvee_x T\Big(A(x), g(R_1(x, y), R_2(x, y))\Big) \; = \qquad (16) \\
&\qquad g\Big(\bigvee_x T(A(x), R_1(x, y)), \bigvee_x T(A(x), R_2(x, y))\Big) \,.
\end{aligned}$$

To continue our discussion and to finish the proof of Theorem 2, we insert two lemmata.

Lemma 1 *Suppose that* $g : [0,1] \times [0,1] \to [0,1]$ *determines a commutative and associative pointwise defined (binary) aggregation operator. Then the condition*

$$\sup_{i\in I} g(a_i, b_i) = g(\sup_{i\in I} a_i, \sup_{i\in I} b_i) \tag{17}$$

is equivalent to the fact that g *is left continuous and satisfies*

$$g(a, b) = g(\max\{a, b\}, \max\{a, b\}) \,. \tag{18}$$

It is easy to see that (17) implies the left continuity of g. So assume (17) and that (18) is not generally satisfied. Then there are $a_0, b_0 \in [0,1]$ such that

$$g(a_0, b_0) \neq g(\max\{a_0, b_0\}, \max\{a_0, b_0\}) \tag{19}$$

and additionally, w.l.o.g., also $b_0 \leq a_0$. This last condition forces even its strengthening $b_0 < a_0$, and together with the isotonicity of g yields $g(a_0, b_0) < g(a_0, a_0)$. But this now means

$$\begin{aligned}
&\max\{g(a_0, b_0), g(b_0, a_0)\} = g(a_0, b_0) \\
&\quad < \quad g(a_0, a_0) = g(\max\{a_0, b_0\}, \max\{a_0, b_0\}) \,, \qquad (20)
\end{aligned}$$

contradicting (17). So the $(\Rightarrow)$-part of the lemma is proved.

If otherwise g is left continuous and satisfies (18), one has

$$g(\sup_{i\in I} a_i, \sup_{i\in I} b_i) \geq \sup_{i\in I} g(a_i, b_i) \tag{21}$$

by the isotonicity of g. But $g(a_j, b_j) \leq \sup_{i\in I} g(a_i, b_i)$ and (18) yield

$$g(c_j, c_j) \leq \sup_{i\in I} g(a_i, b_i) \tag{22}$$

for $c_j = \max\{a_j, b_j\}$, and by the left continuity and isotonicity of g this gives

$$g(\sup_{i\in I} c_i, c_j) \leq \sup_{i\in I} g(c_i, c_i) \leq \sup_{i\in I} g(a_i, b_i), , \tag{23}$$

and thus also

$$g(\sup_{i\in I} a_i, \sup_{i\in I} b_i) \leq g(\sup_{i\in I} c_i, \sup_{i\in I} c_i) \leq \sup_{i\in I} g(a_i, b_i) \,. \tag{24}$$

All together gives (17) and hence the $(\Leftarrow)$-part of the lemma.

The condition (17) obviously means that the corresponding aggregation operator commutes with the supremum.

ISBN: 978-989-95079-6-8

Lemma 2 *Suppose that* $g : [0,1] \times [0,1] \to [0,1]$ *determines a commutative and associative pointwise defined (binary) aggregation operator. Then condition (17) is satisfied iff there exists a left continuous isotonic function* $h : [0,1] \to [0,1]$ *satisfying* $h(0) = 0$, $h(1) = 1$ *and*

$$g(a,b) = \max\{h(a), h(b)\}\,. \tag{25}$$

For the $(\Rightarrow)$-part consider the function $h(x) = g(0,x)$. It is left continuous as well as isotonic, satisfies $h(0) = 0$ and $h(1) = 1$, and one has by Lemma 1

$$\begin{aligned} g(a,b) &= g(\max\{a,b\}, \max\{a,b\}) \\ &= g(\max\{0, \max\{a,b\}\}, \max\{0, \max\{a,b\}\}) \\ &= g(0, \max\{a,b\}) \;=\; \max\{h(a), h(b)\}\,. \end{aligned} \tag{26}$$

The $(\Leftarrow)$-part follows from routine calculations.

So we come back to the proof of Theorem 2. What we did not discuss up to now is that for having an aggregation distributive pair of pointwise defined operators the characterizing function g has to be distributive relative to the t-norm T which determines the CRI-application. So we need to have always satisfied

$$T(a, g(b,c)) = g(T(a,b), T(a,c))\,, \tag{27}$$

which means, via Lemmata 1 and 2, to have always satisfied

$$\begin{aligned} &\max\{T(a,h(b)), T(a,h(c))\} \\ &\quad = \quad \max\{h(T(a,b)), h(T(a,c))\}\,, \end{aligned} \tag{28}$$

which forces that one always has to have

$$T(a,h(b)) = h(T(a,b))\,. \tag{29}$$

And this yields $h = \mathsf{id}$: because otherwise there would exist some c with $h(c) \neq c$ and

$$T(c,h(1)) = T(c,1) = c \neq h(c) = h(T(c,1))\,. \tag{30}$$

So Theorem 2 is finally proved.

4 Conclusion

The type of approach explained in Section 2.2 works actually well only in the FITA case. This was the starting point for the considerations on aggregation distributive operator pairs. They give a transfer possibility to the FATI case.

However, as the main result, i.e. Theorem 2 of the present paper shows, these transfer possibilities are quite restricted under some conditions which have, up to now, been considered rather natural ones.

For the authors understanding this result points into two directions. (i) It may be appropriate to try to find other ways and to discuss the FATI case differently. And this way may become essentially different from the reduction strategy toward fuzzy relation equations which stands behind the generalization in [3, 4]. (ii) It may be suitable to move into the realm of aggregation operators which are no longer pointwise defined, and it may also be suitable to leave the world of the CRI-based approaches.

Particularly point (ii) here seems promising, even having in mind that the actual standard cases all fall into the class of pointwise defined aggregation operators. Further investigations into this topic are necessary.

Abstract— *In this paper a general bottleneck combinatorial optimization problem with uncertain element weights modeled by fuzzy intervals is considered. A rigorous possibilistic formalization of the problem and solution concepts in this setting that lead to finding robust solutions under fuzzy weights are given. Some algorithms for finding a solution according to the introduced concepts and evaluating optimality of solutions and elements are provided.*

Keywords— Bottleneck combinatorial optimization, Interval, Fuzzy interval, Fuzzy optimization and design, Possibility theory.

1 Introduction

A *combinatorial optimization problem* consists in finding an object composed of elements of a given ground set E. In a deterministic case, every element of E has a precise weight. In *bottleneck combinatorial optimization problems*, we wish to find an object that minimizes the weight of its heaviest element. Such formulation encompasses a large variety of classical combinatorial optimization problems, for instance: the bottleneck path [1], the bottleneck assignment [2], the bottleneck spanning tree [3] (or a more general the bottleneck matroid base problem [4]) etc. All these problems are efficiently solvable when the weights of all elements are precisely known. Unfortunately, in real world it is not easy to estimate element weights exactly. In many cases, the exact values of weights are not known in advance and the imprecision must be taken into account.

In this paper, we wish to investigate a general bottleneck combinatorial optimization problem with uncertain element weights modeled by fuzzy intervals. The membership function $\mu_{\widetilde{W}}$ of a fuzzy interval $\widetilde{W}$ is a possibility distribution describing, for each value w of the element weight, the extent to which it is a possible value. Equivalently, it means that the value of this weight belongs to a λ-cut interval $\widetilde{W}^{\lambda} = \{t : \mu_{\widetilde{W}}(t) \geq \lambda\}$ with confidence (or degree of necessity) $1 - \lambda$. Now to each feasible solution or element a *degree of possible optimality* and a *degree of necessary optimality* can be assigned. The notion of the necessary optimality of a solution may be weaken by assigning a *degree of necessary soft optimality*. Moreover, all the degrees of optimality of a solution (an element) can be derived from a *fuzzy deviation*, that is a possibility distribution representing the set of plausible values of deviations of the solution (the element) from optimum. In order to choose a "robust solution" under fuzzy weights, we adopt two criteria. The first one consists in choosing a solution of the maximum degree of necessary optimality, called a *best necessarily optimal solution*. Such a solution, if exists, seems to be an ideal choice. The second criterion is weaker than the first one and consists in choosing a solution of the maximum degree of necessary soft optimality, called a *best necessarily soft optimal solution*. This criterion has been originally proposed in [5, 6] for the linear programming problem with a fuzzy objective function. A best necessarily soft optimal solution seems to be a compromise choice and it minimizes a "distance" to the necessary optimality.

In this paper, we provide some methods for the optimality evaluation and for choosing a solution under fuzzy weights. In Section 3, we investigate the interval case, that is the problems in which the element weights are specified as closed intervals. It turns out, that it is possible to construct some polynomial algorithms for such problems if only their deterministic counterparts are polynomially solvable. In consequence, the interval bottleneck problems are easier to solve than the interval problems with a linear sum objective discussed in [7, 8]. We obtain polynomial algorithms for such problems as the bottleneck shortest path, the bottleneck assignment and the bottleneck matroid base. In Section 4, we show that the optimality evaluation and the problem of choosing a solution under fuzzy weights can be reduced to examining a family of interval problems. In particular, we show that a best necessarily soft optimal solution can be computed in polynomial time for a wide class of problems.

2 Preliminaries

In this section, we recall a formulation of a general bottleneck combinatorial problem with precise weights.

Let $E = \{e_1, \ldots, e_n\}$ be a finite ground set and let $\Phi \subseteq 2^E$ be a set of subsets of E called the set of the *feasible solutions*. A nonnegative real weight w_e is given for every element $e \in E$. A *bottleneck combinatorial optimization problem* $\mathcal{BP}$ consists in finding a feasible solution X that minimizes the weight of its heaviest element, namely:

$$\mathcal{BP}: \quad \min_{X \in \Phi} \max_{e \in X} w_e. \tag{1}$$

A solution that minimizes (1) is called an *optimal solution*. We call an element $e \in E$ *optimal* if it is a part of an optimal solution. If a solution (element) is not optimal a natural question arises how far from optimality this solution (element) is. To answer this question one can introduce the concept of a deviation. *A deviation of solution* $X \in \Phi$ and *a deviation of*

ISBN: 978-989-95079-6-8

element $f \in E$ are defined in the following way:

$$\delta_X = \max_{e\in X} w_e - \min_{Y\in\Phi} \max_{e\in Y} w_e,$$
$$\delta_f = \min_{Y\in\Phi_f} \max_{e\in Y} w_e - \min_{Y\in\Phi} \max_{e\in Y} w_e,$$

where Φ_f is the set of all feasible solutions that contain element f. It is clear that solution X (element f) is optimal if and only if $\delta_X = 0$ ($\delta_f = 0$).

In this paper we will assume that problem $\mathcal{BP}$ is polynomially solvable. Some polynomial algorithms for the bottleneck path, the bottleneck assignment, the bottleneck spanning tree, and the bottleneck matroid base problem can be found for instance in [1, 2, 3, 4]. For all these problems the deviations δ_X and δ_f can be computed in polynomial time.

3 Interval-valued bottleneck combinatorial optimization problems

In this section we consider an *interval* version of problem (1), in which the weights of the elements are ill-known and they are modeled by closed intervals $W_e = [\underline{w}_e, \overline{w}_e]$, $e \in E$. Assigning some interval to an element weight means that the actual weight of this element will take some value within the interval but it is not possible at present to predict which one. Every precise instantiation of the element weights is called a *scenario* and we denote it by S. Thus every scenario is a vector $S = (w_e)_{e\in E}$, $w_e \in W_e$ that expresses a realization of the weights. We denote by Γ the set of all the scenarios, i.e. $\Gamma = \times_{e\in E}[\underline{w}_e, \overline{w}_e]$ and we use $w_e(S)$ to denote the weight of element $e \in E$ in a fixed scenario $S \in \Gamma$. Among the scenarios of Γ, we distinguish the *extreme* ones, which belong to $\times_{e\in E}\{\underline{w}_e, \overline{w}_e\}$. Let $A \subseteq E$ be a fixed subset of elements. In scenario S_A^+ all elements $e \in A$ have weights $\overline{w}_e$ and all the remaining elements have weights $\underline{w}_e$. Similarly, in scenario S_A^- all elements $e \in A$ have weights $\underline{w}_e$ and all the remaining elements have weights $\overline{w}_e$. For a given solution $X \in \Phi$, we define its weight under a fixed scenario $S \in \Gamma$ as $F(X, S) = \max_{e\in X} w_e(S)$. We will denote by $F^*(S)$ the value of the weight of an optimal solution under scenario $S \in \Gamma$, that is $F^*(S) = \min_{X\in\Phi} F(X, S)$.

The optimality in the interval-valued problem $\mathcal{BP}$ can be characterized as follows: a given solution $X \in \Phi$ (element $f \in E$) is *possibly optimal* if and only if it is optimal in some scenario $S \in \Gamma$. A given solution $X \in \Phi$ (element $f \in E$) is *necessarily optimal* if and only if it is optimal in all scenarios $S \in \Gamma$. Similarly to the deterministic case, we can express the possible and necessary optimality in terms of the deviation. Let $\delta_X(S) = F(X, S) - F^*(S)$ and $\delta_f(S) = \min_{Y\in\Phi_f} F(Y, S) - F^*(S)$ denote the deviations of solution X and element f under a fixed scenario $S \in \Gamma$, respectively. Consider the following optimization problems:

$$\underline{\delta}_X = \min_{S\in\Gamma} \delta_X(S), \quad \overline{\delta}_X = \max_{S\in\Gamma} \delta_X(S)$$
$$\underline{\delta}_f = \min_{S\in\Gamma} \delta_f(S), \quad \overline{\delta}_f = \max_{S\in\Gamma} \delta_f(S).$$

The solutions to the above problems determine the so called *deviation interval* $\Delta_X = [\underline{\delta}_X, \overline{\delta}_X]$ containing all possible values of deviations for solution X. Similarly $\Delta_f = [\underline{\delta}_f, \overline{\delta}_f]$ is a deviation interval for element f. It is worth pointing that in literature (see e.g. [9]) the quantity $\overline{\delta}_X$ is called the *maximal regret* or *robust deviation* and it expresses the maximal possible deviation from optimum. Obviously, we can easily deduce the optimality of a solution from the deviation interval. Namely, X is possibly (resp. necessarily) optimal if and only if $\underline{\delta}_X = 0$ (resp. $\overline{\delta}_X = 0$). Similarly, an element f is possibly (resp. necessarily) optimal if and only if $\underline{\delta}_f = 0$ (resp. $\overline{\delta}_f = 0$).

3.1 Asserting possible and necessary optimality

In this section we establish some sufficient and necessary conditions for possible and necessary optimality of solutions and elements in the interval-valued problem. We start by proving the following proposition:

Proposition 1. *Let X be a given feasible solution. Then*

$$\underline{\delta}_X = \max\{0, \max_{e\in X} \underline{w}_e - F^*(S_E^+)\}, \tag{2}$$
$$\overline{\delta}_X = \max_{e\in X} \max\{0, \overline{w}_e - F^*(S_{\{e\}}^+)\}. \tag{3}$$

Proof. Equality (3) has been proved in [10]. We now give a proof sketch of (2). It is easy to verify that

$$\underline{\delta}_X \geq \max\{0, \max_{e\in X} \underline{w}_e - F^*(S_E^+)\}. \tag{4}$$

It remains to show that the inequality $\leq$ also holds in (4). Let Y be an optimal solution under S_E^+ and let $g = \arg\max_{e\in Y} \overline{w}_e$. We consider two cases. (i) $\max_{e\in X} \underline{w}_e > \overline{w}_g$. Denote $h = \arg\max_{e\in X} \underline{w}_e$. Consider scenario S such that $w_e^S = \min\{\underline{w}_h, \overline{w}_e\}$ for all $e \in X$ and $w_e^S = \overline{w}_e$ for all $e \in E \setminus X$. Since $\underline{w}_h \geq \underline{w}_e$ for all $e \in X$, $S \in \Gamma$. It is easy to check that $F(X, S) = \underline{w}_h$ and $F^*(S) = F(S_E^+)$. Hence $\underline{\delta}_X \leq \delta_X(S) = \max_{e\in X} \underline{w}_e - F^*(S_E^+) \leq \max\{0, \max_{e\in X} \underline{w}_e - F^*(S_E^+)\}$, which together with (4) yield (2). (ii) $\max_{e\in X} \underline{w}_e \leq \overline{w}_g$. Consider scenario S such that under this scenario all elements $e \in E \setminus X$ have weights $\overline{w}_e$ and all the elements $e \in X$ have weights $\min\{\overline{w}_e, \overline{w}_g\}$. Since $\underline{w}_e \leq \overline{w}_g$ for all $e \in X$, $S \in \Gamma$. One can easily verify that X is optimal under S, which means that $\underline{\delta}_X = 0 \leq \max\{0, \max_{e\in X} \underline{w}_e - F^*(S_E^+)\}$. This, together with (4), give (2). □

Proposition 1 allows us to compute the solution deviation interval Δ_X and leads to the following two corollaries:

Corollary 1. *A solution $X \in \Phi$ is possibly optimal if and only if $F(X, S_E^-) = \max_{e\in X} \underline{w}_e \leq F^*(S_E^+)$.*

Corollary 2. *A solution $X \in \Phi$ is necessarily optimal if and only if $\max_{e\in X} \max\{0, \overline{w}_e - F^*(S_{\{e\}}^+)\} = 0$.*

Making use of Corollaries 1 and 2, we can efficiently evaluate the optimality of a given solution X if only the underlying bottleneck deterministic problem $\mathcal{BP}$ is efficiently solvable. In order to evaluate the possible optimality of X, it suffices to compute the value of $F^*(S_E^+)$ and check if $F(X, S_E^-) \leq F^*(S_E^+)$. This can be done in $O(|X| + f(|E|))$ time, where $f(|E|)$ is the running time of an algorithm for the deterministic $\mathcal{BP}$ problem. Note that evaluating the possible optimality of a next solution, say $X' \in \Phi$, requires only $O(|X'|)$ time. Evaluating the necessary of optimality of X is a little more complex, since it requires computing the difference $\overline{w}_e - F^*(S_{\{e\}}^+)$ for each $e \in X$ and, consequently, the

ISBN: 978-989-95079-6-8

overall running time of evaluating the necessary optimality is $O(|X|f(|E|))$.

Let us consider the problem of computing an element deviation interval. The following proposition is true and its proof is similar to the proof of Proposition 1:

Proposition 2. *Let f be a specified element. Then*

$$\underline{\delta}_f = \max\{0, \min_{X\in\Phi_f} F(X, S_X^-) - F^*(S_E^+)\}.$$

From Proposition 2 we immediately get the following corollary:

Corollary 3. *An element $f \in E$ is possibly optimal if and only if* $\min_{X\in\Phi_f} F(X, S_X^-) \leq F^*(S_E^+)$.

Corollary 3 shows a significant difference between the problems with the bottleneck objective and the problems with the linear sum objective discussed for instance in [7, 8]. For the latter problems, deciding whether $\underline{\delta}_f = 0$ for a given element $f \in E$ may be NP-hard even if a deterministic counterpart is polynomially solvable [8]. For the bottleneck problems the situation is much better. From Proposition 2, it follows that if problem $\mathcal{BP}$ is solvable in $f(|E|)$ time, then the bound $\underline{\delta}_f$ for a given element f can be determined in $O(f(|E|))$ time.

We are unable here to provide a general formula for computing the upper bound of an element deviation $\overline{\delta}_f$. Also, the complexity status of the problem of checking whether f is necessarily optimal is unknown. This is an interesting subject of further research. In the next section we show how to compute efficiently quantities $\underline{\delta}_f$ and $\overline{\delta}_f$ when $\mathcal{BP}$ has a matroidal structure.

3.1.1 Matroidal problems

Let us recall the notion of a matroid (see e.g. [11]). A *matroid* is a system $(E, \mathcal{I})$, where E is a ground set and $\mathcal{I}$ is a set of subsets of E closed under inclusions (if $A \subseteq B$ and $B \in \mathcal{I}$ then $A \in \mathcal{I}$) and fulfilling the so-called *growth* property (if $A, B \in \mathcal{I}$ and $|A| < |B|$ then there is $e \in B \setminus A$ such that $A \cup \{e\} \in \mathcal{I}$). The maximal (under inclusion) elements of $\mathcal{I}$ are called *bases*. We will denote the set of all bases by $\mathcal{B}$. The minimal (under inclusion) sets not in $\mathcal{I}$ are called *circuits*. Matroids have the following property, which will be used in this section. Namely, if $B \in \mathcal{B}$ is a base and f is an element such that $f \notin B$, then $B \cup \{f\}$ contains the unique circuit C. Furthermore, for every $e \in C$, set $(B \cup \{f\}) \setminus \{e\}$ is a base.

In a *matroidal problem* the set of feasible solutions Φ consists of all bases of a given matroid, $\Phi = \mathcal{B}$. An example of a matroidal problem is bottleneck spanning tree, where Φ consists of all bases of a *graphic matroid* [11]. Due to a matroidal structure of the interval problem $\mathcal{BP}$, we can simplify the computation of $\underline{\delta}_f$ and provide a method of computing $\overline{\delta}_f$. We first show how to evaluate the possible and necessary optimality of a given element f.

Proposition 3. *An element $f \in E$ is possibly optimal if and only if $\underline{w}_f \leq F^*(S_E^+)$.*

Proof. Using Corollary 3, it is sufficient to proof that $\underline{w}_f \leq F^*(S_E^+)$ if and only if there is a base $B \in \mathcal{B}_f$ such that $F(B, S_E^-) \leq F^*(S_E^+)$, where $\mathcal{B}_f$ stands for the set of all bases that contain element f.

($\Leftarrow$) Obvious.

($\Rightarrow$) Let B^* be an optimal base in scenario S_E^+. If $f \in B^*$, then $B^* \in \mathcal{B}_f$, $F(B^*, S_E^-) \leq F(B^*, S_E^+) = F^*(S_E^+)$ and we are done. Otherwise, $B^* \cup \{f\}$ contains an unique circuit C. Set $B' = (B^* \setminus \{e\}) \cup \{f\}$, $e \in C \setminus \{f\}$, is a base and $B' \in \mathcal{B}_f$. Since $F^*(S_E^+) \geq \underline{w}_f$, we have $F^*(S_E^+) = \max_{e\in B^*} \overline{w}_e \geq \max_{e\in B'} \underline{w}_e$. Thus $F^*(S_E^+) \geq F(B', S_E^-)$ and the proposition follows. □

Proposition 4. *An element $f \in E$ is necessarily optimal if and only if $\overline{w}_f \leq F^*(S_{\{f\}}^+)$.*

Proof. ($\Rightarrow$) If f is necessarily optimal, then it is optimal under all scenarios, in particular, under $S_{\{f\}}^+$. Thus there is a base B containing f such that $F^*(S_{\{f\}}^+) = F(B, S_{\{f\}}^+)$, which yields $F^*(S_{\{f\}}^+) \geq \overline{w}_f$.

($\Leftarrow$) Consider any scenario $S \in \Gamma$. We first show that inequality $w_f(S) \leq F^*(S)$ holds for S. Define scenario S' where $w_f(S') = \overline{w}_f$ and the remaining elements, $e \neq f$, have weights $w_e(S') = w_e(S)$. Using the assumption we get $\overline{w}_f \leq F^*(S_{\{f\}}^+) \leq F^*(S')$. After decreasing the weight of f to $w_f(S)$, we get inequality $w_f(S) \leq F^*(S)$. Let B^* be an optimal base under S. If $f \in B^*$ then f is optimal under S. Otherwise, $B^* \cup \{f\}$ contains an unique circuit C. Set $B' = (B^* \setminus \{e\}) \cup \{f\}$, $e \in C \setminus \{f\}$, is a base such that $B' \in \mathcal{B}_f$. Since $w_f(S) \leq F^*(S)$, $F(B', S) \leq F(B^*, S) = F^*(S)$. Hence B' is an optimal base and f is optimal under S. □

Using a similar reasoning to that in Propositions 3 and 4 one can prove the following proposition, which allows us to determine the deviation interval $\Delta_f = [\underline{\delta}_f, \overline{\delta}_f]$.

Proposition 5. *Let X be a given feasible solution. Then*

$$\underline{\delta}_f = \max\{0, \underline{w}_f - F^*(S_E^+)\}, \overline{\delta}_f = \max\{0, \overline{w}_f - F^*(S_{\{f\}}^+)\}.$$

Propositions 3 and 4 allow us to evaluate efficiently the possible (resp. necessary) optimality of a specified element $f \in E$. It suffices to replace the interval weights with their exact values determined according to S_E^+ (resp. $S_{\{f\}}^+$), compute the optimal value of $F^*(S_E^+)$ (resp. $F(S_{\{f\}}^+)$) in the resulting deterministic problem and compare it with $\underline{w}_f$ (resp. $\overline{w}_f$). This can be done in $O(|E| \log^*(|E|))$ time [4], where $\log^* |E|$ is the iterated logarithm of $|E|$. Note also that using Proposition 3 we can detect all possibly optimal elements in $O(|E| \log^*(|E|))$ because we need to execute an algorithm for the deterministic problem only once. On the other hand, Proposition 4 does not allow us to detect all necessary optimal elements without extra effort. Computing the deviation interval Δ_f costs the same time as evaluating the possible and necessary optimality of f (see Proposition 5).

3.2 Choosing a robust solution

An important task in the interval-valued problem is to choose a *robust solution*, that is the one which performs reasonably well under any possible scenario. A necessarily optimal solution ($\overline{\delta}_X = 0$) is an ideal choice because it is optimal regardless of weight realizations. On the other hand, the possible optimality of a chosen solution ($\underline{\delta}_X = 0$) is the minimum requirement that should be satisfied. A possibly optimal solution

ISBN: 978-989-95079-6-8

always exists. But a necessarily optimal solution rarely exists. Hence the possible optimality is too weak criterion while the necessary optimality seems to be too strong. A solution that minimizes the maximal regret $\overline{\delta}_X$ seems to be a compromise choice. It minimizes the maximal possible deviation from optimum. In literature [9] such a solution is called an *optimal minmax regret solution*.

Proposition 6. *Every optimal minmax regret solution X is possibly optimal and is composed of possibly optimal elements.*

Proof. We use a proof by contraposition. Assume that X is not possibly optimal. From Corollary 1, we have $\max_{e\in X} \underline{w}_e > F^*(S_E^+)$. Let Y^* be an optimal solution in scenario S_E^+. Define $g = \arg\max_{e\in Y^*} \overline{w}_e$ and $h = \arg\max_{e\in X} \underline{w}_e$. Thus $w_h(S) > \overline{w}_g$ for all scenarios $S \in \Gamma$. But $\overline{w}_g \geq w_e(S)$ for all $e \in Y^*$ in every scenario S, which yields $w_h(S) > w_e(S)$ for $e \in Y^*$. From this we conclude that $F(X,S) > F(Y^*,S)$ for all $S \in \Gamma$, which implies $\overline{\delta}_X > \overline{\delta}_Y$. In consequence, X cannot be an optimal minmax regret solution. It is obvious that every possibly optimal solution is composed of possibly optimal elements. □

Therefore, any optimal minmax regret solution X is possibly optimal and it minimizes a distance to the necessary optimality. In other words its deviation interval is of the form $\Delta_X = [0, \overline{\delta}_X]$ where $\overline{\delta}_X$ is the smallest among all $X \in \Phi$. Fortunately, the problem of determining an optimal minmax regret solution can be efficiently solved if the underlying bottleneck deterministic problem $\mathcal{BP}$ is polynomially solvable [10]. Using Equality (3) we get

$$\min_{X\in\Phi} \overline{\delta}_X = \min_{X\in\Phi} \max_{e\in X} \hat{w}_e, \tag{5}$$

where weights $\hat{w}_e = \max\{0, \overline{w}_e - F^*(S^+_{\{e\}})\}$, $e \in E$, are deterministic. So, the minmax regret problem can be reduced to a deterministic problem $\mathcal{BP}$. It can be shown [10] that the minmax regret problem can be solved in $O(|E|+|X^*|f(|E|))$ time, where X^* is such that $F(X^*, S_E^-) = F^*(S_E^-)$ and $f(|E|)$ is the running time of an algorithm for $\mathcal{BP}$.

4 Fuzzy-valued bottleneck combinatorial optimization problems

In this section, we study problem $\mathcal{BP}$ with uncertain element weights, where the uncertainty is modeled by fuzzy intervals. We give a rigorous possibilistic interpretation, solution concepts and some solution algorithms in this setting.

4.1 A possibilistic formalization of the problem

We now give a formalization of problem $\mathcal{BP}$, in which the weights of elements of E are uncertain and they are modeled by fuzzy intervals $\widetilde{W}_e$, $e \in E$, in the setting of *possibility theory* [12]. Let us recall that a *fuzzy interval* $\widetilde{W}_e$ is a fuzzy set in the space of real numbers $\mathbb{R}$, whose membership function $\mu_{\widetilde{W}_e} : \mathbb{R} \to [0,1]$ is normal, quasiconcave and upper semicontinuous on $\mathbb{R}$. We will additionally assume that the support of $\widetilde{W}_e$ is bounded. A membership function of $\widetilde{W}_e$ is regarded as a *possibility distribution* for the values of the unknown weight $\mathfrak{w}_e$. The possibility degree of the assignment $\mathfrak{w}_e = v$ is $\Pi(\mathfrak{w}_e = v) = \pi_{\mathfrak{w}_e}(v) = \mu_{\widetilde{W}_e}(v)$. Let $S = (v_e)_{e\in E}$ be a scenario that represents a state of the world in which $\mathfrak{w}_e = v_e$, for all $e \in E$. Assuming that the weights are unrelated to one another, the fuzzy intervals associated with the weights induce the following possibility distribution over all scenarios in $\mathbb{R}^n$ (see [13]): $\pi(S) = \min_{e\in E} \Pi(\mathfrak{w}_e = v_e) = \min_{e\in E} \mu_{\widetilde{W}_e}(v_e)$ The degrees of possibility and necessity that a solution $X \in \Phi$ is optimal are defined as follows:

$$\begin{aligned} \Pi(X \text{ is optimal}) &= \sup_{\{S:\, X \text{ is optimal in } S\}} \pi(S), \\ \mathrm{N}(X \text{ is optimal}) &= \inf_{\{S:\, X \text{ is not optimal in } S\}} (1 - \pi(S)). \end{aligned} \tag{6}$$

As in the deterministic and interval cases we can characterize the optimality of a solution using the concept of deviation. In the fuzzy problem a solution deviation belongs to a fuzzy interval $\widetilde{\Delta}_X$, whose membership function $\mu_{\widetilde{\Delta}_X}$ is a possibility distribution for δ_X defined as follows:

$$\mu_{\widetilde{\Delta}_X}(v) = \Pi(\delta_X = v) = \sup_{\{S:\, \delta_X(S)=v\}} \pi(S). \tag{7}$$

Since the statement "X is optimal in S" is equivalent to condition $\delta_X(S) = 0$, it is easily seen that (7) generalizes the degrees of optimality (6), that is

$$\begin{aligned} &\Pi(X \text{ is optimal}) = \Pi(\delta_X = 0) = \mu_{\widetilde{\Delta}_X}(0), \\ &\mathrm{N}(X \text{ is optimal}) = \mathrm{N}(\delta_X = 0) = 1 - \sup_{v>0} \mu_{\widetilde{\Delta}_X}(v). \end{aligned} \tag{8}$$

Replacing X with f in (6)-(8) we get the same formulae for element f.

In practice the requirement $\delta_X = 0$ may be very strong and the degree of necessary optimality of every solution $X \in \Phi$ may be very small or even equal to 0. Suppose that a decision maker knows his/her preferences about δ_X and expresses it by a *fuzzy goal* $\widetilde{G}$. The membership function of the fuzzy goal $\mu_{\widetilde{G}}$ is a nonincreasing mapping from $[0,\infty]$ into $[0,1]$ such that $\mu_{\widetilde{G}}(0) = 1$. The value of $\mu_{\widetilde{G}}(\delta_X)$ expresses the degree to which deviation δ_X satisfies the decision maker. We can now replace the strong requirement "X is optimal" ($\delta_X = 0$) with weaker "X is soft optimal" ($\delta_X \in \tilde{G}$). Notice that $\delta_X \in \tilde{G}$ is a fuzzy event and the necessity that it holds can be computed as follows [5, 6]:

$$\mathrm{N}(X \text{ is soft optimal}) = \inf_S \max\{1 - \pi(S), \mu_{\widetilde{G}}(\delta_X(S))\}. \tag{9}$$

One can check that $\mathrm{N}(X \text{ is soft optimal}) = \alpha$ means that for all scenarios S such that $\pi(S) > 1 - \alpha$ it holds $\mu_{\widetilde{G}}(\delta_X(S)) \geq \alpha$ or equivalently $\delta_X(S) \in \widetilde{G}^\alpha = [0, \mu^{-1}_{\widetilde{G}}(\alpha)]$, which represents the suboptimality of X. Function $\mu^{-1}_{\widetilde{G}} : [0,1] \to \mathbb{R} \cup \{+\infty\}$ is a pseudo-inverse of $\mu_{\widetilde{G}}$ that is $\mu^{-1}_{\widetilde{G}}(\alpha) = \sup\{v : \mu_{\widetilde{G}}(v) \geq \alpha\}$.

4.2 Computing the optimality degrees

Every fuzzy interval $\widetilde{U}$ can be decomposed into its λ-cuts, i.e. sets $\widetilde{U}^\lambda = \{u : \mu_{\widetilde{U}}(u) \geq \lambda\}$, $\lambda \in (0,1]$. We will assume that $\widetilde{U}^0$ is the smallest closed set containing the support of $\widetilde{U}$. It can be easily verified (see e.g. [12]) that if $\widetilde{U}$ is a fuzzy interval with a bounded support, then $\widetilde{U}^\lambda$ is a closed interval for every $\lambda \in [0,1]$. The membership function $\mu_{\widetilde{U}}$ can be retrieved from the family of λ-cuts in the following way:

$$\mu_{\widetilde{U}}(u) = \sup\{\lambda \in [0,1] : u \in \widetilde{U}^\lambda\}, \tag{10}$$

ISBN: 978-989-95079-6-8

and $\mu_{\widetilde{U}}(u) = 0$ if $v \notin \widetilde{U}^0$.

Let us denote by $\mathcal{BP}^\lambda$, $\lambda \in [0,1]$, the interval-valued problem $\mathcal{BP}$ with element weights $\widetilde{W}_e^\lambda = [\underline{w}_e^\lambda, \overline{w}_e^\lambda]$, $e \in E$. Note that the scenario set in $\mathcal{BP}^\lambda$ is composed of all scenarios S such that $\pi(S) \geq \lambda$. Now $\widetilde{\Delta}_X^\lambda = [\underline{\delta}_X^\lambda, \overline{\delta}_X^\lambda]$ is the interval of possible values of the deviation of solution X in problem $\mathcal{BP}^\lambda$. It contains all values of the deviation of X, whose possibility of occurrence is not less than λ. From (8) and (10), it follows easily that

$$\Pi(X \text{ is optimal}) = \sup\{\lambda \in [0,1] : \underline{\delta}_X^\lambda = 0\} \tag{11}$$

and $\Pi(X \text{ is optimal}) = 0$ if $\underline{\delta}_X^0 > 0$. A similar reasoning leads to the following equality:

$$\mathrm{N}(X \text{ is soft optimal}) = 1 - \inf\{\lambda : \overline{\delta}_X^\lambda \leq \mu_{\widetilde{G}}^{-1}(1-\lambda)\}. \tag{12}$$

Replacing expression $\mu_{\widetilde{G}}^{-1}(1-\lambda)$ with 0 in (12) we get a formula for computing the degree of necessary optimality of X. Exactly the same considerations apply to elements. It is enough to replace X with f in formulae (11)–(12).

Equations (11) and (12) form a theoretical basis for calculating the values of the optimality degrees. The function $\underline{\delta}_X^\lambda$ is nondecreasing, so in order to compute the degree of possible optimality of solution X we can apply a binary search technique on $\lambda \in [0,1]$. Condition $\underline{\delta}_X^\lambda = 0$ means that X is possibly optimal in $\mathcal{BP}^\lambda$ and it can be checked efficiently by using Corollary 1. Similarly, $\overline{\delta}_X^\lambda$ is nonincreasing and $\mu_{\widetilde{G}}^{-1}(1-\lambda)$ is nondecreasing function of λ. Hence the degree of necessary soft optimality (and necessary optimality) can also be computed by using a binary search. We obtain $\overline{\delta}_X$ using Corollary 2. The calculations can be done in $\mathcal{O}(I(|E|)\log \epsilon^{-1})$ time, where $\epsilon > 0$ is a given precision and $I(|E|)$ is time required to find the bound (the lower or the upper) of deviation interval $\widetilde{\Delta}_X^\lambda$ in the corresponding interval problem $\mathcal{BP}^\lambda$. Of course the same reasoning can be repeated for elements.

Fuzzy deviations $\widetilde{\Delta}_X$ and $\widetilde{\Delta}_f$ can also be determined via the use of λ-cuts. That is, we compute interval $\widetilde{\Delta}_X^\lambda = [\underline{\delta}_X^\lambda, \overline{\delta}_X^\lambda]$ (resp. $\widetilde{\Delta}_f^\lambda$) in the interval valued $\mathcal{BP}^\lambda$ for suitably chosen λ-cuts. Then the fuzzy quantity $\widetilde{\Delta}_X$ (resp. $\widetilde{\Delta}_f$) is reconstructed from its λ-cuts by using equality (10). This method gives an approximation of $\widetilde{\Delta}_X$ (resp. $\widetilde{\Delta}_f$). Its overall running time is $\mathcal{O}(rI(|E|))$ time, r is the number of chosen λ-cuts and $I(|E|)$ is time required to determine $\widetilde{\Delta}_X^\lambda$ (resp. $\widetilde{\Delta}_f^\lambda$) in the interval problem $\mathcal{BP}^\lambda$.

From the above it follows that the running time of the proposed methods heavily relies on the interval case, because they can be reduced to the optimality analysis in a sequence of the interval-valued problems $\mathcal{BP}^\lambda$. Thus the main difficulty lies in the interval case. Fortunately, the optimality analysis in the interval case can be efficiently done, see Corollaries 1,2 and Proposition 1 for a solution and Corollary 3 and Proposition 2 for an element. Unfortunately, we cannot give an efficient method for asserting necessary optimality and determining the upper bound on possible values of the deviation of an element in a general problem $\mathcal{BP}^\lambda$. However, we have proposed such method when problem $\mathcal{BP}^\lambda$ has a matroidal structure (see Section 3.1.1).

4.3 Choosing a robust solution

We now propose some concepts of choosing a robust solution in the fuzzy-valued problem $\mathcal{BP}$. An ideal choice is a solution with the highest degree of certainty that it is optimal under all possible scenarios, i.e. an optimal solution to the following problem:

$$\max_{X \in \Phi} \mathrm{N}(X \text{ is optimal}) = \max_{X \in \Phi} \mathrm{N}(\delta_X = 0). \tag{13}$$

A solution of (13) is called a *best necessarily optimal solution*. However, this concept has a drawback, since the criterion used in (13) is very strong. Namely, a solution X such that $\mathrm{N}(X \text{ is optimal}) > 0$ may not exist or even if it exists, its necessary optimality degree may be very small. To overcome this drawback, we can replace the degree of necessary optimality with the degree of soft necessary optimality, which leads to the following problem:

$$\max_{X \in \Phi} \mathrm{N}(X \text{ is soft optimal}). \tag{14}$$

A solution to (14) is called a *best necessarily soft optimal solution*. Let us recall that this solution concept was first applied to fuzzy linear programming in [5, 6]. We can see from (12) that problem (14) is equivalent to the following one:

$$\begin{array}{ll} \min & \lambda \\ s.t. & \overline{\delta}_X^\lambda \leq \mu_{\widetilde{G}}^{-1}(1-\lambda), \\ & \lambda \in [0,1], \\ & X \in \Phi. \end{array} \tag{15}$$

If problem (15) is infeasible then $\mathrm{N}(X \text{ is soft optimal}) = 0$ for all solutions $X \in \Phi$. If λ^* is the optimal objective value of (15) and X is a best necessarily soft optimal solution, then $\mathrm{N}(X \text{ is soft optimal}) = 1 - \lambda^*$. Since $\overline{\delta}_X^\lambda$ is nonincreasing and $\mu_{\widetilde{G}}^{-1}(1-\lambda)$ is nondecreasing function of λ, problem (15) can also be solved by the binary search technique on $\lambda \in [0,1]$. Note that $\overline{\delta}_X^\lambda$ is the maximal regret of X in $\mathcal{BP}^\lambda$ (see Section 3.2). Thus to find the optimal λ^*, we seek solution that minimizes $\overline{\delta}_X^\lambda$ for a fixed λ, i.e. an optimal minmax regret solution in $\mathcal{BP}^\lambda$ (see problem (5)). An optimal solution X^* to problem (15), determined by finding an optimal minmax regret solution at λ-cut, has a nice property. Namely, it is an optimal minmax regret solution in $\mathcal{BP}^{\lambda^*}$ and, by Proposition 6, it is also possibly optimal one in $\mathcal{BP}^{\lambda^*}$. Thus $\mathrm{N}(X^* \text{ is soft optimal}) \leq \Pi(X^* \text{ is optimal})$. Consequently,

$$\begin{array}{rcl} \mathrm{N}(X^* \text{ is optimal}) & \leq & \mathrm{N}(X^* \text{ is soft optimal}) \\ & \leq & \Pi(X^* \text{ is optimal}). \end{array}$$

From this, we conclude that the concept of a necessary soft optimality is a natural extension of the minmax regret approach to the fuzzy case. The running time of the method based on the binary search is $\mathcal{O}(I(|E|)\log \epsilon^{-1})$ time, where $\epsilon > 0$ is a given precision and $I(|E|)$ is time required for seeking an optimal minmax regret solution in $\mathcal{BP}^\lambda$. It is polynomial for the bottleneck path, the bottleneck assignment, the bottleneck spanning tree and the bottleneck matroid base problems.

ISBN: 978-989-95079-6-8

4.4 A parametric approach

We now present a parametric approach to finding a best necessary optimal solution. A similar method can be applied to compute fuzzy deviations $\widetilde{\Delta}_X$ and $\widetilde{\Delta}_f$. It is easy to check that the following parametric problem may be associated with problem (15) (see also problems (15) and (5))

$$\overline{\delta}^{\lambda} = \min_{X\in\Phi} \overline{\delta}^{\lambda}_X = \min_{X\in\Phi} \max_{e\in X}\{\hat{w}^{\lambda}_e\}, \quad \lambda \in [0,1], \tag{16}$$

where $\hat{w}^{\lambda}_e = \max\{0, \overline{w}_e - F^*(S^{+\lambda}_{\{e\}})\}$, $e \in E$, are parametric weights (functions of a parameter λ), $S^{+\lambda}_{\{e\}}$ is the scenario in which we fix the weight of element e to $\overline{w}^{\lambda}_e$ and the weights of elements $g \in E \setminus \{e\}$ to $\underline{w}^{\lambda}_g$. In order to solve (16), we need to compute parametric weights $\hat{w}^{\lambda}_e = \max\{0, \overline{w}_e - F^*(S^{+\lambda}_{\{e\}})\}$, $e \in E$. Determining these weights requires computing functions $F^*(S^{+\lambda}_{\{e\}})$ for each $e \in E$. This can be done by applying known parametric techniques. Observe that $F^*(S^{+\lambda}_{\{e\}})$ is a function of parameter $\lambda \in [0,1]$. We wish to compute sequences $0 = \lambda_0 < \lambda_1 < ... < \lambda_k = 1$ and $X_0, \ldots, X_{k-1}$ such that X_i is an optimal solution for $\lambda \in [\lambda_i, \lambda_{i+1}]$, $i = 0, \ldots, k-1$. Having these sequences it is easy to describe function $F^*(S^{+\lambda}_{\{e\}})$ and, in consequence, $\hat{w}^{\lambda}_e$ for $\lambda \in [0,1]$. It turns out that if elements weights are linear functions of λ for each $e \in E$, then for some particular bottleneck problems their parametric counterparts can be efficiently solved (see e.g. [14]). Now, we are ready to solve (16) with parametric weights $\hat{w}^{\lambda}_e$. Again, we compute sequences $0 = \lambda_0 < \lambda_1 < ... < \lambda_k = 1$ and optimal solutions (optimal minmax regret solutions) $X_0, \ldots, X_{k-1}$ and the upper bounds for their deviations $\overline{\delta}^{\lambda}_{X_i}$, $\lambda \in [\lambda_i, \lambda_{i+1}]$, $i = 0, \ldots, k-1$. Values $\overline{\delta}^{\lambda}_{X_i}$, $\lambda \in [\lambda_i, \lambda_{i+1}]$, $i = 0, \ldots, k-1$, provide an analytical description of function $\overline{\delta}^{\lambda}$ (deviations of optimal minmax regret solutions) for $\lambda \in [0,1]$. To find a best necessary optimal solution, we need solve the following problem

$$\lambda^* = \arg \min_{\lambda\in[0,1]} \{\overline{\delta}^{\lambda}, \mu^{-1}_{\widetilde{G}}(1-\lambda)\},$$

which is equivalent to finding an intersection of $\overline{\delta}^{\lambda}$ and $\mu^{-1}_{\widetilde{G}}(1-\lambda)$. An optimal minmax regret solution that corresponds to the optimal value λ^* is a best necessary optimal solution.

5 Conclusions

In this paper, we have studied a general bottleneck combinatorial optimization problem with uncertain element weights modeled by fuzzy intervals, whose membership functions are regarded as possibility distributions for the values of the unknown weights. We have described, in this setting, the notions of possible and necessary optimality of a solution and an element and the necessary soft optimality of a solution. These notions are natural generalizations of the ones introduced in the interval-valued case. In order to choose a robust solution, we compute a best necessary soft optimal solution. This concept of choosing a solution is also a generalization, to the fuzzy case, of the known from literature minmax regret criterion [9]. Thus, we have shown in the paper that there exists a link between interval and possibilistic uncertainty. Hence, we have discussed first the interval-valued case and then we have extended the notions and the methods introduced for the interval-valued problem to the fuzzy-valued one. Indeed, the optimality evaluation and choosing a robust solution in the fuzzy problem boil down to solving a number of interval problems $\mathcal{BP}^{\lambda}$. Both problems can be solved in polynomial time if the corresponding interval counterparts are polynomially solvable, that holds true for a wide class of classical bottleneck combinatorial problems.

Abstract— *Web Usage Mining is the process of applying data mining techniques to the discovery of usage patterns from data extracted from Web Log files. It mines the secondary data (web logs) derived from the users' interaction with the web pages during certain period of Web sessions. Web usage mining consists of three phases, namely preprocessing, pattern discovery, and pattern analysis. In this paper, web logs of our university web server logs (http://www.um.ac.ir/) are pre-processed. Then, ant-based clustering is applied to pre-processed logs to extract frequent patterns for pattern discovery and then it is displayed in an interpretable format. Result of this paper would be useful for our university web site owner.*

Keywords— web usage mining, ant-based clustering, frequent pattern extraction, web mining.

1 Introduction

Web usage information mining could help to engage new customers, maintain current customers, track customers who are leaving web site, and so on [1]. Usage information can be extracted to increase web server efficiency by pre-fetching and caching strategies [2].Based on several researches done in the area of web mining, we can broadly classify it into three domains: web content mining, web structure mining, and web usage mining.

Web content mining is the process of extracting knowledge from web documents such as text and multimedia. Knowledge extraction from the structure of web and hyperlink references is called web structure mining. Web usage mining is the process of knowledge exploitation from the secondary data [3]. By secondary data, we mean browser logs, user profiles, web server access logs, registration data, user sessions or transactions, cookies, user queries, mouse clicks and any other data that is the result of interaction with the Web.

In the following section we give an overview over the related work. Section 3 explains the problem and ant-based clustering in more detail. Section 4 goes into detail how we implement the proposed method i.e. the experimental procedure of the proposed method and results are shown. We concluded our work in Section 5.

2 Related Work

There are several methods for pattern extraction from the secondary data (web logs) such as Masseglia et al. [2] [7], Spiliopoulou et al. [8], Bonchi et al. [9], Hay et al. [10], Zhu et al. [11], Nakagawa and Mobasher [12]. In [2], Masseglia et al. invented a new method named PSP (Prefix-tree for Sequential Patterns) that follows the basic principles of GSP (Generalized Sequential Patterns algorithm) in [13]. The tree structure in PSP is similar to the *prefix-tree* used in [14]. At the *k*th step, the tree has a depth of *k*. Each branch from the root to a leaf stands for a candidate sequence.

In [8], Spiliopoulou et al. proposed the WUM (Web utilization miner) tool that determines patterns which are noticeable from the statistical view. So, it emphasizes the frequency (minimum support) of the patterns.

Hay et al. in [10] applied the notion of time embedded in the navigations to cluster user sessions. They used an alignment algorithm to compute the distance between sessions.

Zhu et al. in [11] considered navigating between web sites as a Markov chain and mainly discussed about Markov model problems.

In [12], Nakagawa and Mobasher show that depending on whether the propositions are based on frequent itemsets or frequent sequences, the features of the site have an impact on the quality of the refinement shown to users.

In this paper, we propose a new method for extracting patterns from web logs based on ant clustering algorithm. We apply ant-based clustering for pattern discovery, other similar methods applied ant colony clustering to segregate visitors [15]. Some methods applied Markov models for modeling user web navigation behavior. But the proposed method has the similarity and speed of ant-based clustering algorithm rather than other clustering algorithms.

3 Problem description

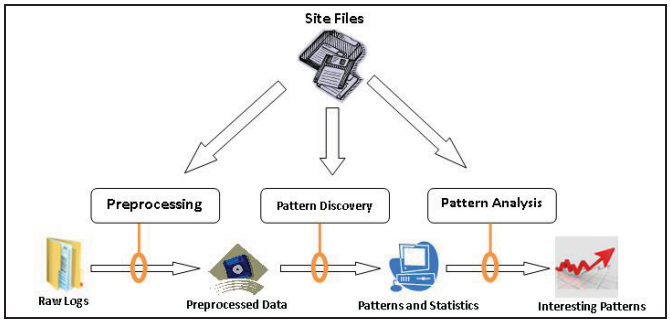

Figure 1: Usage Mining Process.

As shown in Figure 1 from [6], there are three main tasks for performing Web Usage Mining: Pre-processing, Pattern

ISBN: 978-989-95079-6-8

Discovery and Pattern Analysis. This section presents an overview of the tasks for each step.

At least two log file formats exists: Common Log File format (CLF) and Extended Log File format ([16] for more details). Our university log file consists of these fields: Date, Time, client IP address, Method, URI stem, Protocol status, Bytes sent, Protocol version, Host, User Agent and Referrer.

3.1 Pre-processing

As said in [6], pre-processing *"consists of converting the usage, content, and structure information contained in the various available data sources into the data abstractions necessary for pattern discovery"*.

This step can break into at least four substeps: Data Cleaning, User Identification, Session Identification and Formatting.

Unneeded data will be deleted from raw data in web log files in the data cleaning step. When a user requests a page, the request is added to the Log File; but if this page contains images, javascripts, flash animations, video, etc., they are added to the Log file as well. Most of the time, these are not needed for pattern discovery and should be omitted from log files.

There are some methods for User Identification, the second phase: detecting cookies, Identd, through IP address and user name. W3C [17] define cookies as *"data sent by the server to the client, data locally stored in cookies and is sent to the server with each request"*. [18] and [19] use cookies to identify users. But they have two main problems: the users can lock the use of cookies, so server cannot store information locally in the user machine; other problem is the user can delete the cookies.

Identd can be used for user identification. It is a protocol defined in RFC 1413 [20]. It allows us to identify connected users with the unique TCP connection. The problem with Identd is that users should configure with this protocol.

Another way for user detection is through user names added in the log file in field authuser. But this field can be empty (default value dash(-)) according to server/user command.

At last we can identify users through their IP address registered in each record in log file. We used this method although it has several problems: different users can be registered with same IP address; same user can be registered with different IP addresses. But with the help of session identification we can identify a user with IP address and be sure of solving the first problem. The second problem is not important because in this paper, a specific user is not wanted. We want to recognize general user's pattern.

For Session Identification in third phase, first we should define session timeout. Different timeouts considered are between 25-30 minutes .The thirty minute timeout is based on the results of [21]. We assume 30 minutes session timeout for the experimental procedure.

And in the last phase of pre-processing step, we should display pre-processed data in a suitable format, for the second step, pattern discovery.

3.2 Pattern Discovery

As stated in [6], pattern discovery *"draws upon methods and algorithms developed from several fields such as statistics, data mining, machine learning and pattern recognition"*. Several methods and techniques have already been developed for this step as summarized below:

- *Statistical Analysis* such as frequency analysis, mean, median, etc.
- *Clustering* of users help to discover groups of users with similar navigation patterns (provide personalized Web content).
- *Classification* is the technique to map a data item into one of several predefined classes.
- *Association Rules* discover correlations among pages accessed together by a client.
- *Sequential Patterns* extract frequently occurring inter-session patterns such that the presence of a set of items s followed by another item in time order.
- *Dependency Modeling* determines if there are any significant dependencies among the variables in the Web.

We choose clustering to discover users' navigational patterns. Our clustering method is based on Ant-based Clustering algorithm explained in Section 3.4.

3.3 Pattern Analysis

Pattern Analysis is the final stage of WUM (Web Usage Mining), which involves the validation and interpretation of the mined pattern.

- *Validation*: to eliminate the irrelevant rules or patterns and to extract the interesting rules or patterns from the output of the pattern discovery process.
- *Interpretation*: the output of mining algorithms is mainly in mathematic form and not suitable for direct human interpretations.

3.4 Ant-based Clustering

Deneubourg et al. in [22] proposed ant-based clustering and sorting. In the case of ant-based clustering and sorting, two related types of natural ant behaviors are modeled. When clustering, ants gather items to form heaps. And when sorting, ants discriminate between different kinds of items and spatially arrange them according to their properties [23].

Lumer and Faieta in [24] proposed ant-based data clustering algorithm (shown in Figure 2), which resembles the ant behavior described in [22].

As shown in Figure 2, the agents (ants) and data are randomly initialized on a toroidal grid. By moving agents, data is sorted according to its neighbors.

The picking and dropping probabilities, given a grid position and a particular data item *i*, are computed using the density functions:

$$p_{pick}(i) = \left(\frac{k^{+}}{k^{+} + f(i)}\right)^{2} \quad (1)$$

$$p_{drop}(i) = \begin{cases} 2f(i) & if\ f(i) < k^{-} \\ 1 & otherwise, \end{cases} \quad (2)$$

ISBN: 978-989-95079-6-8

where $k+$ and $k-$ are constants, and $f(i)$ is a neighborhood function:

$$f(i) = \max(0, \frac{1}{\sigma^2} \sum_{j \in L} (1 - \frac{d(i,j)}{\alpha})) \quad (3)$$

where, $d(i, j) \in [0, 1]$ is a measure of the dissimilarity between data points i and j , $\alpha \in [0, 1]$ is a data-dependent scaling parameter, and σ^2 is the size of the local neighborhood L.

Handl & Meyer in [25] proposed an extension of this algorithm where the parameter α is adaptively updated during the execution of the algorithm.

We applied Handl & Meyer's Ant-based clustering algorithm for detecting user's patterns.

4 Experimental Procedure and Results

4.1 Experimental Procedure

We used our university (http://www.um.ac.ir/) web server logs of two weeks for the experimental procedure.

For the first step, i.e. pre-processing, we wrote a c++ program compiled using gcc without any optimization flags. As mentioned in section 3.1, this step contains four phases. First, we omit unneeded records from log file. The log file consists of image files (gif, jpg, bmp, jpeg …) and other unneeded resources like javascripts and errors. For user identification, we use IP address and session timeout of 30 minutes. So, a user with an IP address has 30 minutes to navigate in the web site. After a user's navigational sequence is extracted, it is displayed in a suitable format for the second step, Pattern Discovery. We then classify the URLs of the web site into 28 groups and assign a number to each group, as shown in Table 1. Then, each user's requested URL is substituted with its corresponding number. The output of this step is a file that consists of records, each record representing a navigational sequence of users in numbers.

For the second step, Patten Discovery, we used Ant-based Clustering algorithm based on [25]. Julia Handl's written source code is used in Java and changes are made according to our application. Each user's navigational sequence is defined as an array with 28 elements. The element i is 1 if the related user had seen one of the pages in group i; otherwise it is 0.

Dissimilarity of two sequences $s1$ at point i and $s2$ at point j in the grid is computed through the following equation:

$$d(i,j) = \frac{\sqrt{\sum_{k=1}^{28} (s1_k - s2_k)^2}}{28} \quad (4)$$

$d(i,j)$ becomes 1 when two sequences do not have any similar elements, and becomes 0 when they are exactly the same.

Table 1: Classification of URLs.

The output of this program is a grid that contains numbers: >-1 and =-1 indicates if there is/is not a data item, respectively. So, clusters should be extracted according to these numbers and size of the local neighborhood, σ^2. Figure 3 shows the positions of the data points in different phases of running this algorithm. Figure 3.a shows the distribution of data points at the first step of program execution. As the execution continues, Figures 3.b, 3.c and 3.d shows the results after 200, 400 and 600 iterations, respectively. Clusters are created through moving of the ants.

We examined several numbers of ants for the clustering step. The experiments shows that the smaller the number of ants, the slower will be the rate of convergence, but also better results in clustering the data items. On the other hand, the larger the number of ants, the faster will be the speed of convergence, but also weaker results in clustering. So, empirically, we choose number of ants to be %20 of the number of data items.

At last for the third step, Pattern Analysis, the results are shown in an interpretable way. The output of the second step

ISBN: 978-989-95079-6-8

is the clusters of users' navigational sequence. Each cluster may include lots of members, so we should represent a cluster with one pattern and display it in a suitable format for users.

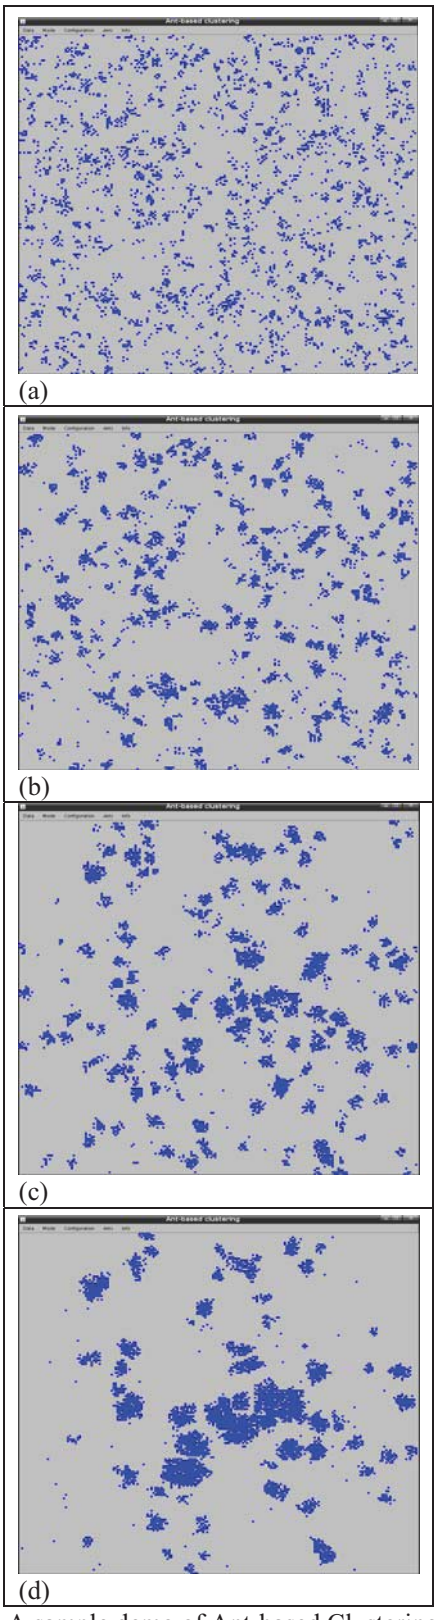

Figure 3: A sample demo of Ant-based Clustering of users' sequences.

The clustering algorithm results in clusters of similar sequences, which is a key element for sequence alignment. The alignment of sequences leads to a weighted sequence (as defined in [26]), represented as follows: $SA = \{I1 : n1, I2 : n2, \ldots, Ir, nr\} : m$. In this representation, m stands for the total number of sequences involved in the alignment. Ip ($1 \leq p \leq r$) is an itemset represented as ($xi1 : mi1 , \ldots xit : mit$), where mit is the number of sequences containing the item xi at the npth position in the aligned sequences. Finally, np is the number of occurrences of itemset Ip in the alignment. Figure 4 shows an example of the alignment process. The approximate sequential pattern can be obtained by specifying k: the number of occurrences of an item in order for it to be displayed. For instance, with the sequence $SA14$ from Figure 4 and $k = 3$, the filtered aligned sequence will be: {2, 4, 8}

To show the results, the aligned patterns that consist of numbers is re-substituted by the groups in Table 1.

S1={	2	4	5	8}

Figure 4: Alignment processing example.

4.2 Results

The above mentioned procedure is applied to our university (http://www.um.ac.ir/) web server logs. All the experiments were performed on an Intel Core 2 Duo 2.5GHz PC running Linux (Mint).

The log files are collected in two different weeks in 2008: first week of June and the middle week of August each have 300 MB. Two different weeks are selected and the result of applying the proposed method on each week is compared. Applying ant-based clustering on each week, on average, took 300 seconds for 800 iterations. Average hourly web traffic for each group in these two weeks can be seen in Figures 5 and 6, respectively. The extracted behaviors from these two weeks are listed in Table 2 and Table 3, respectively. As shown in Table 2 and Table 3, behaviors of users in these two weeks were similar in most of the cases. One should notice that these results show just most frequent patterns of users' navigational behaviors, not all of the users' behaviors. Patterns of single navigations are not listed above, i.e. patterns that contain only one navigation.

Comparing Table 2 and Table 3 with Figure 5 and Figure 6, one could understand that pattern <Web site content → News > is the most popular one. <Professor → Homepages> is frequent, too. On the other hand, groups that do not exist in the patterns, like FAQ and Societies, have the least access in hours of a day, too.

Comparing our method to other methods, it has some advantages:

- It is simple. One only needs to define a suitable dissimilarity function for the clustering step and do

ISBN: 978-989-95079-6-8

not need to involve in complex mathematical relations.

- It does not depend on pattern length. Other similar methods are limited in terms of the length of the extracted patterns. The proposed method is able to extract patterns of any length.

Different patterns can be extracted depending on the occurrence of that page group in a cluster. So, even page groups that are less accessed can be extracted.

These kinds of results are useful for web site owners. They can put their advertisements in these sequences, because these are the most frequent ones. They are useful for page pre-fetching, too.

5 Conclusions

In this paper, we have proposed a new method to extract navigational patterns from web logs. Ant-based clustering has been used for this purpose. It needs a neighborhood function to be defined for. After the clustering is completed, alignment processing has been applied to the extracted sequences in each cluster and extract the representative for each cluster.

We apply the following procedure on our university web server logs for two different weeks (http://www.um.ac.ir/) and the results are satisfactory and true according to the hourly web traffic. These kinds of results are suitable for web site owners, for example, to put their advertisements there or to even change the structure of the web site according to users' navigational behavior.

Multiplicative and implicative importance weighted averaging aggregation operators with accurate andness direction

Henrik Legind Larsen

Department of Electronic Systems
Aalborg University, Denmark
Email: legind@aaue.dk

Abstract— *Importance weighted averaging aggregation operators play a key role in utilizations of electronic data and information resources for retrieving, fusing, and extracting information and knowledge, as needed for decision making. Two central issues in the choice of such operators are the kind of importance weighting and the andness (or conjunction degree) of the operator. We present and discuss two main kinds of importance weighting, namely multiplicative and implicative, each yielding a particular kind of operator for a particular kind of aggregation problems. Importance weighting generalizations of each kind are proposed for each of two classes of averaging operators, namely the Power Means and the Ordered Weighted Averaging operators, each in a De Morgan dual form for increased efficacy. For each class is proposed a function for a rather accurate direct control of the andness. Operators of the same kind appear to behave rather similarly at the same andness, independent of the class of averaging operators generalized.*

Keywords— Aggregation operators, averaging operators, andness, orness, importance weighting, implicative importance.

1 Introduction

With the increasing amount of electronically accessible data in databases, document bases, and data streams, and the need of efficient utilization of such data, aggregation operators have attained new interest. This is due to the central role of such operators in the key reasoning tasks, such as information fusion and pattern recognition, applied in utilizations of many kinds, *e.g.*, information retrieval, information extraction, object recognition, and knowledge discovery. Of particular interest are the aggregations operators between AND (conjunction) and OR (disjunction), *i.e.*, the averaging operators, or generalized conjunction/disjunction functions (GCD) [1], especially the importance weighted generalizations of such operators.

An importance weighted averaging aggregation operator aggregates a number of arguments, each qualified by an importance weight, into a single score. We distinguish between two kinds of importance weighting, namely multiplicative and implicative. Each kind provides an importance weighting generalization of the unweighted averaging operator, in the sense that the latter is retained by the case where all arguments have the same importance weight. We propose such generalizations of two classes of averaging operators, namely the Power Means (PM) and the Ordered Weighted Averaging (OWA) operators [2], each in a De Morgan dual form for increased efficacy, and each with an accurate direct control of the andness, *i.e.*, the degree the operator aggregates like an AND rather than an OR. The generalizations of the PM include the AIWA operators [3].

A few words on the notation applied in the following. $\bigodot_i a_i$, where $\bigodot$ is an operator, is an abbreviation for $\bigodot_{i=1}^{n}(a_i)$; a bold letter like $\mathbf{x}$ denotes the vector $(x_1, \ldots, x_n)$; $\overline{x}$ denotes the standard negation $\overline{x} = 1 - x$; $\overline{\mathbf{x}}$ denotes $(\overline{x_1}, \ldots, \overline{x_n})$. Some specific letters are used all over with the same meaning: I denotes the real unit interval $[0, 1]$; n is the dimension, *i.e.*, number of arguments aggregated by the averaging operator considered; ρ denotes the targeted andness of an averaging operator; $\mathbf{a}$ denotes a vector of arguments $(a_1, \ldots, a_n) \in I^n$; $\mathbf{v}$ denotes an importance weighting vector $(v_1, \ldots, v_n) \in I^n$ that is max-normalized, *i.e.*, $\max_i v_i = 1$; $\mathbf{w}$ denotes an importance weighting vector $(w_1, \ldots, w_n) \in I^n$ that is sum-normalized, *i.e.*, $\sum_i w_i = 1$; $h : I^n \times I^n \to I : (\mathbf{v}, \mathbf{a}) \mapsto h(\mathbf{v}, \mathbf{a})$ is an importance weighted averaging operator, such that v_i is the importance of a_i; for a particular operator h, its name acronym and parameters are attached on the form $h^{\text{acronym}}_{\text{parameters}}$.

Section 2 introduces some basic concepts applied in the following. Sections 3 and 4 introduce, for each class of averaging operators, the PM based and the OWA based, the basis of the class, its multiplicative and implicative importance weighting generalizations, and a function for accurate direct control of the andness of its operators. Sections 5 and 6 discuss, for each kind of importance weighting, the multiplicative and the implicative, the kind of applications they apply to and some key issues of relevance for their application. Section 7 compares and discusses the effect of the two kinds of importance weighting on the common problem of ordering a set of options by their score. Section 8 concludes.

2 Basic concepts

2.1 The andness of an averaging operator

The andness may be viewed as the degree of universal quantification over the arguments, with AND (andness $= 1$) representing *all* and OR (andness $= 0$) representing *at least one*. In this view, the andness is the degree to which all arguments, rather than at least one argument, must support the result of the aggregation. In importance weighted averaging operators, each argument is considered to the degree it is important. The dual interpretation applies to the orness, defined by: orness $= 1 -$ andness.

Since, AND and OR are evaluated by the operators min and max, respectively, the andness of an averaging operator h may be defined as distance between h and the max, relative to the distance between the min and the max, with operators h, max, and min evaluated as the mean of these operators over the ar-

ISBN: 978-989-95079-6-8

gument space, as proposed by Dujmović [4]:

$$\text{andness}(h) = \frac{E(\max_i(\mathbf{x})) - E(h(\mathbf{x}))}{E(\max_i(\mathbf{x})) - E(\min_i(\mathbf{x}))} \qquad (1)$$

where $E(f(\mathbf{x}))$ is the mean of $f(\mathbf{x})$ over the argument space I^n, as defined by $E(f(\mathbf{x})) = \int_{I^n} f(\mathbf{x})d\mathbf{x}$. The terms *andness* and *orness* were coined by Yager for a measure of the OWA operators [2] that is fully consistent with the measure defined by (1).

The andness is, by OWA operators, obtained by positional weights (OWA weights), such that the OWA aggregate is the sum of the products of the i'th OWA weight and the i'th largest argument, whereas it by PM operators is obtained by a power function, yielding emphasis on the smaller or larger valued arguments to the degree the PM represents, respectively, AND and OR (see, *e.g.*, [1]).

2.2 The two kinds of importance weighting

A well-known example of an importance weighted averaging operator is the Weighted Arithmetic Mean (WAM) defined by $h^{\text{WAM}}(\mathbf{v}, \mathbf{a}) = \sum_i (w_i, a_i)$ where, for all i, $w_i = \frac{v_i}{\sum_i v_i}$, for which $\text{andness}(h^{\text{WAM}}) = \text{orness}(h^{\text{WAM}}) = \frac{1}{2}$. The unweighted case, as obtained by $v_i = 1$ for all i, is the Arithmetic Mean (AM): $h^{\text{WAM}}((1, 1, \ldots, 1), \mathbf{a}) = \frac{1}{n}\sum_i a_i = h^{\text{AM}}(\mathbf{a})$. The WAM appears to be the only importance weighted averaging operator that represents both kinds of importance weighting, namely the multiplicative and the implicative. For other degrees and andness than $\frac{1}{2}$, the two kinds of importance weighting provide, as we shall see, different behaviors that apply to different kinds of aggregation problems.

While Multiplicative importance Weighted Averaging (for short, MWA) operators are weighted means, Implicative importance Weighted Averaging (for short, IWA) operators are logic operators for pattern matching inference. In general, the andness of an IWA operator "penalizes" (decreases) the score (the aggregate) to the degree that there are criteria that are important, but not satisfied, while the orness "rewards" (increases) the score to the degree that there are criteria that are important and satisfied.

By the importance weighting, the arguments are, essentially, transformed by the importance weights in a way giving the desired effect, depending on the kind of importance weighting and the andness, in the aggregation. In principle, an argument a with the importance weight w is, by the two kinds of weighting, transformed as follows: by MWA, to the product wa, and by IWA at andness ρ to $\rho(w \Rightarrow a) + \overline{\rho}(\overline{w} \Rightarrow \overline{a})$ where $\Rightarrow$ is a fuzzy implication operator. It is the multiplication in the MWA case and the implication in the IWA case that give name to the two kinds of importance weighting.

As the fuzzy implication $\Rightarrow$ for IWA operators, we choose the Reichenbach implication, $\Rightarrow_{\text{R}}$, as defined by $(v \Rightarrow_{\text{R}} a) = \overline{v\overline{a}} = 1 - v(1-a)$. The reasons for this choice are, first, that it allows us easily to obtain the WAM at $\rho = \frac{1}{2}$, and, second, that the choice of the fuzzy implication appears not to be critical for the behavior of such operators. The latter was tested empirically; the paper doesn't leave space for presenting details from the test.

A key difference between between MWA and IWA operators is that in MWA operators, as opposed to IWA operators, the effect of the importance weights decreases from full effect to no effect as the andness goes from $\frac{1}{2}$ to one of its extremes, 0 or 1. For an appropriate choice of the fuzzy implication operator, the IWA operators represent, like the MWA operators, the WAM at andness $\frac{1}{2}$. These behaviors of the two kind of importance weighted averaging operators are illustrated by Figure 1. We notice, as the figure indicates, that in cases where

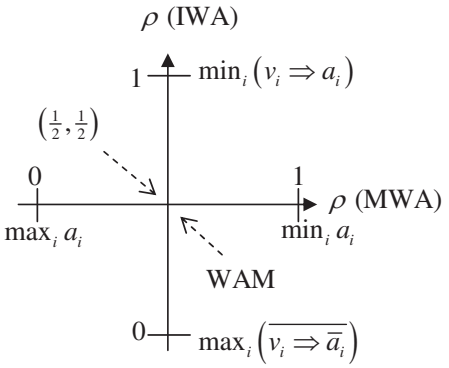

Figure 1: Illustration of MWA and IWA operators

we are completely uncertain about the proper kind of importance weighting and andness for an application, WAM may be a good choice as a starting point.

2.3 The two classes of operators generalized

In the following, we shall in particular consider importance weighted generalizations of two classes of operators, namely the Power Means (PM) and the Ordered Weighted Averaging (OWA) operators, each in a De Morgan dual form for increased efficacy. For each class, we propose two andness-directing functions, $\psi(\rho)$ and $\psi(\rho, n)$, each yielding a value ($\in [1, \infty[$) of the andness controlling parameter of the class. While $\psi(\rho)$ directly yields an andness of the operator that, in general, is somewhat close to the target ρ, $\psi(\rho, n)$ yields the target rather accurately, due to it also being dependent of n, as applied in the definition by (1).

For each class, we provide a common expression of the two kinds of importance weighting generalization, such that the choice of a kind is controlled by a parameter $\gamma \in \{0, 1\}$, yielding the multiplicative generalization by $\gamma = 0$ and the implicative generalization by $\gamma = 1$. The operators are in their common generalized form referred to as, respectively, Andness-directed importance Weighted averaging (AWA) operators and andness-directed importance Weighted OWA operators (W-OWA). Figure 2 gives an overview over the operator name acronyms applied.

Basis	*Without* importance weighting	*With* importance weighting		
		Common class	**M**ultipl. $\gamma = 0$ **MWA**	**I**mpl. $\gamma = 1$ **IWA**
Power Means	AA	AWA	A**M**WA	A**I**WA
OWA	OWA	W-OWA	**M**W-OWA	**I**W-OWA

Figure 2: Operator and operator class name acronyms applied

ISBN: 978-989-95079-6-8

3 AWA operators

3.1 Basis in the Power Means

The AWA (Andness-directed importance Weighted Averaging) operators are based on the Power Means (PM) that (in their unweighted form) are defined by $h^{\text{PM}}_\alpha(\mathbf{a}) = (\frac{1}{n}\sum_i a_i^\alpha)^{\frac{1}{\alpha}}$, $\alpha \in \mathbb{R}$. When α goes from $-\infty$ to $+\infty$, the andness of h^{PM}_α goes from 1 down to 0. It has an asymmetric behavior around andness $= \frac{1}{2}$, as obtained at $\alpha = 1$; in particular, it is "mandatory" for $\alpha \leq 0$, corresponding to andness $\tilde{>}\frac{2}{3}$, in the sense that $h^{\text{PM}}_\alpha(\mathbf{a}) = 0$, if $\min_i(a_i) = 0$, which normally is an undesired property. [1] However, by the De Morgan dual variant PM′, defined by (i) $h^{\text{PM}}_\alpha(\mathbf{a})$, $\alpha \geq 1$, for andness $\leq \frac{1}{2}$, and (ii) $1 - h^{\text{PM}}_\alpha(\overline{\mathbf{a}})$, $\alpha \geq 1$, for andness $\geq \frac{1}{2}$, we obtain a symmetric behavior around andness $= \frac{1}{2}$ and avoid the "mandatory" property. For both (i) and (ii), the arithmetic mean is obtained at $\alpha = 1$; when α goes to $+\infty$, the andness of $h^{\text{PM}'}_\alpha$ goes in case (i) to 0 and in case (ii) to 1.

The AWA operators comprise the multiplicative and implicative importance weighted generalizations of PM′, namely the AMWA (Andness-directed Multiplicative importance Weighted Averaging) operators and the AIWA (Andness-directed Implicative importance Weighted Averaging) operators. The AIWA operators were introduced in [3] where we analyzed their properties and showed that they implement implicative importance weighting by the Riechenbach implication. The AMWA operators is the multiplicative weighting variant of the AIWA operators.

3.2 Definition of AWA operators

The AWA operators are defined by the following semi-recursive expression, where the case of $\rho > \frac{1}{2}$ is defined by its duality to the case of $\rho \leq \frac{1}{2}$:

$$h^{\text{AWA}}_\rho(\mathbf{v},\mathbf{a}) = \begin{cases} \left(\sum_i (y_i a_i^\alpha)\right)^{\frac{1}{\alpha}} & \rho \leq \frac{1}{2} \\ 1 - h^{\text{AWA}}_{\overline{\rho}}(\mathbf{v},\overline{\mathbf{a}}) & \rho > \frac{1}{2} \end{cases} \tag{2}$$

where $\alpha = \psi^{\text{AA}}(\rho) = \overline{\rho}/\rho$, and for all i:

$$y_i = \frac{v_i^{\alpha^\gamma}}{\sum_i v_i^{\alpha^\gamma}} \tag{3}$$

with $\gamma \in \{0,1\}$, $\gamma = 0$ (by which $y_i = \frac{v_i}{\sum_i v_i} = w_i$) yielding the AMWA operators, and $\gamma = 1$ (by which $y_i = \frac{v_i^\alpha}{\sum_i v_i^\alpha}$) yielding the AIWA operators.

By $\mathbf{v} = (1,1,\ldots,1)$ we obtain the common unweighted case of AMWA and AIWA that we shall refer to as Andness-directed Averaging (AA) operators; thus, these operators are, in the case of $\rho \leq \frac{1}{2}$, defined by: $h^{\text{AA}}_\rho(\mathbf{a}) = h^{\text{AWA}}_\rho((1,1,\ldots,1),\mathbf{a}) = (\frac{1}{n}\sum_i a_i^\alpha)^{\frac{1}{\alpha}}$.

3.3 Accurate control of AWA andness

Above, the parameter α is, for a targeted andness ρ, defined by $\alpha = \psi^{\text{AA}}(\rho) = \overline{\rho}/\rho$ in the case $\rho \leq \frac{1}{2}$ (and, by duality, as implemented by the semi-recursive call, $\alpha = \psi^{\text{AA}}(\overline{\rho}) = \rho/\overline{\rho}$ in the case $\rho > \frac{1}{2}$). While by $\psi^{\text{AA}}(\rho)$, andness(h^{AWA}) is equal to ρ, if $\psi^{\text{AA}}(\rho) \in \{0, \frac{1}{2}, 1\}$ and, otherwise, somewhat close to ρ, a much more precise approximation can be obtained by also considering the dimension n, namely through replacing $\psi^{\text{AA}}(\rho)$ by $\psi^{\text{AA}}(\rho, n)$ as defined by:

$$\psi^{\text{AA}}(\rho,n) = (-\log_2 \rho)^{1+(\log_2 n)^{1/3}} \tag{4}$$

An empirical test of the error $\|\rho - \text{andness}(h^{\text{AWA}})\|$, showed that by $\psi^{\text{AA}}(\rho)$ the average error over $\rho \in I$ increases from about 0.03 to about 0.09 as n increases from 2 to 100, while it by $\psi^{\text{AA}}(\rho, n)$ remains around 0.005.

3.4 Decomposability of AWA operators

A property of particular interest for applications of AWA operators is their decomposability, allowing us to update the aggregate if the value of an argument has changed or a new argument has to be considered, without re-computing the whole aggregate. [3] Thus, considering the common case by AWA (2) for $\rho \leq \frac{1}{2}$, let $h^{\text{AWA}}_\rho(\mathbf{v},\mathbf{a}) = c$ to be updated with a new argument a_{n+1} with the importance weight v_{n+1}. Let $\cup$ denote the concatenation of vectors, such that $\mathbf{x} \cup (x_{n+1}) = (x_1,\ldots,x_n) \cup (x_{n+1}) = (x_1,\ldots,x_{n+1})$. Then, the updated aggregate is computed as the AWA aggregate of c and the new argument, as defined by: $h^{\text{AWA}}_\rho(\mathbf{v} \cup (v_{n+1}), (\mathbf{a} \cup (a_{n+1})) = h^{\text{AWA}}_\rho((s, v_{n+1}), (c, a_{n+1})) = \left(\frac{s^{\alpha^\gamma} c^\alpha + v_{n+1}^{\alpha^\gamma} a_{n+1}^\alpha}{s^{\alpha^\gamma} + v_{n+1}^{\alpha^\gamma}}\right)^{1/\alpha}$, with $s = \left(\sum_{i=1}^n v_i^{\alpha^\gamma}\right)^{1/\alpha^\gamma}$.

4 W-OWA operators

4.1 Basis in the OWA operators

The properties of OWA operators [2] are controlled by a vector of sum-normalized position weights $\mathbf{u}$ (called OWA weights) such that the OWA aggregate of an argument vector $\mathbf{a}$ is defined by $h^{\text{OWA}}(\mathbf{a}) = \sum_i (u_i, a_{(i)})$ where $(\cdot)$ is an index permutation such that $a_{(1)} \geq \cdots \geq a_{(n)}$. Two key properties of OWA operators are their andness, defined by andness$(\mathbf{u}) = \frac{1}{n-1}\sum_i ((i-1)u_i)$, and their normalized dispersion (or entropy), defined by $\text{ndisp}(\mathbf{u}) = -\frac{1}{\ln n}\sum_i (u_i \ln u_i)$. This andness measure is consistent with (1).

In [5, 6], Yager proposed an importance weighted generalization of quantifier guided OWA operators that essentially is a multiplicative importance weighting generalization, which we here shall refer to as MW-OWA operators. They are defined by $h^{\text{MW-OWA}}_f(\mathbf{v},\mathbf{a}) = \sum_i (u_i, a_{(i)})$, where $u_i = f(s_i) - f(s_{i-1})$, $i = 1,\ldots,n$, with $s_0 = 0$ and $s_i = \frac{\sum_{k=1}^i v_{(k)}}{\sum_{k=1}^n v_k}$ for $i > 0$, $f : I \to I$ is a regular increasing monotone quantifier (*i.e.*, $f(0) = 0$, $f(1) = 1$, and $f(x) \geq f(y)$ if $x > y$), such as $f(x) = x^\beta$, $\beta \geq 0$, and $(\cdot)$ as before is a permutation of the index such that $a_{(1)} \geq \cdots \geq a_{(n)}$. It is easily seen that when β goes from 0 to $+\infty$, andness$(h^{\text{MW-OWA}})$ goes from 0 to 1, with $h^{\text{MW-OWA}}_f$ representing the max (with andness $= 0$) at $\beta = 0$, the WAM (with andness $= \frac{1}{2}$) at $\beta = 1$, and the min (with andness $= 1$) at $\beta \to +\infty$.

In the case $v_i = 1$, $i = 1,\ldots,n$, we get $s_i = \frac{i}{n}$, and, hence, $\mathbf{u}$ representing the underlying OWA weights (for the OWA operator without importance weighting) that by $f(x) = x^\beta$ are somewhat close to the MEOWA weights [7, 8], *i.e.*, the unique OWA weighting vector with the maximum dispersion at the given andness and dimension n. However, the behavior is not symmetric around andness $= \frac{1}{2}$; in fact, while the dispersion

[1] The mandatory threshold of andness $\tilde{>}\frac{2}{3}$ enforced by the PM is, from a practical point of view, rather arbitrary.

ISBN: 978-989-95079-6-8

of the OWA weights for andness $> \frac{1}{2}$ (*i.e.*, $\beta > 1$) is rather close to the maximum, it is much less for andness $< \frac{1}{2}$ (*i.e.*, $\beta < 1$). For instance, for $n = 5$ the maximum normalized dispersion at andness $= 0.8$ and andness $= 0.2$ is 0.755 in both cases, while the OWA weights with $f(x) = x^\beta$ have the normalized dispersion 0.744 in the first case, but only 0.717 in the second case. Therefore, an improvement with a near optimal dispersion for all degrees of andness, is obtained by defining $h_f^{\text{MW-OWA}}$ as above for andness $\geq \frac{1}{2}$, and by its De Morgan duality for andness $< \frac{1}{2}$, namely (with a change of notation to express the andness ρ) $h_\rho^{\text{MW-OWA}}(\mathbf{v}, \mathbf{a}) = 1 - h_{\overline{\rho}}^{\text{MW-OWA}}(\mathbf{v}, \overline{\mathbf{a}})$. By this improvement, the normalized dispersion in the second case (andness $= 0.2$) above is increased to 0.744, as in the first case, *i.e.*, in both cases only 0.011 lower than the maximum.

4.2 Definition of the W-OWA operators

In the following, we present an extension of the duality based MW-OWA operators to a common class, W-OWA, comprising both the multiplicative importance weighting generalization, MW-OWA, and an implicative importance weighting generalization, IW-OWA, with parametric control of the kind of generalization. The W-OWA operators are defined by:

$$h_\rho^{\text{W-OWA}}(\mathbf{v}, \mathbf{a}) = \begin{cases} \left(\sum_i (u_i b_{(i)})\right) & \rho \geq \frac{1}{2} \\ 1 - h_{\overline{\rho}}^{\text{W-OWA}}(\mathbf{v}, \overline{\mathbf{a}}) & \rho < \frac{1}{2} \end{cases} \tag{5}$$

where, for all i, b_i is defined by:

$$b_i = (v_i^{\gamma(2\rho-1)} \Rightarrow_{\text{R}} a_i) = 1 - v_i^{\gamma(2\rho-1)}(1 - a_i) \tag{6}$$

with $\gamma \in \{0, 1\}$, $\gamma = 0$ (by which $b_i = a_i$) yielding the class of MW-OWA operators, and $\gamma = 1$ (by which $b_i = (v_i^{(2\rho-1)} \Rightarrow_{\text{R}} a_i)$) yielding the class of IW-OWA operators; $u_i = f(s_i) - f(s_{i-1}), i = 1, \ldots, n$, with $s_0 = 0$ and

$$s_i = \frac{\sum_{k=1}^{i} v_{(k)}}{\sum_{k=1}^{n} v_k} \tag{7}$$

for $i > 0$, and $f(x) = x^\beta$, with $\beta = \psi^{\text{W-OWA}}(\rho) = \rho/\overline{\rho}$; finally, $(\cdot)$ is an index permutation such that $b_{(1)} \geq \cdots \geq b_{(n)}$. We notice that the Reichenbach implication applied above may be replaced by any fuzzy implication.

By $\mathbf{v} = (1, 1, \ldots, 1)$ we obtain the common case of MW-OWA and IW-OWA, without importance weighting, namely the duality based, quantifier guided OWA operators that, in the case of $\rho \geq \frac{1}{2}$, are defined by: $h_\rho^{\text{OWA}}(\mathbf{a}) = h_\rho^{\text{W-OWA}}((1, 1, \ldots, 1), \mathbf{a}) = \sum_i (u_i a_{(i)})$ where $u_i = f(\frac{i}{n}) - f(\frac{i-1}{n})$, with $f(x) = x^\beta$.

4.3 Accurate control of W-OWA andness

Above, the parameter β is, for a targeted andness ρ, defined by $\beta = \psi^{\text{W-OWA}}(\rho) = \rho/\overline{\rho}$ in the case $\rho \geq \frac{1}{2}$ (and, by duality, as implemented by the semi-recursive call, $\beta = \psi^{\text{W-OWA}}(\overline{\rho}) = \overline{\rho}/\rho$ in the case $\rho < \frac{1}{2}$). While by $\psi^{\text{W-OWA}}(\rho)$, andness$(h^{\text{W-OWA}})$ is equal to ρ, if $\rho \in \{0, \frac{1}{2}, 1\}$ or $n \to +\infty$, and, otherwise, close to ρ, a more precise approximation can be obtained by also considering the dimension n, namely through replacing $\psi^{\text{W-OWA}}(\rho)$ by $\psi^{\text{W-OWA}}(\rho, n)$ as defined by:

$$\psi^{\text{W-OWA}}(\rho, n) = \frac{0.5 + n\rho}{0.5 + n\overline{\rho}} \tag{8}$$

For instance, by $\rho = 0.8$ (and, through the duality, by $\rho = 0.2$), we get $\beta = \psi^{\text{W-OWA}}(0.8) = \frac{0.8}{1-0.8} = 4$. For $n = 5$, this value of β gives an andness of about of about 0.86, i.e., 0.06 more than the targeted andness, while we by $\beta = \psi^{\text{W-OWA}}(0.8, 5) = \frac{0.5+5\cdot 0.8}{0.5+5(1-0.8)} = 3.0$ obtain the desired andness of 0.8. As n increases from 2 to 100, the average over $\rho \in I$ of the error $\|\rho - \text{andness}(h_\rho^{\text{W-OWA}})\|$ decreases from about 0.07 to about 0.002 by $\psi^{\text{W-OWA}}(\rho)$, and from about 0.0003 to about 0.00001 by $\psi^{\text{W-OWA}}(\rho, n)$.

5 On the multiplicative importance weighting

MWA operators are essentially weighted means that, qua means, are symmetric, monotonic increasing, continuous, and idempotent. They produce means in the interval $[\min_i a_i, \max_i a_i]$, and are monotonically increasing with the orness. If an MWA operator has the andness $= \frac{1}{2}$, it represents the WAM.

5.1 Applications of MWA operators

A common application is for *estimation of a utility variable*. In this case, each argument represents the estimation by an expert (or the measure by some source), while its importance weight represents the decision maker's confidence in the experts's ability to estimate the correct value. The andness and the orness represent decision maker's risk attitude, namely, the degree of, respectively, pessimism and optimism. The aggregate is in this case an estimate of the utility variable, considering the decision maker's risk attitude and, for each expert, the estimate by the expert and the decision masker's confidence in the expert.

Another application is for *selection between (alternative) options*, where the option with the highest score (weighted mean) is winning. In this case, each argument represents the degree to which the option considered has a particular property of interest, while its importance weight represents the importance of having the property to a high degree. The andness represents the degree to which all properties of interest must be present to a high degree. The outcome of the averaging is a ranking of options, possible with a threshold distinguishing acceptable options from unacceptable options.

5.2 Discontinuity property of MWA operators

While MWA and IWA operators both represent the WAM at andness $= \frac{1}{2}$, a key difference is that for MWA, as opposed to IWA, the effect of the importance weights decreases as the andness converges to one of its extremes, 1 or 0. In these cases, MWA evaluates to the smallest argument with a positive weight, yielding a discontinuity, since a small change in an importance weight, from, say, 0.01 to 0, may give a drastic change in the aggregate.

For instance, let h_ρ^{MWA} be an MWA operator (like AMWA or MW-OWA) at andness ρ, and assume $\mathbf{a} = (0.9, 0.1)$. Then $h_1^{\text{MWA}}((1, 0.01), \mathbf{a}) = 0.1$, while $h_1^{\text{MWA}}((1, 0), \mathbf{a}) = 0.9$. Similarly, $h_0^{\text{MWA}}((0.01, 1), \mathbf{a}) = 0.9$, while $h_0^{\text{MWA}}((0, 1), \mathbf{a}) = 0.1$. In both cases, the small decrease from 0.01 to 0 of an importance weight, caused a drastic change (of size 0.8) in the aggregate.

This behavior is an effect of MWA operators as weighted means. It models the attitude of the decision maker, in the cases of extreme pessimism and extreme optimism, to select

ISBN: 978-989-95079-6-8

the most pessimistic, respectively, most optimistic, estimate (argument) by any source with a positive confidence (importance weight). Such behavior is not acceptable in multicriteria aggregation for object recognition; for instance, it is not acceptable that the unimportant second criterion determines the overall satisfaction as by aggregate $h_1^{\text{MWA}}((1, 0.01), \mathbf{a}) = 0.1$. IWA operators avoid this by only considering criteria to the degree they are important; thus $h_1^{\text{IWA}}((1, 0.01), \mathbf{a}) = h_1^{\text{IWA}}((1, 0), \mathbf{a}) = 0.9$.

5.3 Other MWA operators

The PM, on which the AMWA and AIWA operators are based, are in the family of the quasi-arithmetic means (QM) [9, 10]. The weighted QM (WQM) forms the family of MWA operators defined by $h^{\text{WQM}}(\mathbf{v}, \mathbf{a}) = \phi^{-1}(\sum_i (w_i \phi(a_i)))$ where ϕ is a continuous strictly monotonic function, and ϕ^{-1} is the inverse of ϕ. The Weighted PM (WPM), $h^{\text{WPM}}(\mathbf{v}, \mathbf{a}) = (\sum_i (w_i a_i^\alpha))^{1/\alpha}$, $\alpha \in \mathbb{R}$, belong to this family from which they are derived by $\phi_\alpha(x) = x^\alpha$ (with $\phi_\alpha^{-1}(x) = x^{1/\alpha}$).

By $\phi_\alpha(x) = e^{\alpha x}$ (with $\phi_\alpha^{-1}(x) = \frac{\ln x}{\alpha}$), we obtain the Weighted Exponential Means (WEM), $h_\alpha^{\text{WEM}}(\mathbf{v}, \mathbf{a}) = \frac{1}{\alpha} \ln(\sum_i (w_i e^{\alpha a_i}))$, that converges to the WAM for $\alpha \to 0$, and to $\min_i a_i$ and $\max_i a_i$ for α going to, respectively, $-\infty$ and $+\infty$. A nice property of the WEM is its symmetric behavior around andness $= \frac{1}{2}$ as obtained for $\alpha \to 0$. Unlike the WPM, the WEM do not impose the mandatory property.

6 On the implicative importance weighting

6.1 Applications of IWA operators

Implicative importance weighting is applied by IWA operators for pattern matching inference in multicriteria recognition or classification problems, where an observed object (*e.g.*a document or some physical object) is compared to a goal concept (e.g., a query or a class). The goal concept is intensionally characterized by a set of criteria that, in general, are importance weighted. Each criterion expresses a constraint on the values of an object attribute and may, in general, be represented by a fuzzy subset. The importance weight of a criterion expresses the importance of satisfying the criterion in recognizing or classifying an object as an instance of the goal concept.

This scheme applies for querying of the two main kinds, namely object querying and concept querying. [11, 12] In *object querying*, *e.g.*, document retrieval and database querying, the goal concept forms a query. When posed to an object base, the query determines a fuzzy subset of the set of objects, representing the query's fuzzy extension in that set. An object's degree of membership in the extension can be seen as the degree to which the object is an instance of the goal concept and is also referred to as the object's *score* in the goal concept. In *concept querying*, *e.g.*, object recognition and classification, the characterization of the observed object forms a query. When posed to a concept base, *i.e.*, a base of possible goal concepts or classes, the query determines in this case a fuzzy subset of the set of concepts. The answer may in both cases be presented by a ranked list of the objects or concepts (depending on the query type) for which the score is above a given threshold.

6.2 IWA weighting and reasoning scheme

Let C be a goal concept, characterized by the criteria $C_1, \ldots, C_n$ with the importance weights $v_1, \ldots, v_n$, with v_i being the importance of satisfying C_i, and let $a_i = C_i(x) = \mu_{C_i}(x)$ be the degree to which the object x (or, actually, the constrained attribute of x) satisfies C_i. Then, the inference implemented by IWA operators has a Modus Ponens form that in the case of andness = 1 is expressed by:

$$\frac{\begin{array}{l} a_1 = C_1(x), \ldots, a_n = C_n(x) \\ (v_1 \Rightarrow C_1) \wedge \cdots \wedge (v_n \Rightarrow C_n) \to C \end{array}}{C(x) = \wedge_i (v_i \Rightarrow C_i) \ (= h_{\rho=1}^{\text{IWA}}(\mathbf{v}, \mathbf{a}))} \tag{9}$$

Equation 9 expresses that, for an AND aggregation, the goal concept is satisfied by an object to the degree that the requirement *'for all criteria, the criterion is satisfied if it is important'* is met. This may be expressed by $\forall i(\text{important}(\text{C}_\text{i}) \Rightarrow \text{satisfied}(\text{C}_\text{i}))$ that, by $v_i = \text{important}(\text{C}_\text{i})$ and $a_i = \text{satisfied}(\text{C}_\text{i})$, may be written $\forall i(v_i \Rightarrow a_i)$, or, by the standard evaluation of $\forall$ by the min operator, $\min_i(v_i \Rightarrow a_i)$. By other equivalent expressions of $\forall i(v_i \Rightarrow a_i)$, the requirement can be expressed by other words, for instance, by $\neg\exists i(v_i \wedge \neg a_i)$, *'there does not exist a criterion that is important but not satisfied'*.

The transformation of an argument a by an implicative importance weight v for an averaging aggregation at andness ρ is modeled by a function $g_\rho : I^2 \to I : (v, a) \mapsto g_\rho(v, a)$. Thus, for a fuzzy implication $\Rightarrow$, $g_1(v, a) = (v \Rightarrow a)$ is a transformation for an AND aggregation, and $g_0(v, a) = \overline{g_{\overline{0}}(v, \overline{a})} = \overline{v \Rightarrow \overline{a}}$ is its De Morgan dual transformation for an OR aggregation. An important property of g_1 and g_0 is that they for $v = 0$ evaluate to the neutral element for the aggregation, namely, respectively, 1 and 0. In general, for $\rho \in I$, we define g_ρ as the andness-orness weighted sum of g_1 and g_0:

$$g_\rho(v, a) = \rho g_1(v, a) + \overline{\rho} g_0(v, a) \tag{10}$$

which in the case of the Reichenbach implication $\Rightarrow_\text{R}$, with $g_1^\text{R}(v, a) = (v \Rightarrow_\text{R} a) = \overline{v\overline{a}}$ $(= 1 - v(1 - a))$ and $g_0^\text{R}(v, a) = \overline{v \Rightarrow_\text{R} \overline{a}} = va$, evaluates to $g_\rho^\text{R}(v, a) = \rho - v(\rho - a)$. In [13], we presented an (implicative) importance weighting generalization of OWA operators and showed that transformation by g_ρ^R satisfies the requirements for such an importance weighting.

6.3 Other IWA operators

In [3], we introduced another approach to implicative importance weighting generalization of OWA operators, in that case the MEOWA operators [7, 8], namely the IW-MEOWA operators that, by the current notation, are defined by:

$$h_\rho^{\text{IW-MEOWA}}(\mathbf{v}, \mathbf{a}) = \frac{h_\rho^{\text{IW-MEOWA}}(\mathbf{u}, \mathbf{v}, \mathbf{a}) - l}{u - l} \tag{11}$$

where $h_\rho^{\text{IW-MEOWA}}(\mathbf{u}, \mathbf{v}, \mathbf{a}) = \sum_i (u_i b_{(i)})$, $\mathbf{u}$ is the MEOWA weighting vector for the given ρ and n, $b_i = g_\rho^\text{R}(v, a) = \rho - v(\rho - a)$, and $(\cdot)$ is an index permutation, such that $b_{(1)} \geq \cdots \geq b_{(n)}$. Finally, l and u are the lower and upper bounds for $h_\rho^{\text{IW-MEOWA}}(\mathbf{v}, \mathbf{a})$, namely, repectively, $h_\rho^{\text{IW-MEOWA}}(\mathbf{u}, \mathbf{v}, (0, \ldots, 0))$ and $h_\rho^{\text{IW-MEOWA}}(\mathbf{u}, \mathbf{v}, (1, \ldots, 1))$. It was shown that (11) provides a linear transformation of $h_\rho^{\text{IW-MEOWA}}(\mathbf{u}, \mathbf{v}, \mathbf{a})$, such that $h_\rho^{\text{IW-MEOWA}}(\mathbf{v}, \mathbf{a})$ represents the WAM at andness $= \rho = \frac{1}{2}$.

ISBN: 978-989-95079-6-8

7 Comparison of MWA and IWA aggregates

While operators of the same kind, MWA or IWA, tend to behave similarly—in the sense that they provide the same ordering of a given set of options at the same andness and the same importance weights—this is, as we may expect, not the case for operators of difference kinds. This is illustrated by the following examples, where the andness of the MWA and W-OWA classes are targeted by, respectively, $\psi^{\text{AA}}(\rho, n)$ and $\psi^{\text{W-OWA}}(\rho, n)$, as denoted by the aggregation operator symbol; thus, $h^{\text{AMWA}}_{\frac{2}{3},2}$ denotes that h^{AMWA} is applied with $\psi^{\text{AA}}(\frac{2}{3}, 2)$.

Assume that the decision problem is characterized by andness $= \frac{2}{3}$, $n = 2$, $\mathbf{v} = (0.4, 1)$ that is sum-normalized to $\mathbf{w} = (0.286, 0.714)$, and consider the two options represented by the argument vectors $\mathbf{a}_1 = (0.1, 0.7)$ and $\mathbf{a}_2 = (0.9, 0.4)$.

By *MWA aggregation*, the second option, as represented by $\mathbf{a}_2$, get the highest score and is therefore ranked higher than the first option, as the following evaluations, all at andness $= \frac{2}{3}$, show: $h^{\text{AMWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_1) = 0.420 < h^{\text{AMWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_2) = 0.474$ and $h^{\text{MW-OWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_1) = 0.454 < h^{\text{MW-OWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_2) = 0.470$. This is also the case for MWA operators of other classes; thus, for the Weighted Geometric Mean (WGM), $h^{\text{WGM}}(\mathbf{v}, \mathbf{a}) = \prod_i a_i^{w_i}$, that at $n = 2$ has andness $= \frac{2}{3}$, we get $h^{\text{WGM}}(\mathbf{v}, \mathbf{a}_1) = 0.401 < h^{\text{WGM}}(\mathbf{v}, \mathbf{a}_2) = 0.504$; similarly for the Weighted Exponential Means (WEM), $h^{\text{WEM}}_{\alpha}(\mathbf{v}, \mathbf{a}) = \frac{1}{\alpha} \ln \left(\sum_i (w_i e^{\alpha a_i}) \right)$, that at $(\alpha, n) = (-3, 2)$ has andness $= \frac{2}{3}$, we get $h^{\text{WEM}}_{-3}(\mathbf{v}, \mathbf{a}_1) = 0.402 < h^{\text{WEM}}_{-3}(\mathbf{v}, \mathbf{a}_2) = 0.484$.

By *IWA aggregation*, the first option, as represented by $\mathbf{a}_1$, get the highest score and is therefore ranked higher than the second option: $h^{\text{AIWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_1) = 0.579 > h^{\text{AIWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_2) = 0.422$ and $h^{\text{IW-OWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_1) = 0.551 > h^{\text{IW-OWA}}_{\frac{2}{3},2}(\mathbf{v}, \mathbf{a}_2) = 0.473$; similarly, for the IW-MEOWA operator (11), we get $h^{\text{IW-MEOWA}}_{\frac{2}{3}}(\mathbf{v}, \mathbf{a}_1) = 0.530 > h^{\text{IW-MEOWA}}_{\frac{2}{3}}(\mathbf{v}, \mathbf{a}_2) = 0.515$.

This behavior may be explained as follows. By IWA aggregation, the first criterion (argument) is ignored to some degree, due to its rather low importance (0.4); the higher satisfaction of the second, highly important criterion by the first option is the sufficient to give this option the highest rank. By MWA aggregation, the very low value of the first argument in the first option contributes to give this option the lowest rank, despite the rather low importance of the argument.

These observations are supported by the experiment in [3], where the comparison of the IWA operators AIWA and IW-MEOWA for a small data set and a set of implicatively importance weighted queries, indicated a quite similar behavior of the two operators.

8 Conclusion

Importance weighting of two kinds, namely multiplicative and implicative, were proposed as generalizations of two classes of averaging aggregation operators, namely the Power Means (PM) and the Ordered Weighted Averaging (OWA) operators. Each class is applied in a De Morgan dual version, yielding symmetric behavior on both side of andness $= \frac{1}{2}$, and, at the same time, avoiding the mandatory property of the PM and obtaining a near maximum dispersion of OWA at all degrees of andness. The two generalizations of a class are represented by a common expression, where the kind of importance weighting is controlled through a binary parameter.

For each class, were proposed an andness-directing function that allows us to obtain a targeted andness for an operator rather accurately through also considering the number of arguments.

For each kind of importance weighting, we presented and discussed how it works in the operator under different degrees of andness, and the kind of application problems they apply to. Operators of different classes, but with the same kind of importance weighting, appear to have rather similar behavior at the same andness.

For a given choice of the kind of importance weighting, computational issues may affect the choice of operator class. While the PM based operators (AWA) in particular require much computationally rather heavy power functions, OWA based operators (W-OWA) in particular require an ordering (sorting) of the arguments. If reevaluation of a set of options by a modified query occurs frequently, AWA operators have an advantage through their decomposability property.

Abstract— *Information Systems, and in particular Current Research Information Systems (CRISs), are usually quite difficult to query when looking for specific information, due to the huge amounts of data they contain. To solve this problem, we propose to use a personal search agent that uses fuzzy and rough sets to inform the user about newly available information. Additionally, in order to automate the operation of our solution and to provide it with sufficient information, a document classification module is developed and tested. This module also generates fuzzy relations between research domains that are used by the agent during the mapping process.*

Keywords— Automatic classification, Current Research Information Systems, Fuzzy-rough sets, Personal search agents

1 Introduction

Current Research Information Systems (CRISs) are information systems, operating at regional, national, or international level[1], that store and provide access to data on current research carried out by organizations or researchers. These data typically include information on people, projects, organizations, funding possibilities, facilities, etc. CRISs are usually not easy to query, due to several reasons. On the one hand, the data volume is huge. This makes them a very interesting source of information, but can also be overwhelming for the user when he tries to find some specific information in the system. On the other hand, this information is frequently updated, so users are often not aware of new information that could be relevant to them. As a consequence, they are often unable to express their information needs by means of a conventional query. In the last years, personal search agents seem to be the solution to those problems [1]: they gather potentially useful information for users to subsequently present it to them in the form of recommendations. This idea has been received well and can be found not only in research-related applications like CRISs[2] or article recommenders [2, 3], but also in a significant amount of systems from different domains that share the aforementioned problems [4, 5].

However, and despite the fact that these agents can indeed be helpful for the users, they are subject to limitations. Since what they generally do is just to look for exact matches between the user's interests (given as keywords) and the rest of the information in the system, the user will often miss out on useful information as the documents use different terms to refer to the same, or similar, concepts. Furthermore, most CRISs also face other information defects such as missing, ambiguous, or imprecise information [6].

Concepts from fuzzy [7] and rough [8] set theory, upon which the present approach is based, appear as a solution to the problems mentioned above by allowing for a more flexible matching process. Fuzzy sets allow to express partial relationships, which describe reality in a more faithful way than a binary classification, while the rough component provides mechanisms for query expansion: in this way, a user profile and a document may still be matched when they refer to different, but related, keywords, resulting in a higher recall (a higher number of retrieved relevant documents).

To put these ideas into practice, a Personal Alert System (PAS) is currently under development. This system contains profiles of researchers and their interests, activities, papers, etc., as well as documents with information regarding research projects, conference announcements, or funding possibilities. Both these information sources are mapped to a common ontology, which is currently the three-level IWETO[3] taxonomy of the Flemish government. The main goal of the system is to alert users whenever a document can be matched to their research interests by the search agent. A basic prototype has been implemented, using fuzzy-rough algorithms, and in which the user can also influence term relations through a simple feedback process.

While a conceptual version of PAS was described in [9], this work goes further and describes its concrete implementation, paying special attention to the development and evaluation of an automatic classification module which allows the system to classify new documents according to the IWETO taxonomy, as well as to acquire new information with a view to the matching process.

The remainder of this paper is organized as follows: in Section 2, PAS is presented, giving a brief overview of its architecture, and focusing on how the information is represented in the system. In Section 3, the automatic document classification mechanism is described in detail, while in Section 4 we show how the mapper works. Finally, the paper is concluded in Section 5, where we address some issues for future work as well.

2 General design of the system

As said in the introduction, PAS contains information about researchers, projects, funding possibilities, etc., and it will try

[1]Some examples can be found at http://cris.csrees.usda.gov/ (USA), http://www.ris.is/ (Iceland), or http://sicris.izum.si/ (Slovenia). More information can be found at http://www.eurocris.org/, the professional association of CRIS experts and developer of the standard for these systems.

[2]The possibility of using an agent to retrieve funding possibilities is given at EraCareers: http://ec.europa.eu/euraxess/

[3]IWETO, Inventaris Wetenschappelijk en Technologisch Onderzoek Vlaanderen (now FRIS); http://www.iweto.be

ISBN: 978-989-95079-6-8

to match researchers with research information by using the "intelligence" that fuzzy and rough set theories provide. This section first gives a brief, general view on the system, and then focuses on the representation of the information.

2.1 Architecture of the system

Fig. 1 below shows the different modules of the system and how they interact with each other. In brief, the system is organized as follows. Both users (researchers) and documents (information about projects, etc.) are represented by means of profiles. Those profiles, described in more detail in the next subsection, contain several fields, the field storing keywords being the most important one. These keywords represent the researchers' interests (in the cases of the users), or the fields the documents are related to (in the case of the projects), and correspond to the IWETO taxonomy, where they are distributed in three hierarchical levels: a first level with 5 main nodes, a second level with 29 nodes, and a third level containing 359 nodes (in this last level, a node may contain more than one research field, when the fields are closely related). The left-hand side of Fig. 2 shows a sample of the taxonomy. Once a document comes into the system, it is automatically classified (this process will be shown in detail in Section 3), to subsequently be sent to the mapper. The mapper is the central and, thanks to its fuzzy-rough algorithms, intelligent part of the system. It decides whether or not a given document could be interesting for a given user. After this process, and if the mapper has decided so, a notification (about that given document) is sent to the user. Finally, if he desires so, the notified user can give his feedback about his satisfaction degree with the received alert: the system will then use this information to adjust the relations described in Section 2.2.

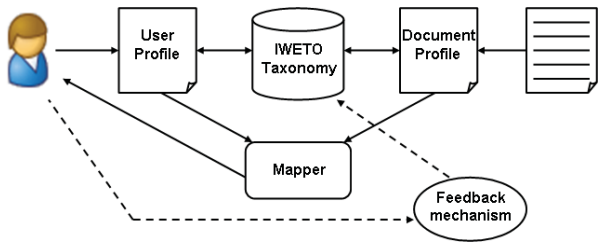

Figure 1: General architecture of PAS

For additional information about the architecture and a more detailed description of the different parts of the system, we refer to [9].

2.2 Representation of the information

A key issue in PAS is the representation of the information: not only how profiles are represented but also how the IWETO taxonomy is stored.

Profiles are based on IWETO keywords, and their representation is common for both users and documents. Leaving aside the fields inherent to users or documents (i.e. "name" for users, "title" or "description" for documents), both user and document profiles contain a field dedicated to store the keywords that will represent them in the system. The structure used for that is a set where the pairs $<$*interest terms*, *degree of interest*$>$ are stored (*degree of relationship*, in the case of the documents). For example, the list $\{$*(AI,1)*, *(T,0.7)*, *(P,0.2)*$\}$ would correspond to a user very interested in *Artificial Intelligence*, quite interested in *Translation*, and slightly interested in *Physics*. The degree of interest/relation lies always between 0 (no interest/relation) and 1 (strong interest/relation). Every profile can therefore be seen as a fuzzy set in the whole collection of keywords X (since the keywords can come from any of the levels of the taxonomy, its hierarchical structure does not play any role at this point).

In the current implementation, the information contained in the profile keywords has different origins. While documents are automatically classified by using the techniques explained in Section 3, users must select their interests from a list of keywords. Users also select the different interest degrees from a list where these are linguistically represented (to subsequently map them onto a numerical value automatically).

Apart from user-keyword and document-keyword relations, we also consider relationships between keywords. A square matrix is used to represent the different relations between keywords, expressed as a degree ranging between 0 (no relation) and 1 (strong relationship). The right-hand side of Fig. 2 gives an example of this representation. A way of assigning degrees to term pairs is based on their co-occurrence during the training process; the more two terms co-occur in training documents, the higher their degree of relationship (see (10) in Section 4 for more detail).

These degrees make it possible to define a fuzzy relation R reflecting how closely two keywords k_1 and k_2 are related. It is important to remark that R is not a fuzzy tolerance relation, since it is not symmetric. It is reflexive, because a term is perfectly related to itself, so $R(k_1, k_1) = 1$, but $R(k_1, k_2)$ and $R(k_2, k_1)$ are not always equal. This is necessary to depict reality in a more faithful way. For instance, and referring to the example shown in Fig. 2, it is logical to think that there is a stronger relation from *Ophtalmology* towards *Medicine* than vice versa: a document related to *Ophtalmology* will always be related to *Medicine*, but a document related to *Medicine* will not be necessarily relevant to *Ophtalmology*.

	BS	M	B	O	D
BS	1	0.4	0.2	0.1	0.1
M	1	1	0.3	0.3	0.2

D	1	1	0	0.1	1

O: Ophtalmology *M: Medicine* *BS: Biomedical Sciences*
D: Dermatology *B: Biophysics*

Figure 2: Example of how the classification is stored

The information about the links between keywords (research fields) contained in the keyword relationship matrix can be used by the system, along with the interest research fields in the profiles, to compute a fuzzy-rough upper approximation for every profile. This process will be explained in more detail in Section 4.

3 Automatic document classification

Clearly, information is the core of any information system, CRISs included. Therefore, it is important for the system to

ISBN: 978-989-95079-6-8

be able to acquire new information easily. Since PAS aims to be as human-independent as possible, it is equipped with an automatic document classification module for this purpose. A representation of the process that documents undergo in this module is shown in Fig. 3 below. To build the module, some of the ideas in [10], such as the usage of keyword vectors for documents and classification, have been used.

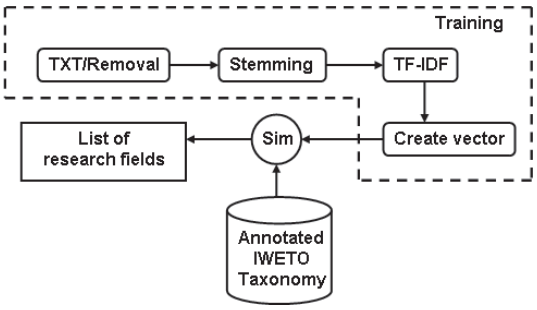

Figure 3: Automatic classification process

3.1 Training

First of all, the system needs to be trained, which is done by means of already classified documents. Currently, these documents come from the FRIS database[4]. Basically, each of them consists of an abstract about a given project, the keywords of that project, and the research fields under which the project was classified in the FRIS database. The documents must first be converted to a format readable by the system, namely txt. Afterwards, every document d is processed by a stemming algorithm. To this purpose, PAS currently uses a purpose-built stemmer, although the list of stopwords that this stemmer uses is an extended version of that which can be found at the site of the implementation of the Porter stemmer [11] in the Snowball language for stemming algorithms[5]. After that, the TF-IDF algorithm [12] is applied to calculate a weight w_i for each term in the document. Those terms with a weight w_i greater than a given threshold γ ($\gamma \geq 0$) are put into a vector $\vec{d}$ that represents the document. This vector $\vec{d}$ is further normalized so that it has unit length.

An important aspect at this point are the terms for which a TF-IDF value is computed. The first implementations of the classifier worked with two-word terms (bigrams), since such terms offer more information and are less ambiguous; for example "information system" is more meaningful than "information" and "system". However, they are also more difficult to match between documents, and some combinations are not so fortunate. So since early tests with one-word terms (unigrams) showed a sensible improvement, the classifier currently works with unigrams. Nevertheless, for some terms composed of more than 1 word, no splitting is applied. This happens for terms extracted via pattern recognition, for example those preceded by the string *"Keywords:"* in a document. In this cases, the terms are added, untouched, to the vector $\vec{d}$, with weight 1.0. Additionally, if the term is not a unigram, another copy of it is added to the rest of the text in the document to be split and processed as described above.

When the training documents have been reduced to their term vector form, the system is ready to start its learning process. It is here where the hierarchy of the IWETO thesaurus is used. First, and based on the information regarding the nodes (research fields) under which the documents have been classified, every vector $\vec{d}$ is assigned to its corresponding node or nodes n. A vector $\vec{n}$ for every node n is then computed. These vectors $\vec{n}$ are normalized vectors containing the terms that are most relevant to node n, or in other words, the terms (and respective weights) contained in the term vectors $\vec{d}$ assigned to n. More formally, let $S(n)$ be the set of subconcepts under concept n (children of node n). Also, let $\{d_1^n, d_2^n, \cdots, d_{k_n}^n\}$ be the individual training documents classified under concept n. $Docs(n)$, the set of all the documents classified under concept n augmented with the documents classified under all its children is defined as:

$$Docs(n) = \left[\bigcup_{n' \in S(n)} Docs(n') \right] \cup \{d_1^n, d_2^n, \cdots, d_{k_n}^n\} \quad (1)$$

The term vector $\vec{n}$ is then computed as:

$$\vec{n} = \left[\sum_{d \in Docs(n)} \vec{d} \right] / |Docs(n)| \quad (2)$$

This term vector $\vec{n}$ is finally normalized into a unit vector.

3.2 Automatic classification

The classification process starts in a similar way to that of the training process, including the application of the stemming and TF-IDF algorithms to create their representative vectors $\vec{d}$. Each test document is then compared to every node in the hierarchical classification. This is done by comparing their representative term vectors $\vec{d}$ and $\vec{n}$ by means of cosine similarity. Those nodes n for which the value of the comparison $sim(\vec{d}, \vec{n})$ is greater than zero are added to a priority queue along with their sim values, ordered with respect to these values. The cosine similarity measure sim for normalized vectors is defined as their inner product, i.e.,

$$sim(\vec{d}, \vec{n}) = \frac{\vec{d} \cdot \vec{n}}{|\vec{d}||\vec{n}|} = \vec{d} \cdot \vec{n} \quad (3)$$

Since the values $sim(\vec{d}, \vec{n})$ reflect how related the document d is to the class represented by node n, they are normalized so that d and n_1, the class with which d has the strongest relation, are related in a degree 1. Finally, the nodes in the N first places of the priority queue (i.e. the nodes with the N greatest values for sim, $N \geq 0$) are retrieved, along with their computed and normalized sim values, as long as they are greater or equal than a given threshold δ, $\delta \geq 0$. Thus, δ controls that only those classes to which d is sufficiently strongly related are taken into account.

The document is then classified under those research fields. This means that a profile is created for the document, with its representative keywords the research fields in which it has been classified, and with the respective sim values giving an idea of how related the document is to them.

3.3 Classification results

The last part of this section is dedicated to show some results obtained with the proposed classifier. At the same time, some design decisions are discussed.

First of all, an evaluation measure is needed. Evaluating hierarchical classification is no trivial problem, a problem that gets yet more complicated by the fact of the classification being multi-label, i.e., documents can be labelled with different keywords. In this work we will use an adaptation to fuzzy sets of the measure hF_β proposed by Kiritchenko et al. in [13]. Specifically:

$$hF_\beta = \frac{(\beta^2+1)\cdot hP \cdot hR}{(\beta^2 \cdot hP + hR)}, \beta \in [0, +\infty) \quad (4)$$

where hP and hR are hierarchical precision and hierarchical recall, respectively. These measures are a variation of the traditional precision and recall evaluation measures which also take into account the hierarchical structure of the classes. In particular, rather than comparing the classes a document belongs to and the ones that were predicted for it, we also consider the ancestors of these classes. Formally:

$$\hat{C}_i = \{\cup_{c_k \in C_i} Anc(c_k)\} \qquad \hat{C}'_i = \{\cup_{c_l \in C'_i} Anc(c_l)\} \quad (5)$$

where C_i and C'_i are the actual and the predicted class sets, respectively, and $Anc(n)$ is the set of ancestors of n, n included. Therefore, $\hat{C}_i$ and $\hat{C}'_i$ are the actual and predicted class sets extended by adding them the ancestors of the classes they contain. Note that $\hat{C}'_i$ is treated as a fuzzy set, with its membership values equal to the predicted sim values, and that $\hat{C}_i$ is actually a crisp set, since a document d is related to all the classes under which it is actually classified in a degree of 1. Measures hP and hR are then defined as:

$$hP = \frac{\sum_i |\hat{C}_i \cap \hat{C}'_i|}{\sum_i |\hat{C}'_i|} \qquad hR = \frac{\sum_i |\hat{C}_i \cap \hat{C}'_i|}{\sum_i |\hat{C}_i|} \quad (6)$$

Since we are dealing with fuzzy sets, corresponding operations are used, defining the intersection of $\hat{C}_i$ and $\hat{C}'_i$ by:

$$(\hat{C}_i \cap \hat{C}'_i)(x) = \min(\hat{C}_i(x), \hat{C}'_i(x)) \quad (7)$$

for a keyword x, and defining the cardinality of $\hat{C}'_i$ as:

$$|\hat{C}'_i| = \sum_{x \in X} \hat{C}'_i(x) \quad (8)$$

By this definition, wrongly predicted classes are penalized less strongly when they belong to the same branch as one of the actual classes. The value of β can be chosen; in our case we will use $\beta = 1$, so both hierarchical precision and hierarchical recall have the same weight in hF.

All the results shown throughout the rest of the section have been calculated with this evaluation measure. On the other hand, the tests to obtain those results were carried out with a dataset formed by 9438 IWETO project descriptions, on which 10-fold cross validation was performed.

The results are subject to a number of parameter settings. The parameters with more impact in the results are the ones related with the term vector $\vec{d}$ used to represent a given document d, and the way the system chooses the classes under which the document d will be classified. Those problems are related with the parameter γ mentioned in Section 3.1, and the parameters N and δ mentioned in Section 3.2, respectively. All these parameters are discussed here and some results about their tuning are presented in Table 1.

Parameter γ is necessary to restrict the number of terms in every term vector $\vec{d}$, mainly because of memory usage and system performance reasons, since terms with very low TF-IDF weights would be probably irrelevant anyway if they were included in the term vector. Due to the short length of the documents we used, parameter γ is not very essential for our purposes. Therefore, the value used for our tests was $\gamma = 0$. Nevertheless, as mentioned above, its use is recommended when dealing with longer documents (or documents with an unknown length).

More relevant in our tests was the number of classes in which the system classifies the document: too many or too few classes probably signify a big difference with respect to the actual classification (resulting in too low precision and/or recall), and will also have an important impact on the user's satisfaction (if a document is classified in too many categories, it will be considered for the matching process even when it is not strongly related to a given category; if it is classified in just one category, it probably will not reach its whole target group of users). Parameters N and δ control this.

As said in Section 3.2, N sets the number of research fields in which a document will be classified, i.e., the number of classes that will be retrieved from the first places of the priority queue. On the other hand, a threshold δ is also necessary, in order to avoid cases of weak relationships: N is the number of classes with the highest value for the similarity measure sim, but that does not necessarily mean that all N values are high. Threshold δ tries to solve this. Since it is applied to normalized results, δ must be a value between 0 and 1, and since strong relationships are desired, the value cannot be too low. The results of the different tests are shown in Table 1.

Table 1: Results for tests with different values for N and δ.

δ	N	6	5	4	3	2	1
0.3	hF_1	0.502	0.512	0.523	**0.53**	0.527	0.478
	hP	0.419	0.442	0.472	0.508	0.555	0.623

0.6	hF_1	0.514	0.519	0.525	0.528	0.524	0.478
	hP	0.458	0.473	0.493	0.52	0.56	0.623
	hR	0.584	0.575	0.562	0.538	0.493	0.388
0.7	hF_1	0.516	0.519	0.522	0.524	0.52	0.478
	hP	0.487	0.496	0.511	0.531	0.564	0.623
	hR	0.549	0.546	0.535	0.518	0.483	0.388
0.8	hF_1	0.514	0.514	0.515	0.516	0.514	0.478
	hP	0.528	0.531	0.537	0.55	0.574	0.623
	hR	0.5	0.499	0.495	0.486	0.465	0.388
0.9	hF_1	0.503	0.503	0.503	0.503	0.501	0.478
	hP	0.577	0.577	0.578	0.581	0.591	0.623
	hR	0.445	0.445	0.444	0.443	0.435	0.388

The average number of classes to which a given document from the dataset belongs is 3. Due to this fact, $N = 3$ offers the best values for the evaluation measure hF_1. It can also be

ISBN: 978-989-95079-6-8

seen that $N = 3$ offers the best equilibrium between hP and hR. Moreover, note that the precision hP is inversely proportional to N: the fewer classes d is classified in, the higher the precision. This is logical since a low value for N means that the document is classified in those classes which offered the highest values for the similarity measure sim, classes that are then probably among those under which the document was actually classified. But that small number of classes has a drawback: the recall is of course lower. In the same way, a higher value of N results in higher values of hR: the document is classified under a lot of concepts and therefore it is more probable that they cover all the classes actually linked with the document. Of course, this higher number of classes makes the classifier less precise.

Also δ is important, mainly for higher values of N: these high values imply taking more classes into account when classifying a document, but δ imposes a threshold that leaves out all those "highest values" that are not actually high enough to be considered for the classification. In that way, δ allows higher values of N to be used in order to avoid leaving out potentially adequate classes, but without the risk of considering classes that probably are not so related to the document.

Note that the combination of $N = 1$ and δ is useless, as reflected by the results: since the results of sim are normalized, the highest value in the priority queue (and therefore the only one that will be retrieved when $N = 1$) will be equal to 1.

Although a high precision is desirable, it is necessary to keep in mind that the system aims to alert the researchers about potentially interesting documents. Therefore, the documents are preferably classified under more than one research field (as long as those fields are relatively strongly related to the document). That means that a balance between precision and recall ($\beta = 1$) is recommended in this case. As the combination $\delta = 0.5$, $N = 3$ offers the best results ($\delta = 0.4$ and $\delta = 0.3$ obtain similar values for hF but a lower precision), they are the values currently used by the system.

There are nonetheless some remarks to be made. In this case, the hierarchical classification problem gets complicated by the fact that the documents in the dataset have been manually classified by different people. This means that in some cases the document has been indexed under all the possible research fields while in other cases it has been vaguely classified under a parent concept. As previously explained, this can cause big differences between the set containing the research fields under which the documents were actually classified and that predicted by the system.

4 Mapper

Since the mapper is the most important part of the system, this section is used to explain in detail how it works. The mapper determines whether a document is interesting enough to notify a user about it. In this process, as discussed in the introduction, the system should be able to identify interesting documents even when their keywords do not exactly match those in the user's profile, but are semantically related to them. To achieve this added intelligence, some ideas from fuzzy-rough set theory are used.

Specifically, fuzzy-rough query expansion is applied. In particular, the system currently uses an adaptation of the approach described in [14]: to assess how well a document profile D matches a user profile U (both represented as fuzzy sets in the set X of keywords) the algorithm first uses a fuzzy relation R to generate their respective upper approximations $R{\uparrow}D$ and $R{\uparrow}U$, where the upper approximation of a fuzzy set A in X under a fuzzy relation R is defined as:

$$(R{\uparrow}A)(y) = \sup_{x \in X} \min(R(x, y), A(x)), \forall y \in X \qquad (9)$$

A keyword belongs to this upper approximation to the extent that it is related, by means of the fuzzy relation R, to at least one of the keywords in A. In other words, (9) defines the set of objects possibly belonging to A to a certain degree. In the current system, the relatedness of two terms is based on their co-occurrence during the training process, as explained in Section 2.2. To be precise, the relation R between two terms x and y can be defined as:

$$R(x, y) = \frac{|Docs(x) \cap Docs(y)|}{|Docs(x)|} \qquad (10)$$

The similarity between D and U is then computed, using α-cuts[6], as

$$Sim_\alpha(U, D) = 1 - \frac{|B_{u\alpha}|}{|(R{\uparrow}D)_\alpha|} \qquad (11)$$

where

$$B_u = R{\uparrow}D \ominus [R{\uparrow}U \cap R{\uparrow}D] \qquad (12)$$

with $\ominus$ the difference of A and B, defined by $(A \ominus B)(x) = \max(0, A(x) - B(x))$.

If $|(R{\uparrow}U)_\alpha| = 0$, the similarity is defined to be 0. Currently, the system uses a fixed value $\alpha = 0.5$, which turned out to yield the best performance experimentally in preliminary tests. It is important to point out that Sim is asymmetric and that therefore the order of U and D is relevant. This keeps the focus of the comparison on the document (B_u is the set of terms in the upper approximation of D that are not shared with the upper approximation of U) and allows the document to reach more users, as long as it is of relevance for them.

The obtained similarity between user and document is then compared to a user-set notification threshold (entered linguistically and then mapped onto a numerical value): if the similarity is greater than or equal to the threshold, user U will be notified by the system about document D. In this way, the user can tune the sensitivity of the mapper: if he only wants to receive alerts about documents that are definitely relevant, he can impose a higher threshold.

5 Conclusion and future work

We have shown how fuzzy relations are used to represent gradual relationships between research fields, and how these relations can be generated from a given dataset. It has also been shown how to construct user and document profiles as fuzzy sets, and how these sets can be matched by applying ideas from fuzzy-rough set theory. In addition, we have also proposed and explained a method to automatically classify documents, in order to keep the system easily updated. However, and despite the promising performance offered by the current

[6] The α-cut of A is defined as $A_\alpha = \{x \in X | A(x) \geq \alpha\}$, where $\alpha \in [0, 1]$

ISBN: 978-989-95079-6-8

implementation of the system, there is still a lot of work to be done.

Since the main goal of the project is to match researchers with documents that can be potentially useful for them, the main effort will be put into the mapping algorithms. New algorithms will be developed and tested to replace the one currently used. This current algorithm, though very interesting, is quite basic, so we think that there is a lot of room for improvement. For example, different similarity measures to compare the upper approximation can be investigated, and we plan to set up an experiment with a group of real test users.

The performance of the fuzzy-rough algorithms is of course also linked to the availability of sufficient document profiles and the quality of the classifier. However, the current version of this module of the system is quite simple, and further improvements could be very interesting and fruitful. For instance, more complex techniques from language technology could be used to refine the keyword extraction. Also, the fuzzy weights of the relationships between concepts can play a more important role, in the classification process as well as in the evaluation of results. The possibility of semi-automatically enriching the IWETO thesaurus with a fourth level, for the sake of precision, will be studied too. Besides, an alternative representation of the information, with the profiles as copies of the classification (which would allow the user to assign his own weights to the relations), will be considered.

Other modules will be added as well. In order to achieve a greater autonomy of the system, the feedback mechanism will be automated, and different techniques will be used to monitor the user's behavior while using the system, so that it can automatically update his list of interests and preferences, adding information that can be useful for the mapper. Also, the classifier could be used to extract additional information from the researcher's publications, when available. All this information can also be used, along with that provided by the feedback mechanism, to refine and adjust the relationships between concepts from the thesaurus. The user will also be free to explore the system on his own: a browsing utility and a search engine will be added with that finality. This engine can also use the same query expansion techniques that are used for personalized notification.

Abstract— Our work is a contribution to the model-theoretic study of equality-free fuzzy predicate logics. We present a *reduced semantics* and we prove a completeness theorem of the logics with respect to this semantics. The main concepts being studied are the *Leibniz congruence* and the *relative relation*. On the one hand, the Leibniz congruence of a model identifies the elements that are indistinguishable using equality-free atomic formulas and parameters from the model, a reduced structure is the quotient of a model modulo this congruence. On the other hand, the relative relation between two structures plays the same role that the isomorphism relation plays in classical predicate languages with equality.

Keywords— Equality-free Language, Fuzzy Predicate Logic, Model Theory, Reduced Structure, Relative Relation.

1 Introduction

This work is a contribution to the model-theoretic study of equality-free fuzzy predicate logics. Model theory is the branch of mathematical logic that studies the construction and classification of structures. Construction means building structures or families of structures, which have some feature that interest us. In our case we devote our investigation to the class of reduced structures, that help us to shed light to the characteristic role played by equality in predicate fuzzy logics.

Classifying a class of structures means grouping the structures into subclasses in a useful way, and then proving that every structure in the collection does belong in just one of the subclasses. The most basic classification in classical model theory is given by the relations of elementary equivalence and isomorphism. Our purpose in the present article is to investigate and characterize the structure-preserving maps between structures in a fuzzy setting. In classical predicate logics with equality, homomorphisms are structure-preserving, but if they are not isomorphisms, they don't necessarily preserve all the formulas of the language. On the contrary, in equality-free fuzzy predicate logics, σ-homomorphisms preserve all the formulas, but unlike isomorphisms, the relation between structures of one being the σ-homomorphic image of another is not an equivalence relation in the class of structures.

The main concepts studied in this work are the *Leibniz congruence* and the *relative relation*. The notion of Leibniz congruence arises in a very natural way. It is said that two elements of a model are related by this congruence when they satisfy exactly the same equality-free atomic formulas with parameters in the model. This congruence always exists, and it turns out to be the greatest congruence of the model. This idea has its origin in the Principle of the identity of the indiscernibles of G. W. Leibniz.

Given a model $(\mathbf{M}, \mathbf{B})$ the quotient structure modulo the Leibniz congruence $\Omega(\mathbf{M}, \mathbf{B})$ is denoted by $(\mathbf{M}, \mathbf{B})^r$ and is called its *reduction*. When we make the quotient modulo the Leibniz congruence, we identify the elements that are indistinguishable using equality-free atomic formulas and parameters in the model, thus the Leibniz congruence of the reduction of a model is always the identity. An structure with the property that its Leibniz congruence is the identity is said to be a *reduced* structure. The importance of reduced structures in equality-free logic comes from the fact that the reduction of a model is a σ- homomorphic image of the model and therefore, the model and its reduction satisfy exactly the same equality-free sentences.

The other main concept analysed is the relative relation. It is said that two structures are *relatives* when they have isomorphic reductions. Along this work we will give different characterizations of this relation. Our aim is to point out that it plays the same role in equality-free logic that the isomorphism relation plays in logic with equality. The actual interest of the Leibniz congruence and the relative relation comes from the work of W. Blok and D. Pigozzi. They introduced the concept of relative relation for the special case of logical matrices in [1], and in [2] they made an extensive use of what they named the Leibniz congruence.

Different definitions have been introduced so far for basic model-theoretic operations on structures. For instance, the notion of *elementary submodel, morphism* and *congruence of a fuzzy model* of [3], *elementary embeddings and submodels* of [4], *fuzzy submodel, elementary fuzzy submodel* and *isomorphism* of structures of first-order fuzzy logic with graded syntax of [5], *complete morphism and congruence* in languages with a similarity predicate of [6] and the notion of σ-embedding of [7]. Being our starting point all these works, in the Preliminaries section we introduce the notions of homomorphism and congruence of a model, trying both to encompass the most commonly used definitions in the literature and to extend the corresponding notions of classical predicate logics.

In section 3 we introduce the notion of reduced structure and some basic model-theoretic properties of this kind of structures. In section 4 we characterize when two structures are relative and we prove that the relative relation is the transitivization of the relation of being a σ-homomorphic image. Finally, section 5 is devoted to future work.

2 Preliminaries

Our study of the model theory of fuzzy predicate logics is focused on the basic fuzzy predicate logic MTL∀ and stronger t-norm based predicate calculi, the so-called *core fuzzy logics*. We start by introducing the notion of core fuzzy logic in the propositional case.

Definition 1 *A propositional logic L is a* core fuzzy logic *iff L satisfies:*

1. *For all formulas ϕ, φ, α, $\varphi \equiv \phi \vdash \alpha(\varphi) \equiv \alpha(\phi)$.*
2. (LDT) Local Deduction Theorem: *for each theory and formulas ϕ, φ:*

   $$T, \varphi \vdash \phi \text{ iff for some natural number } n,\ T \vdash \varphi^n \to \phi.$$

3. *L expands* MTL.

For a thorough treatment of core fuzzy logics we refer to [4], [8] and [7]. A *predicate language* Γ is a triple (P,F,A) where P is a non-empty set of predicate symbols, F is a set of function symbols and A is a function assigning to each predicate and function symbol a natural number called the *arity of the symbol*. Functions f for which $\mathrm{A}(f) = 0$ are called *object constants*. Formulas of the predicate language Γ are built up from the symbols in (P,F,A) together with logical symbols $(\forall, \exists, \&, \to, \overline{0}, \overline{1})$, variables and punctuation. Throughout the paper we consider the equality symbol as a binary predicate symbol not as a logical symbol, we work in equality-free fuzzy predicate logics. That is, the equality symbol is not necessarily present in all the languages and its interpretation is not fixed.

Let L be a fixed propositional core fuzzy logic and $\mathbf{B}$ an L-algebra, we introduce now the semantics for the fuzzy predicate logic $L\forall$. A $\mathbf{B}$-structure for predicate language Γ is a tuple $\mathbf{M} = (M, (P_{\mathbf{M}})_{P\in\Gamma}, (F_{\mathbf{M}})_{F\in\Gamma}, (c_{\mathbf{M}})_{c\in\Gamma})$ where M is a non-empty set and

1. For each n-ary predicate $P \in \Gamma$, $P_{\mathbf{M}}$ is a $\mathbf{B}$-fuzzy relation $P_{\mathbf{M}} : M^n \to \mathbf{B}$.
2. For each n-ary function symbol $F \in \Gamma$, $F_{\mathbf{M}} : M^n \to M$.
3. For each constant symbol $c \in \Gamma$, $c_{\mathbf{M}} \in M$.

Let $\mathbf{M}$ be a $\mathbf{B}$-structure, an $\mathbf{M}$-*evaluation* of the variables is a mapping v which assigns to each variable an element from M. By $\phi(x_1, \ldots, x_k)$ we mean that all the free variables of ϕ are among $x_1, \ldots, x_k$. If v is an evaluation such that for each $0 < i \leq n$, $v(x_i) = d_i$, and λ is either a Γ-term or a Γ-formula, we abbreviate by $\|\lambda(d_1, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}$ the expression $\|\lambda(x_1, \ldots, x_n)\|^{\mathbf{B}}_{\mathbf{M},v}$. Let ϕ be a Γ-sentence, given a $\mathbf{B}$-*structure* $\mathbf{M}$, it is said that $\mathbf{M}$ is a *model* of ϕ iff $\|\phi\|^{\mathbf{B}}_{\mathbf{M}} = 1$.

From now on, we say that $(\mathbf{M}, \mathbf{B})$ is a Γ-structure instead of saying that $\mathbf{M}$ is a $\mathbf{B}$-structure in the language Γ. We say that a structure is *safe*, if a truth value is defined for each formula and evaluation. We assume that all our structures are safe. It is denoted by $(\mathbf{M}, \mathbf{B}) \equiv (\mathbf{N}, \mathbf{A})$ when these two structures are elementarily equivalent. In this section we have presented only a few definitions and notation, a detailed introduction to the syntax and semantics of fuzzy predicate logics can be found in [9].

Definition 2 *Let $(\mathbf{M}_1, \mathbf{B}_1)$ be a Γ_1-structure and $(\mathbf{M}_2, \mathbf{B}_2)$ be a Γ_2-structure with $\Gamma_1 \subseteq \Gamma_2$. We say that the pair (f, g) is a* homomorphism *of $(\mathbf{M}_1, \mathbf{B}_1)$ into $(\mathbf{M}_2, \mathbf{B}_2)$ iff*

1. *$g : \mathbf{B}_1 \to \mathbf{B}_2$ is a L-algebra homomorphism of $\mathbf{B}_1$ into $\mathbf{B}_2$.*
2. *$f : M_1 \to M_2$ is a mapping of M_1 into M_2.*
3. *For each constant symbol $c \in \Gamma_1$, $f(c_{\mathbf{M}_1}) = c_{\mathbf{M}_2}$.*
4. *For each n-ary function symbol $F \in \Gamma_1$ and elements $d_1, \ldots, d_n \in M_1$,*

   $$f(F_{\mathbf{M}_1}(d_1, \ldots, d_n)) = F_{\mathbf{M}_2}(f(d_1), \ldots, f(d_n))$$

5. *For each n-ary predicate $P \in \Gamma_1$ and elements $d_1, \ldots, d_n \in M_1$,*

   $$g(P_{\mathbf{M}_1}(d_1, \ldots, d_n)) = P_{\mathbf{M}_2}(f(d_1), \ldots, f(d_n))$$

We say that (f, g) is a σ-homomorphism *if g preserves the existing infima and suprema (that is, if I is a non-empty set and $\sup_{i\in I} a_i$ and $\sup_{i\in I} g(a_i)$ exist, then $g(\sup_{i\in I} a_i) = \sup_{i\in I} g(a_i)$ and analogously for the infima).*

It is denoted by $(\mathbf{M}, \mathbf{B}) \cong (\mathbf{N}, \mathbf{A})$ when these two structures are isomorphic (that is, there is a homomorphism (f, g) from $(\mathbf{M}, \mathbf{B})$ into $(\mathbf{N}, \mathbf{A})$ with f and g onto and one-to-one). It is easy to check, by induction on the complexity of the formulas, that homomorphisms preserve quantifier-free formulas. Note that, by definition, homomorphisms are not always σ-complete, as are in [3] or [6], and unlike [6] homomorphisms are crisp on the algebraic reduct of the first-order structure. If (f, g) is a σ-homomorphism of $(\mathbf{M}_1, \mathbf{B}_1)$ into $(\mathbf{M}_2, \mathbf{B}_2)$ such that f is onto, then for each formula $\phi(x_1, \ldots, x_n) \in \Gamma_1$ and elements $d_1, \ldots, d_n \in M_1$,

$$g(\|\phi(d_1, \ldots, d_n)\|^{\mathbf{B}_1}_{\mathbf{M}_1}) = \|\phi(f(d_1), \ldots, f(d_n))\|^{\mathbf{B}_2}_{\mathbf{M}_2} \quad (1)$$

The proof can be found in [3] (Propositions 6.1 and 6.2). We will refer to homomorphisms satisfying condition (1) as *elementary homomorphisms*.

Definition 3 *A* congruence *on a Γ-structure $(\mathbf{M}, \mathbf{B})$ is a pair (E, θ) where:*

1. *θ is an L-congruence on the algebra $\mathbf{B}$.*
2. *E is an equivalence relation $E \subseteq M \times M$ such that:*

   - *For each n-ary function symbol $F \in \Gamma$ and elements $d_1, \ldots, d_n, e_1, \ldots, e_n \in M$, if for each $0 < i \leq n$, $(d_i, e_i) \in E$, then*

     $$(F_{\mathbf{M}}(d_1, \ldots, d_n), F_{\mathbf{M}}(e_1, \ldots, e_n)) \in E$$

   - *For each n-ary predicate $P \in \Gamma$ and elements $d_1, \ldots, d_n, e_1, \ldots, e_n \in M$, if for each $0 < i \leq n$, $(d_i, e_i) \in E$, then*

     $$(P_{\mathbf{M}}(d_1, \ldots, d_n), P_{\mathbf{M}}(e_1, \ldots, e_n)) \in \theta$$

Now, given a congruence (E, θ) on $(\mathbf{M}, \mathbf{B})$ we define the *quotient structure* $(\mathbf{M}/E, \mathbf{B}/\theta)$ by:

ISBN: 978-989-95079-6-8

- For each constant symbol $c \in \Gamma$, $c_{(\mathbf{M}/E,\mathbf{B}/\theta)} = [c_{(\mathbf{M},\mathbf{B})}]_E$.
- For each n-ary function symbol $F \in \Gamma$ and elements $d_1, \ldots, d_n \in M$,

$$F_{\mathbf{M}/E}([d_1]_E, \ldots, [d_n]_E) = [F_{\mathbf{M}}(d_1, \ldots, d_n)]_E$$

- For each n-ary predicate $P \in \Gamma$ and elements $d_1, \ldots, d_n \in M$,

$$P_{\mathbf{M}/E}([d_1]_E, \ldots, [d_n]_E) = [P_{\mathbf{M}}(d_1, \ldots, d_n)]_\theta$$

where, given an element $d \in M$ and $b \in B$, $[d]_E$ and $[b]_\theta$ denote respectively the equivalence classes of d modulo E and of b modulo θ. We will say that a (E, θ) is an *elementary* congruence (σ-congruence, respectively) if its canonical mapping (f_E, g_θ) is an elementary homomorphism (σ-homomorphism, respectively).

3 Reduced Structures

In this section we introduce the notions of Leibniz congruence and of reduced structure and we establish some basic model-theoretic properties of this kind of models, giving some examples of first-order theories with reduced models. The study of reduced structures and Leibniz congruences for classical predicate logics was done in [10]. In the context of fuzzy predicate logics, X. Caicedo introduced this notion in [11] for the particular case of models of first-order Rational Pavelka's logic in a language with the $\approx$ symbol. At the end of this section we study similarities on reduced structures.

Definition 4 *Let $(\mathbf{M}, \mathbf{B})$ be a Γ-structure and θ an L-congruence on $\mathbf{B}$. We define the relation $\Omega(\mathbf{M}, \mathbf{B}, \theta) \subseteq M \times M$ as follows: for every $d, e \in M$, $(d, e) \in \Omega(\mathbf{M}, \mathbf{B}, \theta)$ iff for every atomic formula, $\phi(y, x_1, \ldots, x_n) \in \Gamma$ and elements $d_1, \ldots, d_n \in M$,*

$$(\|\phi(d, d_1, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}, \|\phi(e, d_1, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}) \in \theta$$

Fixed an L-congruence θ on the L-algebra $\mathbf{B}$, next lemma shows that $\Omega(\mathbf{M}, \mathbf{B}, \theta)$ is the greatest E such that (E, θ) is a congruence on the model $(\mathbf{M}, \mathbf{B})$.

Lemma 5 *Let $(\mathbf{M}, \mathbf{B})$ be a Γ-structure and θ an L-congruence on $\mathbf{B}$, then*

1. *$(\Omega(\mathbf{M}, \mathbf{B}, \theta), \theta)$ is a congruence on $(\mathbf{M}, \mathbf{B})$.*
2. *For every (E, θ) congruence on $(\mathbf{M}, \mathbf{B})$, $E \subseteq \Omega(\mathbf{M}, \mathbf{B}, \theta)$.*

Proof: 1. Since θ is an equivalence relation, by definition, $\Omega(\mathbf{M}, \mathbf{B}, \theta)$ is also an equivalence relation. For each n-ary predicate $P \in \Gamma$ and elements $d_1, \ldots, d_n, e_1, \ldots, e_n \in M$, if for each $0 < i \leq n$, $(d_i, e_i) \in \Omega(\mathbf{M}, \mathbf{B}, \theta)$, then by using the definition of $\Omega(\mathbf{M}, \mathbf{B}, \theta)$, for every $0 < i \leq n$, we have the following chain:

$$(\|P(d_1, d_2, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}, \|P(e_1, d_2, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}) \in \theta$$

$$(\|P(e_1, d_2, d_3, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}, \|P(e_1, e_2, d_3, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}) \in \theta$$

$$\vdots$$

$$(\|P(e_1, e_2, \ldots, e_{n-1}, d_n)\|^{\mathbf{B}}_{\mathbf{M}}, \|P(e_1, \ldots, e_n)\|^{\mathbf{B}}_{\mathbf{M}}) \in \theta$$

Assume now that $F \in \Gamma$ is an n-ary function symbol and $d_1, \ldots, d_n, e_1, \ldots, e_n \in M$ such that for each $0 < i \leq n$, $(d_i, e_i) \in \Omega(\mathbf{M}, \mathbf{B}, \theta)$. Let $\overline{k} = k_1, \ldots, k_s \in M$, $\phi(y, x_1, \ldots, x_s) \in \Gamma$ an atomic formula and ϕ' the formula obtained from ϕ by substitution of the variable y for the term $F(z_1, \ldots, z_n)$ (where $z_1, \ldots, z_n$ are new variables not occurring in ϕ). By definition of $\Omega(\mathbf{M}, \mathbf{B}, \theta)$, since ϕ' is also atomic, we can build a chain similar to the one defined in the predicate case and then, we obtain $(\|\phi'(d_1, \ldots, d_n, \overline{k})\|^{\mathbf{B}}_{\mathbf{M}}, \|\phi'(e_1, \ldots, e_n, \overline{k})\|^{\mathbf{B}}_{\mathbf{M}}) \in \theta$, consequently,

$$(\|\phi(F_{\mathbf{M}}(d_1, \ldots, d_n), \overline{k})\|^{\mathbf{B}}_{\mathbf{M}}, \|\phi(F_{\mathbf{M}}(e_1, \ldots, e_n), \overline{k})\|^{\mathbf{B}}_{\mathbf{M}}) \in \theta$$

and then $(F_{\mathbf{M}}(d_1, \ldots, d_n), F_{\mathbf{M}}(e_1, \ldots, e_n)) \in \Omega(\mathbf{M}, \mathbf{B}, \theta)$.

2. By definition of $\Omega(\mathbf{M}, \mathbf{B}, \theta)$, because (E, θ) is a congruence. □

Definition 6 *A Γ-structure $(\mathbf{M}, \mathbf{B})$ is* reduced *iff $\Omega(\mathbf{M}, \mathbf{B}, Id_{\mathbf{B}})$ is the identity relation.*

From now on we denote $(\Omega(\mathbf{M}, \mathbf{B}, Id_{\mathbf{B}}), Id_{\mathbf{B}})$ simply by $\Omega(\mathbf{M}, \mathbf{B})$ and we call it the *Leibniz congruence* of $(\mathbf{M}, \mathbf{B})$. Since the identity map clearly preserves infima and suprema, $\Omega(\mathbf{M}, \mathbf{B})$ is always a σ-congruence, therefore for every $(d, e) \in \Omega(\mathbf{M}, \mathbf{B})$, every formula, $\phi(y, x_1, \ldots, x_n) \in \Gamma$ and elements $d_1, \ldots, d_n \in M$,

$$\|\phi(d, d_1, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}} = \|\phi(e, d_1, \ldots, d_n)\|^{\mathbf{B}}_{\mathbf{M}}$$

We will denote by $(\mathbf{M}, \mathbf{B})^r$ the quotient structure modulo the Leibniz congruence $\Omega(\mathbf{M}, \mathbf{B})$ and call it the *reduction* of $(\mathbf{M}, \mathbf{B})$.

Lemma 7 *For every Γ-structure $(\mathbf{M}, \mathbf{B})$ we have:*

1. *$(\mathbf{M}, \mathbf{B}) \equiv (\mathbf{M}, \mathbf{B})^r$.*
2. *$(\mathbf{M}, \mathbf{B})^r$ is a reduced structure.*
3. *$((\mathbf{M}, \mathbf{B})^r)^r \cong (\mathbf{M}, \mathbf{B})^r$.*
4. *If there exists a σ-congruence (E, θ) on $(\mathbf{M}, \mathbf{B})$, then*

$$(\mathbf{M}, \mathbf{B}) \equiv (\mathbf{M}/\Omega(\mathbf{M}, \mathbf{B}, \theta), \mathbf{B}/\theta)$$

Proof: 1. holds because $(\mathbf{M}, \mathbf{B})^r$ is a σ-homomorphic image of $(\mathbf{M}, \mathbf{B})$, 2. and 3. by definition of the Leibniz congruence and of quotient structure. To prove 4. use the fact that for every σ-congruence (E, θ), $(\Omega(\mathbf{M}, \mathbf{B}, \theta), \theta)$ is also a σ-congruence. □

Corollary 8 [Completeness Theorem] *Let $L\forall$ be a fuzzy predicate logic and $\mathbb{K}$ a class of structures such that $L\forall$ is $\mathbb{K}$-complete (strong or finite strong $\mathbb{K}$-complete, respectively), then $L\forall$ is $\mathbb{K}^r$-complete (strong or finite strong $\mathbb{K}^r$-complete, respectively), where $\mathbb{K}^r$ is the class of reductions of the structures in $\mathbb{K}$.*

ISBN: 978-989-95079-6-8

Reduced structures are of common use in computer science and in mathematics. The Rado Graph (infinite random graph) and fuzzy linear orders are examples of reduced structures. However, we can see a more developed example of this process of reduction in the well-known case of similarities. In Section 5 of [9], P. Hájek studies similarities and applies the obtained results to the analysis of fuzzy control in Chapter 7 of of [9]. For a reference about model-theoretic properties of algebras with fuzzy equalities see [8] and [6]. Now (and only for the rest of this section) we assume that our predicate language Γ contains a binary predicate symbol $\approx$. Similarity is understood as fuzzified equality (for a reference see [12] or [13]). Given a core fuzzy logic L, let our axiomatic system for $L\forall$ contain also the following axioms:

1. (Reflexivity) $\forall x\ x \approx x$
2. (Symmetry) $\forall x \forall y (x \approx y \rightarrow y \approx x)$
3. (Transitivity) $\forall x \forall y \forall z ((x \approx y \& y \approx z) \rightarrow x \approx z)$
4. For each n-ary function symbol $F \in \Gamma$, $\forall x_1 \ldots \forall x_n \forall y_1 \ldots \forall y_n ((x_1 \approx y_1 \& \ldots \& x_n \approx y_n) \rightarrow (F(x_1, \ldots, x_n) \approx F(y_1, \ldots, y_n))$
5. For each n-ary predicate $P \in \Gamma$, $\forall x_1 \ldots \forall x_n \forall y_1 \ldots \forall y_n ((x_1 \approx y_1 \& \ldots \& x_n \approx y_n) \rightarrow (P(x_1, \ldots, x_n) \leftrightarrow P(y_1, \ldots, y_n))$

Axioms 1-3 are called *Similarity Axioms* (Sim) and axioms 4-5 *Congruence Axioms* (Cong).

Definition 9 *A Γ-structure $(\mathbf{M}, \mathbf{B})$ has the* equality property (EQP) *if the following condition holds: for every $d, e \in M$, $\|d \approx e\|^{\mathbf{B}}_{\mathbf{M}} = 1$ iff $d = e$.*

Lemma 10 *Given a set Σ of Γ-sentences, $\Sigma \cup Sim \cup Cong$ is satisfiable iff Σ has a model $(\mathbf{M}, \mathbf{B})$ that has* EQP.

Proof: Let $(\mathbf{M}, \mathbf{B})$ be a model of $\Sigma \cup Sim \cup Cong$. If we define $E = \{(a, b) \in M \times M : \|a \approx b\|^{\mathbf{B}}_{\mathbf{M}} = 1\}$, then $(E, Id_{\mathbf{B}})$ is a congruence. Thus, in the quotient structure $(\mathbf{M}/E, \mathbf{B})$, $\|x \approx y\|^{\mathbf{B}}_{\mathbf{M}/E} = 1$ iff $x = y$. □

In [11] X. Caicedo called *reduced structure* to a model of first-order Rational Pavelka's logic with the property EQP. Next lemma shows that Caicedo's notion coincides with ours when we consider axiomatic systems including axioms $Sim \cup Cong$.

Lemma 11 *$(\mathbf{M}, \mathbf{B})$ is a reduced structure iff $(\mathbf{M}, \mathbf{B})$ has property* EQP.

Proof: Assume that $(\mathbf{M}, \mathbf{B})$ is a reduced structure, by definition, the Leibniz congruence $\Omega(\mathbf{M}, \mathbf{B}, Id_{\mathbf{B}})$ is the identity on M. Then, if we define $(E, Id_{\mathbf{B}})$ as in the previous proof, by Lemma 5, $E \subseteq \Omega(\mathbf{M}, \mathbf{B}, Id_{\mathbf{B}})$, consequently E is also the identity and thus $(\mathbf{M}, \mathbf{B})$ has the EQP. Conversely, assume that $(\mathbf{M}, \mathbf{B})$ has the EQP. If $d, e \in M$ and $(d, e) \in \Omega(\mathbf{M}, \mathbf{B}, Id_{\mathbf{B}})$, since $x \approx y$ is an atomic formula and $\|d \approx d\|^{\mathbf{B}}_{\mathbf{M}} = 1$, by definition of the Leibniz congruence, $\|d \approx e\|^{\mathbf{B}}_{\mathbf{M}} = 1$. Then, by EQP, we have that $d = e$, therefore $(\mathbf{M}, \mathbf{B})$ is a reduced structure. □

Note that the interpretation of the $\approx$ symbol in a reduced structure is not necessarily crisp. Adding a new axiom it is possible to obtain crisp interpretations: Crispness Axiom (Crisp) $\forall x \forall y (x \approx y \vee \neg(x \approx y))$ (for the details about this axiom see Chapter 5 of [8]).

Corollary 12 *Let T be a set of Γ-sentences containing axioms $Sim \cup Cong \cup Crisp$. Then, for every formula $\phi(x_1, \ldots, x_n) \in \Gamma$, the following holds:* $T \vdash \forall x_1 \ldots \forall x_n \forall y_1 \ldots \forall y_n ((x_1 \approx y_1 \& \ldots \& x_n \approx y_n) \rightarrow (\phi(x_1, \ldots, x_n) \leftrightarrow \phi(y_1, \ldots, y_n))$

Proof: Since axiom Crisp holds, the interpretation of the $\approx$ symbol in a reduced structure is the identity. Therefore, since the logic is complete with respect to its reduced models, we obtain the desired result. □

4 The relative relation

We now present the notion of relative relation, a relation between structures that will play in fuzzy predicate languages the same role that the isomorphism relation plays in classical predicate languages with equality. This notion was introduced by G. Zubieta in [14], but only for relational structures, and independently by W. Blok and D. Pigozzi in [1], for the special case of logical matrices. A characterization of the relative relation for classical first-order logics can be found in [10].

Definition 13 *Let $(\mathbf{M}_1, \mathbf{B}_1)$ and $(\mathbf{M}_2, \mathbf{B}_2)$ be two Γ-structures, we say that the pair (R, T) is a* relative relation *between $(\mathbf{M}_1, \mathbf{B}_1)$ and $(\mathbf{M}_2, \mathbf{B}_2)$ iff*

1. *$T \subseteq B_1 \times B_2$ is a relation such that $dom(T) = B_1$, $rg(T) = B_2$ and*
   (a) *for every connective $\delta \in L$, if $(a_i, b_i) \in T$, then*
   $$(\delta_{\mathbf{B}_1}(a_1, \ldots, a_n), \delta_{\mathbf{B}_2}(b_1, \ldots, b_n)) \in T$$
   (b) *for every $a \in B_1$, if $b, b' \in rg(a)$, then $dom(b) = dom(b')$.*
   (c) *for every $b \in B_2$, if $a, a' \in dom(b)$, then $rg(a) = rg(a')$.*
2. *$R \subseteq M_1 \times M_2$ is a relation such that $dom(R) = M_1$, $rg(R) = M_2$ and*
   (a) *For each constant symbol $c \in \Gamma$, $(c_{\mathbf{M}_1}, c_{\mathbf{M}_2}) \in R$.*
   (b) *For each n-ary function symbol $F \in \Gamma$, if for every $0 < i \leq n$, $(a_i, b_i) \in R$,*
   $$(F_{M_1}(a_1, \ldots, a_n), F_{M_2}(b_1, \ldots, b_n)) \in R$$
   (c) *For each n-ary predicate $P \in \Gamma$, if for every $0 < i \leq n$, $(d_i, e_i) \in R$,*
   $$(\|P(d_1, \ldots, d_n)\|^{\mathbf{B}_1}_{\mathbf{M}_1}, \|P(e_1, \ldots, e_n))\|^{\mathbf{B}_2}_{\mathbf{M}_2}) \in T$$

where for every $a \in B_1$, $rg(a) = \{b \in B_2 : (a, b) \in T\}$ and for every $b \in B_2$, $dom(b) = \{a \in B_1 : (a, b) \in T\}$. We denote by $(R, T) : (\mathbf{M}_1, \mathbf{B}_1) \sim (\mathbf{M}_2, \mathbf{B}_2)$ when (R, T) is a relative relation (or simply by $(\mathbf{M}_1, \mathbf{B}_1) \sim (\mathbf{M}_2, \mathbf{B}_2)$ when there is a relative relation between them).

ISBN: 978-989-95079-6-8

Theorem 14 *Let* $(\mathbf{M}_1, \mathbf{B}_1)$ *and* $(\mathbf{M}_2, \mathbf{B}_2)$ *be two* Γ*-structures. The following are equivalent:*

1. *There is a relative relation* $(R, T) : (\mathbf{M}_1, \mathbf{B}_1) \sim (\mathbf{M}_2, \mathbf{B}_2)$
2. *There are congruences* (E_1, θ_1) *and* (E_2, θ_2) *such that*

$$(\mathbf{M}_1/E_1, \mathbf{B}_1/\theta_1) \cong (\mathbf{M}_2/E_2, \mathbf{B}_2/\theta_2)$$

Proof: 1. $\Rightarrow$ 2. Assume that (R, T) is a relative relation. We define $\theta_1 = \{(a, a') \in B_1 \times B_1 : rg(a) = rg(a')\}$, $\theta_2 = \{(b, b') \in B_2 \times B_2 : dom(b) = dom(b')\}$, $E_1 = \Omega(\mathbf{M_1}, \mathbf{B_1}, \theta_1)$ and $E_2 = \Omega(\mathbf{M_2}, \mathbf{B_2}, \theta_2)$.

It is clear by definition that θ_1 and θ_2 are equivalence relations. Now we show that they are L-congruences, we prove that, for every connective $\delta \in L$, for every $0 < i \leq n$ and $a_i, a_i' \in B_1$, if $rg(a_i) = rg(a_i')$, then $rg(\delta_{\mathbf{B}_1}(a_1, \ldots, a_n)) = rg(\delta_{\mathbf{B}_1}(a_1', \ldots, a_n'))$. Let us assume that for every $0 < i \leq n$, $rg(a_i) = rg(a_i')$. Since $dom(T) = B_1$, for every $0 < i \leq n$, we choose $b_i \in B_2$ such that $(a_i, b_i) \in T$. Thus, by assumption, since $rg(a_i) = rg(a_i')$, we have also that $(a_i', b_i) \in T$. By condition 1.(a) of the definition of relative relation,

$$(\delta_{\mathbf{B}_1}(a_1, \ldots, a_n), \delta_{\mathbf{B}_2}(b_1, \ldots, b_n)) \in T$$

and $(\delta_{\mathbf{B}_1}(a_1', \ldots, a_n'), \delta_{\mathbf{B}_2}(b_1, \ldots, b_n)) \in T$, finally, by condition 1.(c) of the definition of relative relation, we have that

$$rg(\delta_{\mathbf{B}_1}(a_1, \ldots, a_n)) = rg(\delta_{\mathbf{B}_1}(a_1', \ldots, a_n')).$$

In order to show that θ_2 is a congruence, we can follow an analogous proof, using condition 1.(b) of the definition of relative relation, instead of 1.(c). Now we define a mapping $g : \mathbf{B}_1/\theta_1 \to \mathbf{B}_2/\theta_2$. First we fix enumerations (possibly with repetitions) $(a_i : i \in I)$ and $(b_i : i \in I)$ of $\mathbf{B}_1$ and $\mathbf{B}_2$ respectively, with the property that, for every $i \in I$, $(a_i, b_i) \in T$. And then let, for every $i \in I$, $g([a_i]_{\theta_1}) = [b_i]_{\theta_2}$. By using the definition of relative relation it is easy to check that g is well-defined, and it is an L-isomorphism.

Now, since $dom(R) = M_1$ and $rg(R) = M_2$, we can fix enumerations (possibly with repetitions) $(d_j : j \in J)$ and $(e_j : j \in J)$ of M_1 and M_2 respectively, with the property that, for every $j \in J$, $(d_j, e_j) \in R$. And then let, for every $j \in J$,

$$f([d_j]_{\Omega(\mathbf{M_1}, \mathbf{B_1}, \theta_1)}) = [e_j]_{\Omega(\mathbf{M_2}, \mathbf{B_2}, \theta_2)}$$

Let us see that f is well defined. Let $(d_j, d_j') \in \Omega(\mathbf{M_1}, \mathbf{B_1}, \theta_1)$, we show that $(e_j, e_j') \in \Omega(\mathbf{M_2}, \mathbf{B_2}, \theta_2)$. Let $\phi(y, x_1, \ldots, x_n)$ be an atomic formula, and a sequence of elements $k_1, \ldots, k_n \in M_2$. Since $rg(R) = M_2$, we can choose $l_1, \ldots, l_n \in M_1$ such that for every $0 < i \leq n$, $(l_i, k_i) \in R$. Remark that, since $(d_j, e_j) \in R$ and for every $0 < i \leq n$, $(l_i, k_i) \in R$, by conditions 2.(a) and 2.(b) of the definition of relative relation, we have for every Γ-term t, $(t_{M_1}(d_j, l_1, \ldots, l_n), t_{M_2}(e_j, k_1, \ldots, k_n)) \in R$. Assume that the formula $\phi(y, x_1, \ldots, x_n)$ is of the form $P(t_1, \ldots, t_s)(y, x_1, \ldots, x_n)$, where P is a s-ary predicate symbol and $t_1, \ldots, t_s$ are Γ-terms. Since $(d_j, d_j') \in \Omega(\mathbf{M_1}, \mathbf{B_1}, \theta_1)$, $(\|P(t_1, \ldots, t_s)(d_j, l_1, \ldots, l_n)\|^{\mathbf{B}_1}_{\mathbf{M}_1}$, $\|P(t_1, \ldots, t_s)(d_j', l_1, \ldots, l_n)\|^{\mathbf{B}_1}_{\mathbf{M}_1}) \in \theta_1$, thus, by 2.(c) of the definition of relative relation,
$\|P(t_1, \ldots, t_s)(e_j, k_1, \ldots, k_n)\|^{\mathbf{B}_2}_{\mathbf{M}_2}$ and
$\|P(t_1, \ldots, t_s)(e_j', k_1, \ldots, k_n)\|^{\mathbf{B}_2}_{\mathbf{M}_2}$
$\in rg(\|P(t_1, \ldots, t_s)(d_j, l_1, \ldots, l_n)\|^{\mathbf{B}_1}_{\mathbf{M}_1})$

and by 1.(b), $dom(\|P(t_1, \ldots, t_s)(e_j, k_1, \ldots, k_n)\|^{\mathbf{B}_2}_{\mathbf{M}_2}) = dom(\|P(t_1, \ldots, t_s)(e_j', k_1, \ldots, k_n)\|^{\mathbf{B}_2}_{\mathbf{M}_2})$ and we obtain the desired result:

$$(\|\phi(e_j, k_1, \ldots, k_n)\|^{\mathbf{B}_2}_{\mathbf{M}_2}, \|\phi(e_j', k_1, \ldots, k_n)\|^{\mathbf{B}_2}_{\mathbf{M}_2}) \in \theta_2.$$

In an analogous way it is easy to check that f is one-to-one and that (f, g) is an isomorphism.

2. $\Rightarrow$ 1. Let (f, g) be an isomorphism. Define (R, T) in the following way: for every $b_1 \in B_1, b_2 \in B_2$,$(a, b) \in T$ iff $g([a]_{\theta_1}) = [b]_{\theta_2}$ and for every $d \in M_1, e \in M_2$, $(d, e) \in R$ iff $f([d]_{E_1}) = [e]_{E_2}$. Using the fact that (f, g) is an isomorphism, it is easy to check that $(R, T) : (\mathbf{M}_1, \mathbf{B}_1) \sim (\mathbf{M}_2, \mathbf{B}_2)$ is a relative relation. □

Remark that our approach differs from [6] because the relative relation is not a measure of the degree of similarity between structures. We left for future work the study of the relationship between these two notions.

Definition 15 (R, T) *is an* elementary *relative relation if for every formula* $\phi(x_1, \ldots, x_n) \in \Gamma$ *and for every* $0 < i \leq n$*, if* $(a_i, b_i) \in R$*, then*

$$(\|\phi(a_1, \ldots, a_n)\|^{\mathbf{B}_1}_{\mathbf{M}_1}, \|\phi(b_1, \ldots, b_n))\|^{\mathbf{B}_2}_{\mathbf{M}_2}) \in T$$

By induction on the complexity of the formulas it is straightforward to show that, in case (E_1, θ_1) and (E_2, θ_2) are elementary congruences in Theorem 14, then (R, T) is also an elementary relative relation and $(\mathbf{M}_1, \mathbf{B}_1) \equiv (\mathbf{M}_2, \mathbf{B}_2)$. The following corollary show us that, when we study structures over the same algebra, we can improve Theorem 14.

Corollary 16 *Let* $(\mathbf{M}_1, \mathbf{B})$ *and* $(\mathbf{M}_2, \mathbf{B})$ *be two* Γ*-structures. The following are equivalent:*

1. *There is a relative relation* $(R, Id_{\mathbf{B}}) : (\mathbf{M}_1, \mathbf{B}) \sim (\mathbf{M}_2, \mathbf{B})$
2. $(\mathbf{M}_1, \mathbf{B})^r \cong (\mathbf{M}_2, \mathbf{B})^r$

Proof: By the proof of Theorem 14. □

Let us see now an example of two fuzzy equivalence relations that are relatives but there is no homomorphism from one onto the other. Let $(\mathbf{M}_1, \mathbf{B})$ and $(\mathbf{M}_2, \mathbf{B})$ be defined as follows: the domains of the structures are $M_1 = \{d_1, d_2, e_1, e_2\}$ and $M_2 = \{d_1', d_2', d_3', e_1'\}$ respectively. The fuzzy equivalence relation E_1 is defined by: for every $i, j \in \{1, 2\}$, $E_1(d_i, d_j) = 1 = E_1(e_i, e_j)$ and $E_1(d_i, e_j) = r$, where $r \neq 1$ is a fixed element of $\mathbf{B}$. And the fuzzy equivalence relation E_2 is defined by: for every $i, j \in \{1, 2, 3\}$, $E_2(d_i', d_j') = 1 = E_2(e_1', e_1')$ and $E_2(d_i', e_1') = r$. It is easy

ISBN: 978-989-95079-6-8

to check that $(R, Id_{\mathbf{B}}) : (\mathbf{M}_1, \mathbf{B}) \sim (\mathbf{M}_2, \mathbf{B})$, where R is the relation $R = \{(d_i, d'_j), (e_i, e'_j) : i, j \in \{1, 2, 3\}\}$.

The relation of being either a homomorphic image or a homomorphic counter-image is not in general transitive. Its transitivization is precisely the relative relation, as the following propositions show.

Lemma 17 *Given an L-algebra* $\mathbf{B}$*,* $\sim$ *is an equivalence relation in the class of* $\mathbf{B}$*-structures.*

Proof: By Corollary 16, because $\cong$ is an equivalence relation on the class of reduced structures. □

Notation: Given Γ-structures $(\mathbf{N}, \mathbf{B})$ and $(\mathbf{O}, \mathbf{B})$, we denote by $(\mathbf{N}, \mathbf{B}) \in \mathbf{H}(\mathbf{O}, \mathbf{B})$ the fact that there exists a mapping f from O onto N such that $(f, Id_{\mathbf{B}})$ is a homomorphism.

Proposition 18 *Let* $(\mathbf{M}, \mathbf{B})$ *and* $(\mathbf{N}, \mathbf{B})$ *be two* Γ*-structures. The following are equivalent:*

1. $(\mathbf{M}, \mathbf{B}) \sim (\mathbf{N}, \mathbf{B})$.
2. *There is a natural number* n *and* Γ*-structures* $(\mathbf{O}_1, \mathbf{B}), \ldots, (\mathbf{O}_n, \mathbf{B})$ *such that* $(\mathbf{M}, \mathbf{B}) = (\mathbf{O}_1, \mathbf{B})$*,* $(\mathbf{N}, \mathbf{B}) = (\mathbf{O}_n, \mathbf{B})$ *and for every* $0 < i < n$*, either* $(\mathbf{O}_{n+1}, \mathbf{B}) \in \mathrm{H}(\mathbf{O}_n, \mathbf{B})$ *or* $(\mathbf{O}_n, \mathbf{B}) \in \mathrm{H}(\mathbf{O}_{n+1}, \mathbf{B})$.
3. *There is a* Γ*-structure* $(\mathbf{O}, \mathbf{B})$ *such that* $(\mathbf{M}, \mathbf{B}), (\mathbf{N}, \mathbf{B}) \in \mathrm{H}(\mathbf{O}, \mathbf{B})$.
4. *There is a* Γ*-structure* $(\mathbf{O}, \mathbf{B})$ *such that* $(\mathbf{O}, \mathbf{B}) \in \mathrm{H}(\mathbf{M}, \mathbf{B})$ *and* $(\mathbf{O}, \mathbf{B}) \in \mathrm{H}(\mathbf{N}, \mathbf{B})$.

Proof: 4. $\Rightarrow$ 2. and 3. $\Rightarrow$ 2. are clear. 1. $\Rightarrow$ 4. By Corollary 16. 2. $\Rightarrow$ 1. By the definition of relative relation, given two Γ-structures $(\mathbf{O}, \mathbf{B})$ and $(\mathbf{D}, \mathbf{B})$, if $(\mathbf{O}, \mathbf{B}) \in \mathbf{H}(\mathbf{D}, \mathbf{B})$, then $(\mathbf{O}, \mathbf{B}) \sim (\mathbf{D}, \mathbf{B})$ therefore we can apply the transitive property of the relative relation (Lemma 17).

1. $\Rightarrow$ 3. Assume that there is a relative relation $(R, Id_{\mathbf{B}}) : (\mathbf{M}, \mathbf{B}) \sim (\mathbf{N}, \mathbf{B})$. Since $dom(R) = M$ and $rg(R) = N$, we can fix enumerations (possibly with repetitions) $(d_j : j \in J)$ and $(e_j : j \in J)$ of M and N respectively, with the property that, for every $j \in J$, $(d_j, e_j) \in R$. Now we define a structure $(\mathbf{O}, \mathbf{B})$ and homomorphisms $(f^M, Id_{\mathbf{B}})$ and $(f^N, Id_{\mathbf{B}})$ from $(\mathbf{O}, \mathbf{B})$ onto $(\mathbf{M}, \mathbf{B})$ and $(\mathbf{N}, \mathbf{B})$ respectively.

The algebraic reduct of $(\mathbf{O}, \mathbf{B})$ is the algebra Ter_J of Γ-terms generated by the set of variables $V_J = \{v_j : j \in J\}$. We define the function $f_0^M : V_J \to M$ as follows: for every $j \in J$, $f_0^M(v_j) = d_j$. Then we extend f_0^M in the usual way, to a homomorphism f^M from Ter_J onto M. Finally we define the interpretation of the predicate symbols in $(\mathbf{O}, \mathbf{B})$: for each n-ary predicate $P \in \Gamma$ and elements $t_1, \ldots, t_n \in O$, $P_O(t_1, \ldots, t_n) = P_M(f^M(t_1), \ldots, f^M(t_n))$. So defined $(f^M, Id_{\mathbf{B}})$ is clearly a homomorphism onto $(\mathbf{M}, \mathbf{B})$. Now we define f_0^N by: for every $j \in J$, $f_0^N(v_j) = e_j$ and we extend f_0^N as before, to a homomorphism f^N of the terms algebra onto N. Since for every $j \in J$, $(d_j, e_j) \in R$, for every Γ-term t,

$$(t_M(d_{j_1}, \ldots, d_{j_n}), t_N(e_{j_1}, \ldots, e_{j_n})) \in R$$

and using this fact it is easy to check that $(f^N, Id_{\mathbf{B}})$ is also a homomorphism onto $(\mathbf{N}, \mathbf{B})$. □

5 Conclusions

Work in progress includes the development of usual tools of model theory such as the method of diagrams or ultraproducts in order to work in fuzzy predicate logic. The use of a reduced semantics will allow us to show when one structure is either embeddable or elementarily embeddable in another in terms of extensions of the usual diagrams with special sentences. By using relative relations we could define new operations among structures, such as *ultrafilter-products*, more suitable for working with equality-free languages. Future work will be devoted also to provide different characterizations of the relation of elementary equivalence and some strenghtenings of this notion.

Abstract— *Although an overall knowledge discovery process consists of a distinct pre-processing stage followed by the data mining step, it seems that existing formal concept analysis (FCA) and association rules mining (ARM) approaches, dealing with many-valued contexts, mainly focus on the data mining stage. An "intelligent" pre-processing of input contexts is often absent in existing FCA/ARM approaches, leading to an unavoidable information loss. Usually, many-valued attribute domains need to be first fuzzily partitioned. However, it is unrealistic that the most appropriate fuzzy partitions can be provided by domain experts. In this paper, an unsupervised learning stage, based on Fuzzy C-Means algorithm, is proposed in order to get fuzzy partitions that are faithful to data for quantitative attribute domains, and consequently for avoiding the loss of valuable association rules due to the use of empirical fuzzy partitions. More precisely, the paper reports an experiment where it is shown that some rules are no longer found because their support or confidence is too low when using such empirical partitions. Experimental results show that the learned fuzzy partition outperforms human expert fuzzy partitions. More generally, the paper provide discussions about the handling of many-valued attributes in both fuzzy FCA and fuzzy ARM.*

Keywords— Many-valued formal contexts, fuzzy partitions, fuzzy C-means, association rules.

1 Introduction

Association rules mining (ARM for short) [1] is one of the most widely used data mining technique. This model of knowledge represents the patterns of co-occurrence of items in a collection of transactions. Typically, input data set is in the form of sets of items called transactions (e.g. an item may be things we buy in a market). Thus an example of an association rule is an expression of the form *"beer"* $\wedge$ *"sausage"* $\Rightarrow$ *"mustard"* which represents the fact that purchasing beer and sausage implies purchasing mustard with some degree. It is important to point out that, in the classical setting, considered input data sets (called *contexts* in the rest of this paper) are binary (i.e. are expressed in terms of binary attributes).

Formal concept analysis [2] (FCA for short) consists also of learning some knowledge representation model in an unsupervised way. In the classical setting of this theory, the considered input data set is called *formal context* (also called *context* in this paper). It consists of a binary relation between a set of objects and a set of properties. This relation is usually represented as a table with rows corresponding to objects, columns corresponding to properties (or conversely), and table entries containing 1's or 0's depending on whether an object has or not the corresponding property.

It appears that, in their classical setting, both FCA and ARM are concerned with crisp binary contexts. However real-world data usually contain heterogenous kinds of data (binary, categorical, quantitative, etc...). In order to generalize binary settings to many-valued contexts (i.e. with quantitative or categorical attributes) it is usually suggested to partition quantitative attribute domain into many fuzzy intervals.

Few approaches propose a complete pre-processing stage that is intended to get an optimal fuzzy partition. In [3], authors propose a genetic algorithm-based clustering method that adjusts the centroids of the clusters, which are to be handled as midpoints of the triangular fuzzy partitions. Another approach, also based on genetic algorithms, is proposed in [4]. Based on a linguistic representation model, authors propose to perform a genetic lateral tuning of the membership functions. Authors consider also that each attribute has a predefined number of linguistic terms associated to it. For example, *Low*, *Middle* and *High* are the fuzzy linguistic terms covering the domain of the attribute *Age*.

Concerning these approaches, one may notice that they consider fuzzy partitions restricted to triangular membership functions. On the other hand, the number of clusters has to be empirically fixed for each attribute. Then, the fuzzy partitioning may be considered as ad-hoc to some extent and is far to be information lossless. In other words, the distribution of the data into the context is not taken into account for the assessment of discovered patterns. For this purpose, we present an approach that consists of learning the fuzzy partitions by means of the well-known Fuzzy C-Means algorithm. We also consider cluster validity measures in order to get an optimal multi-prototype context representation.

The paper is organized as follows. Section 2 gives some basic notions of FCA and ARM frameworks, while both crisp and fuzzy partitioning methods are reviewed. The next section highlights the information loss problem with empirical or expert-based fuzzy partitions. In the fourth section, data faithful fuzzy partitions are learned using Fuzzy C-Means algorithm. Experimental results on the *adult* database (UCI Machine Learning Repository) show that the proposed approach avoids information loss and outperforms in terms of support and confidence measures, expert-based partitions. Finally, we conclude and give future perspectives.

ISBN: 978-989-95079-6-8

2 Basic Notions

This section introduces main notions and terminology for both FCA and ARM paradigms and then, presents quantitative context representation and its inherent sharp boundary problem.

2.1 Association Rules Mining

Formally, let $\mathcal{X}$ be a set of objects (called also transactions) $\left(\mathcal{X} = \{x_1, x_2, ..., x_{|\mathcal{X}|}\}\right)$ and let $\mathcal{Y}$ be a set of items $\left(\mathcal{Y} = \{y_1, y_2, ..., y_{|\mathcal{Y}|}\}\right)$. A context $\mathbb{K}$ is denoted as $\mathbb{K} = (\mathcal{X}, \mathcal{Y}, \mathcal{R})$ where $\mathcal{R}$ is a binary relation ($x\mathcal{R}y$ indicates that item y satisfies the transaction x). An association rule is of the form $A \Rightarrow B$ where $A, B \subseteq \mathcal{Y}$, $A \cap B = \emptyset$ and, $A, B \neq \emptyset$. The intended meaning of this rule is that the presence of all of the items of A in a transaction implies the presence of all of the items of B in the same transaction. Association rules are assigned support and confidence measures for a given context. The support defines the percentage of transactions that satisfy (contain) both A and B. Whereas the confidence expresses the conditional probability that B is satisfied given that A is satisfied. These measures denoted respectively `Sup` and `Conf` are defined as:

$$\texttt{Sup}\,(A \Rightarrow B) = \frac{|\{x \in \mathcal{X} \mid \forall y \in A \cup B,\, x\mathcal{R}y\}|}{|\mathcal{X}|} \quad (1)$$

$$\texttt{Conf}(A \Rightarrow B) = \frac{\texttt{Sup}(A \Rightarrow B)}{\texttt{Sup}(A)} \quad (2)$$

Hence, an itemset A is said frequent, if its support is greater than a fixed threshold ξ (i.e. $\texttt{Sup}(A) \geqslant \xi$). A large variety of representational and computational approaches for association rules mining have been published in the literature in the case of binary items. Among them, frequent-based [5] and closed-based [6] approaches. While the former generate the lattice of all frequent itemsets, the latter generate a more condensed representation through the so-called closed itemsets lattice. For instance, based on the notion of closed itemsets, and minimal implication rules base (e.g. Duquenne-Guigues base, Luxemburger base) [7], association rules may be easily inferred from a closed itemsets lattice structure without enumerating them [8]. This kind of approach is closely related to formal concept analysis since the closed itemsets lattice is isomorphic to the concepts lattice which is described below.

2.2 Formal Concept Analysis

Formal concept analysis theory, proposed by [2], deals with a particular kind of analysis of data based on a formal context. Let us consider a similar notation as used above. A set $\mathcal{X}$ of objects, a set $\mathcal{Y}$ of attributes and a formal context $\mathbb{K} = (\mathcal{X}, \mathcal{Y}, \mathcal{R})$ with $\mathcal{R}$ a binary relation ($x\mathcal{R}y$ means that object x verifies attribute y). Let A (resp. B) be a subset of $\mathcal{X}$ (resp. $\mathcal{Y}$), two mappings $\uparrow$ and $\downarrow$ are symmetrically defined:

$$A\uparrow = \{y \mid \forall x \in A,\, x\mathcal{R}y\}$$
$$B\downarrow = \{x \mid \forall y \in B,\, x\mathcal{R}y\}$$

From a formal context, one can construct pairs (A, B) such that $A\uparrow = B$ and $B\downarrow = A$ known as formal concepts, where A and B are called respectively the extent and the intent of the corresponding concept. The set $\mathfrak{B}(\mathbb{K})$ of all formal concepts in the formal context $\mathbb{K}$ is equipped with a partial order (denoted $\preceq$) defined as:

$$(A_1, B_1) \preceq (A_2, B_2) \text{ iff } A_1 \subseteq A_2 \text{ (or, equivalently, } B_1 \supseteq B_2)$$

$(\mathfrak{B}(\mathbb{K}), \preceq)$ forms a complete lattice, called the *concept lattice* of $\mathbb{K}$ (for more details on the lattice structure see [9]).

It appears that ARM and more generally FCA both require, in their classical setting, the same context representation which is a binary context.

2.3 Quantitative Context Representation

In order to generalize binary context settings to many-valued contexts, Srikant et al. [10] suggested to partition a quantitative attribute domain into intervals. In their approach, these authors proposed to map a quantitative or categorical attribute value into a Boolean attribute value in the following way. Let y be an attribute whose domain is quantitative (the principle remains the same with a categorical attribute). Let $Dom\,(y)$ denote the domain of y (according to the relational paradigm, $Dom\,(y)$ is necessarily a finite set). For a given object x we denote by $x[y]$ the value v of y for the object x (i.e. $x[y] = v$).

If the set $Dom\,(y)$ consists of few values, the mapping is straightforward. Conceptually, the authors propose to have instead of the attribute y, as many new attributes as the cardinality of the set $Dom\,(y)$. The new attributes are of the form "$y.v_k$" (where $v_k \in Dom\,(y)$). The values of the new binary formal context are given as:

$$x[y.v_k] = \begin{cases} 1 & \text{if } x[y] = v_k \\ 0 & \text{otherwise.} \end{cases}$$

If the set $Dom\,(y)$ is large, it is partitioned into different intervals $I_1, I_2, ..., I_p$. Attributes of the new binary context are of the form "$y.I_k$" and are given as:

$$x[y.I_k] = \begin{cases} 1 & \text{if } x[y] \in I_k \\ 0 & \text{otherwise.} \end{cases}$$

Note that in the two above cases only particular subsets (singletons or definite intervals) are allowed.

An example of a many-valued context is illustrated in Table 1, while Table 2 gives the corresponding binary mapping.

Table 1: An example of a many-valued context.

Obj\Attr	Age	Marital Status	Native Country	Work Class

ISBN: 978-989-95079-6-8

2.4 Crisp vs. Fuzzy Context Representation

In [10], the authors point out a dilemma between support and confidence measures caused by crisp partitions. On the one hand, if the number of intervals for a quantitative attribute is important, the support for any single interval may be low. Hence, without using larger intervals, some rules involving this attribute may not be found because they lack minimal support. On the other hand, if the intervals are too large, some rules may not have minimal confidence. Indeed, when interval becomes larger, the support of the antecedent A of a rule $A \Rightarrow B$ becomes higher. Consequently, the confidence of the rule i.e. the ratio $\texttt{Supp}\left(A \Rightarrow B\right) / \texttt{Supp}\left(A\right)$ decreases and the rule may not have minimal confidence.

Besides, in [11, 12] other authors point out some undesirable threshold effects caused by crisp partitions. Such effects are well-known, for instance, from histograms in statistics: A slight variation of the boundary points of the intervals can have a noticeable effect on the histogram induced by a number of observations. Likewise, the variation of a partition can strongly influence the evaluation of association rules.

Considering the above dilemma and the undesirable threshold effects, fuzzy partitions (in fuzzy intervals) have been widely used instead of crisp partitions (crisp intervals). This has led to fuzzy association rules [13, 14, 15] and to fuzzy concepts analysis [16, 17]. For example, Table 3 illustrates a fuzzy representation for the many-valued context given in Table 1, when choosing the fuzzy partition $\mathcal{F}_1$ (see Fig. 1).

Table 3: Fuzzy representation of a many-valued context.

Obj\Attr	Age.Very Young	Age.Young	Age. Middle Age	...
Alice	0.4	0.6	0	...
Boris	0.2	0.8	0	...
Cyril	0	1	0	...
David	0	0	0	...

3 Information Loss in Quantitative Context

There are two distinct tendencies to transform a many-valued context into a fuzzy partitioned one. The former is based on human expertise, or is even given empirically. The latter uses dedicated heuristics (e.g. [16]). These partitioning methods induce important information loss as it will be showed in this section. Let us before, recall the definition of a fuzzy partition.

Definition1.
A fuzzy partition of a set X on a universe U is a family $\mathcal{F}\left(X\right) = \left(F_1, ..., F_n\right)$ such that:

1. $\forall i = 1..n \quad F_i \neq \emptyset \wedge F_i \neq U$
2. $\forall u \in U, \quad \sum_i F_i\left(u\right) = 1$

3.1 Empirical Fuzzy Partitions

Classical fuzzy set theory has a powerful tool to manage granularity, namely linguistic variables, introduced by Zadeh [18]. Fuzzy partitions are generally based on those linguistic variables. However the complete specification of a linguistic variable may obviously differ from a user to another. For example, in a survey of the literature [11, 12, 14, 15] related to fuzzy association rules discovery, one may find different fuzzy representations of the attribute *Age*. These partitions $\mathcal{F}_1$, $\mathcal{F}_2$, $\mathcal{F}_3$, $\mathcal{F}_4$ are respectively showed in Fig. 1, Fig. 2, Fig. 3, Fig. 4.

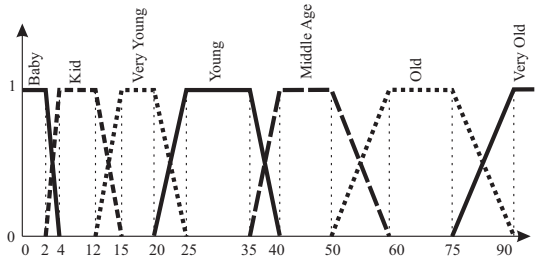

Figure 1: Fuzzy partition $\mathcal{F}_1$ given in [14].

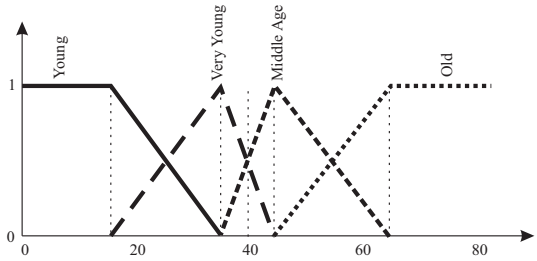

Figure 2: Fuzzy partition $\mathcal{F}_2$ given in [15].

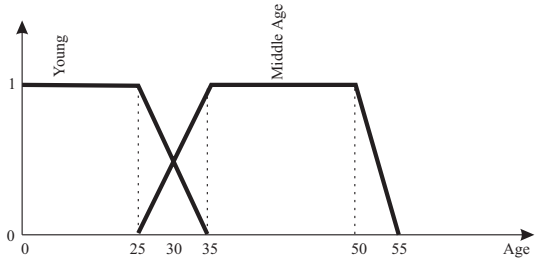

Figure 3: Fuzzy partition $\mathcal{F}_3$ given in [11].

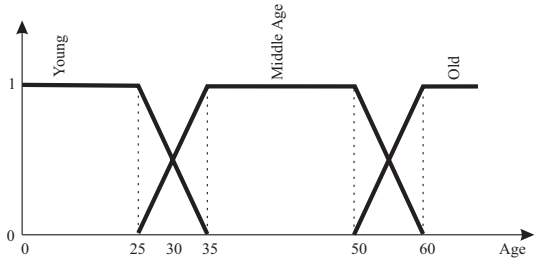

Figure 4: Fuzzy partition $\mathcal{F}_4$ given in [12].

In order to highlight the information loss that may arise with a given fuzzy context compared to another one, we induce all the fuzzy association rules w.r.t a fixed support threshold ξ. The *Adult* benchmark database (UCI Machine Learning Repository) available at http://www.ics.uciedu/mlearn/MLRepositery is taken as a target context for our experiments. Note that, we have restricted the *Adult* context up to six categorical attributes (i.e. *Marital_Status*, *Native_Country*, *Work_Class*, *Salary_Class*, *Education*, *Occupation*) and one quantitative attribute (i.e. *Age*). According to

ISBN: 978-989-95079-6-8

the fuzzy partitions represented respectively in Fig. 1, Fig. 2, Fig. 3, Fig. 4 (namely $\mathcal{F}_1$, $\mathcal{F}_2$, $\mathcal{F}_3$, $\mathcal{F}_4$) we apply the fuzzy association rules mining algorithm that is fully described in [13] for each of the four fuzzy *Adult* contexts.

Note that, the algorithm in [13] uses a co-occurrence semantics [19] for fuzzy rules. However the information loss phenomenon could be observed as well with gradual or certainty semantics [19] .

Thus among the fuzzy rules induced by each partition $\mathcal{F}_1$-$\mathcal{F}_4$, we have chosen the following association rules to illustrate information loss:
$R1$:(Age.young)⇒(MaritalStatus.single)
$R2$:(Age.middle)⇒(WorkClass.private)
$R3$:(Age.young)⇒(WorkClass.private)
$R4$:(Age.middle)∧(WorkClass.private)⇒(NativeCountry.USA)

By analyzing the results, illustrated in Table 4, it may be remarked that:

1. Different support and confidence measures are found. This confers an uncertainty to the final decision process.

2. More important is a clear information loss materialized by the non discovery of many rules. For example, the rule $R1$ does not exist in the fuzzy context $\mathcal{F}_1$ even though this fuzzy context contains the fuzzy label *young*.

Besides, defining such fuzzy partitions may not be intuitive for humans. This is especially true for attributes where there does not exist a more or less standard linguistic vocabulary which fuzzily partition the attribute domain.

Table 4: Information loss for expert fuzzy partitioning.

	$R1$ Sup/Conf	$R2$ Sup/Conf	$R3$ Sup/Conf	$R4$ Sup/Conf
$\mathcal{F}_1$	$\not\models$	0.26/0.72	$\not\models$	0.13/0.90
$\mathcal{F}_2$	0.08/0.77	0.17/0.68	0.31/0.75	0.08/0.88
$\mathcal{F}_3$	0.05/0.98	$\not\models$	$\not\models$	0.20/0.92
$\mathcal{F}_4$	0.13/0.59	0.47/0.77	$\not\models$	0.30/0.94

where the mark $\not\models$ indicates that the rule could not be discovered since it lacks support.

3.2 Heuristic-Based Contexts Mapping

The second family of approaches deals with a particular generalization of many-valued contexts based on some heuristics depending on the nature of the context. In [16] a "single-pivot" representation is proposed. The so-called pivot is taken as the maximum value in the attribute domain. The equivalent fuzzy context is obtained by dividing the quantitative values by the maximal value of the domain, thus achieving the estimation of a fuzzy proximity to the maximum value. For example, the equivalent fuzzy representation of the attribute *Age* given in Table 1 will be: {(Alice,0.38), (Boris,0.4), (Cyril,0.51), (David,1)}. One may remark that some non uniform data distribution (e.g. with few values near the pivot and almost all values far from it) will lead to an unavoidable information loss for any knowledge discovery process.

As a summary, it appears that empirical, or heuristic-based fuzzy partitioning for data mining applications may be not well-suited. Indeed, in [20] two important stages (i.e. *Processing* and *Transformation*) are intended to get a well-suited representation for the next data mining stage. This is why, we propose a fuzzy learning stage.

4 Learning Fuzzy Partitions

The Fuzzy C-Means algorithm [21, 22] is one of the strongest and widely used fuzzy clustering method. It is based on an iterative optimization of a fuzzy objective function. This function characterizes the partition and is given as:

$$J_m(X,U,V) = \sum_{j=1}^{n}\sum_{k=1}^{c} \mu_{jk}^m \left\|x_j - v_k\right\|^2 \tag{3}$$

where $X = \{x_1, ..., x_n\}$ represents the domain to partition, $V = \{v_1, ..., v_c\}$ represents the set of cluster centers and $U = (\mu_{ki})_{n\times c}$ is the fuzzy partition matrix composed of the membership degree of each item x_j in each cluster k. The exponent m is a parameter called *fuzzifier*.

The distance measure usually used is the Euclidian distance between a datum and a prototype (cluster center). Each cluster V_k is determined as:

$$V_k = \frac{\sum_{j=1}^{n}(\mu_{jk})^m x_j}{\sum_{j=1}^{n}(\mu_{jk})^m} \tag{4}$$

Whereas the elements μ_{jk} of the fuzzy partition matrix are given as:

$$\begin{cases} \mu_{jk} = 0 & \text{if } J_j \neq \emptyset \wedge k \notin J_j \\ \sum_{k\in J_j}\mu_{jk} = 1 & \text{if } J_j \neq \emptyset \wedge k \in J_j \\ \mu_{jk} = \dfrac{1}{\sum_{l=1}^{c}\left(\frac{\|x_j - v_k\|^2}{\|x_j - v_l\|^2}\right)^{\frac{1}{m-1}}} & \text{if } J_j = \emptyset \end{cases} \tag{5}$$

with $J_j = \{k \mid 1 \leqslant k \leqslant c, \|x_j - v_k\| = 0\}$

4.1 Algorithm

The proposed algorithm integrates cluster validity measures [23] in order to obtain an optimal fuzzy partition. It takes as input a minimal (resp. maximal) number of fuzzy partitions allowed, denoted $Cmin$ (resp. $Cmax$). It takes also a fixed threshold tolerance denoted θ. The vector V contains the cluster centers and it is randomly initialized. The algorithm is given as follows:

Begin.
1: $Cmin := 2$; $Cmax := 10$;
2: $\theta := 0.001$;
3: **For** l:=$Cmin$ To $Cmax$ **Do**
4: Initialize $V^{(l)}$ randomly;
5: Compute the partition matrix $U^{(l)}$ with expression (5);
6: Compute the objective function J with (3);
7: Update the cluster centers using (4);
8: Compute the new partition matrix with (5);
9: Compute the new objective function J_{new};
10: If $(J - J_{new}) < \theta$ goto 3 else goto 7;
11: **End For**
12: Determine l s.t. $Vpc(l) = \min\left(Vpc(k)\right)_{k=Cmin,Cmax}$
13: Return $V^{(l)}$, $U^{(l)}$

ISBN: 978-989-95079-6-8

End.

Definition2.
The equivalent fuzzy representation of a quantitative attribute y corresponds to the pair $(\mathcal{F}_y, U_y)$ where:

$$\mathcal{F}_y = \{y.V_1, .., y.V_k, .., y.V_c\}$$
$$U_y\,(x_i, y.V_k) = \mu_{ik}$$

This definition means also that we have chosen to label each fuzzy cluster k by its prototype (cluster center) V_k. Considering that membership degrees to these fuzzy clusters are determined using a distance measure (i.e. Euclidian distance), the semantics attached to the discovered fuzzy association rules $Y.V_k(\overrightarrow{y}) \Rightarrow Z.V_l(\overrightarrow{z})$ is of the type: *the presence of $\overrightarrow{y}$'s near to the prototype $Y.V_k$, imply the presence of $\overrightarrow{z}$'s near to the prototype $Z.V_l$.*

4.2 Cluster validity measures

Our algorithm is implemented considering two options:
i) the end-user may specify the number c of partitions, and even the center of classes (i.e. V_1, ..., V_c),
ii) the learning algorithm determines itself the optimal number of classes using the *Vpc* validity measure as done in the above algorithm.

The partition coefficient (*Vpc*) [23] measure has been chosen since this measure is based on the subsethood degrees μ_{jk}. It is given as:

$$Vpc = \frac{1}{n}\sum_{j=1}^{n}\sum_{k=1}^{c}\mu_{jk}^2 \qquad (6)$$

5 Experimental Results

All experiments were performed on a 3.0 Ghz Pentium-IV PC with 512 MB main memory running on Microsoft Windows XP. Algorithms were implemented in C++.

The fuzzy association rules mining algorithm is an A-PRIORI like implementation. Cardinalities of fuzzy sets are computed using a $\Sigma-$count operator. While conjunction in expressions of support and confidence, resp. (1) and (2), is performed using the *min* operator. We have also considered weighted $\alpha-cuts$ for computing support and confidence measures which avoids accumulation of small (irrelevant) cardinalities. The reader is referred to [13] for complete details.

Experiments were performed on the *Adult* database (see section §3.1.). Many objects in the *Adult* context contain missing (null) values. Such objects have been deleted from the initial context which reduces the size of the considered context to 32561 objects. The probability distribution for the *Age* attribute is represented in Fig. 5.

Our fuzzy partition learning process for the *Age* attribute yields two fuzzy clusters and induces the partition:

$$\mathcal{F}_{age} = \{age.25, age.43\}$$

where 25 and 43 correspond to the prototypes (cluster centers). The complete partition is showed in Fig. 6.

According to the partition $\mathcal{F}_{age}$, we show below some new fuzzy association rules that are now discovered.

(Age.25)∧(Workclass.*Private*)⇒(NativeCountry.*USA*)
[support=0.32;confidence=0.89]

(Age.25)∧(Workclass.*Private*)∧(NativeCountry.*USA*)⇒
(Salary_Class.*LeastThan50K$*) [support=0.31;confidence=1]

(Age.43)⇒(Workclass.*Private*)
[support=0.24;confidence=0.69]

(Age.25)⇒(Workclass.*Private*)
[support=0.35;confidence=0.94]

(Age.43)∧(Workclass.*Private*)⇒(NativeCountry.*USA*)
[support=0.32;confidence=0.89]

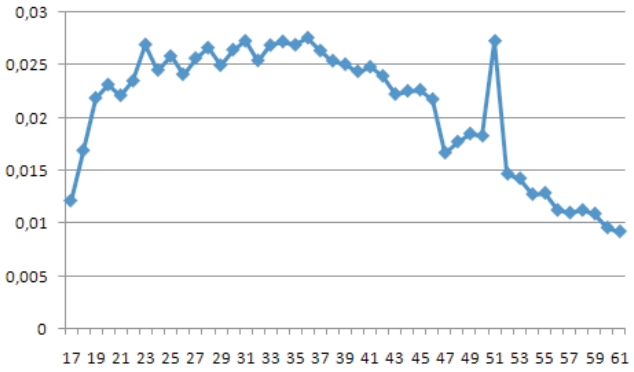

Figure 5: Probability distribution for *Age* attribute in *Adult* context.

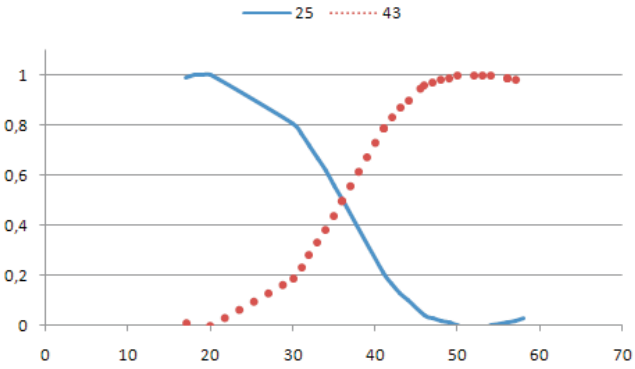

Figure 6: The learned fuzzy partition for *Age* attribute in *Adult* context.

It has been checked that, related to the prototypes, almost all rules are now discovered. For instance, the fourth above rule is a counterpart of the rule $R3$ ((Age.young)⇒(WorkClass.private)), which was not found using the three partitions $\mathcal{F}_1$, $\mathcal{F}_3$, $\mathcal{F}_4$.

6 Conclusion and Perspectives

This paper deals with the transformation stage in a knowledge discovery process. An automatic approach is proposed for the mapping of a many-valued context into a fuzzy context. This mapping is achieved using a fuzzy clustering method. The difficulties of humans for determining fuzzy partitions and fuzzy grades are avoided, which makes things easier for end-users in real life applications. The Fuzzy C-Means algorithm has been

ISBN: 978-989-95079-6-8

chosen as a strong means to get optimized fuzzy partitions. Besides experimental results show that the proposed approach avoids information loss, which departs from the results of almost all existing approaches.

As a first perspective, we intend to enlarge the fuzzy partitions setting by allowing a hierarchical clusters representation. Similar ideas were already explored at least in two different ways. Wolff in [24] proposes a so-called conceptual scale theory which handles many-valued (quantitative) attributes in a fuzzy setting without being restricted to particular subsets (singletons or definite intervals). Bosc et al. in [25] have outlined a knowledge extraction method based on the idea on the fuzzy summarization of data, which may also be used in order to cluster data in a hierarchical-like way.

As pointed out in [26] fuzzy association rules may be also of interest for their increased expressivity. That's why, we intend secondly to investigate other semantics than co-occurrence, namely the one of gradual and certainty rules.

Lastly, it is worth of interest to enlarge fuzzy contexts to incomplete information fuzzy contexts (i.e. with unknown values) [27],[28].

Abstract— *In this paper a wide class of sequencing problems with imprecise parameters is discussed. The imprecision is modeled by using closed intervals and fuzzy intervals, whose membership functions are regarded as possibility distributions for the values of unknown parameters. A possibilistic interpretation of fuzzy problems is provided, some solution concepts are proposed and some algorithms for computing the solutions are designed.*

Keywords— Sequencing, min-max regret, possibility theory, fuzzy interval, fuzzy optimization and design

1 Introduction

In a sequencing problem we wish to find a feasible order of elements, called jobs, to achieve some goal. This goal typically depends on job completion times and may also depend on some other job parameters such as due dates or weights. There are a lot of deterministic sequencing problems with different computational properties and a comprehensive description of them can be found for instance in [1]. Unfortunately, most of sequencing problems turned out to be NP-hard but there are also some important problems for which efficient polynomial algorithms exist.

Sequencing problems involve many parameters whose exact values are often unknown. For instance, a job processing time, which is a crucial parameter in all sequencing problems, is rarely precisely known. In order to model such a situation a stochastic approach can be applied (see e.g. [2]), where for every unknown parameter a probability distribution is specified and, typically, the expected cost of a solution is minimized. The stochastic approach has several drawbacks. Namely, it may be hard or expensive to estimate the probability distributions for the parameters. Also, minimizing the expected performance may be not reasonable if the obtained solution is used only once.

In practice, decision makers are often interested in minimizing the cost of a decision in the worst case, that is under the worst realization of parameters that may occur. In recent years a *robust* approach do discrete optimization has attracted a considerable attention. In this approach we specify a *scenario set* containing all possible realizations of parameters which may occur. No probability distribution over the scenario set is given. One of methods of determining the scenario set consists of specifying an interval of possible values for every unknown parameter. A scenario set is then the Cartesian product of all the uncertainty intervals. A natural criterion for choosing a solution under imprecision is the *maximal regret*, which expresses the maximum distance of a solution from optimality over all scenarios [3]. A deeper discussion on using the maximal regret criterion in decision making under uncertainty can be found in [4]. The class of min-max regret sequencing problem with interval parameters has been discussed in a number of papers, for instance in [5, 6, 7, 8, 9, 10, 11, 12]. We briefly describe the known results in this area later in this paper.

In recent years, theory of fuzzy sets has been applied to model the imprecision in optimization, in particular in sequencing problems. A good review of different concepts in fuzzy optimization can be found in [13]. In papers [14, 15, 16] some single machine sequencing problems with fuzzy processing times, fuzzy due dates and fuzzy precedence constraints have been discussed. In these papers a fuzzy due date expresses a degree of satisfaction with job completion time and a sequence is computed, which maximizes the minimum satisfaction or the sum of satisfactions over all jobs. In [17] an alternative approach has been proposed, where the possibility or necessity of job delays is minimized. Also, in [18] an optimality evaluation of sequences under fuzzy parameters has been investigated. We recall and extend this approach here.

In this paper we wish to propose a new approach to sequencing problems with fuzzy parameters. We generalize the min-max regret problems with interval parameters to the fuzzy case by extending the interval uncertainty representation to the fuzzy interval one. The fuzzy parameters induce a possibility distribution over the scenario set, which becomes then reacher in information than the classical scenario set. We provide a possibilistic interpretation of the obtained fuzzy problem and describe a solution concept, which is an adaptation of the elegant solution method proposed in [19] for fuzzy linear programming. This solution concept has been recently adopted in [20] for a class of combinatorial optimization problems. Apart from showing a general framework, we also point out some difficulties which arise when one try to solve a particular problem. Contrary to the class of combinatorial optimization problems described in [20], the sequencing problems are typically more complex to solve and there are very few general properties that are valid for all problems. However, as for the problems described in [20], the main computational difficulties are in the classical interval case and the algorithms known for the interval uncertainty representation can be generalized to the fuzzy case.

This paper is organized as follows. In Section 2 we recall the definition of the classical deterministic sequencing problem. In Section 3 we present the min-max regret approach to sequencing problems with interval parameters - we provide a

ISBN: 978-989-95079-6-8

general formulation and we recall some known results in this area. Finally, in Section 4 we introduce the class of sequencing problems with fuzzy parameters. We give a link between the fuzzy problems and the min-max regret ones. We construct some general methods of solving a fuzzy problem and we illustrate them using a sample problem.

2 Deterministic sequencing problems

We are given a set of *jobs* $J = \{J_1, \ldots, J_n\}$, which may be partially ordered by some *precedence constraints* of the form $i \rightarrow j$, where $i, j \in J$. For the simplicity of notations we will identify every job $J_i \in J$ with its index $i \in \{1, \ldots, n\}$. A solution is a *sequence* (permutation) $\sigma = (\sigma(1), \ldots, \sigma(n))$ of J and it represents an order in which the jobs are processed. A sequence σ is *feasible* if $i \rightarrow j$, $i \neq j$, implies that job j appears after i in σ. We will denote by $\boldsymbol{\mathcal{S}}$ the set of all feasible sequences. We use $C_i(\sigma)$ to denote the *completion time* of job i in sequence σ. In a *single machine* case, a processing time p_i is given for every job $i \in J$ and if $i = \sigma(k)$, then $C_i(\sigma) = \sum_{j=1}^{k} p_{\sigma(j)}$. If every job must be processed on $m > 1$ machines, first on machine 1 next on machine 2 and so on, then we get the *permutation flow shop problem*. In this case p_{ij} is a processing time of job i on machine j and $C_i(\sigma)$ is the time when job i is finished on the m-th machine (see Figure 1).

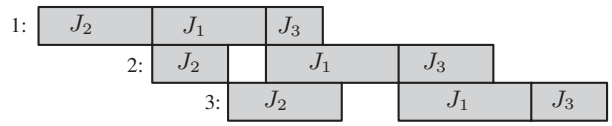

Figure 1: A permutation flow show problem with $m = 3$, $n = 3$ and the schedule that corresponds to the sequence $(2, 1, 3)$.

For every job $i \in J$, there is a cost function $f_i : R \rightarrow R$, which measures the cost of completing i at time t. The value of this function may depend on some other parameters associated with job i such as *due date* d_i or *weight* w_i. Finally, $F(\sigma)$ denotes a cost of sequence σ. There are two general types of the cost function $F(\sigma)$, namely a *bottleneck objective* $F(\sigma) = \max_{i=1,\ldots,n} f_i(C_i(\sigma))$ and a *sum objective* $F(\sigma) = \sum_{i=1}^{n} f_i(C_i(\sigma))$.

In a deterministic sequencing problem we seek a feasible sequence of the minimal cost, that is we solve the following optimization problem:

$$\min_{\sigma \in \boldsymbol{\mathcal{S}}} F(\sigma). \tag{1}$$

Our analysis in the next sections of this paper will be based on the concept of a *deviation*. In the deterministic case the deviation of a sequence σ expresses its distance to optimum and is defined as follows:

$$\delta_\sigma = F(\sigma) - \min_{\rho \in \boldsymbol{\mathcal{S}}} F(\rho). \tag{2}$$

Obviously, σ is optimal if and only if $\delta_\sigma = 0$. If the deviation is positive, then it indicates a distance of σ from optimality.

Sequencing problems are usually described by using a convenient Graham's notation. So, every sequencing problem can be denoted by a triple $\alpha|\beta|\gamma$, where α is the machine environment ($\alpha = 1$ for the single machine case), β specifies the job characteristic and γ describes the objective function. The following examples of sequencing problems are well known and will be explored later in this paper:

- $1|prec|L_{max}$. In this problem we seek a sequence, which minimizes the maximum *lateness*. So, the bottleneck objective is $\max_{i \in J}\{C_i(\sigma) - d_i\}$. We can generalize this problem by minimizing the maximal weighted lateness or modify it to minimize the maximal weighted *tardiness* (see [1]).

- $1||\sum C_i$. In this problem there are no precedence constraints between jobs and we seek a sequence for which the sum of completion times of all jobs, i.e. the *total flow time* $\sum_{i \in J} C_i(\sigma)$, is minimal.

- $1|p_i = 1|\sum w_i U_i$. In this problem there are no precedence constraints between jobs and all jobs have unit processing times. A job is *late* in σ if $C_i(\sigma) > d_i$. In this case we write $U_i(\sigma) = 1$ and $U_i(\sigma) = 0$ otherwise. The cost of σ is $\sum_{i \in J} w_i U_i(\sigma)$, so it expresses the weighted number of late jobs.

- $Fm||C_{max}$. This is the permutation flow shop problem with $m > 1$ machines. There are no precedence constraints between jobs and the bottleneck cost of σ is the *makespan* $\max_{i \in J} C_i(\sigma)$, that is the completion time of the last job on the last machine. The problem is polynomially solvable only if $m = 2$ and becomes NP-hard for $m \geq 3$ (see [1]).

The above examples illustrate a large variety of basic sequencing models. As we will see in the next section, they have quite different computational properties under imprecision and the state of the art in this area is still far from being complete.

3 Minmax regret sequencing problems

In practice, the exact values of parameters in a sequencing problem such as processing times, due dates or weights may be not precisely known. Assume that we have l parameters and the value of a parameter ξ_i, $i = 1, \ldots, l$, may fall within a closed interval $[\underline{\xi}_i, \overline{\xi}_i]$ independently of the values of the other parameters. A parameter ξ_i is *precise* if $\underline{\xi}_i = \overline{\xi}_i$. Every vector $S = (s_1, \ldots, s_l) \in R^l$ such that $s_i \in [\underline{\xi}_i, \overline{\xi}_i]$ is called a *scenario* and it expresses a possible state of the world, where $\xi_i = s_i$ for $i = 1, \ldots, l$. A scenario is called *extreme* if all parameters take the lower or upper bounds in their uncertainty intervals. We use Γ to denote the set of all possible scenarios. Hence Γ is the Cartesian product of all the uncertainty intervals. Now the cost of a sequence σ depends on scenario $S \in \Gamma$ and we will denote it as $F(\sigma, S)$. We will also denote by $F^*(S)$ the cost of an optimal sequence under scenario S. In order to obtain the value of $F^*(S)$ we need to solve problem (1) under the fixed realization of parameters S. It is clear that deviation of σ also depends on scenario S and we will denote it as $\delta_\sigma(S) = F(\sigma, S) - F^*(S)$.

Now the optimality of a sequence σ can be characterized by a *deviation interval* $[\underline{\delta}_\sigma, \overline{\delta}_\sigma]$, where $\underline{\delta}_\sigma = \min_{S \in \Gamma} \delta_\sigma(S)$ is the minimal deviation and $\overline{\delta}_\sigma = \max_{S \in \Gamma} \delta_\sigma(S)$ is the maximal deviation over all scenarios. The quantity $\overline{\delta}_\sigma$ is called in

ISBN: 978-989-95079-6-8

literature the *maximal regret* of σ and it expresses the largest distance of σ from optimum over the scenario set Γ. A scenario S_σ, for which the deviation of σ attains maximum, is called a *worst case scenario* for σ. So, under the interval uncertainty representation, we only know that $\delta_\sigma \in [\underline{\delta}_\sigma, \overline{\delta}_\sigma]$ and we can give the following characterization of a feasible sequence: a sequence σ is *possibly optimal* if $\underline{\delta}_\sigma = 0$ and it is *necessarily optimal* if $\overline{\delta}_\sigma = 0$. Notice that a sequence is possibly optimal if and only if it is optimal under some scenario $S \in \Gamma$ and it is necessarily optimal if and only if it is optimal for all scenarios $S \in \Gamma$.

Now the question arises which sequence of $\boldsymbol{\mathcal{S}}$ should be chosen. A necessarily optimal one is a natural choice. However, it rarely exists in most practical situations, because the necessary optimality is very strong criterion. In a more reasonable approach we can minimize the the maximal regret, that is the quantity $\overline{\delta}_\sigma$, which may be viewed as a distance to the necessary optimality. As a result we get the following *min-max regret sequencing problem*:

$$\min_{\sigma \in \boldsymbol{\mathcal{S}}} \overline{\delta}_\sigma. \tag{3}$$

We call an optimal solution to (3) a *min-max regret sequence*. In the next section we briefly review some known facts on problem (3).

3.1 Complexity of min-max regret sequencing problems

The first problem that arises while analyzing a particular min-max regret sequencing problem is the computation of the maximal regret for a given sequence σ, that is the quantity $\overline{\delta}_\sigma$. Unfortunately, contrary to the class of problems discussed in [20], there is no general method of performing this task. For the problems considered in [20], it is possible to find two extreme scenarios that maximize and minimize the deviation and, consequently, the computation of the maximal regret has the same complexity as the deterministic problem. For sequencing problems the situation is much more complex. First of all, for some problems there may be no extreme scenario that maximizes (minimizes) the deviation [21]. Furthermore, computing the maximal regret may be much more time consuming than solving a deterministic problem. For instance, in the min-max regret $1||\sum C_i$ problem with interval processing times, computing $\overline{\delta}_\sigma$ requires solving an assignment problem while an optimal sequence under a given scenario can be computed in $O(n \log n)$ time. An extreme case has been described in [9], where a permutation flow shop problem with m machines and with interval processing times and with only 2 jobs has been discussed. Since the solution set contains only two sequences, the total computational effort is focused on computing the maximal regret of a given sequence.

It is not surprising that min-max regret sequencing problems are typically hard to solve. There are only several problems that are known to be polynomially solvable. A polynomial algorithm for $1|prec|L_{max}$ with interval processing times and interval due dates has been constructed in [6]. A polynomial algorithm for $1|prec|\max w_i T_i$ with interval weights and precise processing times and precise due dates has been proposed in [8]. Apart from this two problems, only some very special cases are known to be polynomially solvable, for instance $Fm||C_{max}$ with interval processing times and only two jobs [9] and $1|p_i = 1|\sum w_i U_i$ with interval weights and a precise common due date ($d_1 = d_2 = \cdots = d_n$) [21]. This latter problem is equivalent to the min-max regret version of the selecting items problem, which is known to be polynomially solvable [21, 22].

Among the known negative results, the most important one has been obtained in [10], where it has been shown that the min-max regret $1||\sum C_i$ problem with interval processing times is NP-hard. This problem is also known to be approximable within 2 [12] and can be solved by using a mixed integer programming formulation proposed in [11]. However, the complexity status of a number of basic problems is still unknown. We do not know whether $F2||C_{max}$ with interval processing times is NP-hard. We can, however, compute the maximal regret of a given sequence and solve the problem by using a branch and bound algorithm [7, 3]. Also the problem $1|p_i = 1|\sum w_i U_i$ with interval weights and arbitrary precise due dates and the problem $1|prec|\max w_i L_i$ with interval processing times, interval due dates and precise weights are open. The former problem can be solved by a mixed integer programming formulation [21]. There are also a large number of different sequencing problems whose min-max regret versions have never been investigated and they should be the subjects of further research.

4 Fuzzy sequencing problems

In this section we propose an extension of the min-max regret approach to sequencing problems. We will apply fuzzy intervals to model the imprecise parameters and we will use possibility theory to define a solution concept. A comprehensive description of possibility theory can be found in [23].

4.1 Basic notions on possibility theory

A *fuzzy interval* $\tilde{A}$ is a fuzzy set in the space of reals whose membership function $\mu_{\tilde{A}}$ is normal, quasi concave and upper semicontinuous. It is typically assumed that the support of a fuzzy interval is compact. The main property of a fuzzy interval is the fact that all its λ-cuts, that is the sets $\tilde{A}^\lambda = \{x : \mu_{\tilde{A}}(x) \geq \lambda\}$, $\lambda \in (0, 1]$, are closed intervals. We will assume that $\tilde{A}^0$ is the smallest closed set containing the support of $\tilde{A}$. So, every fuzzy interval $\tilde{A}$ can be represented as a family of closed intervals $\tilde{A}^\lambda = [\underline{a}^\lambda, \overline{a}^\lambda]$, parametrized by the value of $\lambda \in [0, 1]$. In many practical applications, the class of *trapezoidal fuzzy intervals* is used. A trapezoidal fuzzy interval, denoted by a quadruple $(\underline{a}, \overline{a}, \alpha, \beta)$, can be represented as the family $[\underline{a} - \alpha(1 - \lambda), \overline{a} + \beta(1 - \lambda)]$ for $\lambda \in [0, 1]$. Notice that this representation contains classical intervals ($\alpha = \beta = 0$) and real numbers (additionally $\underline{a} = \overline{a}$) as special cases.

In this paper we adopt a possibilistic interpretation of a fuzzy interval [23]. Assume that for an imprecise real quantity ξ a fuzzy interval with membership function μ_ξ is given. This membership function expresses a *possibility distribution* for the values of ξ, namely $\Pi(\xi = x) = \mu_\xi(x)$ is the possibility of the event that ξ will take the value of x. It is easily seen that the closed interval $[\underline{\xi}^\lambda, \overline{\xi}^\lambda]$, $\lambda \in [0, 1]$, contains all values of ξ, whose possibility of occurrence is not less than λ. In particular, the interval $[\underline{\xi}^0, \overline{\xi}^0]$ should contain all possible values of ξ, while the interval $[\underline{\xi}^1, \overline{\xi}^1]$ should contain the most plausible ones. Some methods of obtaining the possibility distribution of an unknown quantity can be found in [23].

ISBN: 978-989-95079-6-8

Let $\tilde{G}$ be a fuzzy set in the space of reals with membership function $\mu_{\tilde{G}}$. Then $\xi \in \tilde{G}$ is a *fuzzy event* and the necessity that $\xi \in \tilde{G}$ holds is defined in the following way:

$$\begin{aligned} \mathrm{N}(\xi \in \tilde{G}) &= 1 - \Pi(\xi \notin \tilde{G}) = \\ &= 1 - \sup_{x \in R} \min\{\mu_{\xi}(x), 1 - \mu_{\tilde{G}}(x)\} \end{aligned} \tag{4}$$

where $1 - \mu_{\tilde{G}}(x)$ is the membership function of the complement of the fuzzy set $\tilde{G}$. It is not difficult to see that if $\tilde{G} = (0, \overline{g}, 0, \beta) = (\overline{g}, \beta)$, then the following equality is true:

$$\mathrm{N}(\xi \in \tilde{G}) = 1 - \inf_{\lambda \in [0,1]} \{\overline{\xi}^{\lambda} \leq \overline{g}^{1-\lambda}\} \tag{5}$$

and $\mathrm{N}(\xi \in \tilde{G}) = 0$ if $\overline{\xi}^{1} > \overline{g}^{0}$. Equality (5) is illustrated in Figure 2.

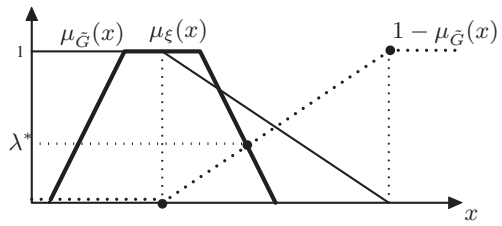

Figure 2: $\mathrm{N}(\xi \in \tilde{G}) = 1 - \lambda^*$.

4.2 Possibilistic sequencing problem

Assume that for every unknown parameter ξ_i, $i = 1, \ldots, l$, in a sequencing problem a fuzzy interval with membership function μ_{ξ_i} is specified. According to the interpretation given in the previous section μ_{ξ_i} is a possibility distribution for the values of ξ_i. Under the assumption that all parameters are unrelated, there is a possibility distribution over all scenarios $S = (s_1, \ldots, s_l) \in R^l$ defined as follows:

$$\begin{aligned} &\pi(S) = \Pi\left(\bigwedge_{i=1}^{l} [\xi_i = s_i]\right) = \min_{i=1,\ldots,l} \Pi(\xi_i = s_i) = \\ &= \min_{i=1,\ldots,l} \mu_{\xi_i}(s_i). \end{aligned} \tag{6}$$

So, the value of $\pi(S)$ express the possibility of the event that scenario S will occur. Notice that we generalize in this way the scenario set $\Gamma \subset R^l$ described in Section 3. Indeed, for the interval uncertainty representation $\pi(S) = 1$ if $S \in \Gamma$ and $\pi(S) = 0$ otherwise. In the fuzzy case $\pi(S)$ may take any value in the interval $[0, 1]$ so fuzzy intervals allow us to model the imprecision in a more sophisticated manner.

In the interval case the value of deviation δ_{σ} falls within a closed interval. Analogously, in the fuzzy case it falls within a fuzzy interval with membership function $\mu_{\delta_{\sigma}}$. Of course, $\mu_{\delta_{\sigma}}$ is a possibility distribution for the values of δ_{σ} and, according to possibility theory, it is defined as follows:

$$\mu_{\delta_{\sigma}}(x) = \Pi(\delta_{\sigma} = x) = \sup_{\{S:\ \delta_{\sigma}(S) = x\}} \pi(S). \tag{7}$$

Recall that the statement "'σ is optimal"' is equivalent to the assertion $\delta_{\sigma} = 0$. Consequently, we can define the degrees of possible and necessary optimality of a given sequence as follows:

$$\Pi(\sigma \text{ is optimal}) = \Pi(\delta_{\sigma} = 0) = \mu_{\delta_{\sigma}}(0), \tag{8}$$

$$\mathrm{N}(\sigma \text{ is optimal}) = \mathrm{N}(\delta_{\sigma} = 0) = 1 - \sup_{x > 0} \mu_{\delta_{\sigma}}(x). \tag{9}$$

As in the interval case, a question arises which sequence should be chosen. In order to perform this task we adopt a concept first applied to fuzzy linear programming in [19]. Assume that a decision maker knows his/her preference about the sequence deviation and expresses it by using a fuzzy interval $\tilde{G} = (\overline{g}, \beta)$. So, the values of deviation in $[0, \overline{g}]$ are fully accepted, the values in $[\overline{g} + \beta, \infty)$ are not at all accepted and the degree of acceptance decreases from 1 to 0 in $[\overline{g}, \overline{g} + \beta]$. Our aim is to compute a feasible sequence $\sigma \in \boldsymbol{\mathcal{S}}$, for which the necessity of the event $\delta_{\sigma} \in \tilde{G}$ is maximal, namely we wish to solve the following optimization problem:

$$\max_{\sigma \in \boldsymbol{\mathcal{S}}} \mathrm{N}(\delta_{\sigma} \in \tilde{G}). \tag{10}$$

This solution concept has been first proposed for linear programming problem with fuzzy objective function coefficients [19]. Observe that (10) can also be expressed as $\min_{\sigma \in \boldsymbol{\mathcal{S}}} \Pi(\delta_{\sigma} \in \tilde{G}^d)$, where $\tilde{G}^d$ is the complement of the fuzzy goal $\tilde{G}$ with membership function $1 - \mu_{\tilde{G}}(x)$. If we fix $\tilde{G} = (0, 0)$ in (10), then we get a special case, in which we seek a feasible sequence that maximizes the degree of necessary optimality:

$$\max_{\sigma \in \boldsymbol{\mathcal{S}}} \mathrm{N}(\delta_{\sigma} = 0) = \max_{\sigma \in \boldsymbol{\mathcal{S}}} \mathrm{N}(\sigma \text{ is optimal}). \tag{11}$$

We focus now on a method of solving the problem (10). According to equality (5), the problem (10) is equivalent to the following optimization problem:

$$\begin{aligned} &\min \lambda \\ &\overline{\delta}_{\sigma}^{\lambda} \leq \overline{g}^{1-\lambda} \\ &\sigma \in \boldsymbol{\mathcal{S}} \\ &\lambda \in [0, 1] \end{aligned} \tag{12}$$

If λ^* is the optimal objective value and σ^* is an optimal solution to (12), then $\mathrm{N}(\delta_{\sigma^*} \in \tilde{G}) = 1 - \lambda^*$. If (12) is infeasible, then $\mathrm{N}(\delta_{\sigma} \in \tilde{G}) = 0$ for all feasible sequences σ. Of course, if we replace expression $\overline{g}^{1-\lambda}$ with 0 in (12), then we get an equivalent formulation of the problem (11).

Let us focus now on the quantity $\overline{\delta}_{\sigma}^{\lambda}$. The closed interval $[\underline{\delta}_{\sigma}^{\lambda}, \overline{\delta}_{\sigma}^{\lambda}]$, $\lambda \in [0, 1]$, contains all values of deviation δ_{σ}, whose possibility of occurrence is not less than λ. So

$$\overline{\delta}_{\sigma}^{\lambda} = \sup_{\{S\,:\,\pi(S) \geq \lambda\}} \{F(\sigma, S) - F^*(S)\} \tag{13}$$

is the greatest deviation of σ, whose possibility of occurrence is not less than λ. From the definition of $\pi(S)$ it is easy to see that $\{S:\ \pi(S) \geq \lambda\} = [\underline{\xi}_1^{\lambda}, \overline{\xi}_1^{\lambda}] \times \cdots \times [\underline{\xi}_l^{\lambda}, \overline{\xi}_l^{\lambda}] = \Gamma^{\lambda}$. Consequently, the quantity $\overline{\delta}_{\sigma}^{\lambda}$ is the maximal regret of σ in the min-max regret version of the problem with scenario set Γ^{λ}. In particular, the condition $\overline{\delta}_{\sigma}^{\lambda} \leq 0$ means that σ is necessarily optimal under Γ^{λ}.

ISBN: 978-989-95079-6-8

Let us point out that the fuzzy problem is not simpler than the corresponding min-max regret one. Indeed, the interval uncertainty representation is a special case of the fuzzy one. If we additionally fix $\tilde{G} = (0, M)$ for a sufficiently large M, then the fuzzy problem is equivalent to the min-max regret one.

Observe that $\overline{\delta}_\sigma^\lambda$ is a nonincreasing and $\overline{g}^{1-\lambda}$ is a nondecreasing function of λ. In consequence, the problem (12) can be solved be a standard binary search technique if we only can decide somehow whether there is a feasible sequence $\sigma \in \boldsymbol{\mathcal{S}}$ fulfilling inequality $\overline{\delta}_\sigma^\lambda \leq \overline{g}^{1-\lambda}$ for a fixed $\lambda \in [0, 1]$. This task is easy if we have an algorithm for the corresponding min-max regret sequencing problem with interval parameters. Solving this problem for scenario set Γ^λ we get a min-max regret sequence σ^*. Then $\overline{\delta}_\sigma^\lambda \leq \overline{g}^{1-\lambda}$ for some $\sigma \in \boldsymbol{\mathcal{S}}$ if and only if $\overline{\delta}_{\sigma^*}^\lambda \leq \overline{g}^{1-\lambda}$. Notice that in the problem (11) it is enough to detect a necessarily optimal sequence for scenario set Γ^λ, which may be computationally easier than solving the min-max regret problem. The binary search algorithm is shown in Figure 3.

1: Find a min-max regret sequence σ under Γ^1
2: **if** $\overline{\delta}_\sigma^1 > \overline{g}^0$ **then return** $\emptyset$
3: $\lambda_1 \leftarrow 0.5$, $k \leftarrow 1$, $\lambda_2 \leftarrow 0$
4: **while** $|\lambda_1 - \lambda_2| \geq \epsilon$ **do**
5: $\quad\lambda_2 \leftarrow \lambda_1$
6: $\quad$Find a min-max regret sequence ρ under Γ^{λ_1}
7: $\quad$**if** $\overline{\delta}_\rho^{\lambda_1} \leq \overline{g}^{1-\lambda_1}$ **then**
8: $\quad\quad\lambda_1 \leftarrow \lambda_1 - 1/2^{k+1}$, $\sigma \leftarrow \rho$
9: $\quad$**else**
10: $\quad\quad\lambda_1 \leftarrow \lambda_1 + 1/2^{k+1}$
11: $\quad$**end if**
12: $\quad k \leftarrow k + 1$
13: **end while**
14: **return** σ

Figure 3: Solving the problem (10) with a given precision $\epsilon \in (0, 1)$. Algorithm returns $\emptyset$ if $\mathrm{N}(\delta_\sigma \in \tilde{G}) = 0$ for all $\sigma \in \boldsymbol{\mathcal{S}}$.

It is easy to check that if the min-max regret problem with interval parameters can be solved in $f(n)$ time, then the corresponding fuzzy problem is solvable in $O(f(n) \log \epsilon^{-1})$ time. W thus can see that the problem with fuzzy parameters boils down to solving a small number of min-max regret sequencing problems. So, every exact algorithm for the min-max regret problem can easily be adopted for the more general fuzzy case. In [6] a polynomial algorithm for the min-max regret $1|prec|L_{max}$ problem with interval processing times and interval due dates has been constructed. Consequently, the fuzzy $1|prec|L_{max}$ problem is solvable efficiently as well because we can use this algorithm as a subroutine in the binary search.

The binary search algorithm is the most general method of solving the fuzzy problem which, however, requires a given precision of calculations. The formulation (12) sometimes allows us to design an exact algorithm based on a mixed integer programming (MIP) formulation. The obtained MIP model can be then solved by using some standard packages such as CPLEX or GLPK. We will show an example in the next section.

4.3 The fuzzy problem $1||\sum C_i$

Assume that for every job $i \in J$, a fuzzy processing time with possibility distribution μ_{p_i} is given. A scenario in this problem is a particular realization of the processing times. The cost of a sequence σ under S is the total flow time, that is the sum of job completion times. Under a given processing times scenario S, an optimal sequence can be obtained in $O(n \log n)$ time by ordering the jobs with respect to nondecreasing processing times [1].

We first show that the problem of computing the most necessarily optimal sequence, i.e. the problem (11), is efficiently solvable. Let us fix $\lambda \in [0, 1]$ and consider the min-max regret $1||\sum C_i$ problem with interval processing times specified by scenario set $\Gamma^\lambda = [\underline{p}_i^\lambda, \overline{p}_i^\lambda] \times \cdots \times [\underline{p}_n^\lambda, \overline{p}_n^\lambda]$. Consider a scenario $S \in \Gamma^\lambda$ such that under this scenario the processing times are $\frac{1}{2}(\underline{p}_i^\lambda + \overline{p}_i^\lambda)$ for $i \in J$. We can compute in $O(n \log n)$ time and optimal sequence ρ under S. It turns out that $\overline{\delta}_\rho^\lambda \leq 2\overline{\delta}_\sigma^\lambda$ for all sequences σ (see [20]). In consequence, if there is a necessarily optimal sequence σ such that $\overline{\delta}_\sigma^\lambda = 0$, then ρ must also be necessarily optimal. We thus have an efficient method of detecting a necessarily optimal sequence and the problem (11) can be solved in $O(n \log n \log \epsilon^{-1})$ time by using the binary search shown in Figure 3.

We now focus on the more general problem (10). Unfortunately, this problem is NP-hard because the corresponding min-max regret problem with interval processing times is NP-hard [10]. Using the formulation (12) we will show that it is possible to design a mixed integer linear programming model to solve the fuzzy problem. Let $\mathcal{A}$ be the set of all binary vectors (x_{ij}), $i = 1, \ldots, n$, $j = 1 \ldots, n$, fulfilling the so called *assignment constraints*, that is $\sum_{i=1}^n x_{ij} = 1$ for all $j = 1, \ldots, n$ and $\sum_{j=1}^n x_{ij} = 1$ for all $i = 1, \ldots, n$. A vector $(x_{ij}) \in \mathcal{A}$ represents a sequence σ in which $x_{ij} = 1$ if job $i \in J$ occupies position j in σ. Obviously, there is one to one correspondence between the sequences of the set of jobs J and the vectors in $\mathcal{A}$ (recall that there are no precedence constraints in J). If $(x_{ij}) \in \mathcal{A}$ corresponds to sequence σ, then the maximal regret of σ under scenario set Γ^λ can be computed in the following way [3, 11]:

$$\overline{\delta}_\sigma^\lambda = \max_{(z_{ij}) \in \mathcal{A}} \sum_{i=1}^n \sum_{j=1}^n c_{ij}^\lambda z_{ij}, \tag{14}$$

where

$$c_{ij}^\lambda = \overline{p}_i^\lambda \sum_{k=1}^{j} (j-k) x_{ik} + \underline{p}_i^\lambda \sum_{k=j+1}^{n} (j-k) x_{ik}. \tag{15}$$

Observe that (14) is an assignment problem. We can construct the dual to (14) and it is well known that this dual has the same optimal objective function value as (14). So, it holds:

$$\begin{aligned} \overline{\delta}_\sigma^\lambda = \quad & \min \sum_{i=1}^n \alpha_i + \sum_{i=1}^n \beta_i \\ & \alpha_i + \beta_j \geq c_{ij}^\lambda \text{ for } i, j = 1, \ldots, n \end{aligned} \tag{16}$$

where α_i and β_i, $i = 1, \ldots, n$, are unrestricted dual variables associated with the assignment constraints. Now, using formulation (12), we can represent the fuzzy problem in the fol-

ISBN: 978-989-95079-6-8

lowing way:

$$\begin{array}{l} \min \lambda \\ \sum_{i=1}^{n} \alpha_i + \sum_{i=1}^{n} \beta_i \leq \overline{g}^{1-\lambda} \\ \alpha_i + \beta_j \geq c_{ij}^{\lambda} \text{ for } i,j = 1,\ldots,n \\ (x_{ij}) \in \mathcal{A} \\ \lambda \in [0,1] \end{array} \tag{17}$$

where c_{ij}^{λ} are given as (15). If trapezoidal fuzzy intervals $(\underline{p}_i, \overline{p}_i, \alpha_i, \beta_i)$, $i = 1,\ldots,n$, are used to model the processing times, then we can substitute $\overline{p}_i^{\lambda} = \overline{p}_i + (1-\lambda)\beta_i$ and $\underline{p}_i^{\lambda} = \underline{p}_i - (1-\lambda)\alpha_i$ in (15). The resulting model will be still not linear because some expressions of the form λx_{ij} will appear. However, we can easily linearize the model by substituting $t_{ij} = \lambda x_{ij}$ and adding additional constraints $t_{ij} - x_{ij} \leq 0$, $\lambda - t_{ij} + x_{ij} \leq 0$, $-\lambda + t_{ij} \leq 0$, $t_{ij} \geq 0$ for all $i,j = 1,\ldots,n$. Hence the resulting model is a mixed integer linear one and can be solved by using an available software. We refer the reader to [11] for some techniques that allow us to refine the formulation and speed up the computations.

5 Conclusions

In this paper we have adopted a general approach to sequencing problems with fuzzy parameters. We have applied possibility theory to model the imprecise parameters and to define a solution concept. We have extended the approach used in [19] and [20] to another class of problems. As in many fuzzy problems, the main computational difficultly is in the classical interval case. Namely, every exact algorithm that computes a min-max regret sequence under interval data can be easily adopted to solve the fuzzy problem. One can use a binary search method or try to design a mixed integer programming model.

Unfortunately, the min-max regret sequencing problems with interval data are mostly hard to solve. There are only few problems that are known to be polynomially solvable and the complexity of some important problems, such as the permutation flow shop on two machines, remains open. Contrary to the class of problems discussed in [20], there is also lack of general properties of the min-max regret sequencing problems. Specifically, there is no general method of computing the maximal regret of a given sequence and there are no general relationships between the optimality evaluation and the min-max regret sequences. In other words, every sequencing problem possesses its own properties and the area of research in this field is still not fully explored.

1 Introduction

Fuzzy systems are one of the best known applications of fuzzy logic. These are usually based on a set of fuzzy rules. Systems using fuzzy rules have been applied in a wide variety of applications, viz., automatic control, decision making, risk analysis, etc.

If X is a classical set, we denote the set of all fuzzy sets on X by $\mathcal{F}(X)$. Given two non-empty classical sets X, Y, a fuzzy rule is usually given in the following form:

$$\textbf{IF } x \text{ is } \mathcal{A} \textbf{ THEN } y \text{ is } \mathcal{B} \,, \tag{1}$$

where $\mathcal{A}, \mathcal{B}$ are membership predicates represented by fuzzy sets $A \in \mathcal{F}(X)$ and $B \in \mathcal{F}(Y)$, respectively. Given a fuzzy observation $A' \in \mathcal{F}(X)$ a corresponding output fuzzy set $B' \in \mathcal{F}(Y)$ is deduced using an inference mechanism.

1.1 Fuzzy Relational Inference

Fuzzy inference systems can be broadly classified as those inference mechanisms that are fuzzy relation based, i.e., those that interpret a given fuzzy rule base as a fuzzy relation, and those that are not. Similarity Based Reasoning (SBR) (see, for instance, TÜRKSEN [1]) and Inverse Truth-functional Modification of BALDWIN [2] are two of the representative examples of the latter type of inference mechanisms that do not use fuzzy relations and which are well established in the literature.

In this work, we focus only on those inference mechanisms that are fuzzy relation based. However, it should be mentioned that, under certain conditions, an equivalent fuzzy relation based description of some of these inference mechanisms can be given (see [3, 4]).

1.2 Compositional Rule of Inference

The earliest inference scheme, proposed by Zadeh himself and well established in the literature, is the Compositional Rule of Inference (CRI) [5]. In CRI, a fuzzy rule is interpreted by a fuzzy relation $R \in \mathcal{F}(X \times Y)$. Given a fuzzy observation $A' \in \mathcal{F}(X)$ an output fuzzy set $B' \in \mathcal{F}(Y)$ is deduced by the CRI based on the fuzzy relation R. From the fuzzy relational point of view the CRI is defined as follows:

$$B'(y) = \bigvee_{x \in X} (A'(x) * R(x, y)), \quad y \in Y \,, \tag{2}$$

where $*$ is a fuzzy conjunction, typically a t-norm (see KLEMENT et al. [6] for more details). We use the following notation to indicate the CRI scheme:

$$B' = A' \circ R \,. \tag{3}$$

1.3 Popularity of CRI

The CRI mechanism is most often and widely used for the following reasons:

(i) An important issue in the applicability of CRI scheme is to determine an appropriate fuzzy relation R based on the given fuzzy rules so as to obtain meaningful conclusions. This pertains to the solvability of the fuzzy relation equations. A necessary and sufficient condition for the solvability of fuzzy relation equations has been well established for long, see DI NOLA et al [7]. Moreover, recently, PERFILIEVA and LEHMKE [8] showed its solvability under conditions that are more favourable and prevalent in many applicational contexts.

(ii) In PERFILIEVA et al. [8, 9] the authors have dealt with the continuity of a fuzzy function adjoint to the CRI mechanism and a fuzzy relation interpreting fuzzy rules (8). The authors, defining continuity suitably, have shown that it is equivalent to the correctness of the model under consideration.

(iii) KLAWONN and CASTRO [10] have proven two important and interesting results about the CRI scheme using fuzzy rules and the indistinguishability inherent to the fuzzy sets considered. They showed the robustness of the CRI mechanism in scenarios where there can be slight discrepancies between the intended input and the actual input. They have also shown that the indistinguishability induced by the fuzzy set representing the linguistic expression in the premise of the rule cannot be overcome.

However, it should be noted that there are still some drawbacks that are usually cited about CRI. Recently, JAYARAM

ISBN: 978-989-95079-6-8

[11] has proposed a modified form of CRI called the Hierarchical CRI that addresses many of these drawbacks. The above properties will be dealt with in more detail in Sec. 3.

1.4 Motivation for this work: Bandler-Kohout Subproduct

Generally, the CRI - represented by $\circ$ - may be replaced by any appropriate image of a fuzzy set under the fuzzy relation R denoted by @, which fulfills some required properties. Besides the most often used CRI inference scheme, another scheme of inference is the Bandler-Kohout subproduct $\lhd$ (BK-Subproduct, for short) proposed by BANDLER and KOHOUT [12]. Considering the fuzzy rule as given in (1), for a given input $A' \in \mathcal{F}(X)$ the inference obtained using the BK-Subproduct is given as follows:

$$B'(y) = \bigwedge_{x \in X} (A'(x) \to R(x,y)), \quad y \in Y \ , \tag{4}$$

where $\to$ is a fuzzy implication (see Sec. 2 for more details), $B' \in \mathcal{F}(Y)$ and R is the fuzzy relation that interprets the fuzzy rule (1).

Later on, PEDRYCZ [13] has shown certain solvability conditions for the BK-Subproduct inference as given in (4). Buoyed by this important result on the BK-Subproduct, this paper is an attempt at studying the suitability of the BK-Subproduct as an inference mechanism, by showing that the BK-Subproduct does have all the above desirable properties possessed by CRI.

1.5 Organisation of the work

In Section 2 we recall the preliminaries required for the rest of the paper. Also the structure and inference in the Compositional Rule of Inference (CRI) mechanism is discussed. Following this, in Section 3 we discuss some of the important properties cited in favor of using CRI,e.g., equivalent and reasonable conditions for their solvability, their interpolative properties and the preservation of the indistinguishability that may be inherent in the input fuzzy sets. Section 4, which contains our main work, shows that all the above mentioned properties are valid even in the case of the BK-Subproduct.

2 Preliminaries

2.1 Fuzzy Inference Mechanisms

An inference mechanism acting upon fuzzy rules is usually based on fuzzy logic connectives. In this work, we restrict ourselves to inference schemes based on fuzzy logic connectives. Let us fix a complete residuated lattice $\mathcal{L} = ([0,1], \wedge, \vee, *, \to, 0, 1)$ (see, for example, NOVÁK et al. [14]) as the basic algebraic structure for the whole paper.

Since the set $[0,1]$ is totally ordered, $\mathcal{L}$ becomes an MTL-algebra and hence, in our context, $*$ becomes a left-continuous t-norm and $\to$ is the residual implication *uniquely* given as follows:

$$a \to b = \bigvee \{t \in \mathcal{L} | a * t \leq b\} \ , \tag{5}$$

which is also a fuzzy implication, for more details we refer the readers to [6, 14, 15].

From the two operations $\wedge, \to$ of $\mathcal{L}$ we can derive yet another operation known as the *biresiduum* which is defined as follows:

$$a \leftrightarrow b = (a \to b) \wedge (b \to a), \qquad a, b \in \mathcal{L} \ . \tag{6}$$

Finally, by an extension of an algebraic operation on $\mathcal{L}$ to an operation between fuzzy sets we mean the following:

$$(C \star D)(u,v) = C(u) \star D(v), \qquad u \in U, v \in V \ , \tag{7}$$

where $\star \in \{\wedge, \vee, *, \to, \leftrightarrow\}$ and where C, D are arbitrary fuzzy sets on arbitrary universes U, V, respectively.

2.2 Structure and Inference in CRI

The CRI inference mechanism given in (2) is for a fuzzy relation $R \in \mathcal{F}(X \times Y)$ that interprets a single fuzzy rule. However, usually multiple fuzzy rules are a necessity. Let us denote the multiple fuzzy rules as follows:

$$\textbf{IF } x \text{ is } \mathcal{A}_i \quad \textbf{THEN} \quad y \text{ is } \mathcal{B}_i \ , \tag{8}$$

where $\mathcal{A}_i, \mathcal{B}_i$ are membership predicates represented by fuzzy sets $A_i \in \mathcal{F}(X)$ and $B_i \in \mathcal{F}(Y)$, respectively, for $i = 1, \ldots, n$.

Then a fuzzy relation interpreting the whole *fuzzy rule base* (altern. *linguistic description*), composed of the n fuzzy rules (8), has to be constructed. basically, there are two main approaches to the construction of such a fuzzy relation.

The following fuzzy relation $\check{R} \in \mathcal{F}(X \times Y)$

$$\check{R}(x,y) = \bigvee_{i=1}^{n} (A_i(x) * B_i(y)) \ , \tag{9}$$

is used in most of the real world applications. This is mainly due to the successful applications of this, say Cartesian product approach, published by Mamdani and Assilian in [16], which was followed by a huge number of researchers and practitioners, see e.g. [17, 18].

Alternatively, to keep the conditional IF-THEN form of the fuzzy rules (8) fuzzy relation $\hat{R} \in \mathcal{F}(X \times Y)$ given as follows

$$\hat{R}(x,y) = \bigwedge_{i=1}^{n} (A_i(x) \to B_i(y)) \ , \tag{10}$$

can be chosen to interpret the fuzzy rule base. It deals with a mathematically correct extension of a classical implication.

To stress the difference between both the approaches, let us recall the work of DUBOIS et al. [19], where the authors state: "*In the view given by* (10)*, each piece of information (fuzzy rule) is viewed as a constraint. This view naturally leads to a conjunctive way of merging the individual pieces of information since the more information, the more constraints and the less possible values to satisfy them*." While the same authors describe the second approach proposed by Mamdani and Assilian as follows: "*It seems that fuzzy rules modelled by* $\check{R}$ *are not viewed as constraints but are considered as pieces of data. Then the maximum in (9) expresses accumulation of data*".

In other words, instead of interpreting fuzzy rules as logical implications, the approach given using $\check{R}$ builds up an input-output relation from smaller units, and those units are examples of fuzzy input-output pairs. And then Mamdani-Assilian approach is a method that interpolates between known input-output pairs [20]. For an extensive study of different fuzzy rules we refer to [21, 22].

ISBN: 978-989-95079-6-8

It should be stressed that both approaches have sound logical foundations but from different viewpoints, see e.g. [23, 24, 14]. However, only the approach using $\check{R}$ was widely used in applications although the implicational approach using $\hat{R}$ is probably as useful as the Mamdani-Assilian one, see [25]. Nevertheless, as we show in Section 4, the implicational approach using $\hat{R}$ does have an important role to play in the case of BK-Subproducts (see Theorem 4.7).

3 Some desirable properties of CRI

Fuzzy rules may be viewed as a partial mapping from $\mathcal{F}(X)$ to $\mathcal{F}(Y)$ assigning $B_i \in \mathcal{F}(Y)$ to $A_i \in \mathcal{F}(X)$ for every $i = 1, \ldots, n$. The inference process then may be viewed as an extension of this partial mapping to a total one [26]. For better understanding, let us adopt the notation from [8] and consider the following structure

$$S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, @) \ ,$$

where $@ : \mathcal{F}(X) \times \mathcal{F}(X \times Y) \to \mathcal{F}(Y)$ is an image of a fuzzy set under a fuzzy relation. For instance, $@$ could be one of $\circ$ or $\triangleleft$. Now, by the choice of the fuzzy relation R interpreting the fuzzy rule base and by the choice of $@$, we define a fuzzy function $f_R(A) : \mathcal{F}(X) \to \mathcal{F}(Y)$ such that $f_R(A) = A@R$, for arbitrary $A \in \mathcal{F}(X)$.

3.1 Solvability of systems of fuzzy relation equations with the $\circ$ image

One of the fundamental properties of such a mapping is its interpolativity, i.e., $f_R(A_i) = B_i$. In this case, we say that R is a *correct model* of given fuzzy rules in the given structure S [8].

This leads us to deal with a system of fuzzy relation equations [27] where generally the system of equations

$$A_i@R = B_i, \quad i = 1, \ldots, n \ , \tag{11}$$

is solved with respect to the known $A_i \in \mathcal{F}(X), B_i \in \mathcal{F}(Y)$ and unknown $R \in \mathcal{F}(X \times Y)$. If R is a solution to (11) then the adjoint fuzzy function fulfills $f_R(A_i) = B_i$.

In the case of CRI, the above system of equations, viz., (11), reduces to the following:

$$A_i \circ R = B_i, \quad i = 1, \ldots, n \ . \tag{12}$$

Let us recall some main results which may be found, e.g., in [7, 27, 28, 29].

Theorem 3.1 *System (12) is solvable if and only if $\hat{R}$ is a solution of the system and moreover, $\hat{R}$ is the greatest solution of (12).*

On the one hand, Theorem 3.1 states the necessary and sufficient condition of the solvability of system (12) and it determines the solution. Moreover, it ensures that the given solution is the greatest one. On the other hand, we still do not know, when $\hat{R}$ is the solution, i.e., how to ensure the solvability.

Theorem 3.2 [29] *Let A_i for $i = 1, \ldots, n$ be normal. Then $\check{R}$ is a solution of (12) if and only if the following condition*

$$\bigvee_{x \in X} (A_i(x) * A_j(x)) \leq \bigwedge_{y \in Y} (B_i(y) \leftrightarrow B_j(y)) \ , \tag{13}$$

holds for arbitrary $i, j \in \{1, \ldots, n\}$.

Theorem 3.2 specifies a sufficient condition under which the system is solvable and moreover, it ensures that not only $\hat{R}$ but also even $\check{R}$ is a solution of system (12).

It is worth mentioning that condition (13) appearing in Theorem 3.2 is from the practical point of view not very convenient. However, if the antecedent fuzzy sets form the so called $*$-semi-partition it forces fulfilling the discussed condition in advance, see DE BAETS and MESIAR [30] for more details.

Another sufficient condition for solvability of the systems with a high practical importance was published in [31].

Theorem 3.3 (Theorem 7 in [31]) *Let A_i for $i = 1, \ldots, n$ be normal and fulfill the Ruspini condition*

$$\sum_{i=1}^{n} A_i(x) = 1, \quad x \in X. \tag{14}$$

Then the system (12) is solvable.

3.2 Continuity of a model of fuzzy rules

In [8, 9] the authors have dealt with the continuity of a fuzzy function adjoint to the CRI mechanism and a fuzzy relation interpreting fuzzy rules (8). They have defined continuity suitably and have shown that it is equivalent to the correctness of the model under consideration.

Although the original definition in [8] of a continuous model was given for the particular inference mechanism CRI, i.e., for $@ \equiv \circ$, the particular image plays absolutely no role in the proof of Theorem 3.6 explaining the nature of the definiton and hence can be generalized for an arbitrary image of a fuzzy set under a fuzzy relation.

Definition 3.4 A fuzzy relation $R \in \mathcal{F}(X \times Y)$ is said to be a *continuous model of fuzzy rules* (8) *in a structure* $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, @)$ if for each $i \in I$ and for each $A \in \mathcal{F}(X)$ the following inequality holds:

$$\bigwedge_{y \in Y} (B_i(y) \leftrightarrow (A@R)(y)) \geq \bigwedge_{x \in X} (A_i(x) \leftrightarrow A(x)) \ . \tag{15}$$

Inequality (15) can be rewritten in terms of the adjoint fuzzy function f_R as follows:

$$\bigwedge_{y \in Y} (B_i(y) \leftrightarrow (f_R(A))(y)) \geq \bigwedge_{x \in X} (A_i(x) \leftrightarrow A(x)). \tag{16}$$

Remark 3.5 Let us explain why formula (15) expresses the continuity. The closeness between fuzzy sets is measured by the biresiduation operation $\leftrightarrow$, i.e. it is a dual information to the metric one. Let us consider a continuous Archimedean t-norm $*$ with an additive generator $g : [0, 1] \to [0, +\infty]$. Then the biresiduum may be written in the form

$$a \leftrightarrow b = g^{-1}(|g(a) - g(b)|) \tag{17}$$

where $g^{-1} : [0, \infty] \to [0, 1]$ is the inverse function and where in the case of $g(0) = \infty$ we define $g(0) - g(0) = 0$. Now, for an arbitrary non-empty universe X it is possible to define a metric D_g on $\mathcal{F}(X)$ generated by g as follows:

$$D_g(A, B) = \bigvee_{x \in X} |g(A(x)) - g(B(x))|. \tag{18}$$

The following theorem justifies the use of the notion of continuity in Definition 3.4. For more details, see PERFILIEVA and LEHMKE [8].

ISBN: 978-989-95079-6-8

Theorem 3.6 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, @)$ be a structure for fuzzy rules* (8) *such that $\mathcal{L}$ be a residuated lattice on $[0,1]$ with a continuous Archimedean t-norm $*$ having a continuous additive generator g. A fuzzy relation $R \in \mathcal{F}(X \times Y)$ is a continuous model of the fuzzy rules in the given structure S if and only if*

$$D_g(B_i, (A@R)) \leq D_g(A_i, A), \quad i = 1, \ldots, n \tag{19}$$

for each fuzzy set $A \in \mathcal{F}(X)$.

The following lemma was crucial for further results published in [8].

Lemma 3.7 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, \circ)$ be a structure for fuzzy rules* (8) *and let $R \in \mathcal{F}(X \times Y)$. Then for any $A \in \mathcal{F}(X)$ and all $i = 1, \ldots, n$ and $y \in Y$ it is true that*

$$B_i(y) \leftrightarrow (A \circ R)(y) \geq \delta_{R,i}(y) * \bigwedge_{x \in X} (A_i(x) \leftrightarrow A(x)) , \tag{20}$$

where $\delta_{R,i}(y) = B_i(y) \leftrightarrow (A_i \circ R)(y)$.

Finally, we recall here the main result in PERFILIEVA et al. [8, 9] concerning the relationship of the above mentioned continuity and the interpolativity for the CRI.

Theorem 3.8 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, \circ)$ be a structure for fuzzy rules* (8)*. A fuzzy relation $R \in \mathcal{F}(X \times Y)$ is a correct model of fuzzy rules* (8) *in the given structure S if and only if it is a continuous model of these rules in S.*

3.3 CRI and the Indistinguishability of Premises

Let X be a classical set and let $\sim$ be an equivalence relation defined on X, i.e., $\sim$ is reflexive, symmetric and transitive. Immediately, $\sim$ partitions X into equivalence classes. It is well-known then that an $M \subseteq X$ belongs to this partition if, and only if, whenever $x \in M$ and $x \sim y$ for some $y \in X$ then $y \in M$. In a sense, the elements of M are indistinguishable and can be represented mathematically as follows:

$$x \in M \text{ and } x \sim y \text{ implies } y \in M .$$

A similar relation between fuzzy equivalence relations and fuzzy sets on X was introduced by KLAWONN and CASTRO [10]. Once again the operation $*$ comes from the residuated lattice $\mathcal{L}$.

Definition 3.9 A fuzzy subset E of the Cartesian product X^2 is called a *fuzzy equivalence* relation on X if the following properties are satisfied for all $x, y, z \in X$:

$$\begin{aligned} &\text{(Reflexivity)} && E(x,x) = 1, && \text{(ER)} \\ &\text{(Symmetry)} && E(x,y) = E(y,x), && \text{(ES)} \\ &\text{(Transitivity)} && E(x,z) \geq E(x,y) * E(y,z) . && \text{(ET)} \end{aligned}$$

Definition 3.10 A fuzzy set $\mu \in \mathcal{F}(X)$ is called *extensional* with respect to a fuzzy equivalence relation E on X if

$$\mu(x) * E(x,y) \leq \mu(y) , \qquad x, y \in X . \tag{21}$$

If a fuzzy set μ is not extensional with respect to the considered fuzzy equivalence relation E, instead one considers the smallest fuzzy set that is extensional with respect to E and contains μ.

Definition 3.11 Let $\mu \in \mathcal{F}(X)$ and let E be a fuzzy equivalence relation on X. The fuzzy set

$$\widetilde{\mu}(x) = \bigwedge \{\nu \mid \mu \leq \nu \text{ and } \nu \text{ is extensional with respect to } E\} , \tag{22}$$

is called the *extensional hull* of μ. Note that by $\mu \leq \nu$ we mean that for all $x \in X$, $\mu(x) \leq \nu(x)$, i.e., we mean ordering in the sense of inclusion, not in the sense of ordering fuzzy quantities.

Proposition 3.12 [10] *Let $\mu \in \mathcal{F}(X)$ and let E be a fuzzy equivalence relation on X.*

(i) $\widetilde{\mu}(x) = \bigvee \{\mu(y) * E(x,y) \mid y \in X\}$,

(ii) $\widetilde{\mu}$ *is extensional with respect to E,*

(iii) $\widetilde{\widetilde{\mu}} = \widetilde{\mu}$.

KLAWONN and CASTRO [10] have proven the following two important and interesting results about the CRI scheme using fuzzy rules and the indistinguishability inherent to the fuzzy sets considered.

Theorem 3.13 *Let $S = (X, Y, \{A, B\}, \mathcal{L}, \circ)$ be a structure for fuzzy rule* (1)*. Let E be a fuzzy equivalence relation on X with respect to which A is extensional. Let $A' \in \mathcal{F}(X)$ be any fuzzy set, then*

$$A' \circ \hat{R} = \widetilde{A'} \circ \hat{R},$$
$$A' \circ \check{R} = \widetilde{A'} \circ \check{R}.$$

The following interpretation of the above result is given in [10]: *The output obtained from CRI for a given fuzzy rule and an input fuzzy set A' does not change if we substitute A' by its extensional hull $\widetilde{A'}$. The indistinguishability inherent in the fuzzy set A cannot be avoided even if the input fuzzy set A' stands for a crisp value*. Further, *a fuzzified input does not change the outcome of a rule as long as the fuzzy set obtained by the fuzzification is contained in the extensional hull of the original crisp input value.* They finally conclude that *it does not make sense to measure more exactly than the indistinguishability admits.*

In other words, this shows the robustness of the inference in scenarios where there can be slight discrepancies between the intended input and the actual input.

It is immediate now, as already observed in [10], that *the indistinguishability induced by the fuzzy set representing the linguistic expression in the premise of the rule cannot be overcome.*

Let us stress that the proof of Theorem 3.13 may be easily modified in order to capture the situation with n fuzzy rules. It can be observed that only the Mamdani-Assilian approach $\check{R}$ generally works in the combination with the CRI.

Theorem 3.14 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, \circ)$ be a structure for fuzzy rules (8). Let E be a fuzzy equivalence relation on X with respect to which A_i is extensional for arbitrary $i = 1, \ldots, n$. Let $A' \in \mathcal{F}(X)$ be any fuzzy set, then*

$$A' \circ \check{R} = \widetilde{A'} \circ \check{R}.$$

4 BK-Subproduct and some desirable properties

4.1 Solvability of systems of fuzzy relation equations with the $\triangleleft$ image

In the case of BK-Subproduct, the system of equations (11), reduces to the following:

$$A_i \triangleleft R = B_i, \quad i = 1, \ldots, n \, . \tag{23}$$

Concerning system (23), let us recall the following two basic theorems .

Theorem 4.1 [13] *System (23) is solvable if and only if $\check{R}$ is a solution of the system and moreover, $\check{R}$ is the least solution of system (23).*

Theorem 4.2 [32] *Let A_i for $i = 1, \ldots, n$ be normal. Then $\hat{R}$ is a solution of (23) if and only if the condition* (13) *holds for arbitrary $i, j \in \{1, \ldots, n\}$.*

Again, condition (13) to which Theorem 4.2 refers to, is not very convenient from a practical point of view and may be a priori fulfilled by using antecedent fuzzy sets which form the $*$-semi-partition.

Fortunately, that the sufficient condition for solvability of the systems with a high practical importance stated in Theorem 3.3 is valid even for system (23).

Theorem 4.3 (Theorem 7 in [31]) *Let A_i for $i = 1, \ldots, n$ be normal and fulfill the Ruspini condition (14). Then the system (23) is solvable.*

4.2 Continuity of BK-Subproduct

The BK-Subproduct, unlike the CRI, was not motivated by approximate reasoning, see BANDLER and KOHOUT [12]. However, as mentioned in GOTTWALD [33], it is not necessary to insist on purely logical foundations for an inference mechanism, and it can simply be a mapping from $\mathcal{F}(X)$ to $\mathcal{F}(Y)$ fulfilling certain properties. Let us also recall that it was PEDRYCZ [13] who firstly proposed the BK-Subproduct as an inference scheme.

We may again state an analogous lemma to Lemma 3.7 also for the case of the BK-Subproduct.

Lemma 4.4 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, \triangleleft)$ be a structure for fuzzy rules* (8) *and let $R \in \mathcal{F}(X \times Y)$. Then for any $A \in \mathcal{F}(X)$ and all $i = 1, \ldots, n$ and $y \in Y$ it is true that*

$$B_i(y) \leftrightarrow (A \triangleleft R)(y) \geq \delta_{R,i}(y) * \bigwedge_{x \in X} (A_i(x) \leftrightarrow A(x)) \, , \tag{24}$$

where $\delta_{R,i}(y) = B_i(y) \leftrightarrow (A_i \triangleleft R)(y)$.

Due to Lemma 4.4, we may state the following analogous theorem to Theorem 3.8 which again shows that the BK subproduct as an inference mechanism carries the same property as the CRI.

Theorem 4.5 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, \triangleleft)$ be a structure for fuzzy rules* (8)*. A fuzzy relation $R \in \mathcal{F}(X \times Y)$ is a correct model of fuzzy rules* (8) *in the given structure S if and only if it is a continuous model of these rules in S.*

4.3 BK-Subproduct and the Indistinguishability of Premises

In this subsection, we show the robustness of the BK-Subproduct inference mechanism along similar lines as KLAWONN and CASTRO [10]. Once again the employed operations come from the residuated lattice $\mathcal{L}$. Firstly note that if a fuzzy set $\mu \in \mathcal{F}(X)$ is extensional with respect to a fuzzy equivalence relation E on X then

$$E(x, y) \to \mu(y) \geq \mu(x), \; x, y \in X \, . \tag{25}$$

Proposition 4.6 *Let $\mu \in \mathcal{F}(X)$ and E a fuzzy equivalence relation on X. Then*

$$\widetilde{\mu}(x) = \bigwedge \{E(x, y) \to \mu(y) \mid y \in X\} \, . \tag{26}$$

Now, we present the main result analogous to Theorem 3.13.

Theorem 4.7 *Let $S = (X, Y, \{A, B\}, \mathcal{L}, \triangleleft)$ be a structure for fuzzy rule* (1)*. Let E be a fuzzy equivalence relation on X with respect to which A is extensional. Let $A' \in \mathcal{F}(X)$ be any fuzzy set, then*

$$A' \triangleleft \hat{R} = \widetilde{A'} \triangleleft \hat{R},$$
$$A' \triangleleft \check{R} = \widetilde{A'} \triangleleft \check{R}.$$

The above result, as already noted in the case of CRI, shows the robustness of the BK-Subproduct inference in scenarios where there can be slight discrepancies between the intended input and the actual input and reinforces the fact that even in the case of BK-Subproduct the indistinguishability induced by the fuzzy set representing the linguistic expression in the premise of the rule cannot be overcome.

And again as in case of the CRI, we may generalize the result concerning the indistinguishability of the premises for an arbitrary finite number of rules. Note that in the case of the BK-Subproduct the $\hat{R}$ is plays the main role.

Theorem 4.8 *Let $S = (X, Y, \{A_i, B_i\}_{i=1,\ldots,n}, \mathcal{L}, \triangleleft)$ be a structure for fuzzy rules (8). Let E be a fuzzy equivalence relation on X with respect to which each A_i is extensional, for arbitrary $i = 1, \ldots, n$. Let $A' \in \mathcal{F}(X)$ be any fuzzy set, then*

$$A' \triangleleft \hat{R} = \widetilde{A'} \triangleleft \hat{R}.$$

5 Conclusions

In this work, after recalling some of the properties that are usually cited in favor of using the Compositional Rule of Inference (CRI) introduced by ZADEH [5], viz., equivalent and reasonable conditions for their solvability, their interpolative properties and the preservation of the indistinguishability that may be inherent in the input fuzzy sets, we have shown that the Bandler-Kohout subproduct introduced in [12] does possess all the above properties and hence is equally suitable for consideration when reasoning with a system of fuzzy rules. Towards this end some new but equivalent results on indistinguishability operations has also been presented.

Early Start Can Inhibit Learning: Towards A New Explanation

Olga Kosheleva

Department of Teacher Education
University in the Texas at El Paso
El Paso, TX 79968, USA
Email: olgak@utep.edu

Abstract— *The age at which we teach different topics change. If it turns out that students do not learn, say, reading by the time they should, a natural idea is to start teaching them earlier. Several decades ago, reading and writing started in the first grade, now they start at kindergarten and even earlier. At first glance, the earlier we start, the better the students will learn. Yes, they may play less, their childhood may be not as careless as it used to be, but at least they will learn better. In practice, however, this does not always work this way: early start often inhibits learning.*

In this paper, we propose a simple model that explains why this can happen, and how we can avoid such situations and enhance the student learning. In particular, we explain why, contrary to the traditional concrete-first way of teaching abstracts concepts of school mathematics, abstract-first approach is often beneficial.

Keywords— Abstract-first, early start, education, optimal education, uncertainty

1 Formulation of the Problem

1.1 Early Start: A Seemingly Natural Idea

The age at which we teach different topics change. If it turns out that students do not learn, say, reading by the time they should, a natural idea is to start teaching them earlier.

Several decades ago, reading and writing started in the first grade, now they start at kindergarten and even earlier. At first glance, the earlier we start, the better the students will learn.

1.2 Early Start: Known Side Effects

With the early start, children may play less, their childhood may be not as careless as it used to be – but a usual expectation is that with an early start, children will learn better.

1.3 Early Start: Serious Problems

In practice, however, early start does not always help: often, early start inhibits learning.

For example, according to [18],

- human infants who started learning to turn their heads to specific sounds at the age of 31 days mastered this task, on average, at the age of 71 days, while
- infants who started learning this task at birth mastered this task, on average, at the age of 128 days.

This phenomenon is not limited to human infants: according to [8], an early start in training rhesus monkeys to discriminate objects decreased their peak performance level.

Numerous examples when an early start inhibits learning are presented and discussed in [2, 3, 4, 6, 19].

1.4 Natural Questions

The empirical fact that an early start often inhibits learning leads to the following natural question: how do take this phenomenon into account when enhancing student learning?

To be able to take this phenomenon into account in the learning process, we must be able to understand this phenomenon – and ideally, understand on the quantitative level.

1.5 These Questions Are Still Largely Open

In [2, 3, 4, 6], an attempt is made to understand why early start can inhibit learning. However,

- the existing understanding is still mostly on the qualitative level, and
- even on this level, the proposed explanations are still not fully satisfactory; see, e.g., [19].

1.6 More General Questions

The above questions about the efficiency of the early start can be viewed as a particular case of more general questions: what is the best order of presenting the material, the order that leads to the best possible learning?

1.7 These More General Questions Are Often Very Important

Many empirical studies have shown that a change in the order in which different parts of the material are presented often drastically changes the learning efficiency; see, e.g., [5, 9, 10, 13, 14, 16, 21, 22].

This is not only about using common sense: sometimes, the empirical results are counter-intuitive. For example:

- it is usually assumed that most students learn mathematical concepts better if
  - they are first presented with concrete examples of these concepts, and
  - they only learn abstract ideas later on;
- however, it turns out that empirically, the abstract-first approach for presenting the material often enhances learning; see, e.g., [9, 10, 14, 21].

1.8 What We Do in This Paper

In this paper, we propose a simple model that attempts:

- to explain the negative effect of early start and,

ISBN: 978-989-95079-6-8

- more generally, to explain the reasons why a change in presentation order can drastically change the efficiency of learning.

We then show how this explanation can be used to avoid inhibition of learning – and to enhance the student learning.

2 Towards A Theoretical Explanation

2.1 Learning: A Natural Geometric Representation

To facilitate reasoning about learning, let us start with a simple geometric representation of learning.

The process of learning means that we change the state of a student:

- from a state in which the student did not know the material (or does not have the required skill)
- to a state in which the student has (some) knowledge of the required material (or has the required skill).

Let s_0 denote the original state of a student, and let S denote the set of all the states corresponding to the required knowledge or skill.

- We start with a state which is not in the set S ($s_0 \notin S$), and
- we end up in a state s which is in the set S.

On the set of all possible states, it is natural to define a metric $d(s, s')$ as the difficulty (time, effort, etc.) needed to go from state s to state s'. Our objective is to help the students learn in the easiest (fastest, etc.) way. In terms of the metric d, this means that we want to go from the original state $s_0 \notin S$ to the state $s \in S$ for which the effort $d(s_0, s)$ is the smallest possible.

In geometric terms, the smallest possible effort means the shortest possible distance. Thus, our objective is to find the state $s \in S$ which is the closest to s_0. Such closest state is called the *projection* of the original state s_0 on the set S.

2.2 Learning Complex Material: Geometric Interpretation

The above geometric description of learning as a transition from the original state s_0 to its projection on the desired set S describes learning *as a whole*. Our objective is to find out which order of presenting information is the best. Thus, our objective is to analyze the *process* of learning, i.e., learning as a multi-stage phenomenon. For this analysis, we must explicitly take into account that the material to be learned consists of several pieces.

Let S_i, $1 \le i \le n$, denote the set of states in which a student has learned the i-th part of the material. Our ultimate objective is to make sure that the student learns all the parts of the material. In terms of states, learning the i-th part of the material means belonging to the set S_i. Thus, in terms of states, our objective means that the student should end up in a state which belongs to all the sets $S_1, \ldots, S_n$ – i.e., in other words, in a state which belongs to the intersection

$$S \stackrel{\text{def}}{=} S_1 \cap \ldots \cap S_n \tag{1}$$

of the corresponding sets S_i.

In these terms, if we present the material in the order S_1, S_2, …, S_n, this means that:

- we first project the original state s_0 onto the set S_1, resulting is a state $s_1 \in S_1$ which is the closest to s_0;
- then, we project the state s_1 onto the set S_2, resulting is a state $s_2 \in S_2$ which is the closest to s_1;
- …
- at the last stage of the cycle, we project the state s_{n-1} onto the set S_n, resulting is a state $s_n \in S_n$ which is the closest to s_{n-1}.

In some cases, we end up learning all the material – i.e., in a state $s_n \in S_1 \cap \ldots \cap S_n$. However, often, by the time the students have learned S_n, they have somewhat forgotten the material that they learned in the beginning. So, it is necessary to repeat this material again (and again). Thus, starting from the state s_n, we again sequentially project onto the sets S_1, S_2, etc.

2.3 The Above Geometric Interpretation Makes Computational Sense

The above "sequential projections" algorithm is actually actively used in many applications; see, e.g., [7, 12, 20]. In the case when all the sets S_i are convex, the resulting Projections on Convex Sets (POCS) method actually guarantees (under certain reasonable conditions) that the corresponding projections converge to a point from the intersection $S_1 \cap \ldots \cap S_n$ – i.e., in our terms, that the students will eventually learn all parts of the necessary material.

In the more general non-convex case, the convergence is not always guaranteed – but the method is still efficiently used, and often converges.

2.4 The Simplest Case: Two-Part Knowledge

Let us start with the simplest case when knowledge consists of two parts. In this simplest case, there are only two options:

- The first option is that:
  - we begin by studying S_1;
  - then, we study S_2,
  - then, if needed, we study S_1 again, etc.
- The second option is that:
  - we begin by studying S_2;
  - then, we study S_1,
  - then, if needed, we study S_2 again, etc.

We want to get from the original state s_0 to the state $\widetilde{s} \in S_1 \cap S_2$ which is the closest to s_0. The effectiveness of learning is determined by how close we get to the desired set $S = S_2 \cap S_2$ in a given number of iterations.

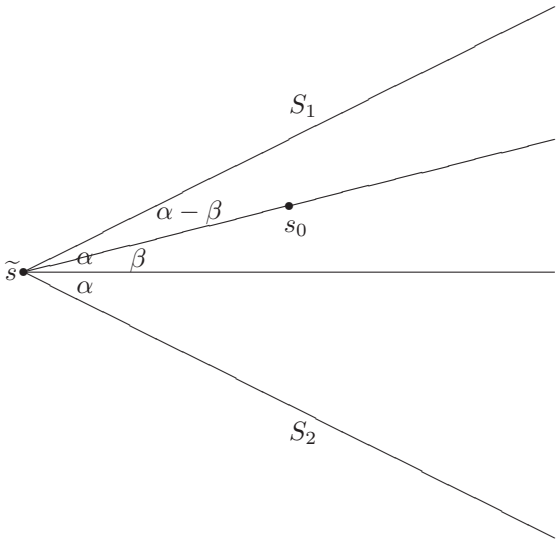
In the case of two-part knowledge, it is natural to conclude that the amount of this knowledge is reasonably small – otherwise, we would have divided into a larger number of easier-to-learn pieces.

In geometric terms, this means that the original state s_0 is close to the desired intersection set $S_1 \cap S_2$, i.e., that the distance $d_0 \stackrel{\text{def}}{=} d(s_0, \widetilde{s})$ is reasonably small.

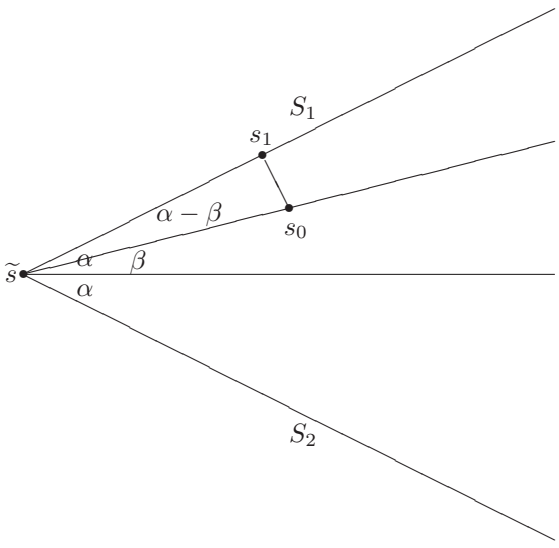
ISBN: 978-989-95079-6-8

Since all the states are close to each other, in the vicinity of the state $\widetilde{s}$, we can therefore expand the formulas describing the borders of the sets S_i into Taylor series and keep only terms which are linear in the (coordinates of the) difference $s - \widetilde{s}$. Thus, it is reasonable to assume that the border of each of the two sets S_i is described by a linear equation – and is hence a (hyper-)plane: a line in 2-D space, a plane in 3-D space, etc.

As a result, we arrive at the following configuration. Let 2α denote the angle between the borders of the sets S_1 and S_2, so that the angles between each of these borders and the midline is exactly α. Let β denote the angle between the direction from $\widetilde{s}$ to s_0 and the midline. In this case, the angle between the border of S_1 and the midline is equal to $\alpha - \beta$. So, we arrive at the following configuration:



In the first option, we first project s_0 onto the set S_1. As a result, we get the following configuration:



Here, the projection line $s_0 s_1$ is orthogonal to the border of S_1. From the right triangle $\triangle \widetilde{s} s_0 s_1$, we therefore conclude that the distance $d_1 \stackrel{\text{def}}{=} d(\widetilde{s}, s_1)$ from the projection point s_1 to the desired point $\widetilde{s}$ is equal to

$$d_1 = d_0 \cdot \cos(\alpha - \beta). \quad (2)$$

On the next step, we project the point s_1 from S_1 onto the line S_2 which is located at the angle 2α from S_1. Thus, for the projection result s_2, we will have

$$d_2 = d(s_2, \widetilde{s}) = d_1 \cdot \cos(2\alpha) = d_0 \cdot \cos(\alpha - \beta) \cdot \cos(2\alpha). \quad (3)$$

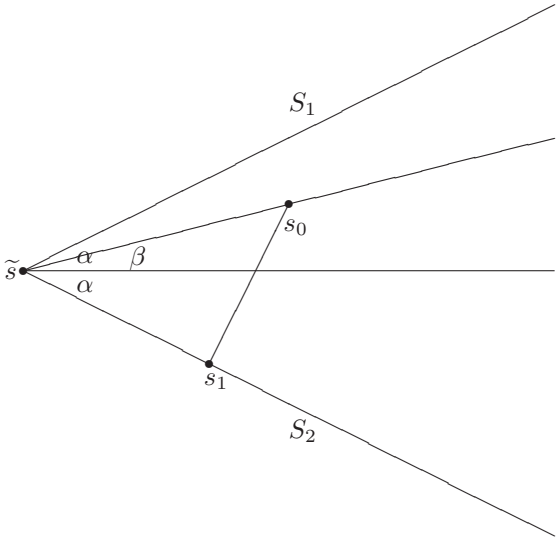
After this, we may again project onto S_2, then again project onto S_1, etc. For each of these projections, the angle is equal to 2α, so after each of them, the distance from the desired point $\widetilde{s}$ is multiplied the same factor $\cos(2\alpha)$.

As a result, after k projection steps, we get a point s_k at a distance

$$d_k = d(s_k, \widetilde{s}) = d_0 \cdot \cos(\alpha - \beta) \cdot \cos^{k-1}(2\alpha) \quad (4)$$

from the desired state $\widetilde{s}$.

In the second option, we start with teaching S_2, i.e., if we first project the state s_0 into the set S_2. In this option, we get the following configuration:



Here, we have

$$d_1 = d_0 \cdot \cos(\alpha + \beta), \quad (5)$$

$$d_2 = d(s_2, \widetilde{s}) = d_1 \cdot \cos(2\alpha) = d_0 \cdot \cos(\alpha + \beta) \cdot \cos(2\alpha), \quad (6)$$

$$\ldots$$

$$d_k = d(s_k, \widetilde{s}) = d_0 \cdot \cos(\alpha + \beta) \cdot \cos^{k-1}(2\alpha). \quad (7)$$

Since, in general, $\cos(\alpha - \beta) \neq \cos(\alpha + \beta)$, we can see that a change in the presentation order can indeed drastically change the success of the learning procedure.

2.5 Conclusion: Dependence Explained

Thus, our simple geometric model explains why the effectiveness of learning depends on the order in which the material is presented.

3 Specific Recommendations: Case of Two-Part Knowledge

3.1 Analysis

Let us extract more specific recommendations from our model. According to the above formulas, starting with S_1

ISBN: 978-989-95079-6-8

leads to a more effective learning than starting with S_2 if and only if

$$d_0 \cdot \cos(\alpha - \beta) \cdot \cos^{k-1}(2\alpha) < d_0 \cdot \cos(\alpha + \beta) \cdot \cos^{k-1}(2\alpha), \quad (8)$$

i.e., equivalently, if and only if

$$\cos(\alpha - \beta) < \cos(\alpha + \beta). \quad (9)$$

Since for the angles $x \in [0, \pi]$, the cosine $\cos(x)$ is a decreasing function, we conclude that projection of S_1 is better if and only if

$$\alpha - \beta > \alpha + \beta. \quad (10)$$

Thus, we arrive at the following recommendation:

3.2 Recommendation

To make learning more efficient, we should start with studying the material which is further away from the current state of knowledge. In other words, we should start with a material that we know the least.

This ties in nicely with a natural commonsense recommendation that to perfect oneself, one should concentrate on one's deficiencies.

This recommendation is also in a very good accordance:

- with the seemingly counter-intuitive conclusion from [9, 10, 14, 21], that studying more difficult (abstract) ideas first enhances learning, and
- with the human infant studies [18] according to which a concentration on teaching, to human infants, skills that they can easily learn is detrimental in the long run.

4 General Case

4.1 Analysis of the Problem

What happens in the general case, when instead of only two knowledge components, we have a large number of different components? In the beginning, it still makes sense to project to the set S_{i_1} which is the farthest from the original state s_0.

After this original projection, in the general case, we still have a choice. We can project to any set S_{i_2}, $i_2 \neq i_1$, in which case the current distance d_1 to the desired state is multiplied by the cosine $\cos(\alpha_{i_1 i_2})$ of the angle between the corresponding sets S_{i_1} and S_{i_2}. After k steps, we get the original distance multiplied by the product of the corresponding cosines.

Our objective is to find the best order, i.e., the sequence S_{i_1}, S_{i_2}, ..., S_{i_n} that covers all n sets $S_1, \ldots, S_n$ and for which the corresponding product

$$\cos(\alpha_{i_1 i_2}) \cdot \cos(\alpha_{i_1 i_2}) \cdot \ldots \cdot \cos(\alpha_{i_n i_1}) \quad (11)$$

attains the smallest possible value.

Usually, it is easier to deal with the sums than with the products. To transform the product into a sum, we can use the fact that:

- minimizing the product is equivalent to minimizing its logarithm, and
- the logarithm of the product is equal to the sum of the logarithms.

Thus, minimizing the product (11) is equivalent to minimizing the sum

$$D(i_1, i_2) + \ldots + D(i_n, i_1), \quad (12)$$

where

$$D(i, j) \stackrel{\text{def}}{=} \log(\cos(\alpha_{ij})). \quad (13)$$

In other words, we arrive at the following problem:

- we have n objects with known distances

$$D(i, j), \ \ 1 \leq i, j \leq n;$$

- we must find a way to traverse all the objects and come back in such a way that the overall traveled distance is the smallest possible.

This is a well-known problem called a *traveling salesman* problem.

It is known that

- in general, this problem is NP-hard (see, e.g., [17]), and
- in many cases, there exist reasonable algorithms for solving this problem; see, e.g., [1].

4.2 Recommendations and the Need for Expert (Fuzzy) Knowledge

Based on the above analysis, we can make the following recommendations:

- To find the optimal order of presenting the material, we must solve the corresponding instance of the traveling salesman problem, with the distances determined by the formula (13).
- Since in general, the traveling salesman problem is computationally difficult (NP-hard), to efficiently solve this problem, we must use expert knowledge – the knowledge for which fuzzy technique have been invented; see, e.g., [11, 15].

Intensity assessment of pedestrian collisions in city of Mashhad based on fuzzy probabilities

Farzaneh Tatari and Mohammad-R. Akbarzadeh-T.

Department of Electrical Engineering, Ferdowsi University of Mashhad, Mashhad, Iran
Email: fa_tatari@yahoo.com, akbarzadeh@ieee.org

Abstract- *Fuzzy probabilities have been widely used in the areas of risk assessment and decision making. Here, we propose a system based on fuzzy probabilities for assessing the intensity of pedestrian collisions and levels of injury. The proposed approach uses possibility probability distributions for demonstrating fuzzy probabilities. A composition of possibility probability distributions (fuzzy probabilities) of collision intensities coming from different environmental variables yields the final fuzzy probability of intensity with higher reliability. The proposed approach is then applied to an actual database of pedestrian collisions from the City of Mashhad for over a period of five years.*

Keywords_ *Collision Intensity, Collision Variables, Fuzzy Probability, Possibility Probability Distribution.*

1 Introduction

Walking is a healthy and natural mean of transposition; it is therefore desirable that it also be safe. However, with the modern society and its rising crowd of transportation vehicles, this aspect of transposition has been sidelined and pedestrian collisions have caused significant social and financial losses every year. The safety of pedestrians during daily transposition is influenced by various variables. An appropriate paradigm for handling the effect of these variables can help insurance companies as well as city planners to better evaluate the safety of pedestrians in different situations and to plan the city environment for their improved safety. Unfortunately, recognizing all of the effective variables in a collision and their precise amount of effectiveness is non-trivial. The available information is highly imprecise and can lead to uncertain conclusions. With respect to the existing uncertainty in the collected information, the first source of data is known as "soft" data [17] that can be represented in linguistic form. This data is from expert opinions based on their background knowledge about the collision's intensity by considering related variables. Due to the linguistic form of this information and imprecision of data in this application, soft computing based methods, and in particular fuzzy-logic based analysis, offer a promising solution paradigm [18] to handle this type of uncertainty. In addition to soft data, the statistical historical data of pedestrian collisions are another valid data source which can be helpful in this case. The statistical data of pedestrian collisions may be incomplete when the number of observed data is not considerably large. Hence the statistical data are also accompanied by uncertainty which is caused by sparsity and insufficiency of data. We have found fuzzy probability framework as a suitable approach which enables us to enhance the reliability of our assessments by employing the both databases of soft data and statistical data at the same time. Fuzzy probabilities were first introduced by Zadeh (1984). Fuzzy probability theory [2] is a fuzzy approach to probability theory and is a generalized form of probability theory. In fuzzy probability, probability theory is complemented with an extra dimension of uncertainty provided by fuzzy set theory [16]. Generally we can divide the applications of fuzzy probabilities to two different main areas. The first is the area of reliability and risk assessment. In this area fuzzy probability has been widely applied in fuzzy fault trees [3,4,8] to assess the fault risk, reliability assessment for pressure piping [20], risk assessment of natural hazards [7] and reliability enhancement by combining expert opinions [14]. The second area is the area of the decision making. In this area, the fuzzy probabilities have been employed for decision making in perception-based theory [19], optimal decision fusion [11,12], inference by aggregation [9], information retrieval [6] and inventory control [1].

At any collision, there are two states for the pedestrian who has been hit by a car, in one state he would be just injured and in the other state he would die. Here, we employ fuzzy probabilities to handle the imprecision in expert opinions as the first dataset to assess the probability of injury and death for the pedestrians of Mashhad. We use fuzzy numbers to show these fuzzy probabilities. The second database is the statistical numeric data of pedestrian's collisions in Mashhad [10]. We combine these two insufficient databases to provide a more reliable result by the use of possibility probability distribution (PPD) which can model fuzzy probabilities in a suitable way.

2 Possibility probability distribution

The idea of representing assessments with PPD has been originally proposed by Haung [5]. This idea was improved by Karimi and Hullermeier [7] which was a new concept of fuzzy probability expressed by PPD. As we mentioned, on one hand, the statistical data in our type of application are typically insufficient, on the other hand background knowledge is often accompanied by imprecision. Therefore we apply the PPD to combine these two databases based on Bayesian approach. In the PPD approach, the prior knowledge (soft data) which is called prior distribution can be specified by a fuzzy number. $\overline{\theta}^{(i)}$ is an estimated probability by an expert for the state of death or injury in any collision where i is the variable that influences this probability and $p_i(\theta)$ is the prior distribution modeled in the form of symmetric, triangular fuzzy number, whose center is given by $\overline{\theta}^{(i)}$ (θ is the variable representing any probability in unit interval of [0,1]). As stated in [7] the support of the fuzzy number is of the form

ISBN: 978-989-95079-6-8

$$[\bar{\theta}^{(i)} - \bar{\theta}^{(i)}(1-\bar{\theta}^{(i)}).s \ , \bar{\theta}^{(i)} + \bar{\theta}^{(i)}(1-\bar{\theta}^{(i)}).s] \quad (1)$$

$$0 \le s \le \min(1/\bar{\theta}^{(i)}, 1/(1-\bar{\theta}^{(i)})) \quad (2)$$

the so-called uncertainty factor, is a constant that specifies the reliability of the point estimation. For combining prior knowledge with empirical data which is the available statistical numeric data, we first divide the unit interval of probabilities into m points, $\theta_j, j = 1,...,m$, and then calculate the posterior probability for each point θ_j as follows [7].

$$p'_i(\theta_j) = \binom{n}{n_i} \theta_j^{n_i} (1-\theta_j)^{n-n_i} . p_i(\theta_j) \approx$$

$$\frac{1}{c}(\gamma_j . q_j + (1-\gamma_j).q_{j+1}),$$

$$q_j = \theta_j^{n_i} (1-\theta_j)^{n-n_i} \, p_i(\theta_j) \quad (3)$$

where n_i is the number of observations that satisfies the features of the ith variable among n observations. $\gamma_j \in [0,1)$ is a unique value such that

$$\theta_j = \gamma_j \theta_j + (1-\gamma_j).q_{j+1} \quad (4)$$

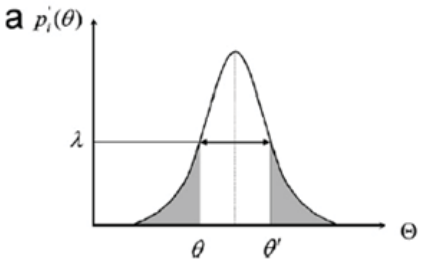
and c is a normalizing constant that guarantees

$$\int_0^1 p_i'(\theta) d\theta = 1 \quad (5)$$

Now is the time of transforming probability distribution to possibility distribution. Suppose a probability measure P on a set X is obtained via some statistical experiment. This probability function is a very rich piece of information, if the number of statistical experiments supporting it, is high enough. According to widely accepted consistence principle, the possibility measures should dominate P in the sense that $P(A) \le \pi(A)$ for all events $A \subseteq X$ and the maximally specific possibility distribution that exists must be unique [7]. As illustrated in [7] the most specific possibility distribution that approximates P from above (in the sense that $P \le \pi$) can be derived quite easily: for obtaining a possibility degree for any θ, $\pi_i(\theta)$, first $\lambda = p_i(\theta)$ is computed. Next, the second boundary point θ' that satisfies $p_i(\theta') = \lambda$ is found. Finally, the possibility degree $\pi_i(\theta)$ can be obtained as:

$$\pi_i(\theta) = \pi_i(\theta') = 1 - \left| \int_\theta^{\theta'} p'_i(x) dx \right|. \quad (6)$$

This possibility is equal to the area shaded grey in Fig. 1.a.



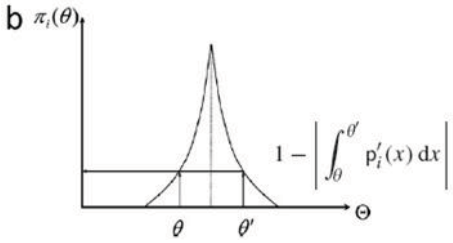


Figure 1: a. probability distribution to be transformed into a possibility distribution; b. transformed possibility distribution

3 Combining experts opinions and statistical data

We collected expert opinions (based on their own background knowledge and their reviews of traffic statics of death and injury in middle east countries [10]) about the percentage of collisions intensity (injury and death) by considering just one certain significant variable. The results of expert opinions are shown in Tables 1~5.

Table 1: Significant variable: hit organ

Injury probability if	Death probability if
Head and neck is hit, is approximately 0.09	Head and neck is hit, is approximately 0.55
Hand and arm is hit, is approximately 0.01	Hand and arm is hit, is approximately 0.001
Chest and stomach is hit, is approximately 0.2	Chest and stomach is hit, is approximately 0.2
Legs and pelvis is hit, is approximately 0.3	Legs and pelvis is hit, is approximately 0.03
More than one organ are hit, is approximately 0.5	More than one organ are hit, is approximately 0.3

Table 2: Significant variable: agility (crossing ability)

Injury probability for a pedestrian	Death probability for a pedestrian
Able to cross is 0.3	Able to cross is 0.4
Unable to cross is 0.6	Unable to cross is 0.6

Table 3: Significant variable: vehicle front shape

Injury probability if vehicle	Death probability if vehicle
Has bonnet is 0.7	Has bonnet is 0.4
Does not have bonnet is 0.2	Does not have bonnet is 0.2

Table 4: Significant variable: collision location

Injury probability if location is	Death probability if location is
In the city is 0.6	In the city is 0.3
Out of city is 0.04	Out of city is 0.05
In the suburb is 0.2	In the suburb is 0.15

Table 5: Significant variable: type of road

Injury probability if the road is a	Death probability if the road is a
Highway is 0.2	Highway is 0.6
Boulevard is 0.5	Boulevard is 0.6
Two_way road is 0.3	Two_way road is 0.2
incidental way is 0.1	incidental way is 0.05

With respect to the resulting experts ideas we obtained the fuzzy numbers for the proposed probability based on the approach illustrated in Section 2 where s is chosen as

$$s = 1/2\,(\min(1/\bar{\theta}^{(i)}, 1/(1-\bar{\theta}^{(i)}))) \quad (7)$$

It should be mentioned that we normalized $P(\bar{\theta}^{(i)})$ of all

ISBN: 978-989-95079-6-8

the prior probability distributions by factor N, to convert the prior probability distributions to fuzzy numbers.

$$N = \begin{cases} 2/(\overline{\theta}^{(i)}) & \overline{\theta}^{(i)} \le 0.5 \\ 2/(1-\overline{\theta}^{(i)}) & \overline{\theta}^{(i)} \ge 0.5 \end{cases} \quad (8)$$

As an example, through Figs. 2~3 we have shown the result of fuzzy probabilities of injury and death based on hit organ variable.

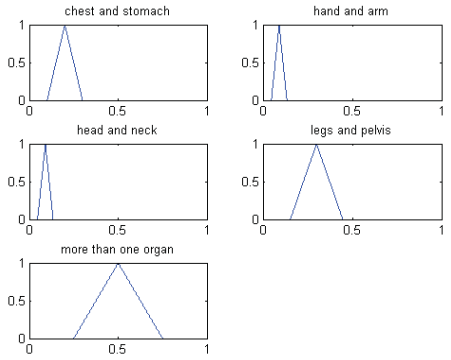

Figure 2: Injury fuzzy probability considering hit organ

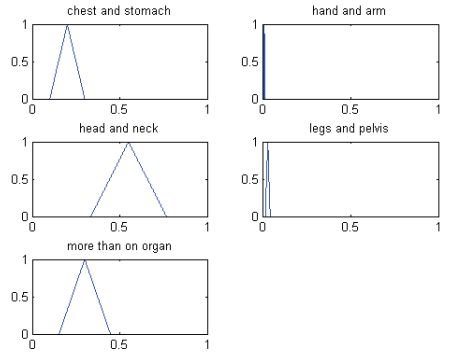

Figure 3: Death fuzzy probability considering hit organ

In the next step we apply (3) to obtain the posterior distribution based on statistical data which was gathered during one month in Shahidkamyab and Emamreza hospitals. In our database among 131 victims 99 of them had just injured and 32 of them had died. While injury and death are two independent states, we have considered the injuries which ends to fatality in the death statistical society. Therefore n=32 for dead pedestrians statistical society and n=99 for injured statistical society, these numbers are distributed through any variable partitions based on the collected data which is available in Tables 6 ~ 10. Among 18 factors which consist of human, vehicle, road and environmental factors, we could find 5 variables (hit organ, agility (crossing ability), vehicle front shape, location of collision and type of road) that had significant relations with collision intensity by the 5 percentage of error using SPSS.

Table 6: Distribution of statistical database on Significant variable of hit organ

Total number of injured pedestrians = 99	Total number of died pedestrians = 32
Head and neck = 10	Head and neck = 17
Hand and arm = 0	Hand and arm = 4
Chest and stomach = 5	Chest and stomach = 2
Legs and pelvis = 33	Legs and pelvis = 1
More than one point = 51	More than one point = 8

Table 7: Distribution of statistical database on Significant variable of agility (crossing ability)

Total number of injured pedestrians = 99	Total number of died pedestrians = 32
Able = 97	Able = 24
Unable =2	Unable = 8

Table 8: Distribution of statistical database on Significant variable of vehicle of front shape

Total number of injured pedestrians = 99	Total number of died pedestrians = 32
Has bonnet = 86	Has bonnet = 23
Does not have bonnet = 13	Does not have bonnet = 9

Table 9: Distribution of statistical database on Significant variable of location of the collision

Total number of injured pedestrians = 99	Total number of died pedestrians = 32
In the city =60	In the city =14
Out of city =3	Out of city =6
Suburb =36	Suburb =12

Table 10: Distribution of statistical database on Significant variable vehicle of type of road

Total number of injured pedestrians = 99	Total number of died pedestrians = 32
Highway = 4	Highway = 7
Boulevard = 51	Boulevard = 10
Two way road = 34	Two way road = 11
Incidental way = 10	Incidental way = 4

The resulting posterior distributions of injury and death for the hit organ variable are as below:

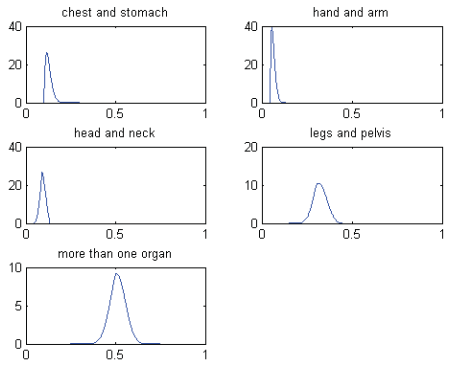

Figure 4: Posterior distribution of injury considering hit organ

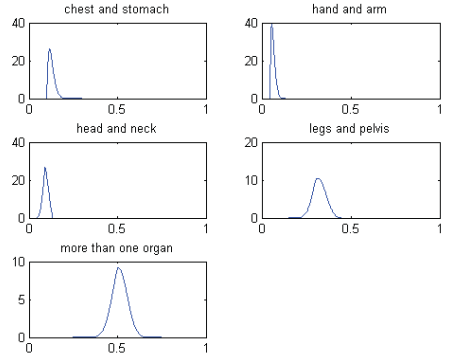

Figure 5: Posterior distribution of death considering hit organ

ISBN: 978-989-95079-6-8

Based on the procedure mentioned for transforming probability distribution to possibility distribution in Section 2, we obtained the possibility distributions of probability distributions. By comparing the prior fuzzy probabilities and possibility-probability distributions (Figs. 6~15), It can be easily interpreted that by combining the information of two databases less ambiguous, i.e. more certain and reliable results, are obtained in PPDs. It is also obvious that the PPD (fuzzy probability) can easily handle the existing uncertainty in the results.

4 Collision intensity assessment

As it was explained before there are various variables which influence the intensity of collisions. If we assess the collision intensity based on one or few known variables the uncertainty of the assessment is so higher in comparison with the time that the assessment is based on more known variables. Therefore we can assess the fuzzy probability of injury or death of the pedestrians based on the combination of all significant variables PPDs. It should be mentioned that the employed method for combining fuzzy probabilities is based on fuzzy arithmetic [2] not Bayesian approach.

Assume that $\overline{A}$ and $\overline{B}$ are fuzzy probabilities of X. By having $\overline{A}$ and $\overline{B}$ which have been calculated based on different variables of X , we want to obtain $\overline{C}$ as a more reliable fuzzy probability of X by considering both variables, as the following

$$P[X(a)] \text{ is } \overline{A} \text{ and } P[X(b)] \text{ is } \overline{B} \equiv P[X(a,b)] \text{ is } \overline{C}.$$

Where a and b are related variables of X which effect assessing the fuzzy probability of X. One of the most common ways to aggregate fuzzy probabilities such as $\overline{A}$ and $\overline{B}$ is to obtain the α _cuts of $\overline{C}$ for any $\alpha \in [0,1]$ as below

$$\overline{A}[\alpha] = [a_1(\alpha), a_2(\alpha)], \overline{B}[\alpha] = [b_1(\alpha), b_2(\alpha)] \Rightarrow$$

$$\overline{C}(\alpha) = [\min(a_1(\alpha), b_1(\alpha)), \max(a_2(\alpha), b_2(\alpha))] \quad (9)$$

We can extend this procedure to more than two fuzzy probabilities with different variables to obtain a more reliable fuzzy probability of X, $\overline{C}$. It is also notable to know that any α _cut in any fuzzy probability is a sub interval of the unit interval of probabilities. However the mentioned method may exhibit shortcomings, first the max and min operations are noninteractive so they tend to lead to the results that are getting close to 1 and 0 respectively. Second, the result of combination at any level of α is entirely dependent upon the extreme bounds. To overcome these shortcomings we propose to calculate the α _cuts of $\overline{C}$ based on fuzzy arithmetic [2].

$$\overline{A}[\alpha] = [a_1(\alpha), a_2(\alpha)], \overline{B}[\alpha] = [b_1(\alpha), b_2(\alpha)] \Rightarrow$$

$$\overline{C}(\alpha) = [a_1(\alpha) \times b_1(\alpha) \ , \ a_2(\alpha) \times b_2(\alpha)] \quad (10)$$

The only drawback of fuzzy arithmetic method is that it results in low fuzzy probabilities which do not conform the reality (statistical data) but we can solve this problem by normalizing the obtained fuzzy probabilities of all the existing states. This normalization is in the way that for each $\alpha -$ cut , $\alpha \in [0,1]$, the summation of $\alpha -$ cut boundary points (probabilities) must be equal to one. In the specific application that we focus on it, we have two states of "X= death, Y= injury" in any collision, therefore we must normalize the final fuzzy probabilities in the way that

$$P'_{X1\alpha} = \frac{P_{X1\alpha}}{(P_{X1\alpha} + P_{Y2\alpha})}, \quad P'_{Y2\alpha} = \frac{P_{Y2\alpha}}{(P_{X1\alpha} + P_{Y2\alpha})},$$

$$P'_{X2\alpha} = \frac{P_{X2\alpha}}{(P_{X2\alpha} + P_{Y1\alpha})}, \quad P'_{Y1\alpha} = \frac{P_{Y1\alpha}}{(P_{X2\alpha} + P_{Y1\alpha})}$$

$$\text{then } P'_{X1\alpha} + P'_{Y2\alpha} = 1 \text{ and } P'_{X2\alpha} + P'_{Y1\alpha} = 1 \ \forall \alpha \in [0,1] \quad (11)$$

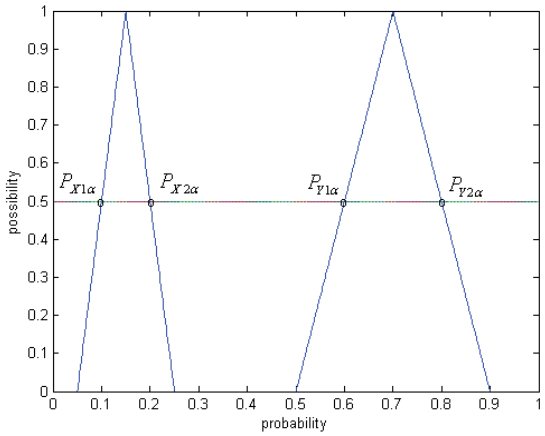

Figure 16: The probabilities which must be normalized at any α level

ISBN: 978-989-95079-6-8

We continue by an example where we used the fuzzy arithmetic procedure to obtain a more reliable fuzzy probability of injury and death based on the obtained results. In the following example for combining the fuzzy probabilities of injury and death which were assessed based on 5 significant variables, we use seven α _cuts (α = 0, 0.1, 0.3, 0.5, 0.7, 0.8, 1) of all fuzzy probabilities (PPDs) to do the combination.

Example: A pedestrian who does not have the agility (crossing ability) is crashed by a mini-bus while crossing a two-way road in city of Mashhad. His chest and stomach are hit by the vehicle. (a) What is the fuzzy probability of his injury? (b) What is the fuzzy probability of his death?

Hit organ: chest and stomach, agility (crossing ability): unable to cross, Vehicle front shape: does not have bonnet, Collision location: in the city, Type of road: two-way road. By combining the PPDs of the related variables we can obtain the final fuzzy probability of injury as below:

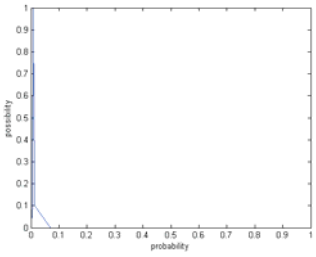

Figure 17: Fuzzy probability of injury before normalization

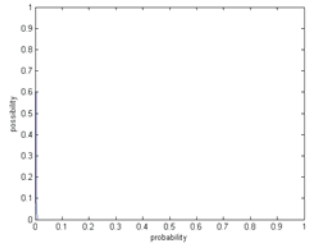

Figure 18: Fuzzy probability of death before normalization

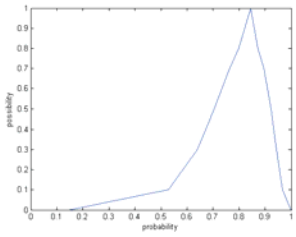

Figure 19: Normalized fuzzy probability of injury

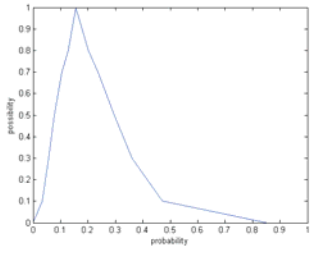

Figure 20: Normalized fuzzy probability of death

The normalized fuzzy probabilities are closer to statistical data and reality and the fuzzy probability of death and injury are complement of each other. The obtained result is more reliable while it has considered 5 significant variables at the same time instead of one.

5 Conclusion

Each year, too many pedestrians die all over the world with significant social and financial losses. The intensity of these collisions is of great importance for city planners and insurance companies alike. Here, we propose the use of fuzzy set theory to complement the probability theory with an additional dimension of uncertainty which leads to fuzzy probability characterized in terms of possibility probability distribution. We assessed the intensity of pedestrian collisions in Mashhad based on the variables that had significant relation with the intensity by use of fuzzy probability. The results indicate that by considering more significant variables in our assessment, we can decrease the amount of uncertainty and reach a more reliable result.

Abstract—*The paper presents a form of rendering classical mathematical notions by formal theories over suitable t-norm fuzzy logics in such a way that references to real numbers are eliminated from definitions and theorems, being removed to the standard semantics of fuzzy logic. Several examples demonstrate how this move conceptually simplifies the theory in exchange for non-classical reasoning, facilitates certain generalizations, and puts the concepts into a different perspective. The formal framework employed for the number-free formalization of mathematical concepts is that of higher-order fuzzy logic, also known as Fuzzy Class Theory.*

Keywords—Fuzzy Class Theory, fuzzy mathematics, fuzzy set, real-valued function, similarity-based limit, t-norm fuzzy logic.

1 Introduction

In the standard semantics of t-norm fuzzy logics [1], truth values are represented by real numbers from the unit interval $[0, 1]$; truth functions of n-ary propositional connectives are certain real-valued functions on $[0, 1]^n$; and the quantifiers $\exists, \forall$ are interpreted as the suprema and infima of sets of truth values. Read inversely, the apparatus of t-norm fuzzy logics expresses, by means of their standard semantics, certain first- and second-order constructions over real numbers. The axioms and rules of t-norm logics are designed to capture basic properties of such constructions and ensure the soundness of formally derivable theorems expressible in the language.

A suitable formal theory in first-order fuzzy logic thus can, by means of its standard semantics, express facts about classical mathematical notions and make them derivable by logical deductions in fuzzy logic. Since real numbers occur in the standard semantics of such a theory, they need no longer be explicitly mentioned by the theory itself. A notion of classical mathematics then becomes represented as the standard model of another notion of formal fuzzy mathematics that makes no explicit reference to real numbers: the reals are only implicitly present behind the logical axioms that govern reasoning in formal fuzzy mathematics.

This way of eliminating real numbers from the theory in favor of reasoning by means of t-norm fuzzy logic will here be called the *number-free* approach.

Number-free formalization of mathematical concepts is not new and has implicitly been around since the beginning of the theory of fuzzy sets: in fact, the notion of fuzzy set itself can be understood as a number-free rendering of the notion of real-valued function (see Section 2). However, it was only after the advancement of t-norm fuzzy logics, mostly in the past decade, that number-free notions could be treated rigorously in formal theories over first-order fuzzy logics. An early example of the number-free treatment of a classical notion is the formalization of finitely additive probability as a modality *Probable* in Łukasiewicz logic (see Section 3). Nevertheless, number-free rendering of more advanced mathematical notions requires more complex concepts of formal fuzzy mathematics—esp. higher-order set-constructions and a formal theory of fuzzy relations. The latter prerequisites have only recently been developed in the framework of higher-order fuzzy logic [2, 3, 4], which made it possible to apply the number-free approach systematically to various classical mathematical notions.

The profit we gain under the number-free approach in exchange for having to use non-classical rules of reasoning is, in the first place, conceptual simplification (roughly speaking, we get 'a set for a function'). Secondly, the number-free rendering often reveals a new perspective upon the notion, exposing the gradual quality of the classical construct, treating its gradualness as a primitive rather than derivative feature, and telling a different story about the concepts than is told by classical mathematics. Thirdly, many theorems of classical mathematics are under this approach detected as provable by simple (often, propositional) logical derivations in a suitable fuzzy logic, instead of complex classical proofs involving arithmetic, infima, functions, etc. Furthermore, adopting a non-standard semantics (e.g., using Chang's MV-algebra instead of the standard real numbers) or a different interpretation of the logical symbols involved (e.g., taking another t-norm for conjunction) yields an effortless generalization that might be harder to find (and motivate) in the classical language of crisp mathematics. Finally, the many-valuedness of all formulae in fuzzy logic makes it possible to consider another kind of graded generalization, by admitting partial satisfaction of the axioms for the represented notion (e.g., a metric to degree .99, cf. [5, 6]).

The particular formal framework in which number-free formalization of classical mathematical concepts is carried out in this paper is that of higher-order fuzzy logic, also known as Fuzzy Class Theory (FCT), over a suitable propositional fuzzy logic at least as strong as $\mathrm{MTL}_\triangle$. A working knowledge of FCT will be assumed throughout; for an introduction to the theory and more information see [2, 5]. For reference, the definitions used in the present paper are repeated below in the Appendix.

The aim of this paper is only to introduce the number-free approach as a distinct paradigm of formalization, rather than to develop particular number-free theories in depth. Therefore it only gives definitions of and a few observations on several number-free notions and discusses the merits of such a formalization; a detailed investigation of number-free theories is left for future work. A slightly more eloquent version of this paper has been made available as a research report [7].

2 Real-valued functions

The very first notion of fuzzy mathematics, namely Zadeh's notion of fuzzy set [8], can be regarded as a number-free representation of classical $[0,1]$-valued functions by non-classical (namely, fuzzy) sets. Even though the formal apparatus of first-order fuzzy logic, which makes it possible to cast fuzzy sets as a primitive notion instead of representing them by classical real-valued functions, was developed years later, the tendency of regarding fuzzy sets and relations as a number-free rendition of real-valued functions has partly been present since the very beginning of the fuzzy set theory, as witnessed by the vocabulary and notation employed. E.g., the function $x \mapsto \min(A(x), B(x))$ is in the traditional fuzzy set theory denoted by $A \cap B$ and called the *intersection* of A and B: that is, the functions $A, B\colon X \to [0,1]$ are regarded as (non-classical) *sets* rather than real-valued functions (as the intersection of real-valued functions is a different thing). Similarly, such notions as fuzzy relational composition or the image under a fuzzy relation would make little sense if the n-ary functions involved were not regarded as (a kind of non-classical) relations. The terminological shift towards the number-free discourse is expressed by the very term "fuzzy set" and by its informal motivation of an unsharp collection of elements.

A certain part of the talk about *real-valued functions* and their properties was thus replaced by a talk about *sets* and *relations* that behave non-classically (e.g., do not follow the rule of excluded middle). This move eliminated references to numbers at least from the wording of some theorems, giving them compact forms and new conceptual meanings.[1] Clearly, the original number-free notion of fuzzy set has proved immensely fruitful even in its semi-formal form of traditional fuzzy mathematics. The formal apparatus of logic-based fuzzy mathematics has provided means for accomplishing the long-present idea and developing a fully fledged number-free approach to fuzzy sets and fuzzy relations.[2]

3 Finitely additive probability measures

Another number-free representation, already based on formal fuzzy logic, was the axiomatization of finitely additive probability measures as models of a fuzzy modality *Probable* over propositional Łukasiewicz logic by Hájek, Godo, and Esteva [10]. Later it was elaborated in a series of papers by Flaminio, Marchioni, Montagna, and the authors of [10]. We shall briefly recapitulate the original axiomatization (adapted from [11]) as another illustration of the number-free approach.

Consider a classical probability space $(\Omega, \mathcal{B}, \pi)$, where Ω is a set of elementary events, $\mathcal{B}$ a Boolean algebra of subsets of Ω, and π a finitely additive probability measure on $\mathcal{B}$, i.e., a function $\pi\colon \mathcal{B} \to [0,1]$ satisfying the following conditions:

$$\pi(\Omega) = 1 \tag{1}$$

$$\text{If } A \subseteq B, \text{ then } \pi(A) \leq \pi(B) \tag{2}$$

$$\text{If } A \cap B = \emptyset, \text{ then } \pi(A \cup B) = \pi(A) + \pi(B) \tag{3}$$

A number-free representation of π draws on the fact that a $[0,1]$-valued function on a Boolean algebra can be understood as a standard model of a fuzzy modality P over an algebra of crisp propositions. The above conditions on π can be transformed into the axioms for P, which (due to the additivity) are expressible in Łukasiewicz logic:[3]

Definition 3.1. The axioms and rules of the logic $\mathrm{FP}(\mathbf{Ł})$ are those of Łukasiewicz propositional logic plus the following axioms and rules, for non-modal φ, ψ:

$$\varphi \vee \neg\varphi \tag{4}$$

$$\text{From } \varphi \text{ infer } P\varphi \tag{5}$$

$$P\varphi, \text{ for all Boolean tautologies } \varphi \tag{6}$$

$$P(\varphi \to \psi) \to (P\varphi \to P\psi) \tag{7}$$

$$P(\neg\varphi) \leftrightarrow \neg P\varphi \tag{8}$$

$$P(\varphi \vee \psi) \leftrightarrow ((P\varphi \to P(\varphi \wedge \psi)) \to P\psi) \tag{9}$$

The axioms and rules of $\mathrm{FP}(\mathbf{Ł})$ ensure the following representation theorem (adapted from [10]):

Theorem 3.2. *Any probability space $(\Omega, \mathcal{B}, \pi)$ is a standard model of $\mathrm{FP}(\mathbf{Ł})$. Vice versa, all standard models of $\mathrm{FP}(\mathbf{Ł})$ are probability spaces.*

The representation theorem shows that the number-free theory faithfully captures the original notion of finitely additive probability measure. Moreover, by the completeness theorem of $\mathrm{FP}(\mathbf{Ł})$ w.r.t. probability spaces, proved in [11], all valid laws of finitely additive probability that are expressible in the language of $\mathrm{FP}(\mathbf{Ł})$ can in $\mathrm{FP}(\mathbf{Ł})$ be also (number-freely) proved.

In a given probability space $(\Omega, \mathcal{B}, \pi)$, i.e., a standard model of $\mathrm{FP}(\mathbf{Ł})$ with $\|P\| = \pi$, the truth value of $P\varphi$ is the probability of the event φ: $\|P\varphi\| = \pi(\|\varphi\|)$; the formula $P\varphi$ can therefore be understood as "φ is probable". Numerical calculations with probabilities are thus in $\mathrm{FP}(\mathbf{Ł})$ replaced by *logical derivations* with the modality "is probable". The key difference is that the latter represent inference *salva probabilitate* (i.e., salvo *probabilitatis gradu,* in the sense of P): e.g., it can be observed that numberless probability is transmitted by modus ponens, as $P\varphi \,\&\, P(\varphi \to \psi) \to P\psi$, i.e., "if φ is probable and $\varphi \to \psi$ is probable, then ψ is probable", is a theorem of $\mathrm{FP}(\mathbf{Ł})$.

The number-free approach to probability facilitates several kinds of generalization. First, generalizations to models over non-standard algebras for Łukasiewicz logic: thus we can have, e.g., probability valued in Chang's MV-algebra, or in non-standard reals (as in [12]). Second, a generalization to measures with only partially satisfied additivity (by a many-valued interpretation of the axioms, see [6]). And third, a generalization to the probability of fuzzy events, where one discards the axiom $\varphi \vee \neg\varphi$ for events and adapts the finite additivity axiom to work well with fuzzy events (e.g., as $P(\varphi \oplus \psi) \leftrightarrow ((P\varphi \to P(\varphi \,\&\, \psi)) \to P\psi)$).[4]

[1] The elimination of numbers also from proofs would have required a consistent use of first-order fuzzy logic. This approach was not embraced in the early works on fuzzy set theory, even though particular first-order fuzzy logics already existed, e.g., [9].

[2] Cf. [2, 3], where the formal theory of fuzzy sets and relations is developed without making any reference to real numbers in definitions, theorems, or proofs (only in explanatory semantic examples).

[3] Ł with rational truth constants is used in [10], but the truth constants are inessential for our account. The language is two-layered, admitting only non-modal formulae and propositional combinations of non-nested modal formulae.

[4] This approach has been taken in [13], though only over finitely-valued events, as the authors strove for the completeness of the logic; in [12] this was generalized to infinitely-valued events, with completeness w.r.t. non-standard reals.

4 Distribution functions

Classical distribution functions present a special way how to define a probabilistic measure on Borel sets, i.e., on the σ-algebra $\mathcal{B}$ of subsets of the real line generated by all intervals $(-\infty, x]$. A function $f\colon \mathbb{R} \to [0,1]$ defines a measure on $\mathcal{B}$ with $\mu(-\infty, x] = f(x)$ and $\mu(\mathbb{R}) = 1$ iff it satisfies the following conditions, which can thus be taken as the axioms for distribution functions:

1. *Monotony:* if $x \leq y$ then $f(x) \leq f(y)$, for all $x, y \in \mathbb{R}$
2. *Margin conditions:* $\lim_{x\to-\infty} f(x) = 0$, $\lim_{x\to+\infty} f(x) = 1$
3. *Right-continuity:* $\lim_{x\to x_0^+} f(x) = f(x_0)$ for all $x_0 \in \mathbb{R}$

Let us translate these conditions into the number-free language.[5] The function $f\colon \mathbb{R} \to [0,1]$ represents a standard fuzzy set of reals, i.e., in FCT over any expansion of MTL_Δ, the standard model of a predicate A on reals.[6] By the standard semantics of MTL_Δ, the above conditions translate into the following axioms on the predicate A:[7]

$$(\forall xy)(x \leq y \to (Ax \to Ay)) \tag{10}$$

$$\neg(\forall x)Ax,\ (\exists x)Ax \tag{11}$$

$$(\forall x_0)[(\forall x > x_0)Ax \to Ax_0] \tag{12}$$

In FCT, these conditions express, respectively, the *upperness* of A in $\mathbb{R}$, the *null plinth* and *full height* of A, and the *left-closedness* of the fuzzy upper class A. Consequently, number-free distribution functions are left-closed upper sets in $\mathbb{R}$ with full height and null plinth, i.e., (weakly bounded) *fuzzy Dedekind cuts on* $\mathbb{R}$. The number-free rendering of distribution functions as fuzzy Dedekind cuts corresponds to the known fact that distribution functions represent Hutton fuzzy reals (cf., e.g., [15]). A use of fuzzy Dedekind cuts for the development of a logic-based theory of fuzzy intervals (or fuzzy numbers) is hinted at in [16].

5 Continuous functions on $\mathbb{R}$

In Section 4 we abused the presence of monotony for the number-free rendering of right-continuity. Yet, if we aim at a graded theory where monotony can be satisfied to partial degrees, we need a different number-free characterization of continuity that does not rely on monotony. We shall work with functions $\mathbb{R} \to [0,1]$ only, even though various generalizations are easy to obtain.

For a number-free rendering of right-continuity, we shall use the following classical characterization. A function $f\colon \mathbb{R} \to [0,1]$ is right-continuous in x_0 iff

$$\limsup_{x\to x_0^+} f(x) = \liminf_{x\to x_0^+} f(x) = f(x_0), \tag{13}$$

where

$$\limsup_{x\to x_0^+} f(x) = \inf_{x_1>x_0} \sup_{x_1>x>x_0} f(x) \tag{14}$$

$$\liminf_{x\to x_0^+} f(x) = \sup_{x_1>x_0} \inf_{x_1>x>x_0} f(x). \tag{15}$$

This translates into the following number-free definitions in FCT over MTL_Δ:[8]

$$\mathrm{LimSup}^+(A, x_0) \equiv_{\mathrm{df}} (\forall x_1 > x_0)(\exists x \in (x_0, x_1))Ax \tag{16}$$

$$\mathrm{LimInf}^+(A, x_0) \equiv_{\mathrm{df}} (\exists x_1 > x_0)(\forall x \in (x_0, x_1))Ax \tag{17}$$

$$\Delta\,\mathrm{Cont}^+(A, x_0) \equiv_{\mathrm{df}} (Ax_0 = \mathrm{LimSup}^+(A, x_0))\ \&\ (Ax_0 = \mathrm{LimInf}^+(A, x_0)) \tag{18}$$

The left-sided predicates LimSup^- and LimInf^- are defined dually (with $<$ for $>$), and the both-sided ones as

$$\mathrm{LimSup}(A, x_0) \equiv_{\mathrm{df}} \mathrm{LimSup}^-(A, x_0) \vee \mathrm{LimSup}^+(A, x_0) \tag{19}$$

$$\mathrm{LimInf}(A, x_0) \equiv_{\mathrm{df}} \mathrm{LimInf}^-(A, x_0) \wedge \mathrm{LimInf}^+(A, x_0). \tag{20}$$

These definitions reconstruct the classical notions in a number-free way in the framework of FCT; the representation theorems follow directly from the above considerations and the standard semantics of MTL_Δ. The following observation shows that many properties of the classical notions can be reconstructed in FCT as well.

Observation 5.1. By shifts of crisp relativized quantifiers valid in first-order MTL_Δ, the following theorems are easily provable in FCT:[9]

1. $\mathrm{LimInf}(A, x_0) \leq \mathrm{LimSup}(A, x_0)$
2. $A \subseteq B \to (\mathrm{LimSup}(A, x_0) \to \mathrm{LimSup}(B, x_0))$ and analogously for LimInf.
3. $\mathrm{LimInf}(\smallsetminus A, x_0) \leq \neg\,\mathrm{LimSup}(A, x_0)$
   $\mathrm{LimSup}(\smallsetminus A, x_0) \geq \neg\,\mathrm{LimInf}(A, x_0)$
   (Equality holds in logics with involutive negation, but not generally in MTL_Δ.)
4. $\mathrm{LimInf}(A \sqcap B, x_0) = \mathrm{LimInf}(A, x_0) \wedge \mathrm{LimInf}(B, x_0)$
   $\mathrm{LimInf}(A \sqcup B, x_0) = \mathrm{LimInf}(A, x_0) \vee \mathrm{LimInf}(B, x_0)$
   and analogously for LimSup.

Since the definitions reconstruct classical notions, we have retained the classical terminology and notation referring to limits and continuity, even though these regard membership functions (i.e., semantic *models* of fuzzy classes), rather than fuzzy classes themselves. In FCT, the fuzzy predicate $\mathrm{LimSup}^+(A, x_0)$ actually expresses the condition that x_0 is a *right-limit point* of the fuzzy class A, and $\mathrm{LimInf}^+(A, x_0)$ that x_0 is an *interior point* of $A \cup \{x_0\}$ in the left half-open interval topology,[10] as these are the properties expressed by the defining formulae if all sets involved are crisp.

[5] Of course, the 'translation' is by no means unique: we always select one which is sufficiently straightforward and which results in *meaningful* concepts of fuzzy mathematics.

[6] Recall that $\mathbb{R}$ as well as other crisp mathematical structures are available in FCT by means of the Δ-interpretation, see [2, §7] and [14, §4]. In this and the next section, we shall understand all first-order quantifications relativized to $\mathbb{R}$, unless specified otherwise.

[7] We use the fact that due to the monotony assumed, the margin conditions reduce to $\inf_x f(x) = 0$ and $\sup_x f(x) = 1$, and the right-continuity to $f(x_0) \geq \inf_{x>x_0} f(x)$. The representation theorem is then immediate by the standard semantics of MTL_Δ. Observe that as the axioms are required to degree 1, they are (due to the crispness of $\leq$) independent of the particular left-continuous t-norm used.

[8] Again it can be observed that the definitions are independent of a particular t-norm and are the same in all expansions of MTL_Δ.

[9] The theorems are stated for both-sided limits only, but hold equally well for one-sided limits.

[10] I.e., the topology with the open base of all half-open intervals $[a, b)$, also known as the lower-limit topology or the Sorgenfrey line.

ISBN: 978-989-95079-6-8

Consequently, the formulae $(\forall x_0 \in A)\,\mathrm{LimInf}(A, x_0)$ and $(\forall x_0 \in A)\,\mathrm{LimSup}(A, x_0)$ express the notions of *openness* resp. *closedness* of A in a fuzzy interval topology on $\mathbb{R}$. The study of this fuzzy topology and its relationship to the fuzzy interval topologies of [17, 18] is left for future work.

Like the definitions of LimInf and LimSup, the theorems of Observation 5.1 have double meanings, too. On the one hand they can be understood as number-free reconstructions and graded generalizations of the classical theorems on (membership) functions. On the other hand, they can be interpreted as fuzzy-mathematical theorems on (fuzzy) sets, under the above fuzzy interval topology on reals. In particular, 1. says that an interior point of a fuzzy set of reals is also its limit point; 2. that a limit point of a fuzzy set is also a limit point of a larger fuzzy set (and dually for interior points); 3. that an interior point of the complement of a fuzzy set A is not a limit point of A (and vice versa); and 4. that x_0 is a limit point of $A \sqcap B$ exactly to the degree it is a limit point of A *and* ($\wedge$) a limit point of B (and dually for $\sqcup$). (The theorems are graded, thus 'is' represents fuzzy implication $\rightarrow$.)

6 Operations on $\mathbb{R}$

In the previous examples, only the codomain of real-valued functions of reals was rendered numberless. Obviously, the domain $\mathbb{R}$ (or more conveniently, $\mathbb{R} \cup \{\pm\infty\}$) can be re-scaled into $[0, 1]$ and regarded as the standard set of truth degrees as well. The functions $\mathbb{R}^n \rightarrow \mathbb{R}$ then become n-ary functions from truth values to truth values, i.e., truth functions of fuzzy propositional connectives.

An apparatus for internalizing truth values and logical connectives in FCT was developed in [4, §3]. As shown there, the truth values can be internalized as the elements of the crisp class $\mathrm{L} = \mathrm{Ker}\,\mathrm{Pow}\{a\}$, i.e., subclasses of a fixed crisp singleton. The class L of internalized truth values is ordered by crisp inclusion $\subseteq^{\Delta}$, and the correspondence between internal and semantical truth values is given as follows:[11] $\alpha \in \mathrm{L}$ represents the semantic truth value of $\emptyset \in \alpha$, and the semantic truth value of φ is represented by the class $\overline{\varphi} =_{\mathrm{df}} \{a \mid \varphi\}$; the correspondences $\varphi \leftrightarrow (a \in \overline{\varphi})$ and $\overline{\varphi} \subseteq \overline{\psi} \leftrightarrow (\varphi \rightarrow \psi)$ then hold.

Logical connectives are then internalized by crisp functions $\mathbf{c}\colon \mathrm{L}^n \rightarrow \mathrm{L}$ (which can be called *internal, inner,* or *formal* connectives). In particular, definable connectives c of the logic are represented by the corresponding class operations $\overline{c} = \{x \in \mathrm{L} \mid c(x \in X_1, \ldots, x \in X_n)\}$ on L (e.g., & by $\cap$; $\vee$ by $\sqcup$; etc.). Since n-ary internal connectives are crisp functions valued in L, they can as well be regarded as fuzzy subsets of L^n, i.e., n-ary fuzzy relations on L. Usual fuzzy class operations and graded predicates, e.g., the graded inclusion

$$\mathbf{c} \subseteq \mathbf{d} \equiv_{\mathrm{df}} (\forall x_1 \ldots x_n)(\mathbf{c}x_1 \ldots x_n \rightarrow \mathbf{d}x_1 \ldots x_n), \quad (21)$$

then apply to them and make their theory graded.

The number-free theory of functions $\mathbb{R}^n \rightarrow \mathbb{R}$ is thus in fact the fuzzy-logical theory of internal connectives, i.e., of fuzzy relations on internal truth values. An elaboration of the theory of unary and binary internal connectives has been sketched in [19, 20]. These preliminary papers focus on the defining properties of *t-norms* (i.e., monotony, commutativity, associativity, and the unit) and the relation of domination between internal connectives, making them graded by reinterpretation of their defining formulae in fuzzy logic (cf. [2, §7], [5, §2.3], or [6, §4]) and studying their graded properties. A full paper on the topic (by the authors of [20]) is currently under construction.

7 Metrics

Recall that a *pseudometric*[12] on a set X is a function $d\colon X^2 \rightarrow [0, +\infty]$ such that

$$d(x, x) = 0 \quad (22)$$
$$d(x, y) = d(y, x) \quad (23)$$
$$d(x, z) \leq d(x, y) + d(y, z). \quad (24)$$

The numberless reduction will first need to normalize the range of pseudometrics from $[0, +\infty]$ to $[0, 1]$, e.g., by setting

$$c(x, y) = 2^{-d(x,y)}. \quad (25)$$

The defining conditions on pseudometric then become the following equivalent conditions on c:[13]

$$c(x, x) = 1 \quad (26)$$
$$c(x, y) = c(y, x) \quad (27)$$
$$c(x, z) \geq c(x, y) \cdot c(y, z) \quad (28)$$

These conditions are nothing else but the defining conditions of *fuzzy equivalences,* also known as *similarity relations* [21], in the standard semantics of product fuzzy logic [1]. We can thus equate number-free pseudometrics with *product similarities,* i.e., standard models of the following axioms in product fuzzy logic:

$$Cxx \quad (29)$$
$$Cxy \rightarrow Cyx \quad (30)$$
$$Cxy \,\&\, Cyz \rightarrow Cxz \quad (31)$$

The definition of a *metric* strengthens the first condition to $d(x, y) = 0$ iff $x = y$, which is equivalent to c being a *fuzzy equality* (also called *separated* similarity), i.e., $c(x, y) = 1$ iff $x = y$, thus replacing the first axiom by $Cxy \leftrightarrow x = y$.

Using a different left-continuous t-norm represents a different way of combining the distances $d(x, y)$ and $d(y, z)$ in the triangle inequality: e.g., with the minimum t-norm, c represents a *(pseudo)ultrametrics* under the same transformation (25), while with the Łukasiewicz t-norm, c represents a *bounded* pseudometric d under a different transformation $c(x, y) = (1 - d(x, y))/d_{\max}$, where $d_{\max} < +\infty$ is an upper bound on the distances. (The obvious both-way representation theorems are left to the reader.) Since furthermore many theorems on number-free metrics hold generally over MTL_{Δ}, it is quite natural to generalize the notion of number-free metrics to any similarity, not only the product one.

Various notions based on such (generalized) number-free metrics can be defined and their properties investigated in the framework of FCT (over MTL_{Δ} or stronger). Only a few

[11] However, see [4, Rem. 3.3] for certain metamathematical qualifications regarding this correspondence.

[12] For simplicity, we shall work with *extended* pseudometrics, allowing the value $+\infty$.

[13] Notice that since the function 2^{-x} reverses the order, the fuzzy relation $c\colon X^2 \rightarrow [0, 1]$ expresses *closeness* rather than distance.

ISBN: 978-989-95079-6-8

observations on number-free limits are given here as a concluding illustration of the numberless approach.

Fix a metric d rendered in the numberless way by a closeness predicate C under the transformation (25). The *limit* $\lim_{n\to\infty} x_n$ of a sequence $\{x_n\}_{n\in\mathbb{N}}$ (abbreviated $\vec{x}$) under C can be defined as follows:[14]

$$\Delta\mathrm{Lim}_C(\vec{x},x) \equiv_{\mathrm{df}} \Delta(\exists n_0)(\forall n > n_0)Cxx_n \qquad (32)$$

Theorem 7.1. *Standard models over product logic validate* $\Delta\mathrm{Lim}_C(\vec{x},x)$ *iff* $x = \lim_{n\to\infty} x_n$ *under* d.

Proof: $\lim x_n = x$ under d iff $\limsup d(x,x_n) = 0$, iff $\liminf 2^{-d(x,x_n)} = 1$, iff $\sup_{n_0} \inf_{n>n_0} c(x,x_n) = 1$, which is the semantics of $\Delta\mathrm{Lim}_C(\vec{x},x)$. □

As noted above, the meaning of $\Delta\mathrm{Lim}_C$ is natural not only in product logic, but also in other t-norm logics, esp. if the relation C is interpreted as *indistinguishability* rather than mere closeness:[15] then (32) expresses the condition that *from some index on, x_n is indistinguishable from x*. Similarly, Theorem 7.2 below expresses the fact that all limits of $\vec{x}$ are indistinguishable (to the degree the indistinguishability relation is symmetric and transitive).

Discarding the Δ in (32) yields a graded number-free notion of limit:[16]

$$\mathrm{Lim}_C(\vec{x},x) \equiv_{\mathrm{df}} (\exists n_0)(\forall n > n_0)Cxx_n \qquad (33)$$

Interestingly, $\mathrm{Lim}_C(\vec{x},x)$ coincides with G. Soylu's notion of *similarity-based fuzzy limit* [23]. Even without employing explicitly the formalism of t-norm fuzzy logic, Soylu was able to prove graded theorems such as [23, Prop. 3.5],

$$\mathrm{Lim}_C(\vec{x},x)\ \&\ \mathrm{Lim}_C(\vec{y},y) \to \mathrm{Lim}_C(\vec{x}+\vec{y},x+y). \qquad (34)$$

With the apparatus of FCT, the gradedness of Soylu's results can be extended even further by not requiring the full satisfaction of the defining properties of the similarity C (this conforms to the standard methodology of constructing graded theories [6, §7]). An example of such graded results is the following theorem on the fuzzy uniqueness of the limit:

Theorem 7.2. FCT *over* MTL_Δ *proves:*

$$\mathrm{Sym}\,C\ \&\ \mathrm{Trans}\,C\ \&\ \mathrm{Lim}_C(\vec{x},x)\ \&\ \mathrm{Lim}_C(\vec{x},x') \to Cxx' \qquad (35)$$

Proof. By $\mathrm{Trans}\,C$ we obtain $Cxx_n\ \&\ Cx_nx' \to Cxx'$; thus $Cx_nx\ \&\ Cx_nx' \to Cxx'$ by $\mathrm{Sym}\,C$, whence

$$((n > n_0) \to Cx_nx)\ \&\ ((n > n_0) \to Cx_nx') \to Cxx' \qquad (36)$$

follows propositionally. By generalization on n and distribution of the quantifier,

$$(\forall n > n_0)Cx_nx\ \&\ (\forall n > n_0)Cx_nx' \to Cxx' \qquad (37)$$

is obtained (as in the consequent the quantification is void). Generalization on n_0 and the shift of the quantifier to the antecedent (as $\exists$) then yields the required formula. □

[14] The Δ in $\Delta\mathrm{Lim}_C$ refers to the Δ in the defining formula, which will later be dropped.

[15] Cf. Menger's probabilistic indistinguishability relations [22].

[16] Observe that Lim_C is a Σ_2-formula: compare it with the classical Π_3-definition and the Π_1-definition in non-standard analysis.

A more detailed investigation of convergence based on fuzzy indistinguishability in the formal framework of FCT exceeds the scope of the present paper, and is therefore left for future research.

Appendix: Fuzzy Class Theory

Fuzzy Class Theory (FCT) is a formal theory over a given first-order fuzzy logic aiming at axiomatic approximation of Zadeh's fuzzy sets of all orders over a fixed crisp domain. It can be characterized as Henkin-style higher-order fuzzy logic, or fuzzified Russell-style simple type theory. FCT can be regarded as a foundational theory for fuzzy mathematics [24], since other axiomatic mathematical theories over fuzzy logic can be formalized within its framework. For more details on FCT see [2, 5]; the relevant definitions of [5] are briefly repeated here for reference.

The reader's familiarity with the logic MTL_Δ and its main extensions is assumed; for details on these logics see [1, 25]. Here we only recapitulate its standard real-valued semantics, which is crucial for number-free mathematics:

$\&$	...	a left-continuous t-norm $*$
$\to$	...	the residuum $\Rightarrow$ of $*$, defined as $x \Rightarrow y =_{\mathrm{df}} \sup\{z \mid z * x \le y\}$
$\wedge, \vee$	...	$\min, \max$
$\neg$	...	$x \Rightarrow 0$
$\leftrightarrow$	...	the bi-residuum: $\min(x \Rightarrow y, y \Rightarrow x)$
Δ	...	$\Delta x = 1 - \mathrm{sgn}(1-x)$
$\forall, \exists$	...	$\inf, \sup$

Łukasiewicz logic further specifies $x * y = (x + y - 1) \vee 0$, product logic sets $x * y = x \cdot y$, and Gödel logic sets $x * y = x \wedge y$.

Fuzzy Class Theory FCT is a formal theory over a given multi-sorted first-order fuzzy logic $\boldsymbol{L}$ (at least as strong as MTL_Δ), with sorts of variables for: atomic objects (lowercase letters $x, y, \ldots$), fuzzy classes of atomic objects (uppercase letters $A, B, \ldots$), fuzzy classes of fuzzy classes of atomic objects (calligraphic letters $\mathcal{A}, \mathcal{B}, \ldots$), etc., in general for fuzzy classes of the n-th order $(X^{(n)}, Y^{(n)}, \ldots)$.

Besides the crisp identity predicate $=$, the language of FCT contains:

- The membership predicate $\in$ between objects of successive sorts
- The class terms $\{x \mid \varphi\}$ of order $n+1$, for any variable x of any order n and any formula φ
- The symbols $\langle x_1, \ldots, x_k\rangle$ for k-tuples of individuals $x_1, \ldots, x_k$ of any order

In formulae of FCT we employ usual abbreviations and defined notions known from classical mathematics or traditional fuzzy mathematics, including those listed in Table 1, for all orders of fuzzy classes.

FCT has the following axioms, for all formulae φ and variables of all orders:

- The logical axioms of multi-sorted first-order logic $\boldsymbol{L}$
- The axioms of crisp identity: $x = x$; $x = y\ \&\ \varphi(x) \to \varphi(y)$; and $\langle x_1, \ldots, x_k\rangle = \langle y_1, \ldots, y_k\rangle \to x_i = y_i$

ISBN: 978-989-95079-6-8

Table 1: Abbreviations and defined notions of FCT

$\varphi = \psi$	$\equiv_{\mathrm{df}}$	$\Delta(\varphi \leftrightarrow \psi)$
$\varphi \leq \psi$	$\equiv_{\mathrm{df}}$	$\Delta(\varphi \rightarrow \psi)$
Ax	$\equiv_{\mathrm{df}}$	$x \in A$
$x_1 \ldots x_k$	$=_{\mathrm{df}}$	$\langle x_1, \ldots, x_k \rangle$
$(\forall x \in A)\varphi$	$\equiv_{\mathrm{df}}$	$(\forall x)(x \in A \rightarrow \varphi)$
$(\exists x \in A)\varphi$	$\equiv_{\mathrm{df}}$	$(\exists x)(x \in A \,\&\, \varphi)$
$\{x \in A \mid \varphi\}$	$=_{\mathrm{df}}$	$\{x \mid x \in A \,\&\, \varphi\}$
$\emptyset$	$=_{\mathrm{df}}$	$\{x \mid 0\}$
$\mathrm{Ker}\, A$	$=_{\mathrm{df}}$	$\{x \mid \Delta Ax\}$
$\smallsetminus A$	$=_{\mathrm{df}}$	$\{x \mid \neg Ax\}$
$A \cap B$	$=_{\mathrm{df}}$	$\{x \mid Ax \,\&\, Bx\}$
$A \sqcap B$	$=_{\mathrm{df}}$	$\{x \mid Ax \wedge Bx\}$
$A \sqcup B$	$=_{\mathrm{df}}$	$\{x \mid Ax \vee Bx\}$
$\mathrm{Pow}\, A$	$=_{\mathrm{df}}$	$\{X \mid X \subseteq A\}$
$\mathrm{Hgt}\, A$	$\equiv_{\mathrm{df}}$	$(\exists x)Ax$
$\mathrm{Plt}\, A$	$\equiv_{\mathrm{df}}$	$(\forall x)Ax$
$\mathrm{Crisp}\, A$	$\equiv_{\mathrm{df}}$	$(\forall x)\Delta(Ax \vee \neg Ax)$
$\mathrm{Sym}\, R$	$\equiv_{\mathrm{df}}$	$(\forall xy)(Rxy \rightarrow Ryx)$
$\mathrm{Trans}\, R$	$\equiv_{\mathrm{df}}$	$(\forall xyz)(Rxy \,\&\, Ryz \rightarrow Rxz)$
$\mathrm{Fnc}\, R$	$\equiv_{\mathrm{df}}$	$(\forall xyy')(Rxy \,\&\, Rxy' \rightarrow y = y')$
$A \subseteq B$	$\equiv_{\mathrm{df}}$	$(\forall x)(Ax \rightarrow Bx)$
$A \subseteq^{\Delta} B$	$\equiv_{\mathrm{df}}$	$(\forall x)(Ax \leq Bx)$

- The comprehension axioms: $y \in \{x \mid \varphi(x)\} \leftrightarrow \varphi(y)$
- The extensionality axioms: $(\forall x)(Ax = Bx) \rightarrow A = B$

Models of FCT are systems of fuzzy sets (and fuzzy relations) of all orders over a crisp universe of discourse, with truth degrees taking values in an $\boldsymbol{L}$-chain $\mathbf{L}$ (e.g., the interval $[0, 1]$ equipped with a left-continuous t-norm); thus all theorems on fuzzy classes provable in FCT are true statements about $\mathbf{L}$-valued fuzzy sets. Note, however, that the theorems of FCT are derived from its axioms by the rules of the fuzzy logic $\boldsymbol{L}$ rather than classical Boolean logic. For details on proving theorems in FCT see [5] or [26].

Abstract— *In many application areas, e.g., in medical applications, it is important to be able to get statistical information about the data without disclosing individual cases. One of the methods to preserve privacy in such statistical databases is to introduce uncertainty, i.e., to replace the exact values with intervals of possible values. In this paper, we show that while the introduction of uncertainty can often enhance privacy, sometimes, the opposite effect occurs: adding uncertainty can decrease privacy.*

Keywords— Fuzzy uncertainty, interval uncertainty, privacy, statistical databases

1 Statistical Databases – Need to Preserve Privacy

1.1 Need for Collecting Data

In many practical situations, it is very useful to collect large amounts of data.

For example, from the data that we collect during a census, we can extract a lot of information about health, mortality, employment in different regions – for different age ranges, and for people from different genders and of different ethnic groups. By analyzing these statistics, we can reveal troubling spots and allocate (usually limited) resources so that the help goes first to social groups that need it most.

Similarly, by gathering data about people's health in a large medical database, we can extract a lot of useful information on how the geographic location, age, and gender affect a person's health. Then, we can improve the public health by appropriate appropriate public health measures to different portions of the population.

Finally, a large database of purchases can help find out what people are looking for, make shopping easier for customers and at the same time, decrease the stores' expenses related to storing unnecessary items.

1.2 Need for Privacy

Privacy is an important issue in the statistical analysis of human-related data. For example, to check whether in a certain geographic area, there is a gender-based discrimination, one can use the census data to check, e.g., whether for all people from this area who have the same level of education, there is a correlation between salary and gender. One can think of numerous possible questions of this type related to different sociological, political, medical, economic, and other questions. From this viewpoint, it is desirable to give researchers *ability to perform* whatever *statistical analysis* of this data that is reasonable for their specific research.

On the other hand, we may not want to give the researchers direct access to the raw census data, because a large part of the census data is *confidential*. For example, for most people (those who work in the private sector) salary information is confidential. Suppose that a corporation is deciding where to built a new plant and has not yet decided between two possible areas. This corporation would benefit from knowing the average salary of people of needed education level in these two areas, because this information would help them estimate how much it will cost to bring local people on board. However, since salary information is confidential, the company should not be able to know the exact salaries of different potential workers.

The need for privacy is also extremely important for *medical* experiments, where we should be able to make statistical conclusions about, e.g., the efficiency of a new medicine without disclosing any potentially embarrassing details from the individual medical records.

Such databases in which the outside users cannot access individual records but can solicit statistical information are often called *statistical databases*.

1.3 Maintaining Privacy is Not Easy

Maintaining privacy in statistical databases is not easy. Clerks who set up policies on access to statistical databases sometimes erroneously assume that once the records are made anonymous, we have achieved perfect privacy. Alas, the situation is not so easy: even when we keep all the records anonymous, we can still extract confidential information by asking appropriate questions.

Many examples of such extraction can be found in a book by D. Denning [1]. For example, suppose that we are interested in the salary of Dr. X who works for a local company. Dr. X's mailing address can be usually taken from the phone book; from the company's webpage, we can often get his photo and thus find out his race and approximate age. Then, to determine Dr. X's salary, all we need is to ask what is the average salary of all people with a Ph.D. of certain age brackets who live in a small geographical area around his actual home address – if the area is small enough, then Dr. X will be the

ISBN: 978-989-95079-6-8

only person falling under all these categories.

Even if we only allow statistical information about salaries $s_1, \ldots, s_q$ when there are at least a certain amount n_0 people within a requested range, we will still be able to reconstruct the exact salaries of all these people. Indeed, for example, we can ask for the number and average salary of all the people who live on Robinson street at houses 1 through 1001, and then we can ask the same question about all the people who live in houses from 1 to 1002. By comparing the two numbers, we get the average salary of the family living at 1002 Robinson – in other words, we gain the private information that we tried to protect.

In general, we can ask for the average

$$\frac{s_1 + \ldots + s_q}{q},$$

and for several moments of salary (variance, third moment, etc):

- if we know the values v_j of at least q different functions $f_j(s_1, \ldots, s_q)$ of s_i,
- then we can, in general, reconstruct all these values from the corresponding system of q equations with q unknowns:

$$f_1(s_1 \ldots, s_q) = v_1,$$

$$\ldots,$$

$$f_q(s_1, \ldots, s_q) = v_q.$$

At first glance, moments are natural and legitimate statistical characteristics, so researchers would be able to request these characteristics. On the other hand, we do not want the researchers to be able to extract the exact up-to-cent salaries of all the people leaving in a certain geographical area.

What restriction should we impose on possible statistical queries that would guarantee privacy but restrict research in the least possible way?

These are anecdotal examples of poorly designed privacy and security, but, as we have mentioned, the problem is indeed difficult: Many seemingly well-designed privacy schemes later turn out to have unexpected privacy and security problems, and it is known that the problem of finding a privacy-preserving scheme is, in general, NP-hard [1].

Different aspects of the problem of privacy in statistical databases, different proposed solutions to this problem, and their drawbacks, are described in [1, 11, 12] (see also references therein).

2 Known Fact: Uncertainty Can Enhance Privacy

A reasonable way to avoid privacy violations is to store ranges (intervals) of values instead of the actual values. For example, instead of keeping the exact age, we only record whether the age is between 0 and 10, 10 and 20, 20 and 30, etc.

In this case, no matter what statistics we allow, the worst that can happen is that the corresponding ranges will be disclosed. However, in this situation, we do not disclose the original exact values – since these values are not stored in the database in the first place; see, e.g., [5, 6, 7].

3 New Observation: Uncertainty Can Decrease Privacy

3.1 What We Do in This Section

The successful use of uncertainty to enhance privacy in statistical databases may lead to an impression that uncertainty *always* enhances privacy. In this paper, we show that uncertainty can actually *decrease* privacy in a statistical database.

3.2 Simplest Possible Case: 1-D Databases

We will show that the privacy decrease phenomenon occurs in the simplest 1-dimensional case, when each record in the statistical database consists of a single value x_i. In this case, the database consists of n values $x_1, \ldots, x_n$.

3.3 1-D Case: Choice of Statistical Characteristics

Among the most important statistical characteristics are the mean values of certain quantities.

In the 1-D case, each record contains the value x_i of a single quantity x. So, in the 1-dimensional case, we are interested in estimating the mean values of different characteristics $u(x)$, i.e., in estimating the values

$$E[u] \stackrel{\text{def}}{=} \frac{1}{n} \cdot \sum_{i=1}^{n} u(x_i). \tag{1}$$

3.4 Smooth Characteristics

Among different statistical characteristics, an important class is formed by characteristics for which the corresponding function $u(x)$ is smooth.

Usually, most values x_i corresponding to different individuals do not differ much. In other words, most values x_i belong to a small-size region. In this region, we can expand the function $u(x)$ in Taylor series and ignore higher-order terms. In the first approximation, we thus approximate the function $u(x)$ by a linear expression

$$u(x) \approx u_0 + u_1 \cdot x. \tag{2}$$

In the next approximation, we approximate an arbitrary smooth function $u(x)$ by a quadratic expression:

$$u(x) \approx u_0 + u_1 \cdot x + u_2 \cdot x^2. \tag{3}$$

In this paper, we will show that the phenomenon of decreasing privacy occurs already for such quadratic characteristics.

3.5 For Exactly Known Values, the Computation of Quadratic Characteristics Preserves Privacy

In applications, we may be interested in the mean values of different statistical characteristics. If we restrict ourselves to quadratic characteristics, this means that we must be able, given an arbitrary quadratic characteristic (3), to estimate the average value (1) of this characteristic.

Substituting the general expression (3) into the formula (1), we can conclude that the desired average value has the form

$$E[u] = u_0 + u_1 \cdot E[x] + u_2 \cdot E[x^2], \tag{4}$$

where

$$E[x] \stackrel{\text{def}}{=} \frac{1}{n} \cdot \sum_{i=1}^{n} x_i \tag{5}$$

ISBN: 978-989-95079-6-8

and

$$E[x^2] \stackrel{\text{def}}{=} \frac{1}{n} \cdot \sum_{i=1}^{n} x_i^2. \tag{6}$$

Thus, in effect, even when we know the mean value $E[u]$ for all possible quadratic characteristics, all we know about the values x_i are the two combinations: the mean $E[x]$ and the second moment $E[x^2]$.

Based on the knowledge of these two values, we cannot reconstruct n different values $x_1, \ldots, x_n$ and thus, privacy is preserved.

3.6 Case of Interval Uncertainty

Let us now consider what happens if instead of the exact value of x_i, we only know the *interval* $[\underline{x}_i, \overline{x}_i]$ of possible values of x_i.

Often, these intervals come from the fact that we know an approximate value $\widetilde{x}_i$, and we know the upper bound Δ_i on the approximation accuracy $\Delta x_i \stackrel{\text{def}}{=} \widetilde{x}_i - x_i$: $|\Delta x_i| \le \Delta_i$. In this case, the only information that we have about the actual (unknown) value x_i is that x_i belongs to the interval $[\widetilde{x}_i - \Delta_i, \widetilde{x}_i + \Delta_i]$. So, we get an interval $[\underline{x}_i, \overline{x}_i]$ with $\underline{x}_i = \widetilde{x}_i - \Delta_i$ and $\overline{x}_i = \widetilde{x}_i + \Delta_i$.

In general, every interval $[\underline{x}_i, \overline{x}_i]$ can be represented in the form $[\widetilde{x}_i - \Delta_i, \widetilde{x}_i + \Delta_i]$: it is sufficient to take:

- as $\widetilde{x}_i$, the midpoint of the interval, i.e., the value

$$\widetilde{x}_i = \frac{\underline{x}_i + \overline{x}_i}{2}; \tag{7}$$

  and

- as Δ_i, the radius (half-width) of the interval, i.e., the value

$$\Delta_i = \frac{\overline{x}_i - \underline{x}_i}{2}. \tag{8}$$

3.7 Estimating Statistical Characteristics under Interval Uncertainty: Formulation of the Problem

Suppose that we are interested in the mean value $E[u]$ of a statistical characteristic $u(x)$. In the ideal case when we know the exact values $x_1, \ldots, x_n$, this mean value is simply equal to the arithmetic average of the corresponding values $u(x_i)$.

Under interval uncertainty, we can have different values $x_i \in [\underline{x}_i, \overline{x}_i]$. In general, different values x_i can lead to different values of the mean. We are interested in computing the *range* $[\underline{u}, \overline{u}]$ of possible values of this mean, i.e., the interval

$$[\underline{u}, \overline{u}] \stackrel{\text{def}}{=} \left\{ \frac{1}{n} \cdot \sum_{i=1}^{n} u(x_i) : x_i \in [\underline{x}_i, \overline{x}_i] \right\}. \tag{9}$$

3.8 Estimating Quadratic Characteristics under Interval Uncertainty: Algorithm

How can we compute the range of the mean

$$E[u] = \frac{1}{n} \cdot \sum_{i=1}^{n} u(x_i)?$$

Each of the variables x_i can take any value from the corresponding interval $[\underline{x}_i, \overline{x}_i]$. Thus,

- the mean $E[u]$ takes the *largest* value if and only if each term $u(x_i)$ takes the *largest* possible value on the interval $[\underline{x}_i, \overline{x}_i]$; we will denote this largest value by $\overline{u}_i$;
- similarly, the mean $E[u]$ takes the *smallest* value if and only if each term $u(x_i)$ takes the *smallest* possible value on the interval $[\underline{x}_i, \overline{x}_i]$; we will denote this smallest value by $\underline{u}_i$.

For a given quadratic function $u(x_i)$ on a given interval $[\underline{x}_i, \overline{x}_i]$, computing its smallest value $\underline{u}_i$ and its largest value $\overline{u}_i$ is an easy computational task. Indeed, according to calculus, if a function attains its minimum or maximum at some point inside an interval, then its derivative is 0 at this point. Thus, to find the minimum and the maximum of a given function $u(x_i)$ on a given interval $[\underline{x}_i, \overline{x}_i]$, it is sufficient to compute the values of this function

- at the endpoints $\underline{x}_i$ and $\overline{x}_i$ of this interval and
- at the point(s) (if any) where the derivative $u'(x)$ of the function $u(x)$ is equal to 0.

Then,

- the smallest of these values is the desired minimum $\underline{u}_i$, and
- the largest of these values is the desired maximum $\overline{u}_i$.

For a quadratic function $u(x) = u_0 + u_1 \cdot x + u_2 \cdot x^2$, the derivative is a linear function $u'(x) = u_1 + 2 \cdot u_2 \cdot x$, so computing the point where the derivative is 0 is a straightforward task: $u_1 + 2 \cdot u_2 \cdot x = 0$ implies $x = -u_1/(2u_2)$.

Once we compute the values $\underline{u}_i$ and $\overline{u}_i$, we can now find the desired range $[\underline{u}, \overline{u}]$ as

$$\underline{u} = \frac{1}{n} \cdot \sum_{i=1}^{n} \underline{u}_i, \ \ \overline{u} = \frac{1}{n} \cdot \sum_{i=1}^{n} \overline{u}_i. \tag{10}$$

3.9 Under Interval Uncertainty, Privacy Is No Longer Preserved: Result

Let us show that in this case, privacy is no longer preserved. To be more precise, we assume that we are given a 1-D database, i.e., a collection of intervals $[\underline{x}_1, \overline{x}_1], \ldots, [\underline{x}_n, \overline{x}_n]$. We do not have an explicit access to intervals from this collection, but for every quadratic function $u(x)$, we can generate the range of the mean value $E[u]$ over these intervals.

We will show that in almost all cases, based on these ranges, we can actually reconstruct all the original intervals $[\underline{x}_i, \overline{x}_i]$. In other words, adding uncertainty leads to a loss of privacy.

Comment. By "almost all" cases, we mean all cases in which all n midpoints $\widetilde{x}_i$ are different. Situations when two midpoints coincide are indeed degenerate, since a minor modification of the original data leads to $\widetilde{x}_i \neq \widetilde{x}_j$.

3.10 Under Interval Uncertainty, Privacy Is No Longer Preserved: Proof

In our proof, for every real number a, we consider the quadratic function $u(x) = (x - a)^2$. For this function, the derivative is equal to 0 at the minimum point $x = a$. Thus, this function attains its largest value on the interval $[\widetilde{x}_i - \Delta_i, \widetilde{x}_i + \Delta_i]$ at one of the endpoints $\widetilde{x}_i - \Delta_i$ or $\widetilde{x}_i + \Delta_i$. One can easily check that:

ISBN: 978-989-95079-6-8

- when $a \le \widetilde{x}_i$, then the largest possible value $\overline{u}_i$ of $u(x)$ on the interval $[\widetilde{x}_i - \Delta_i, \widetilde{x}_i + \Delta_i]$ is attained when $x_i = \overline{x}_i = \widetilde{x}_i + \Delta_i$ and is equal to $\overline{u}_i = (\overline{x}_i - a)^2$;
- when $a \ge \widetilde{x}_i$, then the largest possible value $\overline{u}_i$ of $u(x)$ on the interval $[\widetilde{x}_i - \Delta_i, \widetilde{x}_i + \Delta_i]$ is attained when $x_i = \underline{x}_i = \widetilde{x}_i - \Delta_i$ and is equal to $\overline{u}_i = (\underline{x}_i - a)^2$.

Let us use this fact to describe the dependence of $\overline{u}$ on the parameter a.

When $a \ne \widetilde{x}_i$, the value $\overline{u}$ is the average of n smooth expressions.

At each point $a = \widetilde{x}_i$, all the terms $\overline{u}_j$ in the sum $\overline{u}$ are smooth except for the term $\overline{u}_i$ that turns from $(\overline{x}_i - a)^2$ to $(\underline{x}_i - a)^2$. The derivative of $\overline{u}_i$ with respect to a changes from $2 \cdot (a - \overline{x}_i)$ to $2 \cdot (a - \underline{x}_i)$, i.e., increases by

$$2 \cdot (a - \underline{x}_i) - 2 \cdot (a - \overline{x}_i) = 2 \cdot (\overline{x}_i - \underline{x}_i) = 4 \cdot \Delta_i. \quad (11)$$

Since all the other components $\overline{u}_j$ are smooth at $a = \widetilde{x}_i$, at $a = \widetilde{x}_i$, the derivative of the average $\overline{u}(a)$ increases by $\frac{4}{n} \cdot \Delta_i$.

Thus, once we know the value $\overline{u}$ for all a,

- we can find the values $\widetilde{x}_i$ as the values at which the derivative is discontinuous; and
- we can find each value Δ_i as $n/4$ times the increase of the derivative at the corresponding point $\widetilde{x}_i$.

The statement is proven.

3.11 Case of Fuzzy Uncertainty

In many practical situations, the estimates $\widetilde{x}_i$ come from experts. Experts often describe the inaccuracy of their estimates in terms of imprecise words from natural language, such as "approximately 0.1", etc. A natural way to formalize such words is to use special techniques developed for formalizing this type of estimates – specifically, the technique of fuzzy logic; see, e.g., [4, 10].

In this technique, for each possible value of $x_i \in [\underline{x}_i, \overline{x}_i]$, we describe the degree $\mu_i(x_i)$ to which this value is possible. For each degree of certainty α, we can determine the set of values of x_i that are possible with at least this degree of certainty – the *α-cut* $\mathbf{x}_i(\alpha) = \{x \,|\, \mu_i(x) \ge \alpha\}$ of the original fuzzy set. Vice versa, if we know α-cuts for every α, then, for each object x, we can determine the degree of possibility that x belongs to the original fuzzy set [2, 4, 8, 9, 10]. A fuzzy set can be thus viewed as a nested family of its (interval) α-cuts.

3.12 From the Computational Viewpoint, Fuzzy Uncertainty Can Be Reduced to the Interval One

Once we know how to propagate interval uncertainty, i.e., how to compute the range

$$f(\mathbf{x}_1, \ldots, \mathbf{x}_n) \stackrel{\text{def}}{=} \{f(x_1, \ldots, x_n) : x_i \in \mathbf{x}_i\} \quad (12)$$

of a given function $f(x_1, \ldots, x_n)$ over given intervals $\mathbf{x}_i$, then, to propagate the fuzzy uncertainty, we can consider, for each α, the fuzzy set y with the α-cuts

$$\mathbf{y}(\alpha) = f(\mathbf{x}_1(\alpha), \ldots, \mathbf{x}_n(\alpha)); \quad (13)$$

see, e.g., [2, 4, 8, 9, 10]. This is equivalent to using Zadeh's extension principle.

So, from the computational viewpoint, the problem of propagating fuzzy uncertainty can be reduced to several interval propagation problems.

For example, the fuzzy value of $E[u]$ can be described as follows: for each α, the corresponding α-cut is equal to the range of $E[u]$ when for each i, all values x_i belong to the corresponding α-cuts: $x_i \in \mathbf{x}_i(\alpha)$.

3.13 Under Fuzzy Uncertainty, Privacy Is Also Not Preserved: Result

Let us assume that we are given a 1-D database, i.e., a collection of fuzzy numbers $\mu_1(x_1), \ldots, \mu_n(x_n)$. We do not have an explicit access to fuzzy numbers from this collection, but for every quadratic function $u(x)$, we can generate the fuzzy number $\mu(u)$ corresponding to the mean $E[u]$.

We will show that in almost all cases (i.e., when the midpoints are all different), based on the resulting fuzzy numbers $\mu(u)$, we can actually reconstruct all the original fuzzy numbers $\mu_i(x_i)$.

In other words, adding fuzzy uncertainty also leads to a loss of privacy.

3.14 Under Fuzzy Uncertainty, Privacy Is Also Not Preserved: Proof

For each α, the α-cuts of the resulting fuzzy number $\mu(u)$ is the range of $E[u]$ when $x_i \in \mathbf{x}_i(\alpha)$.

We already know that from the ranges computed for all possible quadratic functions $u(x)$, we can reconstruct all the intervals. Thus, for every α, we can reconstruct all the α-cuts of all the membership functions $\mu_i(x_i)$.

Since we can thus reconstruct all α-cuts for all α, hence, we can uniquely reconstruct all the membership functions.

The statement is proven.

***Abstract*—** *The paper proposed to use recurrent Fuzzy-Neural Multi-Model (FNMM) identifier for decentralized identification of a distributed parameter anaerobic wastewater treatment digestion bioprocess, carried out in a fixed bed and a recirculation tank. The distributed parameter analytical model of the digestion bioprocess is used as a plant data generator. It is reduced to a lumped system using the orthogonal collocation method, applied in three collocation points (plus the recirculation tank), which are used as centers of the membership functions of the fuzzyfied plant output variables with respect to the space variable. The local and global weight parameters and states of the proposed FNMM identifier are used to design hierarchical FNMM direct and indirect controllers. The comparative graphical simulation results of the digestion system direct and indirect control, obtained via learning, exhibited a good convergence, and precise reference tracking. The comparative numerical results, giving the final means squared error of control of each output variable showed that the indirect adaptive decentralized fuzzy-neural control outperformed the direct one, and the it outperformed the linearized proportional optimal control too.*

***Keywords*—** Decentralized control, direct adaptive control, indirect adaptive control, distributed parameter digestion bioprocess system, recurrent neural network model, hierarchical fuzzy neural identification and control.

1 Introduction

The Distributed Parameter Systems (DPS) are distinguished by the fact that the states, controls, and outputs may depend on spatial position, [1]. Thus the natural form of the system description is by Partial Differential Equations (PDE), integral equations, or transcendental transfer functions, [1]. On the other side, in the last two decades, a new identification and control tools like Neural Networks (NN), used for biotechnological plants, [2], rose fame. Among several possible network architectures the ones most widely used are the Feedforward NN (FFNN) and the Recurrent NN (RNN), [3]. The main NN property namely the ability to approximate complex non-linear relationships without prior knowledge of the model structure makes them a very attractive alternative to the classical modeling and control techniques. This property has been proved for both types of NNs by the universal approximation theorem [3]. The preference given to NN identification with respect to the classical methods of process identification is clearly demonstrated in the solution of the "bias-variance dilemma" [3]. The FFNN and the RNN have been applied for DPS identification and control too. In [4], a RNN is used for system identification and process prediction of a DPS dynamics - an adsorption column for wastewater treatment of water contaminated with toxic chemicals. In [5, 6], a spectral-approximation-based intelligent modeling approach is proposed for the distributed thermal processing of the snap curing oven DPS that is used in semiconductor packaging industry. In [7], it is presented a new methodology for the identification of DPS, based on NN architectures, motivated by standard numerical discretization techniques used for the solution of PDE. In [8], an attempt is made to use the philosophy of the NN adaptive-critic design to the optimal control of distributed parameter systems. In [9] the concept of proper orthogonal decomposition is used for the model reduction of DPS to form a reduced order lumped parameter problem. In [10], measurement data of an industrial process are generated by solving the PDE numerically using the finite differences method. Both centralized and decentralized NN models are introduced and constructed based on this data. The models are implemented on FFNN using Backpropagation (BP) and Levenberg-Marquardt learning algorithms. In [11, 12, 13, 14], Baruch et al. defined direct and indirect Fuzzy Neural Multi-Model (FNMM) control system, based on Takagi-Sugeno (T-S) fuzzy rules, [15], containing in its consequent parts computational procedure of a Backpropagation Learning (BP) of a Recurrent Trainable NN (RTNN), [14]. In the present paper, the direct and indirect FNMM control system are modified and used for decentralized identification and control of a digestion anaerobic DPS of wastewater treatment, [16]. The anaerobic bioprocess plant model, used as an input/output plant data generator, is described by PDE/ODE, and simplified using the orthogonal collocation technique in three collocation points and a recirculation tank, [16], [17].

2 Analytical Model of the Anaerobic Digestion Bioprocess

The anaerobic digestion systems conformed by a fixed bed reactor and a recirculation tank is depicted on Fig. 1. It contained a fixed bed bioreactor and a recirculation tank. The anaerobic digestion process is modeled using PDE, [16]:

$$\frac{\partial X_1}{\partial t} = (\mu_1 - \varepsilon D) X_1 , \quad \mu_1 = \mu_{1\max} \frac{S_1}{K_{s_1}^{'} X_1 + S_1}, \tag{1}$$

$$\frac{\partial X_2}{\partial t} = (\mu_2 - \varepsilon D) X_2 , \quad \mu_2 = \mu_{2s} \frac{S_2}{K_{s_2}^{'} X_2 + S_2 + \frac{S_2^2}{K_{I_2}}}, \tag{2}$$

Where: X_1 is concentration of acidogenic bacteria; X_2-

ISBN: 978-989-95079-6-8

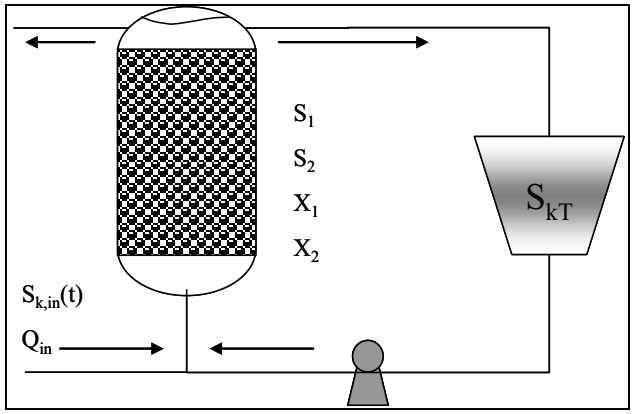

Figure 1: Block-Diagram of Anaerobic Digestion Bioreactor

concentration of methanogenic bacteria; S_1 - chemical oxygen demand; S_2 - volatile fatty acids; μ_1, μ_2- Monod functions, representing the acidogenesis and methanogenesis growth rate; D - dilution rate; ε - bacteria fraction in the liquid phase. The next equations of the bioprocess model are:

$$\frac{\partial S_1}{\partial t} = \frac{E_z}{H^2}\frac{\partial^2 S_1}{\partial z^2} - D\frac{\partial S_1}{\partial t} - k_1\mu_1 X_1\,, \tag{3}$$

$$\frac{\partial S_2}{\partial t} = \frac{E_z}{H^2}\frac{\partial^2 S_2}{\partial z^2} - D\frac{\partial S_2}{\partial t} + k_2\mu_1 X_1\,, \tag{4}$$

$$S_1(0,t) = \frac{S_{1,in}(t) + RS_{1T}}{R+1},\quad S_2(0,t) = \frac{S_{2,in}(t) + RS_{2T}}{R+1},\quad R = \frac{Q_T}{DV_{eff}} \tag{5}$$

$$\frac{\partial S_1}{\partial z}(1,t) = 0\,,\quad \frac{\partial S_2}{\partial z}(1,t) = 0\,. \tag{6}$$

$$\frac{dS_{1T}}{dt} = \frac{Q_T}{V_T}\left(S_1(1,t) - S_{1T}\right),\quad \frac{dS_{2T}}{dt} = \frac{Q_T}{V_T}\left(S_2(1,t) - S_{2T}\right). \tag{7}$$

Where: S_{1T} , S_{2T} are concentrations of the chemical oxygen demand and the volatile fatty acids in the recirculation tank, respectively; H - fixed bed length; Q_T - recycle flow rate; V_T - volume of the recirculation tank. The physical meaning of the other constants and initial values of the variables of the process model are given in [16]. For practical purpose, the full PDE process model, [16], could be reduced to an ODE system using an early lumping technique and the Orthogonal Collocation Method (OCM), [16], [17]. The precision of the OCM approximation of the PDE model depended on the number of measurement (collocation) points, but the approximation is always exact in that points. If the number of points is very high and the point positions are chosen inappropriately, the ODE model could loose identifiability. Furthermore the ODE plant model here is used as a plant data generator for neural identification and control of PDE system and the number of point not need to be too high. So to fulfill this objective we need a reduced order model having only three points, (0.25H, 0.5 H, 0.75H), but generating 14 measured variables. The reference set points generated for all that variables keep the form but differ in amplification due to its position. The plant ODE system model, obtained by OCM is taken from [16] and used as a plant process input/output data generator so to obtain identification and control simulation results.

3 Description of the Direct and Indirect Fuzzy-Neural Multi-Model Control System

3.1 Direct Adaptive FNMM Control System Design

The block-diagrams of the complete control system and its identification and control parts are schematically depicted in Fig. 2, Fig. 3 and Fig. 4.

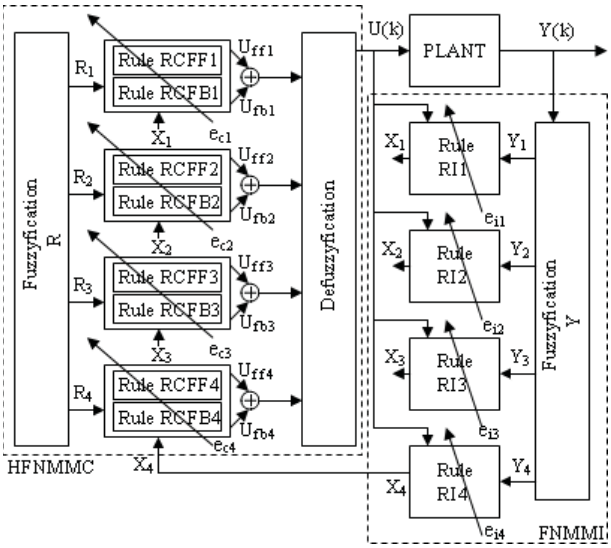

Figure .2: Block-Diagram of the FNMM Control System.

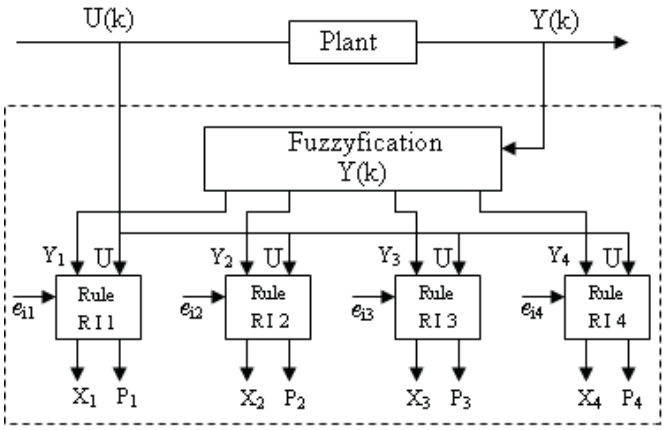

Figure 3: Detailed block-diagram of the FNMM identifier

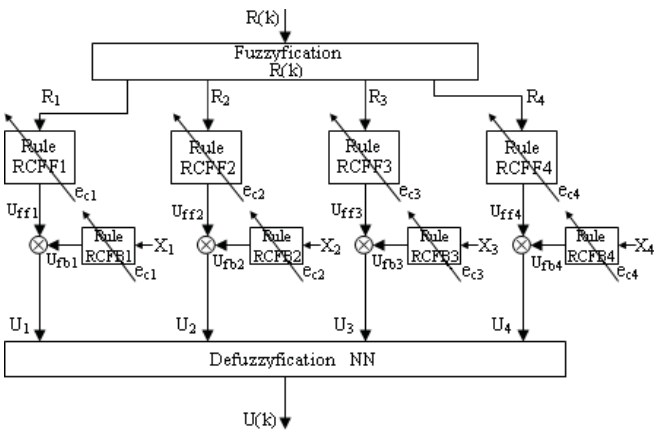

Figure 4: Detailed block-diagram of the HFNMM controller

ISBN: 978-989-95079-6-8

The structure of the entire control system, [12, 14], contained Fuzzyfier, Fuzzy Rule-Based Inference System (FRBIS), containing four identification, four feedback control and four feedforward control T-S rules (RI_i, $RCfb_i$, $RCff_i$) and a Defuzzyfier. The plant output variable and its correspondent reference variable depended on space and time, and they are fuzzyfied on space. The membership functions of the fixed-bed output variables are triangular/trapezoidal ones and that belonging to the output variables of the recirculation tank are singletons. The centers of the membership functions are the respective collocation points of the plant. The main objective of the Fuzzy-Neural Multi-Model Identifier (FNMMI), containing four rules, is to issue states for the direct adaptive Fuzzy-Neural Multi-Model Feedback Controller (FNMMFBC) when the FNMMI outputs follows the outputs of the plant in the four measurement (collocation) points with minimum Means Squared Error (MSE) of approximation. The direct fuzzy neural controller has also a direct adaptive Fuzzy-Neural Multi-Model Feedforward Controller (FNMMFFC). The objective of the direct adaptive FNMM controller, containing four Feedback (FB) and four Feedforward (FF) T-S control rules is to reduce the error of control. The upper hierarchical level of the FNMM control system is one layer perceptron which represented the defuzzyfier, [12, 14]. The hierarchical FNMM controller has two levels – Lower Level of Control (LLC), and Upper Level of Control (ULC). It is composed of three parts: 1) Fuzzyfication, where the normalized reference vector signal contained reference components of four measurement points; 2) Lower Level Inference Engine, which contains twelve T-S fuzzy rules (four rules for identification and eight rules for control- four in the feedback part and four in the feedforward part), operating in the corresponding measurement points; 3) Upper Hierarchical Level of neural defuzzification.

The detailed block-diagram of the FNMMI, given on Fig. 3, contained a space plant output fuzzyfier and four identification T-S fuzzy rules, labeled as RI_i, which consequent parts are RTNN learning procedures, [14]. The identification T-S fuzzy rules have the form:

$$RI_i\text{: } \textbf{\textit{If}}\ \mathrm{x(k)}\ \textbf{\textit{is}}\ \mathrm{A_i}\ \textbf{\textit{and}}\ \mathrm{u(k)}\ \textbf{\textit{is}}\ \mathrm{B_i}\ \textbf{\textit{then}}\ \mathrm{Y_i = \Pi_i\ (L,M,N_i,Y_{di},U,X_i,A_i,B_i,C_i,E_i),\ i=1,2,..,4} \tag{8}$$

The detailed block-diagram of the FNMMC, given on Fig. 4, contained a spaced plant reference fuzzyfier and eight control T-S fuzzy rules (four FB and four FF), which consequent parts are also RTNN learning procedures, [12, 14], using the state information, issued by the corresponding identification rules. The consequent part of each feedforward control rule (the consequent learning procedure) has the M, L, N_i RTNN model dimensions, R_i, Y_{di}, E_{ci} inputs and U_{ffi}, outputs used to form the total control. The T-S fuzzy rule has the form:

$$RCFF_i\text{: } \textbf{\textit{If}}\ \mathrm{R(k)}\ \textbf{\textit{is}}\ B_i\ \textbf{\textit{then}}\ \mathrm{Uff_i = \Pi_i\ (M, L, N_i, R_i, Y_{di}, X_i, J_i, B_i, C_i, E_{ci}),\ i =1,2,..,4} \tag{9}$$

The consequent part of each feedback control rule (the consequent learning procedure) has the M, L, N_i RTNN model dimensions, Y_{di}, X_i, E_{ci} inputs and U_{fbi}, outputs used to form the total control. The T-S fuzzy rule has the form:

$$RCFB_i\text{: } \textbf{\textit{If}}\ \mathrm{Y_{di}}\ \textbf{\textit{is}}\ A_i\ \textbf{\textit{then}}\ \mathrm{Ufb_i = \Pi_i\ (M, L, N_i, Y_{di}, X_i, X_{ci}, J_i, B_i, C_i, E_{ci}),\ i =1,2,..,4} \tag{10}$$

The total control corresponding to each of the four measurement points is a sum of its corresponding feedforward and feedback parts:

$$U_i\,(k) = -U_{ffi}\,(k) + U_{fbi}\,(k) \tag{11}$$

The defuzzyfication learning procedure, which correspond to the single layer perceptron learning, performed a weighted sum of the control variables Ui, [15]. It is described by:

$$\mathrm{U = \Pi\ (M, L, N, Y_d, Uo, X, A, B, C, E)} \tag{12}$$

3.1 Indirect Adaptive FNMM Control System Design

The block-diagram of this control system is schematically depicted in Fig.5. The structure of the entire control system, [14, 15], contained Fuzzyfier, Fuzzy Rule-Based Inference System (FRBIS), containing four identification and four control T-S rules (RI_i, RC_i), and a Defuzzyfier. The plant output variable and its correspondent reference variable depended on space and time, and they are fuzzyfied on space. The membership functions and the Identifier (FNMMI) are the same used in the direct controller. The objective of the indirect adaptive FNMM controller is equivalent to that of the direct controller. The hierarchical FNMM controller has two levels – Lower Level of Control (LLC), and Upper Level of Control (ULC). It is composed of three parts: 1) Fuzzyfication, where the normalized reference vector signal contained reference components of four measurement points; 2) Lower Level Inference Engine, which contains eight T-S fuzzy rules (four rules for identification and four rules for control), operating in the corresponding measurement points; 3) Upper Hierarchical Level of neural defuzzification. The detailed block-diagram of the FNMMC is given on Fig. 6. It contained a spaced plant reference fuzzyfier and four sliding mode control T-S fuzzy rules, which consequent parts are SMC procedures, [13, 14], using the state, and parameter information, issued by the corresponding identification rules. The control T-S fuzzy rules have the form:

$$RC_i\text{: } \textbf{\textit{If}}\ \mathrm{R(k)}\ \textbf{\textit{is}}\ \mathrm{C_i}\ \textbf{\textit{then}}\ \mathrm{U_i = \Pi_i\ (M, L, N_i, R_i, Y_{di}, X_i, A_i, B_i, C_i, E_{ci}),\ i =1, 2,\ldots, 4} \tag{13}$$

The defuzzyfication of the control variable is a learning procedure, which correspond to the single layer perceptron learning. It is described by:

$$\mathrm{U = \Pi\ (M, L, N, Y_d, Uo, X, A, B, C, E)} \tag{14}$$

The T-S rule and the defuzzification of the plant output of the fixed bed with respect to the space variable z ($\lambda i,z$ is the correspondent membership function), [14, 15], are given by:

$$RO_i\text{: } \textbf{\textit{If}}\ \mathrm{Y_{i,t}}\ \textbf{\textit{is}}\ \mathrm{A_i}\ \textbf{\textit{then}}\ \mathrm{Y_{i,t} = a_i^T Y_t + b_i,\ i=1,2,3} \tag{15}$$

$$\mathrm{Y_z=[\Sigma_i\ \gamma_{i,z}\ a_i^T]\ Y_t + \Sigma_i\ \gamma_{i,z}\ b_i\ ;\ \gamma_{i,z} = \lambda_{i,z} / (\Sigma_j\ \lambda_{j,z})} \tag{16}$$

The indirect adaptive neural control algorithm, which is the consequent part of the local fuzzy control rule RCi (13) is viewed as a Sliding Mode Control (SMC), [13, 14], using the

ISBN: 978-989-95079-6-8

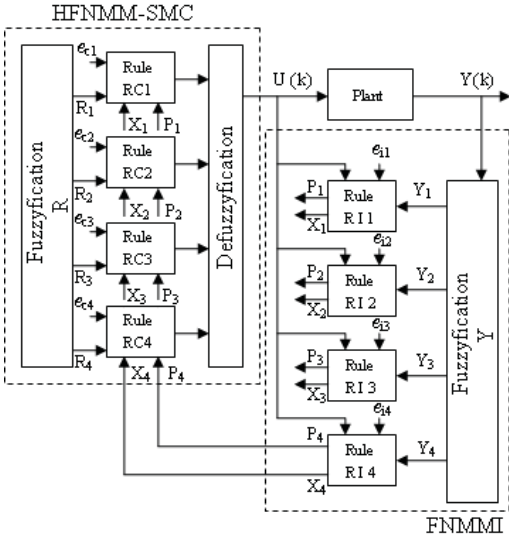

Figure 5: Block-diagram of the FNMM Control system.

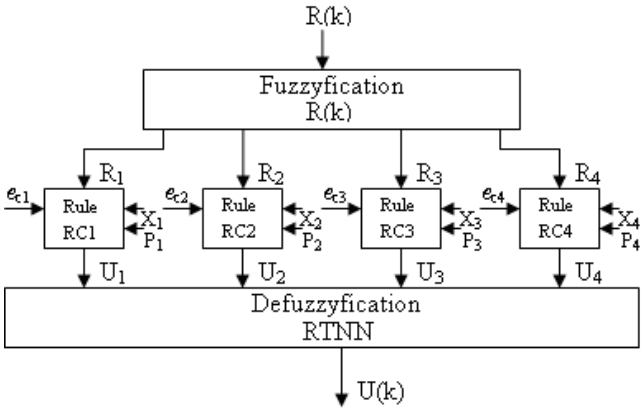

Figure 6: Detailed block-diagram of the HFNMM controller

parameters and states issued by the correspondent identification local fuzzy rule RIi (8). The equivalent control capable to lead the system to the sliding surface in the case when L>M is given by the equations:

$$U_{eq}(k) = (CB)^{+}\left[-CAX(k) + R(k+1) + \sum_{i=1}^{P}\gamma_i E(k-i+1)\right] + Of \qquad (17)$$
$$(CB)^{+} = [(CB)^{T}(CB)]^{-1}(CB)^{T}$$

Here the added offset Of is a learnable M-dimensional constant vector which is learnt using a simple delta rule (see [3]), where the error of the plant input is obtained backpropagating the output error through the adjoint RTNN model (see [18, 14]). The SMC avoiding chattering is taken using a saturation function inside a bounded control level Uo, taking into account plant uncertainties. So the SMC takes the form:

$$U(k) = \begin{cases} U_{eq}(k), & if \ \|U_{eq}(k)\| < U_0 \\ -U_0 U_{eq}(k)/\|U_{eq}(k)\|, & if \ \|U_{eq}(k)\| \geq U_0 \end{cases} \qquad (18)$$

The proposed SMC cope with the characteristics of the wide class of plant model reduction neural control with reference model, and represents an indirect adaptive neural control, given by [11, 13, 14].

3.1 Description of the RTNN and its Learning Algorithm

The RTNN topology, including thresholds in both layers, and its learning algorithm, which appeared in the consequent part of the identification fuzzy rule as a learning procedure, are described in vector-matrix form as:

$$X(k+1) = AX(k) + BU(k);\ B = [B_1 ; B_0];\ U^T = [U_1 ; U_2] \quad (19)$$
$$Z_1(k) = G[X(k)] \quad (20)$$
$$V(k) = CZ(k);\ C = [C_1 ; C_0];\ Z^T = [Z_1 ; Z_2] \quad (21)$$
$$Y(k) = F[V(k)];\ A = \text{block-diag}\ (Ai),\ |Ai| < 1 \quad (22)$$
$$W(k+1) = W(k) + \eta\,\Delta W(k) + \alpha\,\Delta W_{ij}(k-1) \quad (23)$$
$$E(k) = T(k) - Y(k);\ E_1(k) = F'[Y(k)]\,E(k) \quad (24)$$
$$\Delta C(k) = E_1(k)\,Z^T(k);\ F'[Y(k)] = [1 - Y^2(k)] \quad (25)$$
$$E_3(k) = G'[Z(k)]\,E_2(k);\ E_2(k) = C^T(k)\,E_1(k) \quad (26)$$
$$\Delta B(k) = E_3(k)\,U^T(k);\ G'[Z(k)] = [1 - Z^2(k)] \quad (27)$$
$$\Delta A(k) = E_3(k)\,X^T(k);\ Vec(\Delta A(k)) = E_3(k) \square X(k) \quad (28)$$

Where: X, Y, U are vectors of state, output, and augmented input with dimensions N, L, (M+1), respectively, Z is an (L+1) –dimensional input of the feedforward output layer, where Z_1 and U_1 are the (Nx1) output and (Mx1) input of the hidden layer; the constant scalar threshold entries are $Z_2 = -1$, $U_2 = -1$, respectively; V is a (Lx1) pre-synaptic activity of the output layer; T is the (Lx1) plant output vector, considered as a RNN reference; A is (NxN) block-diagonal weight matrix; B and C are [Nx(M+1)] and [Lx(N+1)]-augmented weight matrices; B_0 and C_0 are (Nx1) and (Lx1) threshold weights of the hidden and output layers; F[.], G[.] are vector-valued tanh(.)-activation functions with corresponding dimensions; F'[.], G'[.] are the derivatives of these tanh(.) functions; W is a general weight, denoting each weight matrix (C, A, B) in the RTNN model, to be updated; ΔW (ΔC, ΔA, ΔB), is the weight correction of W; η, α are learning rate parameters; ΔC is an weight correction of the learned matrix C; ΔB, ΔA are weight corrections of the learned matrices B, A; the diagonal of the matrix A is denoted by Vec (.) where (28) represents its learning as an element-by-element vector product; E, E_1, E_2, E_3, are error vectors with appropriate dimensions. The stability of the RTNN model is assured by the activation functions [-1, 1] bounds and by the local stability weight bound condition, given by (22). The learning procedure having forward and backward steps (19)-(28), could be denoted by Y(k) = Π (L, M, N, Y_d, U, X, A, B, C, E). The defuzzyfication learning procedure, corresponding to the single layer perceptron, denoted by (14) is a simple delta rule (see [3]), where the error of the plant controlled input is obtained backpropagating the output error through the adjoint RTNN model, [18].

4 Simulation Results

The decentralized FNMM identifier used a set of four T-S fuzzy rules containing in its consequent part RTNN learning procedures (see Fig. 3). The topology of the first three RTNNs is (2-6-4) (2 inputs, 6 neurons in the hidden layer, 4 outputs) and the last one has topology (2-6-2) corresponding to the fixed bed plant behavior in each collocation point and the recirculation tank. The RTNNs identified the following fixed bed variables: X_1 (acidogenic bacteria), X_2

ISBN: 978-989-95079-6-8

(methanogenic bacteria), S_1 (chemical oxygen demand) and S_2 (volatile fatty acids), in the following collocation points, z=0.25H, z=0.5H, z=0.75H, and the following variables in the recirculation tank: S_{1T} (chemical oxygen demand) and S_{2T} (volatile fatty acids). The graphical simulation results of RTNNs learning are obtained on-line during 100 days with a step of 0.1 day (To=0.1 sec.; Nt=1000 iterations). The learning rate parameters of RTNN have small values which are different for the different measurement point variables. The Fig. 7, Fig.8, Fig. 9, Fig. 10 showed similar three dimensional and two dimensional graphical simulation results of the direct and indirect decentralized FNMM control of X_1, X_2, where the outputs of the plant are compared with the reference signals at the collocation points. The reference signals for all variables are proportional train of pulses with uniform duration and random amplitude. The Means Squared Error (MSE%) of identification, direct, indirect and optimal control for each output signal and each measurement point are given on Table 1, 2, 3, 4, respectively. The comparison showed a slight preference of the indirect FNMM-SMC control over the direct FNMM control, due to the better adaptation of the first low.

5 Conclusions

The paper performed decentralized recurrent fuzzy-neural identification, direct and indirect control of an anaerobic digestion wastewater treatment bioprocess, composed by a fixed bed and a recirculation tank represented a DPS. The simplification of the PDE process model by ODE is realized using the orthogonal collocation method in three collocation points (plus the recirculation tank) represented centers of membership functions of the space fuzzyfied output variables. The obtained from the FNMMI state and parameter information is used by a HFNMM direct and indirect control. All graphical control results exhibited good convergence and precise reference tracking. All obtained comparative numerical identification and control results (final MSE%) exhibited a high precision and showed that the indirect decentralized FNMM control is the better one outperforming the linearized optimal control and the direct decentralized fuzzy-neural control.

Enforcing Local Properties in Online Learning First Order TS-fuzzy Systems by Incremental Regularization

Nils Rosemann Werner Brockmann Bastian Neumann
University of Osnabrück
Albrechtstraße 28
D–49069 Osnabrück

Abstract— *Embedded systems deseminate more and more. Because their complexity increases and their design time has to be reduced, they have to be increasingly equipped with self-tuning properties. One form is self-adaption of the system behavior, which can potentially lead the system into safety critical states. In order to avoid this and to speed up the self-tuning process, we apply a specific form of regularization, incremental regularization. The SILKE approach has been developed as an incremental regularization scheme for a special class of online learning Takagi-Sugeno fuzzy systems. Its aim is to control the process of self-tuning by guiding the online learning process towards local meta-level characteristics such as a smooth system behavior without outliers. This ability has been investigated experimentally and formally for zero order systems before. This paper now analyzes the regularization ability of the SILKE approach to enforce local smoothness in first order TS-fuzzy systems in order to enlarge the methodological basis for more complex applications.*

Keywords— First order Takagi Sugeno fuzzy systems, incremental learning, self-optimization, incremental regularization, fuzzy control

1 Introduction

1.1 Background

Due to the growing dissemination of embedded technical systems and their higher integration into critical environments, the requirements for the next generation of those technical systems will change. The systems will have to adapt intelligently to different environments, different aims and changes within the environment in order to open up new application areas. This greatly increases the complexity of such new systems. At the same time, it will become necessary to decrease the design time. We tackle these problems within the context of Organic Computing, There one tries to face these challenges by introducing self-x properties into the systems, e.g., self-organization and self-optimization [1]. This means that technical systems are equipped with a much higher flexibility. They have to adapt their behavior based on changing demands and prior experience.

But although such a technical system adapts its behavior at run time, safety and trustworthiness are a must. This is especially problematic as the higher integration into natural, i.e., not specially prepared, environments comes with many sources of uncertainty. Thus, any form of adaption based on uncertain interaction with the environment will be uncertain itself. Accordingly, a self-tuning system has to be both flexible enough to react dynamically to new conditions, and stable enough to protect already learned knowledge from transient disturbances, noise and other uncertainties (*stability-plasticity-dilemma*). And, what is more, at the same time it has to be guaranteed that the system does not enter critical states by learning. This means that the self-tuning process has to be controlled, but without limiting its flexibility.

Within this paper, we address issues of self-tuning the control behavior of an embedded system, i.e., a form of self-adaptive control. This online changing of the behavior is done by *incremental online learning*. It has a strong influence on the stability of the system: In addition to the feedback loop between the control system and the environment into which it is embedded, online learning creates another, indirect feedback loop [2]. Whatever is learned in a certain situation changes the system's (future) behavior, and thus also what is learned in the future. Because of this, small deviations of (initial) conditions or the self-optimization process as such might have arbitrarily high impact and can potentially lead to a chaotic system behavior.

Different candidate function approximators have been used in adaptive control by online learning, each of them fullfilling the different requirements to a varying degree. An overview over the different families of function approximators is given in [3]. Accordingly, one has to choose an appropriate approximator to represent the control behavior in a way which suits the application specific needs, e.g., concerning expressiveness, complexity, interpretability and, what is more in our context, controllability of the learning process itself.

For adaptive nonlinear modeling and control, Takagi-Sugeno systems are a favoured trade-off [4, 5]. We hence build upon a specific variant. Then, in order to employ incremental online learning for adaptive control in uncertain environments, one has to address the stability-flexibility-dilemma. In the next section it is argued that this can be done by an appropriate form of regularization.

1.2 Related Work

In data-driven function approximation, regularization techniques have been successfully applied in many different areas, especially in nonlinear system identification [6] and nonlinear adaptive control [7]. Typical for these applications is that the distribution of data points is dense in one region of the input space and sparse in another. For practical reasons it might be impossible to obtain enough data in a sparse region, e.g., because it is related to critical states of a controlled process. Hence regularization techniques have found widespread use in data-driven fields. The reason is that in many cases data-driven problems are ill-posed because there is no unique solution [8]. This is usually due to a misbalance between the degrees of freedom of the function approximator and the amount of data available.

The idea of regularization is to incorporate additional in-

ISBN: 978-989-95079-6-8

formation about the solution into the problem statement, i.e., to reformulate it [9]. Usually this is some kind of structural or meta-information. A well known example is to assign a penalty to non-zero parameter values [10]. Another example is to assign a penalty to solutions with a high overall curvature [11]. They are called ridge regression or Tikhonov regularization. Despite missing data, sparse regions and large input spaces, regularization is able to improve the generalization performance of the identified models.

Basically, these approaches require all data points to be accessible at once in order to find a globally optimal solution, i.e., they are offline approaches. But for many online applications, there is a change of requirements while new data points are generated (continuously), for example because the system which is to be modeled changes or is modelled from scratch.

Recent approaches for these kind of applications have so far neglected the problem of requiring regularization [4]. In order to tackle the above challenges online, these approaches learn incrementally, i.e., by looking at every data point only once. But without access to the whole dataset, it is not *a priori* clear how to apply the conventional regularization techniques. Other approaches use regularization techniques for ill-posed matrix inversions [12] which is suitable for certain modeling applications.

Because of our background of adaptive nonlinear control by direct adaptation [2], we are developing schemes for *incremental regularization*, i.e., which perform special forms of regularization online, for appropriate function approximators. The control tasks which we address typically have only a low number of input dimensions (less than 10). In the case of more input dimensions, it is usually possible and advisable to decompose the overall problem into subproblems. Thus, the first one of the schemes has been developed for special Takagi-Sugeno fuzzy systems which are especially suited for adaptive nonlinear modeling and control [13, 5]. They employ an all-coverage approach for generating the rule base which allows for a high interpretability albeit limiting the maximal possible number of input dimensions. These fuzzy systems and the incremental regularization, called SILKE approach, will be reviewed in section 2. Up to now, we have developed incremental regularization schemes for zero order Takagi-Sugeno fuzzy systems [14]. They have been investigated experimentally and formally [15, 16]. The purpose of this paper is to extend the SILKE approach to first order Takagi-Sugeno fuzzy systems. In section 3 it is then shown that each incremental application of our approach to a first order Takagi-Sugeno system increases its smoothness. Because of this, the SILKE approach can be seen as a kind of incremental Tikhonov regularization which is also applicable to first order TS-fuzzy systems.

2 Controlled Self-optimization by the SILKE Approach

2.1 Basic Concept

The basis of the SILKE approach is a special class of Takagi-Sugeno fuzzy systems (hereinafter called sTS fuzzy systems) with polynomial functions as rule conclusions. They use linear B-spline input membership functions, such that each input dimension is split by a partition of unity. This allows for an intuitive handling by the system designer and an implementation which requires a very low computational effort. The

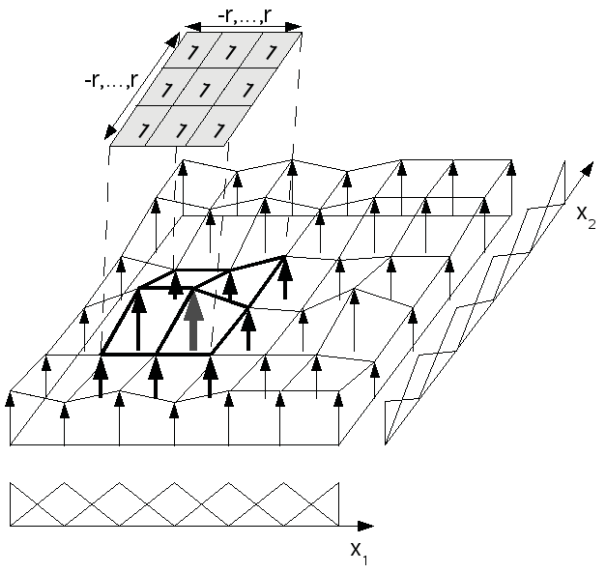

Figure 1: Schematic correspondence of a SILKE-template (shaded in grey) to the conclusions of a part of an sTS-fuzzy rule base in a two-dimensional system. The membership functions determine the lattice of rule conclusions. The thick arrow indicates the active rule under consideration. The numbers within the template are the coefficients of the averaging template mask [15].

rule inference is done by the *sum-prod* technique. These sTS-systems are ideally suited for application to online learning within embedded systems [3].

The idea of the SILKE approach is then to enhance learning in sTS-systems by a correction step which introduces an additional feedback loop at a higher, functional level in order to rate the learning process itself online [17]. This is done by implementing so called *SILKE templates* which determine whether the rule base of the sTS-system complies with predefined meta-level properties. If this *monitoring* detects too strong deviations, then the rule base should be corrected, which closes the feedback loop at a higher level. It should be noted that such a template acts only on those rules which apply to the current system state and which form a local neighborhood (*active rules*), i.e., a template acts only locally and incrementally on each new data point.

Many different meta-level properties can be expressed, e.g., steadiness, monotonicity, local linearity or gradient ratios of the underlying function. One of the most important examples of meta-properties in the field of adaptive control is *smoothness* of the approximated function, i.e., the learned knowledge, because smoothness means that small changes of the inputs do not cause strong changes at the output. So given a process which is smooth, then one wants a rule base which is also smooth. If online learning changes the rule base in a way that it is smooth, then the process of learning harmonizes with its environment. Hence, robustness of learning is increased when faced with learning stimuli which would otherwise violate the smoothness property and smoothness is enforced, for example the effect of outliers is reduced.

In the next section, it is formally shown that this smoothness property can be enforced for first order sTS-systems by

ISBN: 978-989-95079-6-8

using the SILKE approach. For this purpose, the formalism of the SILKE approach is presented in its general form. Afterwards, a measure for local smoothness in zero and first order sTS-systems is developed. This measure is then used to investigate the effect of the SILKE approach in a simplified, one-dimensional scenario for clarity reasons.

2.2 Formalization

Let n be the number of inputs of a first order sTS-fuzzy system. By compilation of an sTS rule base, it becomes normalized, so that one can imagine it as a lattice [17]. This is illustrated by the schematic in Fig. 1. It shows a two-dimensional lattice of a rule base with two input variables, x_1 and x_2. Both inputs are partitioned by triangular membership functions. For every combination of two membership functions, one from each dimension, there is a single rule. Due to normalization, the rules thus form a lattice given by these membership functions. The membership functions can be numbered sequentially in each input dimension. As there is a single rule for each combination of membership functions, one can assign a vector of the individual membership function indixes to each rule. For example, in a two-dimensional rule base, the index vector $(2, 1)$ is assigned to the rule which has the second membership function of the first input dimension and the first membership function of the second input dimension as its antecedents.

The rule conclusions (which are affine functions) can be viewed as being placed upon the nodes of this lattice. It is useful here to identify the affine conclusions by vectors of their parameters, i.e., a function $g : \mathbb{R}^n \to \mathbb{R}$ with

$$g(\mathbf{x}) = c_0 + c_1 x_1 + \ldots + c_n x_n, \quad \mathbf{x} = (x_1, \ldots, x_n)^T \in \mathbb{R}, \tag{1}$$

can be identified by the vector of the parameters

$$\mathbf{c} = (c_0, \ldots, c_n)^T \in \mathbb{R}^{n+1}. \tag{2}$$

With this, the rule base of a first-order sTS fuzzy system can be seen as a map $o : \mathbb{N}^n \to \mathbb{R}^{n+1}$ from the space $\mathbb{N}^n$ of rule index vectors to the space $\mathbb{R}^{n+1}$ of parameter vectors. A single node $p \in \mathbb{N}^n$ of the lattice corresponds to a rule, and $o(p)$ to the parameters of an affine function, i.e., the rule conclusion.

A so called SILKE template T is than a map

$$T : \mathbb{N}^n \to \mathbb{R}^{n+1}. \tag{3}$$

The value $\|T(p)\|$ is called *violation degree* of the rule p with respect to T. It indicates how much a rule p violates the meta-level property which is given by T with respect to the neighboring rules. $\|T(p)\| = 0$ means a complete compliance with this property. The higher $\|T(p)\|$, the further rule p is violating the property.

The core of the SILKE approach is then to correct the given rule p according to

$$o(p) \leftarrow (1 - \alpha) \cdot o(p) + \alpha \cdot (o(p) - T(p)). \tag{4}$$

Obviously, if $\|T(p)\| = 0$, the rule is not changed. The *adjustment rate* $\alpha \in [0; 1]$ determines how much the meta-level property is enforced, i.e., $\alpha = 0$ results in no correction of the rule base, whereas $\alpha = 1$ makes it fully compliant with the meta-level property in one step. As said before, such a correction step is done directly after each learning step. Every rule which has been changed by learning is subject to the SILKE template(s). This means that $\alpha = 1$ ignores all changes of the rules by learning. Instead, the meta-level property is fully enforced. Thus, high values of α limit the influence of learning severely but increase the stability.

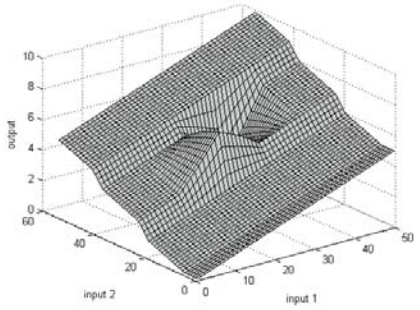

Figure 2: Original graph of a sample two-dimensional sTS-system which is smoothed by the SILKE approach, see Fig. 3 and Fig. 4.

In the following, only SILKE templates are considered which can be represented by a convolution of the rule base:

$$T(p) = o(p) - \frac{1}{(2r+1)^n} \sum_{u \in U} o(p-u)m(u). \tag{5}$$

Here, $r \in \mathbb{N}^+$ is a radius. All neighbor rules with a L_1-distance to the given rule p of less than or equal to r are considered by the template (For illustration, in Fig. 1 an exemplary template is shown with radius $r = 1$). So the sum indices u are in

$$U = [-r, r]^n. \tag{6}$$

The map $m : U \to \mathbb{R}$ is called a *mask* and determines the effect of the SILKE template, i. e., the represented meta-level property, by specific coefficients. Because of this, the mask is the most important part of the SILKE approach concerning design. The designer has to use the right coefficients in the mask in order to represent the desired meta-level properties. The mask thus gives the SILKE approach the necessary flexibility to express a wide range of local meta-level properties. The example in Fig. 1 shows the mask for an averaging template which is given by $m(u) = 1 \forall u \in U$. This mask can be used to guide zero order sTS systems towards a higher smoothness [15]. Another example is the one-dimensional averaging template which only use one of the input dimensions. It is given by $m(u) = 1 \forall u \in \{0\}^{a-1} \times [-r, r] \times \{0\}^{n-a}$ with a denoting the dimension to be used.

3 Smoothness in First Order sTS Fuzzy Systems

In order to extend the formal investigations of the SILKE approach to first order sTS fuzzy systems, they are investigated concerning their smoothness properties. In this section, based on the definition of a measure of smoothness for the individual rules, it is proven that the application of an averaging SILKE

ISBN: 978-989-95079-6-8

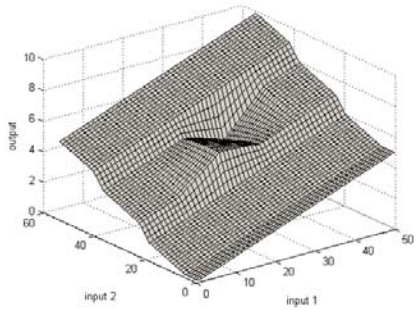

Figure 3: Graph of the sample two-dimensional sTS-system from Fig. 2 after the first application of an averaging template ($\alpha = 0.5$).

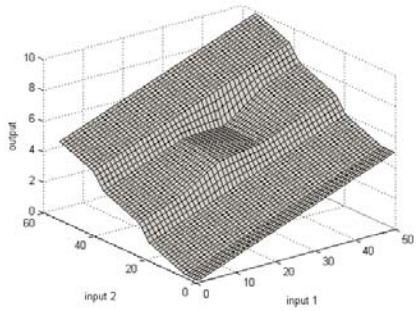

Figure 4: Graph of the sample two-dimensional sTS-system from Fig. 2 after applying an averaging template for two times ($\alpha = 0.5$).

template to a rule increases its smoothness. This can be seen as a form of incremental regularization.

For clarity reasons, we first consider a one dimensional first order sTS-fuzzy system f with triangular membership functions which sum up to 1. Then the input space is covered completely by a set of neighboring membership functions. Due to the normalization of the rule base, there is a single rule for each membership function. Thus, the rules can be ordered according to the ordinality of the membership functions so that they can be addressed by an index $i \in \mathbb{N}$, such that the indices i and $i+1$ address neighboring rules. The rule conclusion of rule number i is given by

$$f_i(x) = c_{0,i} + c_{1,i} \cdot x \tag{7}$$

with x as the input to the fuzzy system.

In the following, let $p_i \in \mathbb{R}$ denote the core of the membership function of rule i. As the membership functions are triangular, it is convenient here to distinguish between the left and the right part, $\mu_{i,l}(x)$ and $\mu_{i,r}(x)$, respectively, of each of them:

$$\begin{aligned} \mu_{i,l}(x) &= \frac{x - p_{i-1}}{p_i - p_{i-1}}, \quad p_{i-1} \le x < p_i \\ \mu_{i,r}(x) &= \frac{p_{i+1} - x}{p_{i+1} - p_i}, \quad p_i \le x < p_{i+1}. \end{aligned} \tag{8}$$

We are now considering the smoothness of the sTS fuzzy system in the environment of p_i. The functional behavior in this environment is determined by the neighboring rules, i.e., the rules $i-1$, i and $i+1$. To analyze the smoothness, we first calculate the first derivative of the sTS fuzzy system on the left and on the right of p_i. Between p_{i-1} and p_i, the output of the fuzzy system is then given by

$$f(x) = \mu_{i-1,r}(x) f_{i-1}(x) + \mu_{i,l}(x) f_i(x) \tag{9}$$

because of the linear interpolation due to sum-prod inference. Similarly, between p_i and p_{i+1}, the output is

$$f(x) = \mu_{i,r}(x) f_i(x) + \mu_{i+1,l}(x) f_{i+1}(x). \tag{10}$$

With these preparations, one can calculate the first derivative f' of f between the cores. For $p_{i-1} < x < p_i$ one gets

$$\begin{aligned} f'(x) &= \mu'_{i-1,r}(x) f_{i-1}(x) + \mu_{i-1,r}(x) f'_{i-1}(x) \\ &\quad + \mu'_{i,l}(x) f_i(x) + \mu_{i,l}(x) f'_i(x) \end{aligned} \tag{11}$$

and for $p_i < x < p_{i+1}$

$$\begin{aligned} f'(x) &= \mu'_{i,r}(x) f_i(x) + \mu_{i,r}(x) f'_i(x) + \\ &\quad \mu'_{i+1,l}(x) f_{i+1}(x) + \mu_{i+1,l}(x) f'_{i+1}(x). \end{aligned} \tag{12}$$

We can now determine the difference between the right and the left limit of $f'(x)$ with $x \to p_i$ and simplify it as the membership functions are either 0 or 1 at p_i:

$$\begin{aligned} \Delta_i &= \lim_{x \searrow p_i} f'(x) - \lim_{x \nearrow p_i} f'(x) \\ &= (\mu'_{i,r}(p_i) - \mu'_{i,l}(p_i)) f_i(p_i) \\ &\quad + \mu_{i+1,l}(p_i) f_{i+1}(p_i) - \mu'_{i-1,r}(p_i) f_{i-1}(p_i) \\ &= \left(\frac{-1}{p_{i+1} - p_i} + \frac{-1}{p_i - p_{i-1}} \right) (c_{0,i} + c_{1,i} p_i) \\ &\quad + \frac{1}{p_{i+1} - p_i} (c_{0,i+1} + c_{1,i+1} p_i) \\ &\quad + \frac{1}{p_i - p_{i-1}} (c_{0,i-1} + c_{1,i-1} p_i). \end{aligned} \tag{13}$$

ISBN: 978-989-95079-6-8

This expression means that in general one obtains a different result for the first derivative when approaching p_i from left than from right. To put it otherwise, Δ_i is a measure of the violation of the smoothness property at rule i.

Now suppose that our sTS fuzzy system contains a rule i with $\Delta_i \neq 0$. We will now prove that we can use a special SILKE template to reduce the violation of the smoothness property. This special SILKE template is given by the radius $r = 1$ and the mask

$$\begin{aligned} m(-1) &= \frac{3(p_{i+1} - p_i)}{p_{i+1} - p_{i-1}} \\ m(0) &= 0 \\ m(1) &= \frac{3(p_i - p_{i-1})}{p_{i+1} - p_{i-1}}. \end{aligned} \tag{14}$$

The application of this mask according to (4) and (5) changes $c_{0,i}$ and $c_{1,i}$ to $\hat{c}_{0,i}$ and $\hat{c}_{1,i}$, respectively:

$$\begin{aligned} \hat{c}_{a,i} &= c_{a,i} + \alpha \left(\frac{p_{i+1} - p_i}{p_{i+1} - p_{i-1}} c_{a,i-1} \right. \\ &\quad \left. + \frac{p_i - p_{i-1}}{p_{i+1} - p_{i-1}} c_{a,i+1} - c_{a,i} \right), \; a \in \{1, 2\}. \end{aligned} \tag{15}$$

This yields an updated value $\hat{\Delta}_i$ for the violation of the smoothness property. By comparing the updated value $\hat{\Delta}_i$ with the old value Δ_i, we can prove that the SILKE template (14) has the desired effect:

$$\begin{aligned} \hat{\Delta}_i &= \left(\frac{-1}{p_{i+1} - p_i} + \frac{-1}{p_i - p_{i-1}} \right) (\hat{c}_{0,i} + \hat{c}_{1,i} p_i) \\ &\quad + \frac{1}{p_{i+1} - p_i} (c_{0,i+1} + c_{1,i+1} p_i) \\ &\quad + \frac{1}{p_i - p_{i-1}} (c_{0,i-1} + c_{1,i-1} p_i) \\ &= \Delta_i + \alpha \left(\frac{-1}{p_{i+1} - p_i} + \frac{-1}{p_i - p_{i-1}} \right) \\ &\quad \cdot \left(\frac{p_{i+1} - p_i}{p_{i+1} - p_{i-1}} (c_{0,i-1} + c_{1,i-1} p_i) \right. \\ &\quad + \frac{p_i - p_{i-1}}{p_{i+1} - p_{i-1}} (c_{0,i+1} + c_{1,i+1} p_i) \\ &\quad \left. + \frac{-1}{1} (c_{0,i} + c_{1,i} p_i) \right) \\ &= \Delta_i + \alpha \left(\left(\frac{1}{p_{i+1} - p_i} + \frac{1}{p_i - p_{i-1}} \right) (c_{0,1} + c_{1,i} p_i) \right. \\ &\quad + \frac{-1}{p_{i+1} - p_i} (c_{0,i+1} + c_{1,i+1} p_i) \\ &\quad \left. + \frac{-1}{p_i - p_{i-1}} (c_{0,i-1} + c_{1,i-1} p_i) \right) \\ &= \Delta_i - \alpha \Delta_i \\ &= (1 - \alpha) \Delta_i. \end{aligned} \tag{16}$$

From this, it can be concluded that

$$|\hat{\Delta}_i| \leq |\Delta_i|. \tag{17}$$

The effect of this parameter update on a sample two-dimensional sTS-system is illustrated in Fig. 2 to 4. The figures demonstrate that each application of (4) on the central rule (in this case with $\alpha = 0.5$) increases the smoothness.

4 Discussion

The above investigations have shown that first order sTS-fuzzy systems with triangular membership functions have discontinuities of their first derivative precisely at the cores of the input membership functions, i.e., at the nodes of the normalized rule base. These discontinuities correspond to violating the *local smoothness* of the system behavior. It was shown for the one dimensional case that the SILKE approach reduces the discontinuity locally by a special averaging template, i.e., it increases the local smoothness. The effect depends on the adjustment rate α. For $\alpha = 0$, the rule base is not changed at all. But for higher values of α, the discontinuity of the first derivative is more and more reduced. Thus, the learning process is guided towards the meta-property of global smoothness expressed by the template function. Up to now, the formal proof is for the one dimensional case, although the SILKE algorithm is of course applicable to arbitrary dimensionality. We have shown by examplary investigations that the smoothing property also holds for higher dimensions. The extension of the formal proof is currently in progress.

In contrast to prior work on regularization, the SILKE approach has the advantage of working incrementally. It is thus well suited for incremental online learning which is required for self-adapting systems or building models online. During online operation, it is applied periodically and affects all currently active rules of the fuzzy system. This way, SILKE templates get a global influence although they work locally, which results in a low computational effort and good real-time capabilities. But what is more, sufficient plasticity of learning is still given due to locality, although the learning process is guided towards global meta-level properties.

Incremental online learning in a closed-loop setting is potentially chaotic. But with the SILKE approach, the influence of learning on the behavior of an embedded system in its environment can be guided by correcting the learned knowledge locally towards higher smoothness or towards compliance with other local meta-level properties when other templates are used. Depending on the adjustment rate, this yields a system which is very flexible in the face of learning stimuli that comply the meta-properties, but which is also very robust against learning stimuli which violate these meta-properties. So for this case, self-adaptive systems can fight outliers and overcome the stability-plasticity-dilemma to a certain extent. Based on this it is clear that the focus of this work is not to achieve the highest possible modeling quality, but to stabilize adaptive control systems.

At system level, the presented approach is an effective and efficient method for controlling incremental online learning without limiting the required flexibility. Such a system can cope with changes online and in a reliable way. It is based on the use of rules. On the one hand this aids engineerability at design time. On the other hand, rules which have been modified by self-tuning can also be analyzed directly. By that good engineerability and high trustworthiness are achieved.

In future work, the interplay between closed-loop incremental online learning and the SILKE approach will be investigated especially for the application of other template functions to zero and first order sTS-fuzzy systems in order to achieve other meta-properties such as monotony and curvature. As before, this will be done in experiments as well as

ISBN: 978-989-95079-6-8

in formal analysis. In addition, the extension of the results to more than one dimension has to be addressed.

Abstract— Adversarial decision making is aimed at determining optimal decision strategies to deal with an adversarial and adaptive opponent. One defense against this adversary is to make decisions that are intended to confuse him, although our rewards can be diminished. It is assumed that making decisions in an uncertain environment is a hard task. However, this situation is of upmost interest in the case of adversarial reasoning as what we want is to *force the presence of uncertainty* in order to confuse the adversary in situations of repeated conflicting encounters. Using simulations, the use of dynamic vs. static decision strategies is analyzed. The main conclusions are: a) the use of the proposed dynamic strategies has sense, b) the presence of an adversary may produce a decrease of, at least, 45% with respect to the theoretical best payoff and c) the relation between this reduction and the way the uncertainty is forced should be further investigated.

Keywords— Adversarial reasoning, uncertain environment, decision strategies, simulation

1 Introduction

Adversarial decision is largely about understanding the minds and actions of one's opponent. It is relevant to a broad range of problems where the actors are actively and consciously contesting at least some of each others' objectives and actions [1]. The field is also known as decision making in the presence of adversaries or adversarial reasoning.

In its most basic form, adversarial decision making involves two participants, white and black, each of which chooses an action to respond to a given event without knowing the choice of the other. As a result of these choices, a payoff is assigned to the participants. When this scenario is repeated many times, i.e. situations of repeated conflicting encounters arise, then the situation becomes complex as the participants have the possibility to learn the others strategy. Examples of this type can be found in the military field, but also in problems of real-time strategy games, government vs government conflicts, economic adversarial domains, team sports (e.g., RoboCup), competitions (e.g., Poker), etc. [1]

Adversarial decision making is aimed at determining optimal strategies (for white) against an adversarial and adaptive opponent (black). One defense against this adversary is to make decisions that are intended to confuse him, although white's rewards can be diminished.

It is assumed that making decisions in an uncertain environment is a hard task. However, this situation is of upmost interest in the case of adversarial reasoning as what white wants is to make its behaviour as uncertain or unpredictable as possible. In other words, white wants to *force the presence of uncertainty* in order to confuse the adversary while its payoff is as less affected as possible.

In previous work [2], we proposed a model to study the balance between the level of confusion induced and the payoff obtained and we concluded that one way to produce uncertainty is through decision strategies for white that contain certain amount of randomness. Here we focus on learning strategies that white can use as a means of optimizing his payoffs in situations of repeated conflicting encounters. Essentially we are studying how white can defend against an opponent who is trying to learn their decision rules.

In this paper, we want to analyze the case where white's decision strategy is not constant along the time, but modified following certain rules. We explore two alternatives, one is to vary the number of candidates alternatives in terms of their associated payoffs and second is based on the basic concept of α-cuts, where the value of α is varied.

The contribution is organized as follows: some basic concepts on adversarial reasoning are outlined in Section 2. Then, Section 3 describes the main characteristics and components of the model used. Section 4 introduces static decision strategies for both agents and then, shows how they can be transformed into dynamic ones. In Section 5 we describe the computational experiments performed and the results obtained and finally, Section 6 is devoted to discussions and further work.

2 Adversarial Reasoning

As stated before, adversarial decision making is largely about understanding the minds and actions of one's opponent. A typical example is the threat of terrorism and other applications in Defense, but it is possible to envisage less dramatic applications in computer games where the user is the adversary and the computer characters are provided with adversarial reasoning features in order to enhance the quality, hardness and adaptivity of the game. The development of intelligent training systems is also an interesting field.

The threat of terrorism, and in particular the 9/11 event, fueled the investments and interest in the development of computational tools and techniques for adversarial reasoning. However, the field has earlier developments. For example, almost twenty years ago, P. Thagard [3] states

> In *adversarial problem solving*, one must anticipate, understand and counteract the actions of an opponent. Military strategy, business, and game playing all require an agent to construct a model of an

ISBN: 978-989-95079-6-8

opponent that includes the opponent's model of the agent.

Game theory is perceived as a natural good choice to deal with adversarial reasoning problems. For example, a brief survey of techniques where the combination of game theory with other approaches is highlighted, jointly with probabilistic risk analysis and stochastic games is presented in [4]

However, nowadays it is assumed that the field transcends the boundaries of game theory [1]. As stated in [5]: "we argue that practical adversarial reasoning calls for a broader range of disciplines: artificial intelligence planning, cognitive modeling, control theory, and machine learning in addition to game theory. An effective approach to problems of adversarial reasoning must combine contributions from disciplines that unfortunately rarely come together".

3 The model

The framework used to conduct our study is a slight modification of the previously proposed in [2].

It is based on two agents white W and black B (the adversary), a set of possible inputs or events $E = \{e_1, e_2, \ldots, e_n\}$ issued by a third agent R, and a fuzzy set of potential responses or actions $A_i = \{a_1, a_2, \ldots, a_m\}$ associated with every event. These fuzzy sets are organized as rows in a matrix P as :

$$P(n \times m) = \begin{pmatrix} p_{11} & p_{12} & \cdots & p_{1m} \\ p_{21} & p_{22} & \cdots & p_{2m} \\ p_{31} & p_{32} & \cdots & p_{3m} \\ \\ p_{n1} & p_{n2} & \cdots & p_{nm} \end{pmatrix}$$

where $p_{ij} \in [0, 1]$ is the level of suitability of action j to respond to the event i. More precisely, p_{ij} is the degree of membership of action j to the fuzzy set of *suitable actions* associated with event e_i. We do not require these fuzzy sets to be normalized.

Agent W has a strategy to decide which action to take given a particular event e_k and perfect knowledge of matrix P. The aim for W is to maximize the sum of the profits or payoffs given a set of inputs. These inputs or events are issued one at a time by R and, in principle, they are independent.

The payoff of a given action is proportional to its suitability with respect to the given event. For the sake of simplicity, in this contribution we assume that the payoff is the value of suitability.

Agent B wishes to learn the actions that W is going to take given a particular input e_k so as to reduce agent W payoff. Agent B does not know matrix P. It has access to the decisions made previously by W and, if the guess matched the decision taken by W, then B obtains some reward. We may think the situation as an "imitation game", where the aim for W is to avoid being imitated.

A graphical view of the model is shown in Figure 1 while the whole procedure is described in Algorithm 1.

The payoff's calculation for W at stage j is defined as:

$$p' = p_{jk} \times F(a_g, a_k) \tag{1}$$

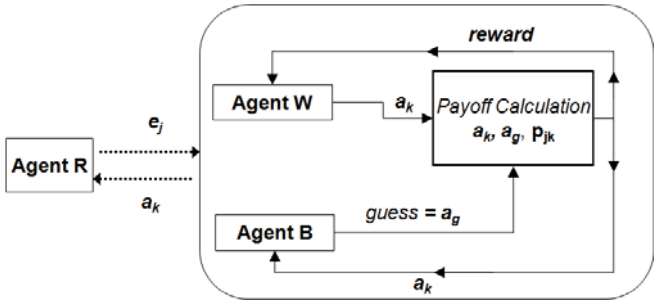

Figure 1: Graphical representation of the model. Events e_j are issued by agent R while response or actions a_k are taken by agent W.

for $j = 1$ to N **do**
  A new event e_j arises.
  Agent B "guesses" an action a_g
  Agent W determines an action a_k
  Calculate payoff for W
  Agent B records the pair e_j, a_k
end for

where F is:

$$F(a, b) = \begin{cases} 0 & \text{if a = b} \\ 1 & \text{otherwise} \end{cases} \tag{2}$$

As stated before, the aim for W is to maximize the sum of the payoffs. In other words, a strategy for W should be aimed at defining a sequence of actions that gives the higher payoff while avoiding being correctly guessed.

The terms *event* and *action* used here should be understood in a broad sense. For example, an event may represent a particular simulation scenario while an action may represent a full plan. Also, the actions may represent a Dempster-Schaffer belief structure to reflect the ideas posed in [6].

4 Modeling the Behavior of the Agents

In this section, we provide alternatives for modeling the behavior of both agents. For simplicity, we assume that the inputs issued by agent R are equiprobable and that the number of inputs equals the number of actions (i.e, the payoff matrix is square).

4.1 Strategies for Agent B

Agent B applies a very simple frequency-based decision strategy. We define a matrix of observations O with $M \times M$ dimensions, where each O_{ij} stores the number of times that action i was observed (from W) when the event was e_j. Given an event e_j, the following decision strategy for B is used:

Proportional to the Frequency (PF): the probability of selecting an action i is proportional to O_{ij} (the observed frequency from agent W) [2].

4.2 Strategies for Agent W

Agent W knows he is being observed, so the idea is to change its behavior in order to confuse the adversary. The agent needs to take sub-optimal decisions in order to get benefits in the long term.

ISBN: 978-989-95079-6-8

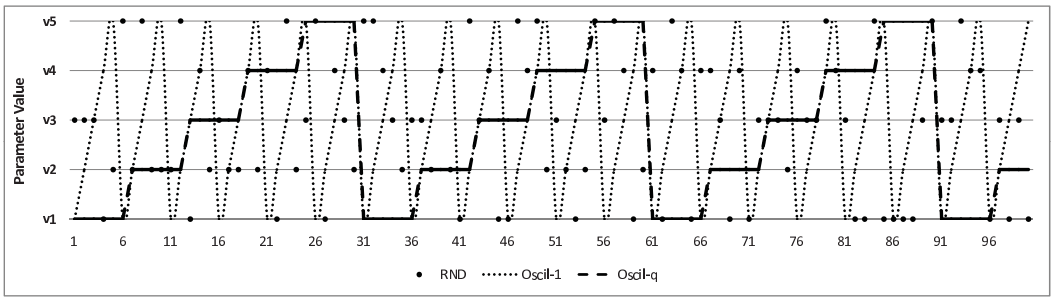

Figure 2: Adaptation schemes for the parameters in the dynamic strategies. The example shows the case where a parameter takes values from a set of possible discrete alternatives $\{v_1, v_2, v_3, v_4, v_5\}$

Given an observed input e_i and the suitability matrix P, we propose two basic strategies:

1. *Random-Among $< k >$ Best Actions (R-k-B)*: Select randomly an alternative among the k most suitable ones [2].
2. *Random-From α-cut (R-α)*: select randomly an alternative among those with a minimum level of suitability α.

We remark here that these strategies are not *mixed strategies* in the sense of game theory as we do not define a probability distribution over the set of alternatives. Once a subset of alternatives is selected, then any of them can be selected with equal probability.

It is clear that both parameters, k and α, can be used to control the amount of uncertainty in the action selection. Some specific values for those parameters lead to interesting behaviours:

- $k = 1$: always select the most suitable action.
- $k = M$: any action is considered equally suitable.
- $0 < k < M$ lead to a behaviour where suboptimal actions may have the chance of being selected.

Particular cases for α:

- $\alpha = 1$: always select the action whose level of suitability is 1. This is not a good strategy as it is easily learnable.
- $\alpha = 0$: any action is considered equally suitable.
- $0 < \alpha < 1$ lead to a behaviour where suboptimal actions may have the chance of being selected.

Although at first sight both strategies look similar, there is an important difference. The former strategy (*R-k-B*) is independent of the suitability scale: it just selects the k most suitable alternatives and then takes a decision. The later strategy is based on α-cuts, so if the value of α is high, then it may happen that the subset of alternatives of the corresponding α-cut becomes empty. In this case, an alternative would be randomly selected.

4.2.1 Dynamic Strategies

When α and k are assigned specific values, then a "static strategy" is obtained. Here, we propose a set of "dynamic strategies" where the values of the control parameter are varied along the time following the patterns shown in Fig. 2.

In order to adapt the parameter k, we propose three schemes:

1. *RND*: at each stage, k is a value from a uniform distribution in $[1, M]$.
2. *Oscil-1*: after each event, $k = k + 1$. When $k = M + 1$ then $k = 1$.
3. *Oscil-10*: the same as before but the value of k is changed after ten events.

For the adaptation of α we propose similar schemes:

1. *RND*: at each stage, α is selected randomly from the set $V = \{0.15, 0.3, 0.45, 0.6, 0.75\}$
2. *Oscil-1*: after each event, $i = i + 1$, $\alpha = V[i]$. When $i = M + 1$ then $i = 1$
3. *Oscil-10*: the same as before but the value of α is changed after ten events.

5 Experiments and Results

The aim of the experiment is to evaluate how W's payoff is affected when dynamic vs. static decision strategies are used.

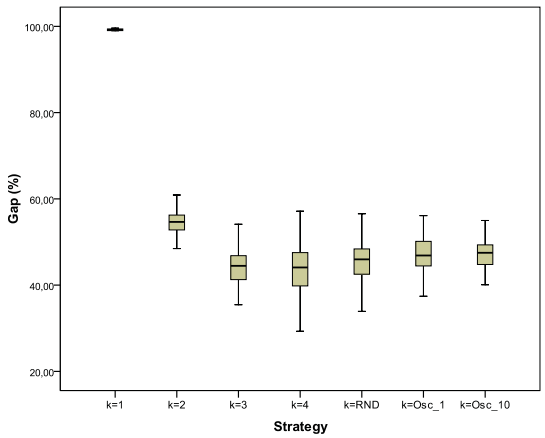
In order to do this, the following considerations are taken. We fix the number of events and alternatives to $M = 5$. Then, for every W's strategy we made 100 repetitions of the scheme shown in Algorithm 1, where $N = 500$. The matrix P is randomly generated each repetition. In this way we avoid potential biases due to particular configuration of values in P. At the end of each repetition, we record:

- Gap: the gap (as percentage) between the payoff obtained by W and the optimum (calculated as the sum of the payoffs associated with the best action for every event),
- $Guess$: the number of times that B correctly guessed the action of W (also as percentage with respect to 500 actions).

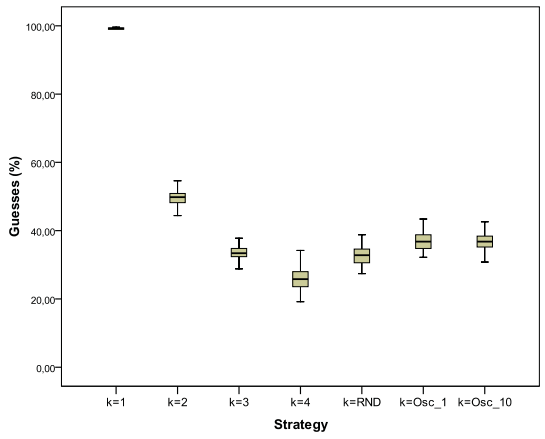
For both cases, the lower the values are, the better the performance of the strategy is.

We evaluated six dynamic strategies (three for α and three for k), four static strategies *R-k-B* using $k = 1, 2, 3, 4$ and five static strategies *R-α* using $\alpha = \{0.15, 0.3, 0.45, 0.6, 0.75\}$.

ISBN: 978-989-95079-6-8



(a)



(b)

Figure 3: Strategy *R-k-B*: average Gap (a) and $Guess$ (b) for each static and dynamic configuration

5.1 Results

In first place we will analyze the results for the *R-k-B*. Figure 3 shows boxplots for the average Gap and $Guess$ (the average number of correct guesses) when the parameter k is fixed or adapted during the repetition.

As it also occurred in [2], the value $k = 1$ is the worst alternative in terms of both measures. In this case, the best action is always selected, thus after a few events the frequency of those actions in the observations matrix kept by B are the only ones different than zero and B always choose them. As k increases, the performance is better on average but the standard deviation is increased. The proposed adaptive schemes for k do not show big differences among them. What is clear, is the reduction in the standard deviation from the $k = RND$ strategy to the one that force oscillations for k every ten events. In terms of the $Guess$ measurement, it is interesting to note that a variation of this single parameter can decrease the number of correct predictions from 50% when $k = 2$ to a lowest value of 25% when $k = 4$.

In order to assess if the differences among the strategies in the average gap have statistical significance, we performed an ANOVA test followed by a post-hoc analysis using Tamhane's test with $p < 0.05$. The results are shown in Table 1; the signs indicate that the average gap between strategies (i, j) (row,col) is different with statistical significance. A '+ sign indicates that strategy i is better, while a '- denotes that j is better. Absence of symbol indicates that the difference had no statistical significance. In this case, the best results are obtained by static strategies with parameters $k = 3$ and $k = 4$. The strategy RND shows a similar performance, however it is not so good to outperform the other dynamic strategies.

Table 2: Summary of the statistical testing for *R-*α strategies. See text for details.

A similar analysis can be done for the *R-*α strategy. Figure 4 shows boxplots for the average Gap and $Guess$ when the parameter α is fixed or adapted during the repetition. The label A in the plots stands for α.

As α increases, the performance becomes worst. The reason is related with the way the matrix P is generated. It may happen that no action has a level of suitability with a degree of membership higher than α. In other words, the corresponding α-cut leads to an empty set of alternatives. In this case, a pure random decision strategy is taken. The counterpart is that now, the proposed adaptive schemes for α are clearly better than the static alternatives. Between the adaptive schemes, no clear differences appeared.

As before, in order to assess if the differences among the strategies in the average Gap have statistical significance, we performed statistical testing. The results are shown in Table 2. It can be confirmed that when using a static strategy, lower values of α like 0.15 or 0.3 led to better results than those obtained with higher ones. However, any of the dynamic strategies proposed, even RND, obtained the same average Gap. Moreover, the strategy *Osc-10* (that changed the α value every ten events) provided better performance than all the static strategies, excepting $\alpha = 0.15$.

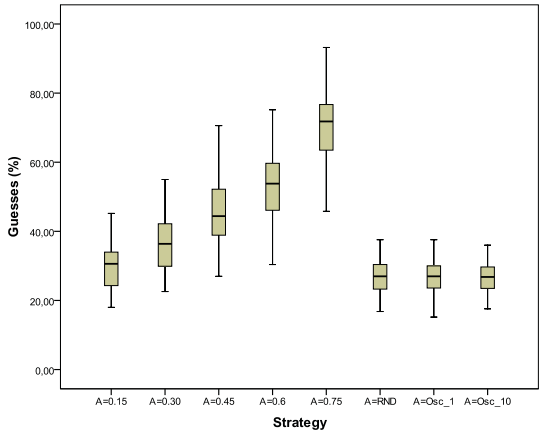
(a)



(b)

Figure 4: Strategy *R*-α: average Gap (a) and $Guess$ (b) for each static (A stands for α) and dynamic configuration

It is reasonable to assume that a relation exist between the number of correct guesses and the payoff obtained. If the former is high, it is clear that the payoff should be low (this is the case when $k = 1$). But what happen when the number of correct guesses is low? What are the payoff values that can be reached?. Figure 5 shows the average of each measure for every strategy (the case when $k = 1$ is omitted for visualization purposes). Within each kind of strategy (*R-k-B*, R-α), the alternatives are ordered increasingly in terms of Gap.

It is clear that just reducing the number of guesses is not enough to improve the gap. For example, *A=Osc-10* achieved a lower value of $Guess$ than $k = 3$ but a higher value of Gap. This was also already notice in [2], where a purely random strategy led to the lowest value of $Guess$. Interestingly, all the cases where the curve for $Guess$ stands below the one for Gap correspond to strategies based on α-cuts. The reason is not clear and further investigations are needed.

To conclude the analysis, Figure 6 shows several scatter plots displaying the relation between both measures. Every point correspond to a particular repetition, thus 100 point per plot are displayed. Plots on the left correspond to *R*-α strategy while those on the right to *R-k-B*. Three static values are shown per each parameter, while the bottom plot corresponds to the best dynamic strategy. The X axis is the Gap while Y axis shows the measure $Guess$.

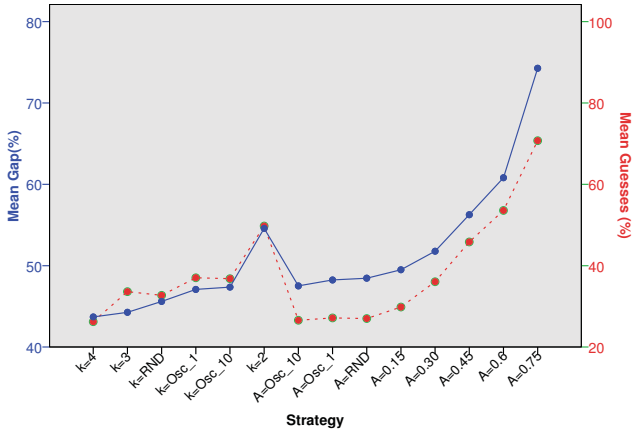


Figure 5: Average Gap (left Y axis) and $Guess$ (right Y axis) for every strategy. The dotted line is used for $Guess$.

Several elements can be observed in the Figure. Let's start with the *R*-α strategy (left). As α increases, we can observe a progressive concentration of the points towards the upper right corner of the plot. This means that the results are getting worse: more guesses, higher gap (agent W is getting much lower payoff than the potential optimum). It is noticeable the high variation the results are showing. For instance, when $\alpha = 0.45$ (second plot, in the left), one can observe simulation with guesses around 30% and gap around $30\% - 45\%$ and others with guesses higher than 60% and gap higher than 60%. When a simple dynamic strategy is used ($\alpha = RND$), then the number of correct guesses is almost always below 30%. However, the range of values that can be obtained for gap value is quite wide, going from 30% to 60%.

The plots are a bit different for the *R-k-B* strategy. As k increases, the percentage of guesses decrease. This is reasonable taking into account how the strategy works: take the k best alternatives and then, choose random. In the experiments performed, the total number of actions is 5, so, when $k = 4$, then just the worst strategy is eliminated. In other words, as k increases, agent B may conclude that W is behaving randomly. In turn, the gap value is more variable, ranging from 35% to 55% approx.

6 Discussion and Future Work

In this work we focused in the context of adversarial reasoning where a player W wants to *force the presence of uncertainty* in order to confuse the adversary B while its payoff is as less affected as possible in situations of repeated conflicting encounters. We extended a previous work where the decision strategies were fixed along the time, to consider dynamic strategies: the way the decisions are taken varies with the time.

When the decision strategy is based on α-cuts, then a dynamic variation of α led to better results than the static counterpart. Moreover, none of the adaptation schemes proposed led to worst results than those obtained by a specific configuration of the control parameter. However, in the $R - k - B$ case, the results are not so clear but still good. The best results are obtained with $k = 3, k = 4$. Using any of these values, the strategy obtained performed better than four of the other

ISBN: 978-989-95079-6-8

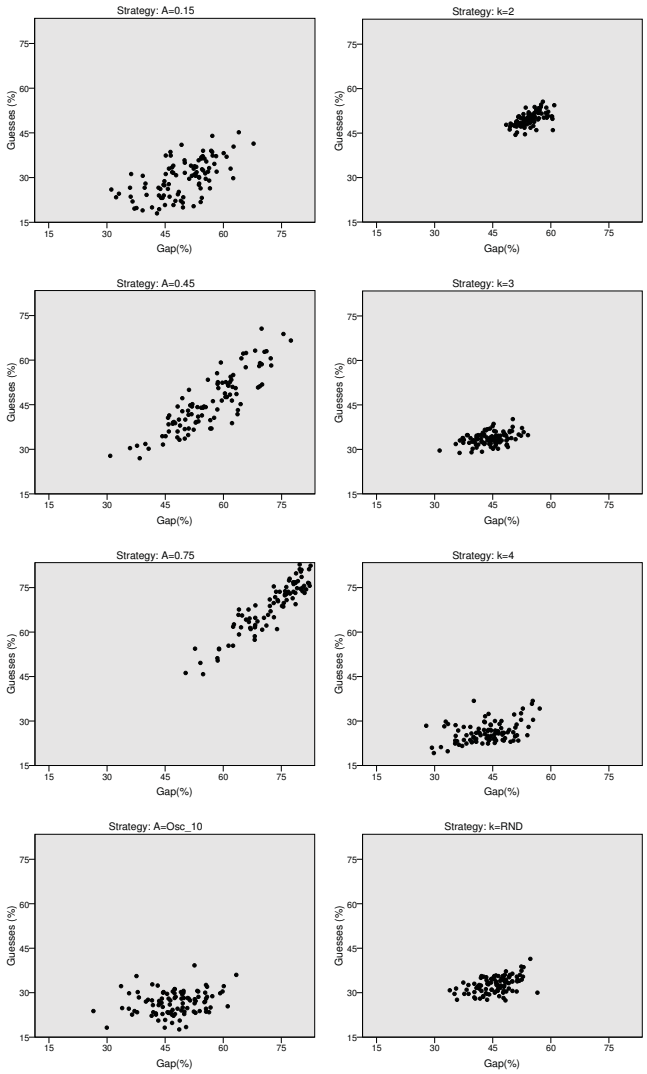

Figure 6: Every point represents the result $(Gap, Guess)$ of a repetition.

strategies available. The best dynamic alternative is RND which assigns a random value to k before applying the strategy. This strategy achieved a similar performance (on average) with respect to $k = 3, k = 4$.

The use of dynamic strategies, besides its potential performance, has another benefit which is to avoid determining a specific value for the control parameter. This is not a trivial matter as there is no simple way to infer which setting will provide the best value for a different simulation scenario.

The study performed also revealed an interesting point: the lowest average Gap value for a dynamic strategy was 45% when using $k = RND$ and this implies that W's payoff is 45% lower than the theoretical optimum one. In [2], we showed that using a purely random decision strategy, the gap is higher than 50%. The question now is: would it be possible to design a strategy with guaranteed (in a formal sense) performance?.

The way the dynamism is included in this proposal is quite simple, but several alternatives are available for producing improvements. Now, agent W is not analyzing the payoff obtained against the one expected (which is stored in matrix P). Agent W can use the fact that its payoff is being affected in order to produce an intelligent adaptation of its strategy. In this context, the use of fuzzy rules may play an important role as it would help to model adaptation strategies as: *if the reduction of payoff is high, then increase uncertainty*, or *if this event occurred a high number of times then increase uncertainty*. Other lines of research are related with the model used. Here, the way the payoff matrix is generated may affect the results obtained by the strategy based on α-cuts as the differences between the suitability of alternatives may be low. Other ways to define such matrix may be necessary. Also, the sequence of events is completely random now, but other options are available.

The relation between the number of correct guesses and the gap value is clear in some situations but in others (as shown in Fig. 6), it is possible to obtain a broad range of gap values for the same number of guesses. In this context, it seems not trivial to use the number of guesses as a predictor for the gap value. A different alternative may take into account that the presence of uncertainty is reflected in the matrix of observations O that agent B construct, so it would be interesting to look for correlations between the gap value and some measures about this matrix O. The ideas posed here are left as future work.

Finally, we would like to mention that one of the reviewers claimed that the problem posed here can be solved with the standard tools of game theory arguing that the problem can be seen as a sequence of n independent non cooperative games. However, we do not think that this is the case as, for example, the matrix of observations changes at each step, we are not dealing with mixed strategies and so on. Moreover, we claim that this kind of analysis can be applied when the events are correlated in some way, and also, when more sophisticated adaptation and learning mechanisms are considered in both agents.

Abstract— In this work we introduce the concept of *Generalized Atanassov's Intuitionistic Fuzzy Index*. We characterize it in terms of fuzzy implication operators and we propose a construction method with automorphisms. Finally, we study some special properties of the generalized Atanassov's intuitionistic fuzzy index.

Keywords— Atanassov's Intuitionistic Fuzzy Index, Fuzzy Implication Operator, Automorphisms.

1 Introduction

In 1983 Atanassov [1] introduced Atanassov's intuitionistic fuzzy sets ($A-IFSs$) in such a way that each element of the set has two values assigned, the membership degree and the non-membership degree. In this direction, Atanassov defined these sets also indicating that the index of intuitionism of each element obtained by subtracting the sum of membership and non-membership from one (a subtraction that should be positive and less than or equal to one), it is a measurement of the effect of working with Atanassov's intuitionistic fuzzy sets. We consider this intuitionistic index (or condition of intuitionism) a very important characteristic of $A-IFSs$ since from it we can obtain very valuable information of each element and taking on advantage of this potentiality in different applications. For example, in image processing the task of divide into disjoint parts a digital image is denoted as segmentation. The most commonly used strategy for segmenting images is global thresholding that refers to the process of dividing the pixels in an image on the basis of their intensity levels of gray. The experts have uncertainty when assigning the pixels either to the background or to the object trough the choice of the membership functions. Moreover, this choice has proven to be of uttermost importance regarding the algorithms performance. In order to overcome this problem, we consider using the Atanassov's intuitionistic fuzzy index values for representing the uncertainty of the expert in determining that the pixel belongs to the background or that it belongs to the object. From this point of view, we can consider the expert provides the degree of membership of an element to an $A-IFS$ and also the degree of intuitionism the expert has in given this membership degree (see [9]). This fact has led us to present the new concept of *Generalized Atanassov's Intuitionistic Fuzzy Index* that generalize the expression given by Atanassov. We also provide a characterization method by means of fuzzy implication operators. Moreover, we study a construction method using automorphisms that allow us to present simple expressions of said index.

Pankowska and Wygralak ([16, 17, 21]) proposed another generalization of the intuitionistic index based on strong negations and triangular norms. This approach is used to construct flexible algorithms of group decision making which involve relative scalar cardinalities defined by means of generalized sigma counts of fuzzy sets.

2 Preliminary definitions

Let U be an ordinary finite non-empty set. An *Atanassov's intuitionistic fuzzy set* ($A-IFS$) [1] in U is an expression A given by

$$A=\{(u,\mu_A(u),\nu_A(u))|u\in U\} \tag{1}$$

where

$$\begin{array}{l}\mu_A\ :\ U\longrightarrow[0,1]\\ \nu_A\ :\ U\longrightarrow[0,1]\end{array}$$

satisfy the condition $0\leq\mu_A(u)+\nu_A(u)\leq 1$ for all u in U.

The numbers $\mu_A(u)$ and $\nu_A(u)$ denote respectively the degree of membership and the degree of non-membership of the element u in set A. We will also use the notation $A(u)=(\mu_A(u),\nu_A(u))$. We will represent as $A-IFSs(U)$ the set of all the Atanassov's intuitionistic fuzzy sets in U.
Atanassov defined the *Atanassov's intuitionistic fuzzy index* of the element u in $A\in A-IFSs(U)$ as:

$$\Pi_A(u)=1-\mu_A(u)-\nu_A(u). \tag{2}$$

We know fuzzy sets are represented exclusively by the membership function degree, that is,

$$A=\{(u,\mu_A(u))|u\in U\}. \tag{3}$$

Hereinafter, fuzzy sets have associated a non-membership degree given by one minus the membership degree:

$$\begin{array}{ll}A= & \{(u,\mu_A(u),\nu_A(u))|u\in U\}=\\ & \{(u,\mu_A(u),1-\mu_A(u))|u\in U\}.\end{array} \tag{4}$$

Since $\mu_A(u)+\nu_A(u)=\mu_A(u)+1-\mu_A(u)=1$, in this sense fuzzy sets are considered as a particular case of Atanassov's intuitionistic fuzzy sets. We will represent as $FSs(U)$ the set of all the fuzzy sets in U.

We will call automorphism of the unit interval every function $\varphi:[0,1]\to[0,1]$ that is continuous and strictly increasing such that $\varphi(0)=0$ and $\varphi(1)=1$.

A function $n:[0,1]\to[0,1]$ such that $n(0)=1$ and $n(1)=0$ is called a *strong negation* whenever it is strictly decreasing, continuous and involutive. Trillas ([19, 20]) proved that $n:[0,1]\to[0,1]$ is a strong negation if and only if there exists an automorphism φ of the unit interval such that

ISBN: 978-989-95079-6-8

$n(x) = \varphi^{-1}(1 - \varphi(x))$. In this work we will only consider strong negations.

We denote as L^* the following set:

$$L^* = \{(x, y) | (x, y) \in [0, 1] \times [0, 1] \; and \; x + y \leq 1\} \quad (5)$$

and the elements $0_{L^*} = (0, 1)$ and $1_{L^*} = (1, 0)$.

For every $(x, y), (z, t) \in L^*$ the following expressions are known ([1]-[8],[12]-[14]):

- $(x, y) \leq_{L^*} (z, t) \; if \; and \; only \; if \; x \leq z \;\; and \; y \geq t$. This relation is transitive, reflexive and antisymmetric.
- $(x, y) = (z, t) \;\; if \;\; and \;\; only \;\; if \;\; (x, y) \leq_{L^*} (z, t) \;\; and \;\; (z, t) \leq_{L^*} (x, y)$.
- $(x, y) \preceq (z, t) \; if \; and \; only \; if \; x \leq z \;\; and \; y \leq t$.

  In [14] is proven $(L^*, \leq_{L^*})$ is a complete lattice.

Therefore, if $A \in FSs(U)$, then

$$A_c = \{(u, 1 - \mu_A(u), \mu_A(u)) | u \in U\}. \quad (6)$$

Next, we recall the definition of Atanassov's intuitionistic fuzzy t-norm and t-conorm and also the notion of t-representability, in such a way, Deschrijver *et al.* gave a construction method of Atanassov's intuitionistic fuzzy t-norms and t-conorms by means of t-norms and t-conorms on $[0, 1]$ (see [14]).

Definition 1 *A function* $\mathbf{T} : (L^*)^2 \to L^*$ *is said to be an Atanassov's intuitionistic fuzzy t-norm if it is commutative, associative, and increasing (in both arguments with respect to the order* $\leq_{L^*}$*), with neutral element* 1_{L^*}*. In the same way, a function* $\mathbf{S} : (L^*)^2 \to L^*$ *is said to be an Atanassov's intuitionistic fuzzy t-conorm if it is commutative, associative, increasing and with neutral element* 0_{L^*}*.*

Definition 2 *An Atanassov's intuitionistic fuzzy t-norm* $\mathbf{T}$ *is called t-representable if and only if there exist a t-norm* T *and a t-conorm* S *on* $[0, 1]$ *such that, for all* $(x, y), (z, t) \in L^*$

$$\mathbf{T}((x, y), (z, t)) = (T(x, z), S(y, t)) \in L^*. \quad (7)$$

An Atanassov's intuitionistic fuzzy t-conorm $\mathbf{S}$ *is called t-representable if and only if there exist a t-norm* T *and a t-conorm* S *on* $[0, 1]$ *such that, for all* $(x, y), (z, t) \in L^*$

$$\mathbf{S}((x, y), (z, t)) = (S(x, z), T(y, t)) \in L^*. \quad (8)$$

Example 1 *Let be* $(x, y), (z, t) \in L^*$, $T = min$ *and* $S = max$ *on* $[0, 1]$

$$(a) \quad \mathbf{min}((x, y), (z, t)) = (min(x, z), max(y, t)). \quad (9)$$

$$(b) \quad \mathbf{max}((x, y), (z, t)) = (max(x, z), min(y, t)). \quad (10)$$

Definition 3 *([10, 14]) An Atanassov's intuitionistic fuzzy negation is a function* $\mathbf{n} : L^* \to L^*$ *that is decreasing (with respect to* $\leq_{L^*}$*) such that* $\mathbf{n}(0_{L^*}) = 1_{L^*}$ *and* $\mathbf{n}(1_{L^*}) = 0_{L^*}$*. If for all* $(x, y) \in L^*$ $\mathbf{n}(\mathbf{n}((x, y))) = (x, y)$ *it is said that* $\mathbf{n}$ *is involutive.*

The characterization of the Atanassov's intuitionistic fuzzy negations and the following result are presented in [14], for interval-valued fuzzy sets are proven in [10].

Theorem 1 *A function* $\mathbf{n} : L^* \to L^*$ *is an involutive Atanassov's intuitionistic fuzzy negation if and only if there exists an involutive fuzzy negation* n *such that*

$$\mathbf{n}((x, y)) = (n(1 - y), 1 - n(x)). \quad (11)$$

Throughout this work we will restrict to involutive Atanassov's intuitionistic fuzzy negations $\mathbf{n}$ generated from a given negation n, as in Theorem 1.

3 Generalized Atanassov's Intuitionistic Fuzzy Index

In this section we propose the definition of generalized Atanassov's intuitionistic fuzzy index and we characterize such index by means of fuzzy implication operators and automorphisms.

Definition 4 *A function* $\Pi_G : L^* \to [0, 1]$ *is called a generalized Atanassov's intuitionistic fuzzy index associated with the strong negation* n*, if it satisfies the following conditions:*

(i) $\Pi_G((x, y)) = 1$ *if and only if* $x = 0$ *and* $y = 0$*;*

(ii) $\Pi_G((x, y)) = 0$ *if and only if* $x + y = 1$*;*

(iii) If $(z, t) \preceq (x, y)$*, then* $\Pi_G((x, y)) \leq \Pi_G((z, t))$*;*

(iv) $\Pi_G((x, y)) = \Pi_G(\mathbf{n}((x, y)))$ *for all* $(x, y) \in L^*$ *such that* $\mathbf{n}$ *is generated from an involutive fuzzy negation* n*, as in Theorem 1.*

Example 2

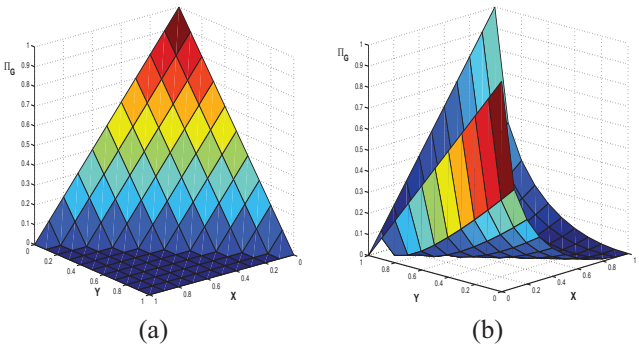
$$(a) \quad \Pi_G((x, y)) = 1 - y - x, \quad (12)$$

with $n(x) = 1 - x$ *for all* $x \in [0, 1]$*. As we can observe, this expression is equal to the expression (2) given by Atanassov.*

$$(b) \quad \Pi_G((x, y)) = ((1 - y)^{0.5} - x^{0.5})^2 \quad (13)$$

with $n(x) = (1 - x^{0.5})^2$ *for all* $x \in [0, 1]$.

Fig. 1 depicts the expressions given by Example 2.



(a) (b)

Figure 1: (a) $\Pi_G((x, y)) = 1 - y - x$ (b) $\Pi_G((x, y)) = ((1 - y)^{0.5} - x^{0.5})^2$

Next, we study the symmetry property of Π_G and we prove that only it is satisfied if we take as n the standard negation. Later, we introduce a construction method of the generalized Atanassov's intuitionistic fuzzy index using two automorphisms. In this way, it is quite simple to give different expressions of the intuitionistic index. Moreover, we analyze the case if the two automorphisms that we are taking are equal.

ISBN: 978-989-95079-6-8

Proposition 1 *Let Π_G be a generalized Atanassov's intuitionistic fuzzy index associated with the strong negation n. Then,*

$$\Pi_G((x,y)) = \Pi_G((y,x))$$

if and only if

$$n(x) = 1 - x;\ that\ is, \mathbf{n}((x,y)) = (y,x).$$

Proof. If $\Pi_G((x,y)) = \Pi_G((y,x))$ and by means of item (iv) of Definition 4 and Theorem 1, we obtain, $\Pi_G((x,y)) = \Pi_G((y,x)) = \Pi_G(\mathbf{n}((x,y))) = \Pi_G((n(1-y), 1-n(x)))$. Therefore, $n(1-y) = y$ and $n(x) = 1-x$.
On the other side, if n is the standard negation, then $\Pi_G((x,y)) = \Pi_G(\mathbf{n}((x,y))) = \Pi_G((n(1-y), 1-n(x))) = \Pi_G((y,x))$.

Proposition 2 *If φ_1, φ_2 are two automorphisms of the unit interval, then*

$$\Pi_G((x,y)) = \varphi_1^{-1}(\varphi_2(1-y) - \varphi_2(x)) \tag{14}$$

with $n(x) = \varphi_2^{-1}(1 - \varphi_2(x))$ is a generalized Atanassov's intuitionistic fuzzy index associated with the strong negation n.

Proof. We must proof the four properties of a generalized Atanassov's intuitionistic fuzzy index. The proof of properties (i) and (ii) is direct bearing in mind the bound conditions of automorphisms definition. (iii) if $(z,t) \preceq (x,y)$ then, $z \leq x$ and $t \leq y$. Automorphisms are strictly increasing therefore, $\varphi_2(z) \leq \varphi_2(x)$ and $\varphi_2(1-y) \leq \varphi_2(1-t)$, so we obtain $\Pi_G((x,y)) \leq \Pi_G((z,t))$. (iv) Bearing in mind Teorem 1 and also $n(x) = \varphi_2^{-1}(1-\varphi_2(x))$, we have $\Pi_G(\ \mathbf{n}((x,y))) = \Pi_G((n(1-y), 1-n(x))) = \varphi_1^{-1}(\varphi_2(n(x)) - \varphi_2(n(1-y))) = \varphi_1^{-1}(\varphi_2(\varphi_2^{-1}(1-\varphi_2(x))) - \varphi_2(\varphi_2^{-1}(1-\varphi_2(1-y)))) = \Pi_G((x,y))$.

Proposition 3 *In the conditions of Proposition 2:*

$$\Pi_G((0,y)) = 1 - y$$

if and only if

$$\varphi_1(x) = \varphi_2(x) \quad for\ all \quad x \in [0,1].$$

Proof. Direct.

For us, a fuzzy implication operator will be an implication in the sense of Fodor and Roubens [15], that is, a function $I : [0,1]^2 \to [0,1]$ that satisfies the following properties:

I_1. If $x \leq z$ then $I(x,y) \geq I(z,y)$ for all $y \in [0,1]$;

I_2. If $y \leq t$ then $I(x,y) \leq I(x,t)$ for all $x \in [0,1]$;

I_3. $I(0,x) = 1$ (dominance of falsity) for all $x \in [0,1]$;

I_4. $I(x,1) = 1$ for all $x \in [0,1]$.

I_5. $I(1,0) = 0$.

Depending on the application the following properties can also be demanded to a fuzzy implication operator:

I_6. $I(1,x) = x$ (neutrality of truth).

I_7. $I(x, I(y,z)) = I(y, I(x,z))$ (exchange property).

I_8. $I(x,y) = 1$ if and only if $x \leq y$.

I_9. $I(x,y) = I(n(y), n(x))$ (contraposition) with a strong negation n.

I_{10}. I is a continuous function.

In [6] is provide the following important result.

Proposition 4 *Let $I : [0,1]^2 \to [0,1]$. For all $x, y, z \in [0,1]$, the following properties hold:*

(i) *I satisfies I_1 if and only if $I(max(x,y), z) = min(I(x,z), I(y,z))$.*

(ii) *I satisfies I_1 if and only if $I(min(x,y), z) = max(I(x,z), I(y,z))$.*

(iii) *I satisfies I_2 if and only if $I(x, min(y,z)) = min(I(x,y), I(x,z))$.*

(iv) *I satisfies I_2 if and only if $I(x, max(y,z)) = max(I(x,y), I(x,z))$.*

Next, we will give a characterization of the generalized Atanassov's intuitionistic fuzzy index Π_G by means of a function $I : [0,1]^2 \to [0,1]$ that satisfies some properties of fuzzy implication operators.

Theorem 2 *Let n be a strong negation. A function $\Pi_G : L^* \to [0,1]$ is a generalized Atanassov's intuitionistic fuzzy index associated with the strong negation n*

if and only if

there exists a function $I : [0,1]^2 \to [0,1]$ satisfying $I1, I8, I9$, and $I(x,y) = 0$ if and only if $x = 1$ and $y = 0$, such that

$$\Pi_G((x,y)) = n(I(1-y, x)).$$

Proof. Sufficiency. We need to prove the four properties of Definition 4. Properties (i) and (ii) are direct. Property (iii) we must consider the result proven in [6] that if I satisfies I_1 and I_9, then I satisfies I_2. Property (iv) is direct bearing in mind that I satisfies I_9 and n is a strong negation. In order to prove necessity, let us suppose that Π_G is a generalized Atanassov's intuitionistic fuzzy index associated with the strong negation n. Define I

$$I(x,y) = \begin{cases} 1 \text{ if } x \leq y \\ n(\Pi_G((y, 1-x))) \text{ if } x > y. \end{cases} \tag{15}$$

Now it is easy to prove that I satisfies I_1, I_8, I_9 and also $I(x,y) = 0$ if and only if $x = 1$ and $y = 0$.

Example 3 *We build these generalized Atanassov's intuitionistic fuzzy indices associated with the strong negation $n(x) = 1 - x$ for all $x \in [0,1]$.*

(a) Lukasiewicz implication: $I(x,y) = min(1, 1-x+y)$. Then,

$$\Pi_G((x,y)) = n(I(1-y,x)) =$$

$$n(min(1, 1-1+y+x)) = n(y+x) = 1-y-x. \tag{16}$$

(b) Fodor implication:

$$I(x,y) = \begin{cases} 1 & \text{if } x \leq y \\ max(1-x,y) & \text{if } x > y \end{cases} \quad (17)$$

In this case we have

$$\Pi_G((x,y)) = \begin{cases} 0 & \text{if } x+y=1 \\ n(max(y,x)) & \text{if } x+y<1. \end{cases} \quad (18)$$

Corollary 1 *Let n be a strong negation. A continuous function $\Pi_G : L^* \to [0,1]$ such that $\Pi_G((x,0)) = n(x)$ for all $x \in [0,1]$ is a generalized Atanassov's intuitionistic fuzzy index associated with the function $I : [0,1]^2 \to [0,1]$ with I satisfying $I7$ and $I10$*

if and only if

there exists an automorphism φ of the unit interval such that

$$\Pi_G((x,y)) = \varphi^{-1}(\varphi(1-y) - \varphi(x)) \text{ and}$$

$$n(x) = \varphi^{-1}(1-\varphi(x))$$

Proof. It's enough to take into account Theorem 2, the relations between the properties of I studied in [6] and the following theorem proved in 1987 by Smets and Magrez (see [18]): a function $I : [0,1]^2 \to [0,1]$ verifies $I2$, $I7$, $I8$ and $I10$ if and only if there exists an automorphism φ of the unit interval such that $I(x,y) = \varphi^{-1}(min(1, 1-\varphi(x)+\varphi(y)))$.

Example 4 *if $\varphi(x) = x^2$ for all $x \in [0,1]$, then*

$$\Pi_G((x,y)) = ((1-y)^2 - x^2)^{0.5}, \quad (19)$$

with $n(x) = (1-x^2)^{0.5}$ for all $x \in [0,1]$.

Next, we provide the expressions of Π_G when it is applied to the meet operator min and the join operator max on L^*.

Theorem 3 *Under conditions of Theorem 2 the following items hold:*

$$(1)\ \Pi_G(\mathbf{max}((x,y),(z,t))) = min\{max(\Pi_G((x,y)), \Pi_G((x,t))), max(\Pi_G((z,y)), \Pi_G((z,t)))\}$$

$$(2)\ \Pi_G(\mathbf{min}((x,y),(z,t))) = max\{min(\Pi_G((x,y)), \Pi_G((x,t))), min(\Pi_G((z,y)), \Pi_G((z,t)))\}$$

Proof. (1) We must take into account the definition of meet operator min and the join operator max on L^*, also if I satisfies I_1 and I_9, then I satisfies I_2 and finally the items (i), (iv) of Proposition 4.

$\Pi_G(\mathbf{max}((x,y),(z,t))) = \Pi_G((max(x,z), min(y,t))) = n(I(1-min(y,t), max(x,z)))$. Therefore,

$$\begin{array}{ll} n(\Pi_G((max(x,z), min(y,t)))) & = \\ I(1-min(y,t), max(x,z)) & = \\ I(max(1-y,1-t), max(x,z)) & = \\ max\{I(max(1-y,1-t),x), & \\ I(max(1-y,1-t),z)\} & = \\ max\{min(I(1-y,x), I(1-t,x)), & \\ min(I(1-y,z), I(1-t,z))\} & = \\ max\{min(n(\Pi_G((x,y))), n(\Pi_G((x,t)))), & \\ min(n(\Pi_G((z,y))), n(\Pi_G((z,t))))\} & = \\ max\{n(max(\Pi_G((x,y)), \Pi_G((x,t)))), & \\ (n(max(\Pi_G((z,y)), \Pi_G((z,t))))\} & = \\ n(min\{max(\Pi_G((x,y)), \Pi_G((x,t))), & \\ max(\Pi_G((z,y)), \Pi_G((z,t)))\}). & \end{array}$$

(2) It is quite similar to the previous one but we must take into account items (ii) and (iii) of Proposition 4.

Note the result presented in Theorem 3 is not valid for any t-norm, t-conorm in L^*. The reason is that we have not defined the order relation $\leq_{L^*}$ in Definition 4, only we have defined the item (iii) If $(z,t) \preceq (x,y)$, then $\Pi_G((x,y)) \leq \Pi_G((z,t))$. That is, $\mathbf{max}((x,y),(z,t)) = (max(x,z), min(y,t)) \leq_{L^*} (S(x,z), T(y,t)) = \mathbf{S}((x,y),(z,t))$ and we obtain that $\Pi_G(\mathbf{max}((x,y),(z,t)))$ and $\Pi_G(\mathbf{S}((x,y),(z,t)))$ are imcomparable.

4 Conclusions

We define the concept of *generalized Atanassov's intuitionistic fuzzy index* and we give different construction methods. We consider this concept could be applied to image processing and we want to relate it with the concept of local contrast of a window of an image, that is, the local variations in brightness. In [11] we proposed an expression of the local contrast constructed from Atanassovs intuitionistic index by means of Atanassov's intuitionistic fuzzy S-implications. Local contrast, from our point of view, must satisfy some specific properties and we would like to study the performance of the new concept presented in this work with regard to our definition of local contrast of an image.

Abstract— *A new methodology for analysis and forecasting of time series is proposed. It directly employs two techniques: the fuzzy transform and the perception-based logical deduction. Due to the usage of both of them and due to the innovative approach consisting in a construction of several independent models, the methodology is successfully applicable for robust long time predictions.*

Keywords— Time series, fuzzy transform, perception-based logical deduction, fuzzy partition.

1 Introduction

We propose a new methodology for forecasting time series which is based on combination of two techniques: fuzzy transform and perception-based logical deduction. The proposed methodology consists of two phases: analysis of a time series and its forecast. In both phases, the above mentioned techniques play an essential role.

The organization of the work is as follows. After preliminaries and recalling the techniques in Section 2, we continue with a detailed description of the proposed approach in Section 3. Then we demonstrate the results in Section 4.

2 Preliminaries

Let us briefly recall the main tools employed in the suggested approach, the *fuzzy transform* (F-transform) [1] and the *perception-based logical deduction* [2, 3], in particular.

2.1 Fuzzy (F)-Transform

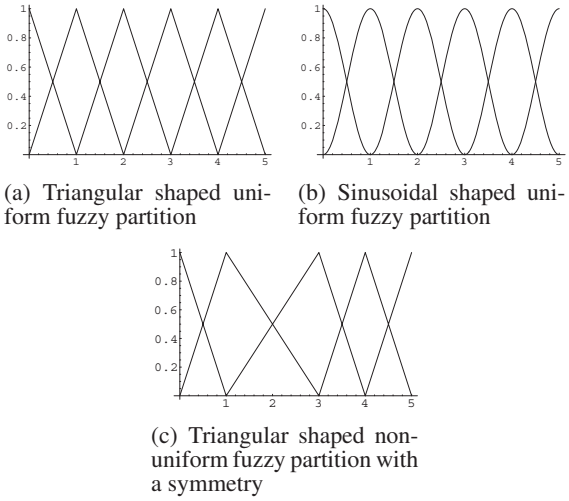
Fuzzy transform, in detailed described in [1], consists in two transformations. The first one, sometimes called the direct one, maps a continuous function defined on a fixed real interval $[a, b]$ into an n-dimensional vector. The inverse one maps the vector back to the space of continuous functions.

The F-transform is defined with respect to *basic functions* forming a fuzzy partition.

Definition 2.1 Let $c_1 < \cdots < c_n$ be fixed nodes within $[a, b]$, such that $c_1 = a, c_n = b$ and $n \geq 2$. We say that fuzzy sets $A_1, \ldots, A_n \in \mathcal{F}([a, b])$ are *basic functions* forming a fuzzy partition of $[a, b]$ if they fulfill the following conditions for $i = 1, \ldots, n$:

1. $A_i(c_i) = 1$;
2. $A_i(x) = 0$ for $x \notin (c_{i-1}, c_{i+1})$ where for the uniformity of the denotation we put $x_0 = x_1 = a$ and $x_{n+1} = x_n = b$;
3. A_i is continuous
4. A_i strictly increases on $[c_{i-1}, c_i]$ and strictly decreases on $[c_i, c_{i+1}]$;
5. for all $x \in [a, b]$

$$\sum_{i=1}^{n} A_i(x) = 1. \tag{1}$$



(a) Triangular shaped uniform fuzzy partition

(b) Sinusoidal shaped uniform fuzzy partition

(c) Triangular shaped non-uniform fuzzy partition with a symmetry

Figure 1: Graphic presentation of distinct fuzzy partitions.

Usually, the *uniform fuzzy partition* is used i.e. n equidistant nodes $c_i = c_{i-1} + h$ are fixed. Let us remark that the shape of the basic functions is not predetermined and it can be chosen based on further requirements. For some examples of fuzzy partitions fulfilling the Definition 2.1, see Fig. 1.

Definition 2.2 Let a fuzzy partition of $[a, b]$ be given by basic functions $A_1, \ldots, A_n, n \geq 2$ and let $f : [a, b] \to \mathbb{R}$ be an arbitrary continuous function. The n-tuple of real numbers $[F_1, \ldots, F_n]$ given by

$$F_i = \frac{\int_a^b f(x)A_i(x)dx}{\int_a^b A_i(x)dx}, \ i = 1, \ldots, n \tag{2}$$

is the *direct fuzzy transform (F-transform)* of f with respect to the given fuzzy partition. $F_1, \ldots, F_n$ are the *components* of the F-transform of f.

ISBN: 978-989-95079-6-8

In practice, function f is usually not given analytically but we are at least provided by some data obtained, e.g., by some measurements. In this case, Definition 2.2 can be modified in such a way that finite summations replace definite integrals in formula (2).

Let us be given n basic functions forming a fuzzy partition of $[a, b]$ and let the function f be given at $T > n$ fixed nodes $x_1, \ldots, x_T \in [a, b]$. We say that the set of nodes $\{x_1, \ldots, x_T\}$ is *sufficiently dense with respect to the fuzzy partition* if

$$(\forall i)(\exists t) \quad A_i(x_t) > 0. \tag{3}$$

Definition 2.3 Let a fuzzy partition of $[a, b]$ be given by basic functions $A_1, \ldots, A_n, n \geq 2$ and let $f : [a, b] \to \mathbb{R}$ be a function known at a set $\{x_1, \ldots, x_T\}$ of sufficiently dense nodes with respect to the given fuzzy partition. The n-tuple of real numbers $[F_1, \ldots, F_n]$ given by

$$F_i = \frac{\sum_{t=1}^{T} f(x_t)A_i(x_t)}{\sum_{t=1}^{T} A_i(x_t)}, \; i = 1, \ldots, n \tag{4}$$

is the *(discrete) direct F-transform* of f with respect to the given fuzzy partition. $F_1, \ldots, F_n$ are the *components* of the F-transform of f.

Since this paper deals with the application of the F-transform to the analysis and prediction of time series, i.e., discrete problem, there is no danger of confusion and we may easily, for the sake of simplicity, omit the word "discrete" and simply talk about the "F-transform" in the rest of the paper.

The F-transform of f with respect to $A_1, \ldots, A_n$ will be denoted by $F_n[f] = [F1, \ldots, Fn]$. It has been proved [1] that the components of the F-transform are the weighted mean values of an original function where the weights are given by the basic functions.

The original function f can be approximately reconstructed (with the help of the inversion formula) from its fuzzy transform $F_n[f]$. The function represented by the inversion formula is called the *inverse F-transform*.

Definition 2.4 Let $F_n[f]$ be the direct F-transform of f with respect to $A_1, \ldots, A_n \in \mathcal{F}([a, b])$. Then the function $f_{F,n}$ given on $[a, b]$ as follows

$$f_{F,n}(x) = \sum_{i=1}^{n} F_i A_i(x), \tag{5}$$

is called the *inverse F-transform* of f.

The inverse F-transform is a continuous function on $[a, b]$ no matter whether we have started from analytically given continuous f or we have been given only function values on a sufficiently dense set. Anyhow, for the time series problem, we consider the inverse F-transform at the same points where the original function is given.

2.2 Perception-based Logical Deduction

In this subsection, we briefly recall the main idea of the *perception-based logical deduction* (PbLD). For details, let us refer to [2, 3].

The PbLD is a method of deducing conclusions on the basis of a *linguistic description* which is a set of m fuzzy/linguistic rules:

IF x_1 is $\mathcal{A}_{11}$ **AND** $\cdots$ **AND** x_q is $\mathcal{A}_{1q}$ **THEN** z is $\mathcal{B}_1$
$\ldots$
AND
$\ldots$
IF x_1 is $\mathcal{A}_{m1}$ **AND** $\cdots$ **AND** x_q is $\mathcal{A}_{mq}$ **THEN** z is $\mathcal{B}_m$ (6)

where $\mathcal{A}_{11}, \ldots, \mathcal{A}_{nq}, \mathcal{B}_1, \mathcal{B}_m$ are specific linguistic expressions called *evaluative expressions* which have the form

$$\langle \text{ linguistic hedge } \rangle \; \{ \textit{ small, medium, big } \}.$$

Note that extension of $\mathcal{A}$ is a functional value of its intension in a point w. These extensions are specific fuzzy sets having the form depicted in Fig.2. Let us shortly mention, that formal theory of evaluative linguistic expression is a deep and firm theory and it would be out of range of the conference paper to recall it in a more detailed way to readers. Therefore, we refer to its detailed description and justification published in [4].

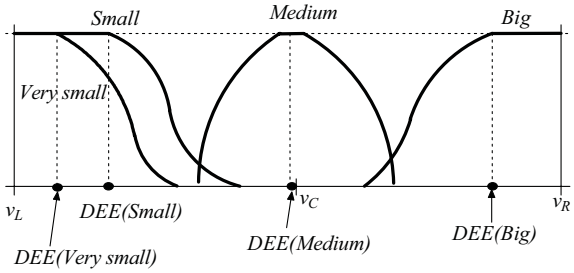


Figure 2: Fuzzy sets representing typical evaluative linguistic expressions.

In the frame of the above outlined theory, that the rules in (6) are taken as genuine conditional expressions of natural language that are interpreted accordingly, see [5], i.e. intension and extensions of them are also defined. The extension of each rule is a special fuzzy relation computed using a t-norm (usually minimum) and Łukasiewicz (residual) implication.

By *perception* we understand an evaluative expression assigned to the given value in the given context. The choice of perception is not arbitrary and besides the context, it also depends on the topic of the specified linguistic expression. The PbLD method uses a sophisticated algorithm for choosing the best fitting rule(s). The most proper crisp output is obtained using a DEE (Defuzzification of Evaluative Expressions) method [2].

2.3 Time Series

Let

$$\{x_t | t = 1, \ldots, T\} \subset \mathbb{R}, \quad T \geq 3 \tag{7}$$

be a given time series. The task is to analyze and forecast the time series, i.e., to determine values

$$\{x_t | t = T + 1, \ldots, T + k\} \subset \mathbb{R}, \quad k \geq 1. \tag{8}$$

There are two standard approaches to forecast a time series. The first one uses autoregressive and moving averages models of the so called *Box-Jenkins methodology* [6]. This approach,

ISBN: 978-989-95079-6-8

no matter how useful and successful in forecasts it may be, besides stationarity and seasonality provides us with a non-transparent and non-interpretable analysis. Therefore, it is not appropriate for an extension by means and tools directly using the fuzzy sets theory, where the interpretability and transparency play a crucial role.

Remark 2.5 A study presenting Takagi-Sugeno rules [7] in the view of the autocorrelation Box-Jenkins methodology has been published [8]. Nevertheless, the Takagi-Sugeno rules are rather regression-based than linguistic-based in comparison with (6). Analogously, distinct neuro-fuzzy approaches, which are on the border of neural networks, Takagi-Sugeno models and evolving fuzzy systems, are very often and successfully used [9, 10]. But well tuned Gaussian fuzzy sets with a centroid at node 5.6989 and a width parameter equal to 2.8893 (see [10]) constructed as a product of an employed optimization technique are undoubtably far from the interpretability of systems using models of fragments of natural language. Therefore, these approaches, no matter how effective and powerful, are closer to standard regression methods.

The second approach consists in the so called *decomposition* [11] of a time series where each element x_t of the time series is decomposed into the following components

$$x_t = Tr_t + S_t + C_t + E_t \tag{9}$$

where Tr_t, S_t, C_t, E_t are the t-th *trend, seasonal, cyclic* and *error* components, respectively.

Trend and seasonal components may be analyzed. The cyclic component is a bit problematic. The name "cyclic" comes from the economical cycles which are not regular and they are dependent on many outer factors to be analyzed from the past. The error component is a random noise which basically cannot be forecasted and therefore is omitted from our further considerations.

After these omissions, for further investigation, usually the following simplified decomposed model is considered

$$x_t = Tr_t + S_t. \tag{10}$$

Remark 2.6 Formulas (9) and (10) describe so called additive decomposition. Using multiplications instead of summations, we would get the multiplicative decomposition. Since the treatment is analogous, for the sake of simplicity we restrict our focus on the additive ones but the further methods and results are similar.

3 Proposed approach

Let us introduce our suggested approach directly employing the techniques briefly recalled in Section 2.

3.1 Trend and Seasonal Analysis

Traditional approach to the trend analysis assumes the trend to be an a priori given function, e.g., linear, polynomial, exponential or a kind of a saturation function such as sigmoidal function, for instance. This approach simplifies the analysis, which consists in a regressive determination of parameters of the predetermined function, and even the prediction, which consists in a simple prolongation – i.e. in an evaluation of the determined trend function at nodes $T+1, \ldots, T+k$.

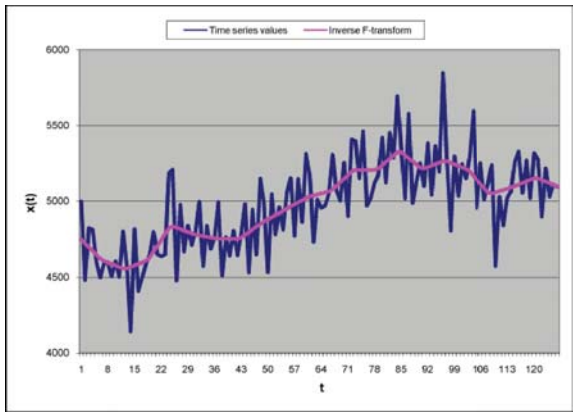

Figure 3: Time series with its inverse F-transform. Standard trend analysis would be inappropriate due to irregular cyclic changes.

But such an approach is not always the most proper one, see Fig. 3. The problem is that such an approach where we fix a trend function for the whole domain is too restrictive. The trend may change during the measurements of a time series especially in case of a long time series. For such cases, complicated adaptive trend changing models are constructed. As a typical example, we may especially in these days of the financial crisis recall the equity indexes where we may hardly simply prolong the trends while very often after robust growth radical and dramatic falls come followed by stagnation and then again by growths, due to the cyclic influences. Here, the prolongation might be very often the worst thing we may apply in predictions.

We propose the F-transform method for the trend description. The F-transform does not fix any shape of the curve, but it possess powerful approximation, noise reduction and computational properties [12].

The time series x_t may be viewed as a function x on the interval $[0, T]$ which we are not given analytically, but we are provided by measurements $x(t) = x_t$ at nodes $t = 1, \ldots, T$. Let us build a uniform fuzzy partition according to Definition 2.1 such that each basic function $A_2, \ldots, A_{n-1}$ "cover" the number of nodes equal to the number of nodes belonging to a season. For example, in case of a time series on the monthly basis, each basic function covers 12 point except basic functions A_1, A_n which cover the first and the last 6 nodes, respectively. So, the set of nodes is sufficiently dense with respect to the fuzzy partition. From now on, we will explicitly refer to such a time series on the monthly basis since everything may be easily generalized for a different seasonality.

Remark 3.1 Usually, we are provided by some additional information about a time series, for example that it is a GDP growth per month. In cases, when such information is not at disposal or does not lead to a sufficient knowledge to determine the seasonality (diesel engine pressure etc. [13]), the perception-based logical deduction with appropriate rules may be successfully used. For details, we refer the reader to [14].

Let $F_n[x] = [X_1, \ldots, X_n]$ be the F-transform of the function x w.r.t. the given fuzzy partition and let $x_{F,n}$ be its inverse F-transform. The inverse F-transform will serve us as a model

ISBN: 978-989-95079-6-8

of the trend component (including cyclic changes). It does not fix a priori some shape of the function. Therefore, we may easily from (9) with omitted error component determine the seasonal components S_t

$$S_t = x_t - x_{F,n}(t) \tag{11}$$

where $x_{F,n}(t) = Tr_t + C_t$.

3.2 Trend Forecast

The suggested approach to the trend analysis implicitly treats also possible cyclic component influences without complicated adaptive trend changing mechanisms. This is a significant difference to the classical approach, where we first model the trend only and then determine the seasonal components which are influenced by the cyclic irregular changes. Our approach treats the problem the other way around and the trend model $x_{F,n}$ primarily serves us to get pure seasonal components without the cyclic influences.

On the other hand, we cannot easily forecast such a trend model by the prolongation, i.e. by the evaluation of the predetermined fixed trend function at nodes $t = T+1, \ldots, T+k$. Due to the drawback of such a traditional approach, it is not disadvantage but vice-versa, as explained below.

We follow the idea of [15] and for the trend forecast, we employ the perception-based logical deduction. As antecedent variables, we consider the F-transform components of the given time series X_i, $i = 1, \ldots, n$ as well as their differences of the first and the second order

$$\begin{array}{rcll} \Delta X_i & = & X_i - X_{i-1}, & i = 2, \ldots, n \\ \Delta^2 X_i & = & \Delta X_i - \Delta X_{i-1}, & i = 3, \ldots, n \end{array} \tag{12}$$

respectively.

So, we will deal, e.g., with fuzzy rules such as the following one

$$\textbf{IF } \Delta X_{i-1} \text{ is } \mathcal{A}_{\Delta i-1} \textbf{ AND } X_i \text{ is } \mathcal{A}_i \textbf{THEN } \Delta X_{i+1} \text{ is } \mathcal{B}. \tag{13}$$

The differences of the F-transform components expressing the time series trend (and the cycle) of distinct orders are capable to describe the dynamics of the time series better than the F-transform components itself. Fuzzy rules such as (13) may describe logical dependencies of the trend changes (hidden cycle influences) which is highly desirable and suggested in comparison with the standard prolongation of the trend observed in the past. The advantage of the transparently interpretable form of the rules using fragments of natural language is doubtless. This might be helpful in better understanding of functionalities and motive factors determining the changes in a process yielding the analyzed times series.

Let us mention that fuzzy rules such as (13) are automatically generated by the *linguistic learning* algorithm [16] implemented in the software package LFLC 2000 [17] from the F-transform components of the time series and their differences.

Remark 3.2 Although the fuzzy rules are also generated from the past, the suggested approach may be able to learn, describe and successfully predict the future of equity indexes mentioned as a motivation example at the beginning of Subsection 3.1. Of course, if a similar progress has been observed and measured in the past. Prolongation of a trend function is not capable of this task.

3.3 Independent Models

Fuzzy rules and the perception-based logical deduction may help us to forecast next F-transform components $X_{n+1}, \ldots, X_{n+\ell}$ of the time series from which we easily determine trend components of the time series as the values of the inverse F-transform $x_{F,n+\ell}(T+1), \ldots, x_{F,n+\ell}(T+k)$, where $\ell < k$.

The problem may appear when the forecast is supposed to be for a too long term. In case if we want to predict the time series x_t on a monthly basis for the next 18 months, we first have to forecast X_{n+1}. For this, we use components $X_1, \ldots, X_n$ and differences $\Delta X_2, \ldots, \Delta X_n$, $\Delta^2 X_3, \ldots, \Delta^2 X_n$. Then, using the same fuzzy rules and antecedent variables $X_1, \ldots, X_{n+1}$, $\Delta X_2, \ldots, \Delta X_{n+1}$ and $\Delta^2 X_3, \ldots, \Delta^2 X_{n+1}$ we may forecast X_{n+2}. And finally, we are able to forecast X_{n+3} based on $X_1, \ldots, X_{n+2}$, $\Delta X_2, \ldots, \Delta X_{n+2}$ and $\Delta^2 X_3, \ldots, \Delta^2 X_{n+2}$.

Clearly, there is a danger of the forecast error propagation since we forecast from forecasted values. The longer-term prediction, the higher is the damage.

To overcome this problem, we suggest to build a finite number of independent trend forecasting models using the technique described in Subsection 3.2. For the sake of simplicity, let us consider ΔX_{i-1} and X_i as the antecedent variables. Then set of rules (13) will serve us as a model for the prediction the next F-transform component X_{n+1}.

Similarly, a set of rules

$$\textbf{IF } \Delta X_{i-1} \text{ is } \mathcal{A}_{\Delta i-1} \textbf{ AND } X_i \text{ is } \mathcal{A}_i \textbf{ THEN } \Delta X_{i+2} \text{ is } \mathcal{B} \tag{14}$$

generated again by the linguistic learning algorithm from the differences of the F-transform components, will serve us as a model for the prediction the next but one F-transform component X_{n+2}. And analogously, we may build the third model

$$\textbf{IF } \Delta X_{i-1} \text{ is } \mathcal{A}_{\Delta i-1} \textbf{ AND } X_i \text{ is } \mathcal{A}_i \textbf{ THEN } \Delta X_{i+3} \text{ is } \mathcal{B} \tag{15}$$

and further models, if necessary because of a longer-term forecast than just to next 18 values $x_{T+1}, \ldots, x_{T+18}$.

The suggested approach fully avoids the problem of the error accumulation due to the "forecasting from forecasted".

3.4 Seasonal Component Forecast

Forecasted F-transform components $X_{n+1}, \ldots, X_{n+\ell}$ determine the trend and cyclic components of the time series predicted for the future which are given as the values of the inverse F-transform $x_{F,n+\ell}(T+1), \ldots, x_{F,n+\ell}(T+k)$. To forecast the seasonal components and to compose them with the latter values is the last step in the time series prediction procedure.

The seasonal components are forecasted as follows. Let

$$\mathbf{S}_\xi = [S_{p\cdot(\xi-1)}, S_{p\cdot(\xi-1)+1}, S_{p\cdot(\xi-1)+2}, \ldots, S_{p\cdot(\xi-1)+p-1}] \tag{16}$$

be the ξ-th vector of the seasonal components (11) where p denotes the period of the seasonality, i.e., in our case of a time series on a monthly basis $p = 12$ and the $\mathbf{S}_\xi$ is the vector of the January, February etc. to December measurements of the ξ-th year.

Stationarity assumption on the seasonal component of the time series is considered, i.e., we assume that $\mathbf{S}_\xi$ is a linear

ISBN: 978-989-95079-6-8

combination of previous θ vectors $\mathbf{S}_{\xi-\theta}, \ldots, \mathbf{S}_{\xi-1}$. It means that we generate the following system of equations

$$\mathbf{S}_\xi = \sum_{j=1}^{\theta} d_j \cdot \mathbf{S}_{\xi-j}, \quad \xi > \theta \tag{17}$$

to which we search for the optimal solution with respect to coefficients $d_1, \ldots, d_\theta$. The computed coefficients are then used to determine the $\mathbf{S}_\xi$

Let us mention that the stationarity is a standard assumption which might be easily checked, see [6, 18].

Composition of both forecasts, of the forecasted F-transform components and the seasonal components is the last step to get the overall time series forecast. It is done inversely to the original decomposition which was either additive or multiplicative.

3.5 Optimization

There are some unknown parameters in the whole procedure which are to be determined individually for every single time series. Basically, it is the list of antecedent variables for the prediction of the F-transform components, the number of the antecedent variables and the parameter θ.

The time series is divided into the *learning set* and the *validation set* in such a way that the latter one is given by the last values of the times series of the length equal to the expected forecast. It means, the learning set is given by $\{x_1, \ldots, x_{T-k-1}\}$ and we cut $\{x_{T-k}, \ldots, x_T\}$ off the time series to determine the validation.

There is a software [19], developed at the *Institute for Research and Applications of Fuzzy Modeling*, where the parameters θ and the maximal number of antecedent variables are set up by a user. Then the software computes all possible combinations of antecedent variables up to the maximal number and combines it with seasonal components determined based on the optimal solution of (17) for all possible θ, again up to the pre-specified maximal one. For this computations, only the learning set is used.

All computed models are used to forecast $\{x'_{T-k}, \ldots, x'_T\}$ and these forecasts are compared with the validation set $\{x_{T-k}, \ldots, x_T\}$. As a suggestion to a user, all models are ordered according to a pre-specified error criterion which may be generally arbitrarily. A user may then employ any of the optimized and tuned models for the forecast of $x_{T+1}, \ldots, x_{T+k}$.

4 Demonstration

We applied our approach to analyze and forecast 111 time series on a monthly basis from the *Artificial Neural Network & Computational Intelligence Forecasting Competition NN3*. All the time series were "real-world" and chosen from different fields such as economy, meteorology, industry etc. while no such an information about the meaning or an origin of any time series was provided to participants.

There were 580 participants who registered to the competition and downloaded the time series but only 25 finally afforded to submit their results which illustrates the complicacy of the task to deal with such a huge and heterogenous set of time series. This fact is even supported by the average 15.44% error result (measured by SMAPE - Symmetric Mean Absolute Percent Error) obtained by commercial statistical software *ForecastPro* for the whole set of time series. Let us note that the *ForecastPro* software was used only as a benchmark together with five other benchmarks. Let us also remark that it employs all the existing standard techniques from the Box-Jenkins methodology while participants were limited by a single method of a non-statistical nature.

Our approach (without the construction of independent models at that times) took the 12th position with the overall average error 18.81%. In an unofficially evaluated subset of time series with a seasonal character, our approach took the 3rd rank among all participants and even beaten four of the six statistical benchmarks. The average error in this category measured by SMAPE was 12.7%.

The construction of independent models may even improve the results. For an illustration, let us turn the attention to the time series NN3_106 from the competition, see Fig. 4.

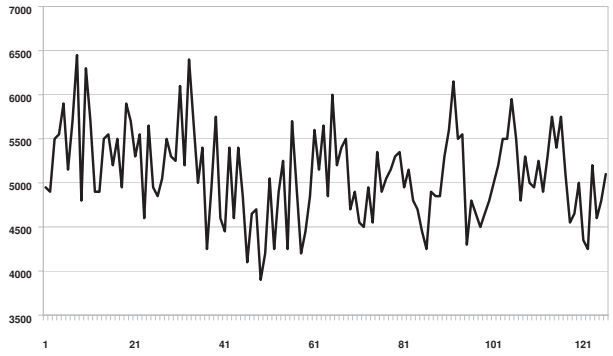

Figure 4: Time series NN3_106 from the NN3 competition.

It is a 126 months long time series with a hardly determinable trend - a typical representative of an appropriate time series for our approach. We cut off last 18 months to create a validation set and we use the first 114 months as a learning set to determine our model. The model may be used to forecast the last 18 months and then compared with the original time series values forming the validation set. There is the black line displaying the validation set of the original time series in Fig. 5.

The dotted grey line in the same figure denotes the forecast made by our methodology with a single trend prediction model optimized as described in Subsection 3.5. The generated model consisted of 15 fuzzy rules with the following 3 input variables $X_i, \Delta^2 X_i, \Delta^2 X_{i-1}$ and the output variable ΔX_{i+1}. The SMAPE error was 5.70%.

If we generate 3 independent models – all of them with the following 3 input variables $X_i, \Delta^2 X_i, \Delta^2 X_{i-1}$, every one of them predicting a different F-transform component – $\Delta X_{i+1}, \Delta X_{i+2}, \Delta X_{i+3}$, respectively, we improve the results. Due to the F-transform, the above mentioned 3 models predicting independently 3 first order differences of the F-transform components are fully sufficient to forecast values

ISBN: 978-989-95079-6-8

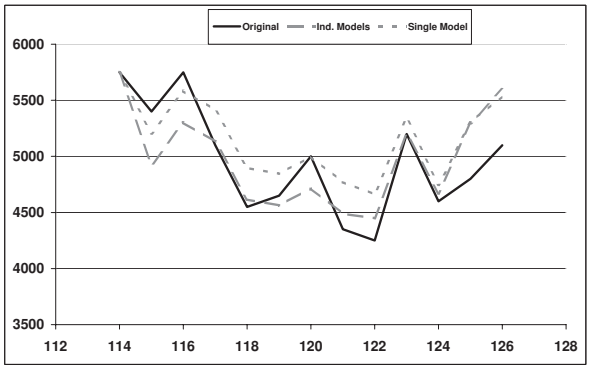

Figure 5: Time series NN3_106 (black line) and its two forecasts, one based on our methodology with a single model (dotted grey line), one forecast employs our methodology with 3 independent models (dashed grey line).

of 18 months ahead. The improve results are depicted by the grey dashed line on Fig. 5 and yielded error 4.77%.

5 Conclusions

We have proposed a novel fuzzy approach to analysis and prediction of time series. It directly uses two techniques, the F-transform and the perception-based logical deduction. Their combination helps to avoid the classical problem with prolongation of a pre-specified curve. Moreover, due to the interpretability of fuzzy rules used by the perception-based logical deduction, a user may get into a deeper understanding not only of the automatically generated model but also to the whole process whose measured samples yielded the analyzed time series.

Furthermore, due to the F-transform and the possibility to construct several independent trend forecasting models using fuzzy rules, we may easily produce long-time forecasts without the influence of the propagated and accumulated error due to the forecasting from forecasted values.

***Abstract*—**
Nowadays, the management of sequential and temporal data is an increasing need in many data mining processes. Therefore, the development of new privacy preserving data mining techniques for sequential data is a crucial need to ensure that sequence data analysis is performed without disclosure sensitive information. Although data analysis and protection are very different processes, they share a few common components such as similarity measurement.

In this paper we propose a new similarity function for categorical sequences of events based on OWA operators and fuzzy quantifiers. The main advantage of this new similarity function is the possibility of incorporating the user preferences in the similarity computation. We describe the implications of the application of different user preference policies in the similarity measurement when microaggregation, a well-known data protection method, is applied to sequential data.

***Keywords*—** Microaggregation, Privacy, Sequence aggregation, OWA operators.

1 Introduction

The development of new methods for managing sequential and temporal relationships is becoming an strategic area. Nowadays, thanks to the new technologies, categorical sequences of data are easily available in many scenarios. Initially, sequential data was originated by the study of gene information (DNA), but novel classes of applications based on geo-spatial information are currently appearing [1]. For instance, many applications use personal or vehicular tracking data, this information allows us to find interesting patterns to be used in many different applications, such as traffic control, sustainable mobility management, accessibility of services or even tracking patients with Alzheimer [2]. This type of data is known as Event Sequences [3].

Classical data mining algorithms and decision making techniques were developed for static data (*i.e.* data whose feature values do not depend on time). Consequently, the sequential nature of temporal data makes difficult to apply classical data mining and decision making methods. Some areas of Artificial Intelligence have started to develop new methods to deal with event sequences, such as temporal data mining algorithms [4, 5] or sequence data analysis, both interested in studying how feature values change with regards to time, in order to identify interesting temporal patterns.

As in classical data mining, in order to ensure that sequence data analysis is performed without disclosure sensitive information of data owners, statistical disclosure control (SDC) [6] and privacy preserving data mining (PPDM) [7] techniques should be applied. In this way, the privacy of the individuals can be guaranteed. A very common way to achieve a certain level of privacy on a database is to ensure k-anonymity [8, 9]. Microaggregation [10, 11] is the standard SDC technique to achieve the k-anonymity in a database. Essentially, microaggregation builds clusters of at least k records and replaces the original records with the centroid of the cluster that the record belongs to. In this way, k-anonymity is ensured because in the protected database there are at least k identical records.

In this paper we address the problem of measuring the similarity between sequences of events. Similarity measurement is a key point in data analysis but also in microaggregation. This problem was already studied in [12], where a new approach to calculate the similarity for event sequences was presented: the *Ordered-based Sequence Similarity* (OSS). This similarity is greately improved in this paper. The new version presented in this paper, applies the OWA operator to let the user to define different preference policies for the similarity comparison of two event sequences, thus, it is called OSS_{OWA}. Preference policies can be expressed using different fuzzy measures. We will present the implications that some policies (fuzzy measure) have on the results of a microaggregation procedure with an illustrative example.

This paper is organized as follows. Firstly, in Section 2 we give some preliminaries about aggregation functions and microaggregation methods for SDC. Then, in Section 3 we present a detailed description of our new similarity function for categorical sequences of events. Section 4 provides some experiments combining our similarity function with microaggregation. Finally, Section 5 draws some conclusions and describes some lines for future work.

ISBN: 978-989-95079-6-8

2 Preliminaries

In this section we give a short overview of aggregation operators, focused on the OWA operator, and microaggregation (a data protection method).

2.1 Aggregation functions

Aggregation functions [13] are functions used for information fusion. They typically combine N data values supplied by N data sources into a single datum.

In this paper, we use them to define a new similarity measure among sequences of categorical events. In particular, we consider the Ordered Weighted Aggregation (OWA) operator.

Two different definitions for this operator can be found in the literature. One applicable when the number of data sources is known in advance, and another that does not require to know how many data sources are combined. We use this latter definition, which is based on fuzzy quantifiers.

Definition 1 *A function $Q : [0, 1] \to [0, 1]$ is a* regular monotonically non-decreasing fuzzy quantifier *(non-decreasing fuzzy quantifiers for short) if it satisfies: (i) $Q(0) = 0$; (ii) $Q(1) = 1$; (iii) $x > y$ implies $Q(x) \geq Q(y)$.*

Two examples of families of fuzzy quantifiers Q_1 and Q_2 are given below. Q_1 corresponds to Yager α-quantifiers, for $\alpha > 0$.

$$Q_1^\alpha(x) = x^\alpha \tag{1}$$

$$Q_2^\alpha(x) = \begin{cases} 0 & \text{if } x = 0 \\ 1/(1 + e^{(\alpha - x)*10}) \text{ for } \alpha > 0 & \text{if } 0 < x < 1 \\ 1 & \text{if } x = 1 \end{cases} \tag{2}$$

A graphical representation of these two fuzzy quantifiers is given in Figure 1 for some particular α. $\alpha = \{0.2, 0.4, \ldots, 1.8, 2.0\}$ are used for $Q_1^\alpha(x)$, and $\alpha = \{0, 0.1, \ldots 0.9\}$ are used for $Q_2^\alpha(x)$. We can observe that for small α values, the function increases quickly near $x = 0$, whereas the increase is smoothly for larger values of α.

Using fuzzy quantifiers, the OWA operator [14, 15] is defined as follows.

Definition 2 *Let Q be a non-decreasing fuzzy quantifier, then $OWA_Q : \mathbb{R}^N \to \mathbb{R}$ is an* Ordered Weighted Averaging (OWA) operator *if*

$$OWA_Q(a_1, ..., a_N) = \sum_{i=1}^{N} (Q(i/N) - Q((i-1)/N)) a_{\sigma(i)}$$

where σ is a permutation such that $a_{\sigma(i)} \geq a_{\sigma(i+1)}$.

The interest of the OWA operators is that they permit the user to aggregate the values giving importance to large (or small) values. In the case of the quantifiers given above, the smaller the α is, the larger the importance for the largest values being aggregated. In contrast, the higher the α is, the lower the importance of the largest values (and the higher the importance given to low values). This different behaviour can be seen in Figure 1.

2.2 Microaggregation

Microaggregation [10, 11] is one of the most commonly employed data protection methods [16]. From the operational point of view, given a database with A attributes, microaggregation proceeds by building clusters of at least k records and, then, replacing each record by the centroid of the cluster to which the record belongs to. A certain level of privacy is ensured because for each attribute, there are always k records with an identical value. This assures the k-anonymity property at the attribute level [8, 9]. The goal of a microaggregation is to find clusters of at least k records while minimizing the total Sum of the Square Error:

$$SSE = \sum_{i=1}^{c} \sum_{x_{ij} \in C_i} (x_{ij} - \bar{x}_i)^T (x_{ij} - \bar{x}_i), \tag{3}$$

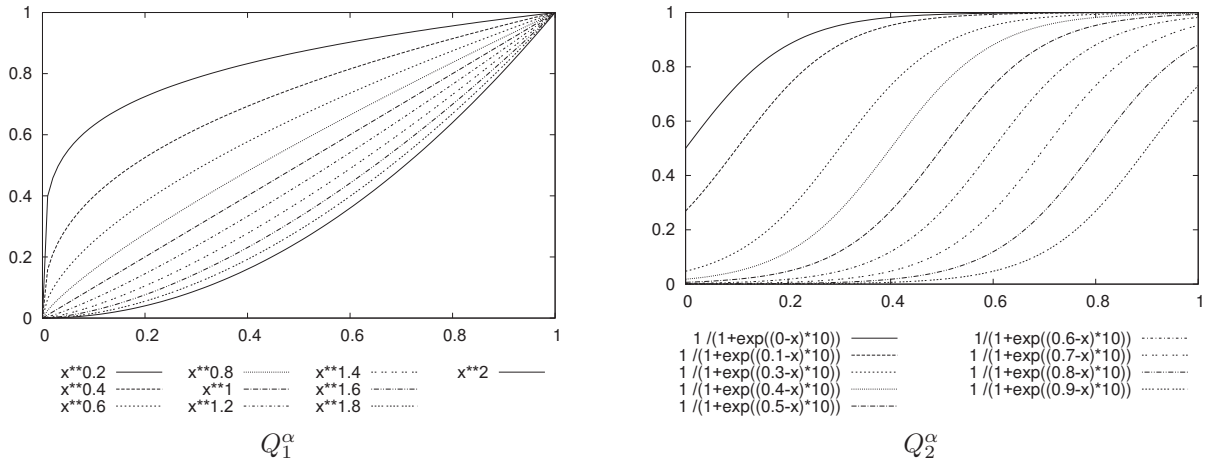
where c is the total number of clusters, C_i is the i-th cluster and $\bar{x}_i$ is the centroid of C_i. The restriction is $|C_i| \geq k$, for all $i = 1, \ldots, c$.

In the simplest case (when $A = 1$), there are polynomial time algorithms to obtain the optimal microaggregation [17]. However, for the general case ($A > 1$), the problem of finding the optimal microaggregation is NP-hard [18]. For this reason, microaggregation methods are heuristic.

It is worth to mention that most of the classical microaggregation techniques are based on the assumption that an average record for all the elements in the database can be computed, like MDAV algorithm [19]. For the case of dealing with sequences of events, this is not a feasible assumption, since sequences can be very diverse and the definition of a single average sequence is not meaningful. Other methods rely on an Euclidean space, which is also not the case of the event sequences space.

In [3] the use of hierarchical clustering algorithms for sequences of events was presented. Those methods are sequential algorithms based on a similarity measure between pairs of elements [20]. The result is a hierarchical tree of non-overlapping clusters that can be cut at any level to obtain a partition. For the experiments of this paper, the k-Sized Hierarchical Clustering method (KSHC) has been applied [21]. This method is a modification of the classical hierarchical sequential agglomerative non-overlapping clustering methods in data mining [20]. The clustering process is structured in two main steps: (1) the construction of a dissimilarity matrix for all pairs of individuals, using an appropriate similarity measure according to the type of data and problem characteristics and (2) the exploitation of the similarity matrix to build a tree of non-overlapping clusters. In this second stage, an iterative process is executed, which consists of finding the pair of elements (i.e. individuals or clusters) that are at minimum dissimilarity (i.e. the most similar) and build a new cluster with these elements. Then, those elements are removed from the dissimilarity matrix, and the dissimilarity of the new cluster with respect to the rest of elements is computed. Different methods for calculating this dissimilarity have been defined: Single Linkage (if the minimum distance with respect to the elements in the cluster is taken), Complete Linkage (if the maximum distance is taken), Average Linkage, Median Linkage, etc. The resulting tree can be cut at any level to produce a partition of the individuals. The KSHC approach keeps the

ISBN: 978-989-95079-6-8



Q_1^α Q_2^α

Figure 1: Graphical representation of Q_1^α and Q_2^α.

tradictional clustering process, but modifies it properly in order to produce a partition that respects the k-anonymity property.

2.3 The Cluster Prototype

Methods for defining cluster prototypes (or centroids) are needed in microaggregation as well as in some unsupervised machine learning techniques (*e.g.* in clustering). In general, a prototype is defined as a typical example, basis, or standard for other elements of the same cluster. Prototypes combine the most representative values for the attributes of the elements that belong to the cluster. Consequently, prototypes are typical instances that represent the content of the cluster. They are calculated using an averaging function (in most of the cases, a weighted mean is used). However, when dealing with categorical sequences of events, those averaging functions are not applicable.

In [22] a new method for generating prototypes of event sequences was presented. This method is based on the calculation of an *Element Scoring Table (EST)*, where the elements can be either individual events or patterns of consecutive events considered as an indivisible unit. So, the method is called *Ordered Element Scoring Prototyping (OESP)*. Different scores are assigned to each event depending on its position in the sequences of the cluster. The ranking given by those scores is used to iteratively append an event to the prototype (initially the prototype is an empty sequence) until the prototype has a length similar to the average lengths of the sequences in the cluster.

This method will be used to calculate the centroids of the clusters obtained by the new similarity measure, which is needed to calculate the Sum of Square Error (3).

3 OSS_{OWA}: A new dissimilarity function for categorical sequences of events

From a formal point of view, a dissimilarity function f over two sequences of events s_1 and s_2 has to fulfill the following conditions:

1. Symmetry: $f(s_1, s_2) = f(s_2, s_1)$
2. Positivity: $f(s_1, s_2) \geq 0$ for any s_1 and s_2
3. Reflexivity: $f(s_1, s_1) = 0$

Some dissimilarity measures for sequences of symbols have been defined. For instance, Hamming distance [23] or Edit (Levenstein) distance [24] are usually considered [3]. However, such distances are quite simple when it is necessary to deal with the relative ordering positions of the symbols in the sequence, as it is needed in tracking studies such as the ones presented in the introduction. Another drawback is the difficulty of incorporating user (expert) preference policies in the computation of these measures.

As we are interested in comparing temporal event sequences, the results of those traditional categorical distances are not good since they disregard a lot of information that should be taken into account to obtain a more appropriate similarity value [12]. Two good examples of temporal event sequences are web logs and the itineraries of the tourists. In these scenarios, there are two key issues to be considered:

- The number of common elements inside the sequences.
- The order (position) among the common elements inside the sequences.

On one hand, the first consideration allows us to evaluate the common part of two different sequences, if this common part is large, then the two sequences have to be similar, because such sequences show that their owners have done the same things. On the other hand, the second consideration takes into account whether the events have been done in the same order or not. This second information is very useful when applying data mining processes. For example, when detecting common itineraries for planning new bus lines. Note that in this latter case, if two sequences have the same events placed in the same order, they have to be more similar than two sequences in which the events are placed in different order. Based on those two assumptions, in [12], the Ordered-based Sequence Similarity was defined (OSS).

However, in the context of event sequence comparison, apart from these two issues, it is also interesting to incorporate any user (expert) preferences on the similarity function. In some scenarios, it is more important to group sequences sharing a large number of events even though the events are not in the same order. On the contrary, in other scenarios, the

ISBN: 978-989-95079-6-8

user is interested in tracking the sub-sequences of common events, considering that two sequences with a few events in the same order are more similar than two sequences with a larger common set of unsorted events. Let us take as an example, an analysis of the tourist behaviour in a theme park. In the first case, the manager wants to find groups of visitors that have been at the same attractions (same locations) in spite of the order of visiting them. In the second case, the manager is interested in studying the flow of visitors in the park, and to know the common paths between attractions for planning or user-recommendation purposes.

The OWA operator with a fuzzy quantifier can be used to introduce the user aggregation policy into the computation of the similarity between pairs of temporal event sequences. This permits us to tackle the issues explained before. Based on this approach, a new similarity function can be defined, $d_{OSS-OWA}$. It is calculated in two steps.

Firstly, partial distances between the elements of the two sequences are calculated as follows.

Definition 3 *Let s and r be two event sequences. Let s_i be the i-th event of the sequence s, then the event distance of s_i with respect to r is defined as*

$$d(s_i, r) = \begin{cases} \frac{min_{s_i=r_j}|i-j|}{|s|+|r|} & if\ s_i \in r \\ 1 & otherwise \end{cases} \quad (4)$$

where $|s|$ and $|r|$ stand for the sequence lengths of sequences s and r respectively.

If s_i appears n times in s and m times in r, the occurrences in s and r are matched forming pairs that minimize $|i-j|$, if some occurrences do not have a couple ($n \neq m$), they are treated as if they do not appear in r, that is, they have a distance to r of 1.

Then, those partial distances are aggregated using the OWA operator, which permits to apply different aggregation policies[14].

Formally, given sequences s and r, we compute the event distances $d(s_i, r)$ for all $i = 1, \ldots, |s|$ and $d(r_i, s)$ for all $i = 1, \ldots, |r|$. Then, the OSS_{OWA} measure is defined as follows.

Definition 4 *Let s and r be two temporal event sequences with length $|s|$ and $|r|$, respectively, then the $d_{OSS-OWA}$ dissimilarity function of s and r is defined as*

$$d_{OSS-OWA(Q)}(s, r) =$$

$$OWA_Q(d(s_1, r), \ldots, d(s_{|s|}, r), d(r_1, s), \ldots, d(r_{|r|}, s))$$

where Q is a non-decreasing fuzzy quantifier, and $d(s_i, r)$ stands for the event distance of s_i with regards to r.

Following Definition 3, all event distances equal to 1 represents the case of two sequences with non-common events. On the contrary, distances smaller than 1 represent the shift between the common events in both sequences. In this case, the larger the event distance, the larger the shift. OWA operators permit the user to aggregate the values giving more importance to large or small values when appropriate quantifiers are selected. This stands for considering more important non-common events (large distance values) or common events (small distance values). In this way we are modeling the two scenarios described above.

4 Experiments

In this section, we present the results obtained with a synthetic sequences database (see Table 1). Figure 2 shows a graph representation of those sequences as paths between a set of 11 locations. These could be places inside a theme attractions park. The arrows indicate a transition from one attraction to the next one. The labels refer to the tourists that have followed each path step.

In order to test the $d_{OSS-OWA}$ function, the k-sized hierarchical clustering (KSHC) microaggreagtion algorithm has been used on this database. It has been applied to a k-anonymity value of $k = 2$, which means that cluster of 2 or 3 elements can be generated (recall that the number of elements is constrained by k and $2k-1$). Then, the method explained in section 2.3 for prototype generation has been performed to obtain the centroids of the clusters and calculate the information loss, that is, the SSE (3) .

Six different fuzzy quantifiers have been tested: $Q_1^{0.4}$, Q_1^1, Q_1^2, $Q_2^{0.1}$, $Q_2^{0.5}$ and $Q_2^{0.8}$. They define different aggregation policies in order to show how to introduce expert knowledge in the sequence similarity computation. Quantifiers with small α parameter consider more similar those sequences with a large set of common events. On the contrary, quantifiers with large α parameter consider more similar those sequences with few common events but placed in the same order. Note that, quantifiers with medium α parameter consider common events as important as events placed in the same order.

Table 2 shows the results obtained for the dataset given in Table 1. Each row corresponds to a different parametrization of the fuzzy measure used to compute the OSS_{OWA} dissimilarity function between pairs of sequences. The first three

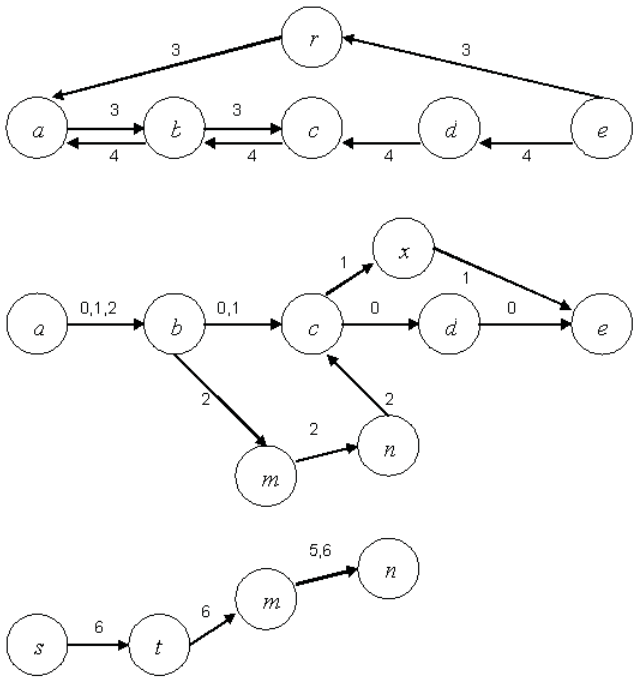

Figure 4: Clusters obtained with a medium α.

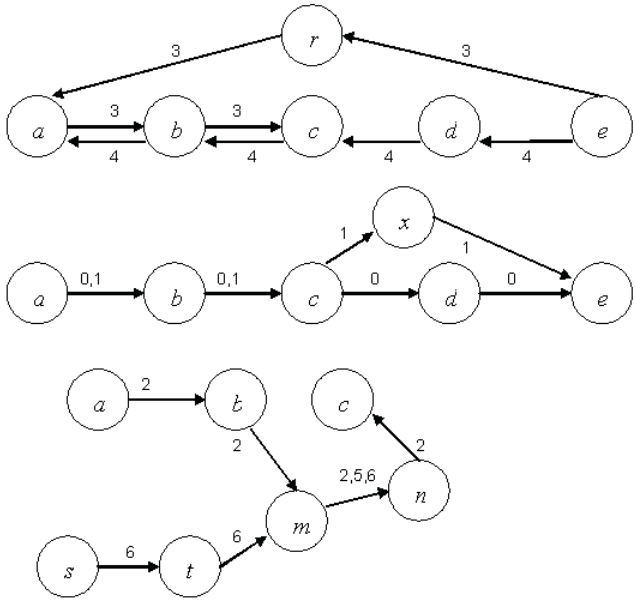

Figure 5: Clusters obtained with large α.

rows correspond to the fuzzy measure Q_1 (1) and the three last rows correspond to the fuzzy measure Q_2 (2).

The first thing to note is that the results for Q_1 and Q_2 are the same for low, medium and high α values. Using low values in the parameterization of the fuzzy measures (*e.g.* α equal to 0.4 for Q_1 and 0.1 for Q_2) generates a similarity function that stress the importance of visiting the same places, disregarding the event order. For this reason, the sequence $abcde$ is similar to the sequence $edcba$. In the same way, the sequence $abcxe$ is more similar to $erabc$ (with 4 equal elements) than to $abmnc$ (with only 3 common elements).

Oppositely, when large α values are selected (*e.g.* α equal to 4 for Q_1 and 0.8 for Q_2), the order among the common events plays a more important role in the similarity measurement. Consequently, the sequence $edcba$ is more similar to the sequence $erabc$ than to the sequence $abcde$, because the path between elements a , b and c is exactly the same. Note also that the sequences $abcxe$ and $abmnc$ also change their cluster with regards to the case of low α values.

To balance these two polices, a medium α value can be selected (*e.g.* α equal to 2 for Q_1 and 0.5 for Q_2). In this case, the groups obtained take into account both issues (common events and event order) in a similar way. Notice that in this case, the final groups are different from the ones in the other two cases.

ISBN: 978-989-95079-6-8

The clusters obtained for the different α values are graphically displayed in Figures 3, 4 and 5, for small, medium and large α, respectively. From them, it can be more easily seen that the itineraries are grouped in a different manner depending on the aggregation policy.

To sum up, it can be said that the $d_{OSS-OWA}$ function permits to model different similarity measurement polices. This fact is crucial for data mining analysis and for privacy preserving data mining. If a microaggregation method does not consider the different semantics that the similarity function can have, the partition obtained may put together individuals that should be distinguished. Moreover, if the information of those individuals is then replaced by their prototype values, the posterior analysis of these masked data will not be able to retrieve some relevant knowledge for the user.

5 Conclusions and future work

In this paper, we have introduced a new similarity function for categorical event sequences using OWA operators. We have illustrated how it is possible to introduce expert knowledge inside the similarity computation using well-known fuzzy quantifiers. We have also presented some results about the application of this similarity function to a very recent microaggregation algorithm for categorical event sequences.

As future work we include the analysis of the microaggregation with respect to information loss and disclosure risk measures when it is applied to event sequences. These measures are required to properly evaluate the performance of the microaggregation when it is applied to event sequences and compare it with other approaches. Moreover, the effect of different fuzzy measures must be studied.

Abstract— *In this paper, the notion of a fuzzy vector of normalized weights is introduced, and its application in decision making models based on the weighted average operation is studied. The fuzzy vector of normalized weights represents a generalization of normalized fuzzy weights that authors formerly applied for modeling uncertain weights of criteria and/or uncertain probabilities of states of the world. Illustrative examples show that fuzzy vectors of normalized weights extend the possibilities of utilizing the vague expert information concerning weights of criteria. For three particular forms of the fuzzy vectors of normalized weights, fuzzy weighted averages of given values are calculated and the obtained results are compared. Finally, the fuzzy models of multiple criteria decision making and decision making under risk based on the fuzzy weighted average operation are described.*

Keywords— Decision making under risk; Fuzzy vectors; Fuzzy weighted average; Multiple criteria decision making; Normalized fuzzy weights.

1 Introduction

In decision making models, the weighted average is the most often used aggregation operator. In multiple criteria decision making, overall evaluations of alternatives are mostly calculated as weighted averages of their evaluations with respect to particular criteria. The weighted average operator is also used in discrete stochastic models of decision making under risk where the alternatives are usually ranked according to their expected evaluations. The expected evaluations are in fact weighted averages of evaluations of alternatives under possible states of the world; probabilities of the states of the world play the role of normalized weights.

Decision making models based on the weighted average operation can be fuzzified in two aspects: First, uncertain weighted values, i.e. uncertain evaluations with respect to particular criteria in the models of multiple criteria decision making and/or uncertain evaluations under possible states of the world in decision making under risk, can be considered. Such fuzzification is useful because it enables to process correctly e.g. the vague expert evaluations of alternatives with respect to qualitative criteria. This approach is described in detail e.g. in [1]. Second, normalized weights, i.e. weights of criteria and/or probabilities of states of the worlds, can be fuzzified. It makes the mathematical models substantially more complicated. But as the values of normalized weights are commonly set expertly, such fuzzification is very eligible.

The fuzzy extension of the weighted average operation for the case when both the weighted values and the weights are fuzzy has been studied since the second half of 70's. In [2, 3, 4], the fuzzy weights are supposed to be non-negative fuzzy numbers that express the importance of particular criteria; they are normalized only in the process of the fuzzy weighted average calculation. Later, it was shown in [5, 6] that uncertain weights expressing shares of the partial evaluation in the overall one or uncertain probabilities of states of the world have to be modeled by means of a special structure of fuzzy numbers which is called a tuple of normalized fuzzy weights. The tuple of normalized fuzzy weights is formally identical with a so called feasible tuple of fuzzy probabilities mentioned in [7]. The fuzzy weights normalization, i.e. the transformation of fuzzy weights into the normalized fuzzy weights, was studied in [8, 9].

This paper describes a new approach to modeling the uncertain normalized weights of criteria and/or the uncertain probabilities of states of the world - a notion of a fuzzy vector of normalized weights is introduced here. It will be shown that, in comparison with normalized fuzzy weights, fuzzy vectors of normalized weights extend the possibilities of utilizing the vague expert information concerning the weights.

2 Preliminaries

A fuzzy set A on a non-empty set X is characterized by its membership function $A : X \to [0,1]$. By $Ker\,A$ and $Supp\,A$, we denote a kernel of A, $Ker\,A = \{x \in X \mid A(x) = 1\}$, and a support of A, $Supp\,A = \{x \in X \mid A(x) > 0\}$, respectively. For any $\alpha \in [0,1]$, A_α means an α-cut of A, $A_\alpha = \{x \in X \mid A(x) \geq \alpha\}$. The family of all fuzzy sets on X will be denoted by $\mathcal{F}(X)$.

The intersection of two fuzzy sets $A, B \in \mathcal{F}(X)$ is defined as a fuzzy set $A \cap B \in \mathcal{F}(X)$ whose membership function is for all $x \in X$ given by $(A \cap B)(x) = \min\{A(x), B(x)\}$. Since the minimum operation is used, $(A \cap B)_\alpha = A_\alpha \cap B_\alpha$ holds for all $\alpha \in [0,1]$.

Let $X_1, X_2, \ldots, X_m$ be non-empty sets. An m-ary fuzzy relation on $X_1 \times X_2 \times \ldots \times X_m$ is defined as a fuzzy set $R \in \mathcal{F}(X_1 \times X_2 \times \ldots \times X_m)$. A particular case of an m-ary fuzzy relation is the Cartesian product of fuzzy sets, $R^C = R_1 \times R_2 \times \ldots \times R_m$, where $R_i \in \mathcal{F}(X_i)$, $i = 1, 2, \ldots, m$, and $R^C(x_1, x_2, \ldots, x_m) = \min\{R_1(x_1), R_2(x_2), \ldots, R_m(x_m)\}$ for all $(x_1, x_2, \ldots, x_m) \in X_1 \times X_2 \times \ldots \times X_m$. Since the minimum operation is used, $R^C_\alpha = R_{1\alpha} \times R_{2\alpha} \times \ldots \times R_{m\alpha}$ holds for any $\alpha \in [0,1]$.

Let us denote the index set $\{1, 2, \ldots, m\}$ by N_m throughout the paper. For any $i \in N_m$, the i-th projection of an m-ary

ISBN: 978-989-95079-6-8

fuzzy relation $R \in \mathcal{F}(X_1 \times X_2 \times \ldots \times X_m)$ is the fuzzy set $[R]_i \in \mathcal{F}(X_i)$ whose membership function is for all $x_i \in X_i$ given by

$$[R]_i(x_i) = \sup_{\substack{y_j \in X_j,\ j \in N_m \\ y_i = x_i}} R(y_1, y_2, \ldots, y_m). \qquad (1)$$

A fuzzy number is a fuzzy set C on the set of all real numbers $\mathbb{R}$ that fulfils the following conditions: a) $Ker\ C \neq \emptyset$, b) for all $\alpha \in (0,1]$, C_α are closed intervals, c) $Supp\ C$ is bounded. If $Supp\ C \subseteq [a,b]$, then C is referred to as a fuzzy number on $[a,b]$. The family of all fuzzy numbers will be denoted by $\mathcal{F}_N(\mathbb{R})$, and the family of all fuzzy numbers on $[a,b]$ will be denoted by $\mathcal{F}_N([a,b])$.

In [9, 10], it was shown that any fuzzy number C can be also determined by a couple of functions $\underline{c} : [0,1] \to \mathbb{R}$ and $\overline{c} : [0,1] \to \mathbb{R}$ that describe the minimal and maximal values of the α-cuts of C and of the closure of the support of C. The functions $\underline{c}$ and $\overline{c}$ are left-continuous on $(0,1]$, right-continuous at 0 and satisfy $\underline{c}(\alpha) \leq \underline{c}(\beta) \leq \overline{c}(\beta) \leq \overline{c}(\alpha)$ for all $0 \leq \alpha < \beta \leq 1$. In the sequel, the notation $C = \{[\underline{c}(\alpha), \overline{c}(\alpha)]\}_{\alpha \in [0,1]}$ will be used for the fuzzy number C such that $C_\alpha = [\underline{c}(\alpha), \overline{c}(\alpha)]$ for all $\alpha \in (0,1]$, and $Cl(SuppC) = [\underline{c}(0), \overline{c}(0)]$ where $Cl(SuppC)$ means the closure of the support of C. For the membership function of the fuzzy number $C = \{[\underline{c}(\alpha), \overline{c}(\alpha)]\}_{\alpha \in [0,1]}$, the following relation holds

$$C(x) = \begin{cases} \max\limits_{\alpha \in [0,1]:\ x \in [\underline{c}(\alpha), \overline{c}(\alpha)]} \alpha, & \text{for } x \in [\underline{c}(0), \overline{c}(0)], \\ 0, & \text{elsewhere.} \end{cases} \qquad (2)$$

Let us note that if $\underline{c}(\alpha) = \overline{c}(\alpha) = c$ for all $\alpha \in [0,1]$, then C represents a real number c. Furthermore, if $\underline{c}(\alpha) = a$ and $\overline{c}(\alpha) = b$ for all $\alpha \in [0,1]$, where $a < b$, then C represents a closed interval $[a,b]$.

In this paper, a fuzzy number $C = \{[\underline{c}(\alpha), \overline{c}(\alpha)]\}_{\alpha \in [0,1]}$ is called linear if both the functions $\underline{c}$ and $\overline{c}$ are linear. Any linear fuzzy number C can be fully characterized by a quadruple of real numbers $c^1 \leq c^2 \leq c^3 \leq c^4$, where $Cl(Supp\ C) = [c^1, c^4]$ and $Ker\, C = [c^2, c^3]$. In this case, the functions $\underline{c}$ and $\overline{c}$ are given for all $\alpha \in [0,1]$ as follows

$$\underline{c}(\alpha) = c^1 + \alpha(c^2 - c^1) \quad \text{and} \quad \overline{c}(\alpha) = c^4 - \alpha(c^4 - c^3). \qquad (3)$$

The notation $C = \langle c^1, c^2, c^3, c^4 \rangle$ will be used for such a linear fuzzy number C. For $c^2 \neq c^3$, the linear fuzzy number C is usually referred to as a trapezoidal fuzzy number; for $c^2 = c^3$, as a triangular fuzzy number.

The extension from functions having crisp arguments to functions with fuzzy set arguments is done according to the extension principle. Let X and Y be non-empty sets and let $f : X \to Y$ be a mapping. Then a fuzzy extension of f is the mapping $f_F : \mathcal{F}(X) \to \mathcal{F}(Y)$ such that for any $A \in \mathcal{F}(X)$, the membership function of $f_F(A)$ is defined for all $y \in Y$ as follows

$$f_F(A)(y) = \begin{cases} \sup\limits_{x \in X:\ f(x) = y} A(x), & \text{if } f^{-1}(y) \neq \emptyset, \\ 0, & \text{otherwise.} \end{cases} \qquad (4)$$

3 Fuzzy Vectors

Since an uncertain value of one continuous variable is expressed by a fuzzy number, then, by means of analogy, a fuzzy vector is used for expressing uncertain values of m continuous variables. An m-dimensional fuzzy vector $\mathbf{V}$ is a fuzzy set on $\mathbb{R}^m$ that fulfils the following conditions: a) $Ker\ \mathbf{V} \neq \emptyset$, b) for all $\alpha \in (0,1]$, $\mathbf{V}_\alpha$ are closed and convex subsets of $\mathbb{R}^m$, c) $Supp\ \mathbf{V}$ is bounded. If $Cl(Supp\ \mathbf{V}) \subseteq Q \subset \mathbb{R}^m$, then $\mathbf{V}$ is called a fuzzy vector on Q. Let us remark that the α-cuts $\mathbf{V}_\alpha$ are compact subsets of $\mathbb{R}^m$ for all $\alpha \in (0,1]$. The family of all m-dimensional fuzzy vectors will be denoted by $\mathcal{F}_V(\mathbb{R}^m)$, and the family of all m-dimensional fuzzy vectors on $Q \subset \mathbb{R}^m$ will be denoted by $\mathcal{F}_V(Q)$. Obviously, since a closed and convex subset of $\mathbb{R}$ is a closed interval, for $m = 1$ a fuzzy number is obtained, i.e. $\mathcal{F}_V(\mathbb{R}) = \mathcal{F}_N(\mathbb{R})$.

In literature, the requirement of convexity of $\mathbf{V}_\alpha$ is often weakened, e.g. in [11], the α-cuts of fuzzy vectors are supposed to be closed and simply connected subsets of $\mathbb{R}^m$. As convexity is the characteristic property of expertly given uncertain values, the convexity of α-cuts of fuzzy vectors will be considered in the paper.

For any $i \in N_m$, the i-th projection of the m-dimensional fuzzy vector $\mathbf{V}$ will be denoted by $[\mathbf{V}]_i$. It was proved in [9, 10] that $[\mathbf{V}]_i$ is a fuzzy number and its membership function is defined for all $y \in \mathbb{R}$ by the following formula

$$[\mathbf{V}]_i(y) = \max_{\substack{x_j \in \mathbb{R},\ j \in N_m \\ x_i = y}} \mathbf{V}(x_1, x_2, \ldots, x_m). \qquad (5)$$

In the fuzzy models of decision making discussed in this paper, the expert setting of uncertain input data by fuzzy vectors is based on the following results that were proved in [9, 10].

If $X_1, X_2, \ldots, X_m$ are fuzzy numbers, then the Cartesian product $\mathbf{X} = X_1 \times X_2 \times \ldots \times X_m$ is an m-dimensional fuzzy vector, and $[\mathbf{X}]_i = X_i$ for all $i \in N_m$. Similarly, if $\mathbf{X}_i \in \mathcal{F}_V(\mathbb{R}^{n_i})$ for all $i \in N_m$, then the Cartesian product $\mathbf{X} = \mathbf{X}_1 \times \mathbf{X}_2 \times \ldots \times \mathbf{X}_m$ is an n-dimensional fuzzy vector where $n = \sum_{i=1}^m n_i$.

If the uncertain values of m variables are expressed by fuzzy numbers $X_1, X_2, \ldots, X_m$, and the set of all admissible combinations of their values is given by a crisp nonseparable m-ary relation $Q \subset \mathbb{R}^m$, then the maximal fuzzy relation (in the sense of ordering given by inclusion) expressing available information concerning the values of the m-tuple of variables is given by $\mathbf{X}_Q = (X_1 \times X_2 \times \ldots \times X_m) \cap Q$. If Q is closed and convex, then the fuzzy set $\mathbf{X}_Q$ is an m-dimensional fuzzy vector on Q if and only if

$$(Ker\ X_1 \times Ker\ X_2 \times \ldots \times Ker\ X_m) \cap Q \neq \emptyset. \qquad (6)$$

Moreover, $[\mathbf{X}_Q]_i \subseteq X_i$ for all $i \in N_m$. The equality $[\mathbf{X}_Q]_i = X_i$ holds for all $i \in N_m$ if and only if for all $i \in N_m$ and for all $\alpha \in (0,1]$ the following holds:

$$\text{For any } x_i \in X_{i\alpha},\ \text{there exist } x_j \in X_{j\alpha},\ j \in N_m,\ j \neq i, \\ \text{such that } (x_1, \ldots, x_i, \ldots, x_m) \in Q. \qquad (7)$$

Calculations with fuzzy vectors are based on the following well-known result, the proof of which can be found e.g. in [11]. Let $D \subseteq \mathbb{R}^m$, $m \geq 1$, let $f : D \to \mathbb{R}$ be a continuous function, and let $\mathbf{X} \in \mathcal{F}_V(D)$. Then $f_F(\mathbf{X})$ is a fuzzy number whose membership function is given by

$$f_F(\mathbf{X})(y) = \begin{cases} \max\limits_{\mathbf{x} \in D:\ f(\mathbf{x}) = y} \mathbf{X}(\mathbf{x}), & \text{if } f^{-1}(y) \neq \emptyset, \\ 0, & \text{otherwise,} \end{cases} \qquad (8)$$

ISBN: 978-989-95079-6-8

and for all $\alpha \in (0,1]$ the following holds

$$f_F(\mathbf{X})_\alpha = f(\mathbf{X}_\alpha). \tag{9}$$

Employing the notation $f_F(\mathbf{X}) = \{[\underline{y}(\alpha), \overline{y}(\alpha)]\}_{\alpha\in[0,1]}$, then it follows from (9) that for any $\alpha \in (0,1]$, the values $\underline{y}(\alpha)$ and $\overline{y}(\alpha)$ can be obtained by solving the following problems of mathematical programming

$$\underline{y}(\alpha) = \min_{\mathbf{x}\in\mathbf{X}_\alpha} f(\mathbf{x}), \tag{10}$$

$$\overline{y}(\alpha) = \max_{\mathbf{x}\in\mathbf{X}_\alpha} f(\mathbf{x}). \tag{11}$$

Furthermore, since the functions $\underline{y}(\alpha)$ and $\overline{y}(\alpha)$ are right-continuous at 0, the values $\underline{y}(0)$ and $\overline{y}(0)$ are given as follows

$$\underline{y}(0) = \lim_{\alpha\to 0+} \underline{y}(\alpha) \quad \text{and} \quad \overline{y}(0) = \lim_{\alpha\to 0+} \overline{y}(\alpha). \tag{12}$$

If $\mathbf{X} = X_1 \times X_2 \times \ldots \times X_m$ where $X_i \in \mathcal{F}_N(\mathbb{R})$ for any $i \in N_m$, $X_i = \{[\underline{x}_i(\alpha), \overline{x}_i(\alpha)]\}_{\alpha\in[0,1]}$, then for all $\alpha \in [0,1]$ the following holds

$$\underline{y}(\alpha) = \min_{x_i\in[\underline{x}_i(\alpha),\overline{x}_i(\alpha)],\ i\in N_m} f(x_1, x_2, \ldots, x_m), \tag{13}$$

$$\overline{y}(\alpha) = \max_{x_i\in[\underline{x}_i(\alpha),\overline{x}_i(\alpha)],\ i\in N_m} f(x_1, x_2, \ldots, x_m). \tag{14}$$

If $\mathbf{X}_Q = (X_1 \times X_2 \times \ldots \times X_m) \cap Q$, where the crisp relation $Q \subset \mathbb{R}^m$ and fuzzy numbers $X_i = \{[\underline{x}_i(\alpha), \overline{x}_i(\alpha)]\}_{\alpha\in[0,1]}$, $i \in N_m$, fulfil the condition (6), then the values $\underline{y}(\alpha)$ and $\overline{y}(\alpha)$ can be obtained for all $\alpha \in [0,1]$ as follows

$$\underline{y}(\alpha) = \min_{\substack{x_i\in[\underline{x}_i(\alpha),\overline{x}_i(\alpha)],\ i\in N_m \\ (x_1,x_2,\ldots,x_m)\in Q}} f(x_1, x_2, \ldots, x_m), \tag{15}$$

$$\overline{y}(\alpha) = \max_{\substack{x_i\in[\underline{x}_i(\alpha),\overline{x}_i(\alpha)],\ i\in N_m \\ (x_1,x_2,\ldots,x_m)\in Q}} f(x_1, x_2, \ldots, x_m). \tag{16}$$

The formulas (15) and (16) correspond to the concept of constrained fuzzy arithmetics that was studied e.g. in [12].

4 Fuzzy Vectors of Normalized Weights

An m-dimensional fuzzy vector of normalized weights is an arbitrary m-dimensional fuzzy vector $\mathbf{W}$, whose support $Supp\ \mathbf{W}$ is a subset of the m-dimensional probability simplex $\mathcal{S}_m = \big\{(w_1, w_2, \ldots, w_m) \in \mathbb{R}^m \mid w_i \geq 0 \text{ for all } i \in N_m,\ \sum_{i=1}^m w_i = 1\big\}$. The family of all m-dimensional fuzzy vectors of normalized weights will be denoted by $\mathcal{F}_V(\mathcal{S}_m)$. Figure 1 illustrates an example of a 3-dimensional fuzzy vector of normalized weights.

From the general point of view, an m-dimensional fuzzy vector of normalized weights expresses an uncertain division of a unit into m fraction. In this paper, we will apply the fuzzy vectors of normalized weights to model the uncertain shares of partial objectives of evaluation in the overall one in fuzzy models of multiple criteria decision making, and to model the uncertain probabilities of states of the world in fuzzy-stochastic models of decision making under risk.

In the decision making models, direct expert setting of a fuzzy vector of normalized weights could be quite complicated. Therefore, three procedures of setting of fuzzy vectors of normalized weights will be proposed now.

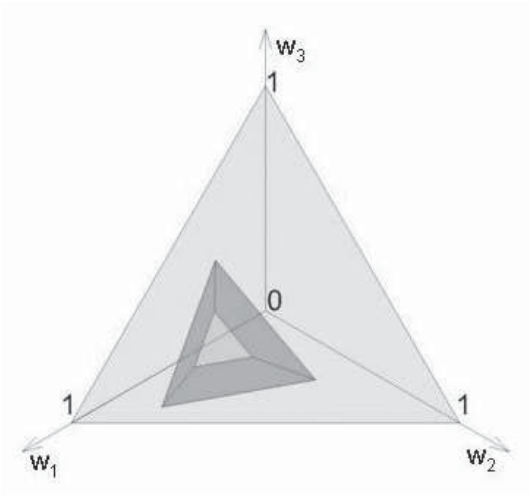

Figure 1: A 3-dimensional fuzzy vector of normalized weights.

Firstly, an expert can describe the uncertain values of normalized weights by a special structure of fuzzy numbers called normalized fuzzy weights. The normalized fuzzy weights are defined as fuzzy numbers $W_1, W_2, \ldots, W_m \in \mathcal{F}_N([0,1])$ that satisfy for all $\alpha \in (0,1]$ and for all $i \in N_m$ the following condition:

$$\text{For any } w_i \in W_{i\alpha},\ \text{there exist } w_j \in W_{j\alpha},\ j \in N_m,\ j \neq i,\ \text{such that } w_i + \sum_{j=1,\ j\neq i}^{m} w_j = 1. \tag{17}$$

The condition (17) represents the special case of (7) for $Q = \mathcal{S}_m$. Since the probability simplex $\mathcal{S}_m$ is closed and convex, the fuzzy set $\mathbf{W} = (W_1 \times W_2 \times \ldots \times W_m) \cap \mathcal{S}_m$ is a fuzzy vector of normalized weights, and $[\mathbf{W}]_i = W_i$ for all $i \in N_m$. The procedures of practical setting of normalized fuzzy weights were described in [6, 9].

Example 1 Let $m = 3$. An expert describes the uncertain values of normalized weights by the triple of linear normalized fuzzy weights $W_1 = \langle 0.4, 0.5, 0.65, 0.8\rangle$, $W_2 = \langle 0.15, 0.2, 0.35, 0.55\rangle$ and $W_3 = \langle 0.05, 0.15, 0.3, 0.45\rangle$. The corresponding fuzzy vector of normalized weights is the fuzzy set $\mathbf{W} = (W_1 \times W_2 \times W_3) \cap \mathcal{S}_3$. For all $\alpha \in (0,1]$, the α-cuts $\mathbf{W}_\alpha$ are given as follows

$$\begin{aligned} \mathbf{W}_\alpha = \big\{&(w_1, w_2, w_3) \in \mathcal{S}_3 \mid \\ &w_1 \in [0.4 + 0.1\alpha, 0.8 - 0.15\alpha], \\ &w_2 \in [0.15 + 0.05\alpha, 0.55 - 0.2\alpha], \\ &w_3 \in [0.05 + 0.1\alpha, 0.45 - 0.15\alpha]\big\}. \end{aligned} \tag{18}$$

The normalized fuzzy weights W_1, W_2, W_3 and the fuzzy vector of normalized weights $\mathbf{W} = (W_1 \times W_2 \times W_3) \cap \mathcal{S}_3$ are depicted in Figure 2. □

Secondly, an expert can give the information about normalized weights by a crisp relation $Q \subseteq \mathcal{S}_m$. If Q is non-empty, closed and convex, then it represents a special type of the fuzzy vector of normalized weights. For any $i \in N_m$, the

ISBN: 978-989-95079-6-8

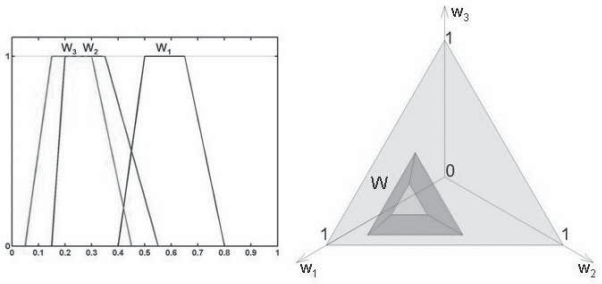

Figure 2: Normalized fuzzy weights W_1, W_2 and W_3 and the fuzzy vector of normalized weights $\mathbf{W} = (W_1 \times W_2 \times W_3) \cap \mathcal{S}_3$.

uncertain value of the i-th weight is expressed by

$$[Q]_i = \big\{w_i \in [0,1] \mid w_i \text{ is the } i\text{-th component of at least one vector } \mathbf{w} \in Q\big\}. \tag{19}$$

Example 2 Let $m = 3$. An expert gives only the ordinal information about the normalized weights by the crisp relation $T = \{(w_1, w_2, w_3) \in \mathcal{S}_3 \mid w_1 \geq w_2 \geq w_3\}$. Since T is closed and convex, T forms a 3-dimensional fuzzy vector of normalized weights $\mathbf{T}$ (see Fig. 3). Obviously, it follows from (19) that $[\mathbf{T}]_1 = [\frac{1}{3}, 1]$, $[\mathbf{T}]_2 = [0, \frac{1}{2}]$ and $[\mathbf{T}]_3 = [0, \frac{1}{3}]$. □

Thirdly, an expert can give both information about the uncertain values of weights, i.e. normalized fuzzy weights $W_1, W_2, \ldots, W_m$, and information about the crisp relations among normalized weights, i.e. the crisp relation $Q \subset \mathcal{S}_m$. If Q is non-empty, closed and convex and if $(Ker\ W_1 \times Ker\ W_2 \times \ldots \times Ker\ W_m) \cap Q \neq \emptyset$, then $\mathbf{W}_Q = (W_1 \times W_2 \times \ldots \times W_m) \cap Q$ is the corresponding fuzzy vector of normalized weights. For any $i \in N_m$, the true uncertain value of the i-th weight is expressed by $[\mathbf{W}_Q]_i \subseteq W_i$; the α-cuts of $[\mathbf{W}_Q]_i$ can be obtained for all $\alpha \in (0,1]$ in the following way

$$[\mathbf{W}_Q]_{i\alpha} = \big\{w_i \in W_{i\alpha} \mid (W_{1\alpha} \times \ldots \times W_{i-1\alpha} \times \{w_i\} \times W_{i+1\alpha} \times \ldots \times W_{m\alpha}) \cap Q \neq \emptyset\big\}. \tag{20}$$

Example 3 Let $m = 3$. First, an expert gives the ordinal information about the normalized weights by a crisp relation $T = \{(w_1, w_2, w_3) \in \mathcal{S}_3 \mid w_1 \geq w_2 \geq w_3\}$. Later on, he/she adds an uncertain cardinal information by a triple of linear normalized fuzzy weights $W_1 = \langle 0.4, 0.5, 0.65, 0.8\rangle$, $W_2 = \langle 0.15, 0.2, 0.35, 0.55\rangle$ and $W_3 = \langle 0.05, 0.15, 0.3, 0.45\rangle$. As $W_1 \geq W_2 \geq W_3$, i.e. $W_{1\alpha} \geq W_{2\alpha} \geq W_{3\alpha}$ for all $\alpha \in (0,1]$, it holds that $(KerW_1 \times KerW_2 \times KerW_3) \cap T \neq \emptyset$. The fuzzy set $\mathbf{W}_T = (W_1 \times W_2 \times W_3) \cap T$ represents the corresponding fuzzy vector of normalized weights (see Fig. 3). For all $\alpha \in (0,1]$, the following holds

$$\begin{aligned}\mathbf{W}_{T\alpha} = \big\{&(w_1, w_2, w_3) \in \mathcal{S}_3 \mid w_1 \geq w_2 \geq w_3,\\ &w_1 \in [0.4 + 0.1\alpha, 0.8 - 0.15\alpha],\\ &w_2 \in [0.15 + 0.05\alpha, 0.55 - 0.2\alpha],\\ &w_3 \in [0.05 + 0.1\alpha, 0.45 - 0.15\alpha]\big\}.\end{aligned} \tag{21}$$

According to (20), the projections of $\mathbf{W}_T$ are given as follows: $[\mathbf{W}_T]_1 = W_1$, $[\mathbf{W}_T]_2 = \{[\underline{w}_{T2}(\alpha), \overline{w}_{T2}(\alpha)]\}_{\alpha\in[0,1]}$, where $\underline{w}_{T2}(\alpha) = 0.15 + 0.05\alpha$, $\overline{w}_{T2}(\alpha) = 0.475 - 0.05\alpha$ for $0 \leq \alpha \leq 0.5$ and $\overline{w}_{T2}(\alpha) = 0.55 - 0.2\alpha$ for $0.5 < \alpha \leq 1$, and $[\mathbf{W}_T]_3 = \langle 0.05, 0.15, 0.25, 0.3\rangle$.

Let us note that although the fuzzy numbers W_1, W_2 and W_3 satisfy $W_1 \geq W_2 \geq W_3$, the crisp relation T represents an additional information for the model. Since the normalized fuzzy weights W_1, W_2 and W_3 satisfy with respect to T only the condition (6), but not (7), the projections $[\mathbf{W}_T]_1, [\mathbf{W}_T]_2$ and $[\mathbf{W}_T]_3$ are less uncertain then the normalized fuzzy weights W_1, W_2 and W_3. □

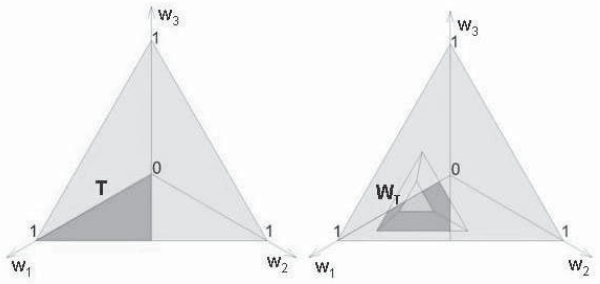

Figure 3: Fuzzy vectors of normalized weights $\mathbf{T} = \{(w_1, w_2, w_3) \in \mathcal{S}_3 \mid w_1 \geq w_2 \geq w_3\}$ and $\mathbf{W}_T = (W_1 \times W_2 \times W_3) \cap T$.

5 Fuzzy Weighted Average of Fuzzy Numbers with a Fuzzy Vector of Normalized Weights

A weighted average of real numbers $u_1, u_2, \ldots, u_m$ with a vector of normalized weights $\mathbf{w} = (w_1, w_2, \ldots, w_m)$ is defined by the following formula

$$a(\mathbf{w}, u_1, u_2, \ldots, u_m) = \sum_{i=1}^{m} w_i u_i. \tag{22}$$

Since the weighted average operation is a continuous real function defined on $\mathcal{S}_m \times \mathbb{R}^m$, its fuzzy extension a_F has the property that $a_F(\mathbf{X})$ is a fuzzy number for all $\mathbf{X} \in \mathcal{F}_V(\mathcal{S}_m \times \mathbb{R}^m)$. In decision making models, the vector of normalized weights is usually supposed to be independent of the weighted values, and the weighted values to be mutually independent as well. Therefore, only the fuzzy vectors $\mathbf{X} = \mathbf{W} \times U_1 \times U_2 \times \ldots \times U_m$, where $\mathbf{W} \in \mathcal{F}_V(\mathcal{S}_m)$ and $U_i \in \mathcal{F}_N(\mathbb{R})$ for all $i \in N_m$, will be considered in this paper.

According to (8), the fuzzy weighted average of fuzzy numbers $U_1, U_2, \ldots, U_m$ with a fuzzy vector of normalized weights $\mathbf{W}$ is a fuzzy number $U = a_F(\mathbf{W}, U_1, U_2, \ldots, U_m)$ whose membership function is for all $u \in \mathbb{R}$ given by the formula

$$U(u) = \max_{\substack{\mathbf{w}\in\mathcal{S}_m \\ u_i\in\mathbb{R},\, i\in N_m \\ \sum_{i=1}^m w_i\cdot u_i = u}} \min\big\{\mathbf{W}(\mathbf{w}), U_1(u_1), \ldots, U_m(u_m)\big\}. \tag{23}$$

Since the weighted average operation is an increasing function in variables $u_1, u_2, \ldots, u_m$, it was proved in [9] that the general mathematical programming problems (10) and (11) can be simplified. Let us denote $U_i = \{[\underline{u}_i(\alpha), \overline{u}_i(\alpha)]\}_{\alpha\in[0,1]}$ for any $i \in N_m$. For the fuzzy weighted average U, $U =$

ISBN: 978-989-95079-6-8

$\{[\underline{u}(\alpha), \overline{u}(\alpha)]\}_{\alpha\in[0,1]}$, the values of the functions $\underline{u}$ and $\overline{u}$ can be calculated for all $\alpha \in (0, 1]$ as follows

$$\underline{u}(\alpha) = \min_{(w_1,w_2,\ldots,w_m)\in \mathbf{W}_\alpha} \sum_{i=1}^{m} w_i \cdot \underline{u}_i(\alpha), \qquad (24)$$

$$\overline{u}(\alpha) = \max_{(w_1,w_2,\ldots,w_m)\in \mathbf{W}_\alpha} \sum_{i=1}^{m} w_i \cdot \overline{u}_i(\alpha). \qquad (25)$$

Hence, complexity of the calculation of U depends only on the form of the α-cuts $\mathbf{W}_\alpha$.

It is worth noting that in the case of fuzzy weighted average of fuzzy numbers with normalized fuzzy weights $W_1, W_2, \ldots, W_m$, i.e. when $\mathbf{W} = (W_1 \times W_2 \times \ldots \times W_m) \cap \mathcal{S}_m$, it is not necessary to solve the mathematical programming problems (24) and (25). For such a case, the following effective algorithm for computing the values $\underline{u}(\alpha)$ and $\overline{u}(\alpha)$, $\alpha \in [0, 1]$, was described in [6]. Let us denote $W_i = \{[\underline{w}_i(\alpha), \overline{w}_i(\alpha)]\}_{\alpha\in[0,1]}$ for any $i \in N_m$. For each $\alpha \in [0, 1]$, let $\{i_k\}_{k=1}^m$ be such a permutation on an index set N_m that $\underline{u}_{i_1}(\alpha) \le \underline{u}_{i_2}(\alpha) \le \ldots \le \underline{u}_{i_m}(\alpha)$. For $k \in N_m$, let us denote

$$w_{i_k}(\alpha) = 1 - \sum_{j=1}^{k-1} \overline{w}_{i_j}(\alpha) - \sum_{j=k+1}^{m} \underline{w}_{i_j}(\alpha). \qquad (26)$$

Let $k^* \in N_m$ be such an index that $\underline{w}_{i_{k^*}}(\alpha) \le w_{i_{k^*}}(\alpha) \le \overline{w}_{i_{k^*}}(\alpha)$. Then

$$\underline{u}^N(\alpha) = \sum_{j=1}^{k^*-1} \overline{w}_{i_j}(\alpha) \cdot \underline{u}_{i_j}(\alpha) + w_{i_{k^*}}(\alpha) \cdot \underline{u}_{i_{k^*}}(\alpha) + \sum_{j=k^*+1}^{m} \underline{w}_{i_j}(\alpha) \cdot \underline{u}_{i_j}(\alpha). \qquad (27)$$

Let $\{i_h\}_{h=1}^m$ be such a permutation on an index set N_m that $\overline{u}_{i_1}(\alpha) \ge \overline{u}_{i_2}(\alpha) \ge \ldots \ge \overline{u}_{i_m}(\alpha)$. For $h \in N_m$, let us denote

$$w_{i_h}(\alpha) = 1 - \sum_{j=1}^{h-1} \overline{w}_{i_j}(\alpha) - \sum_{j=h+1}^{m} \underline{w}_{i_j}(\alpha). \qquad (28)$$

Let $h^* \in N_m$ be such an index that $\underline{w}_{i_{h^*}}(\alpha) \le w_{i_{h^*}}(\alpha) \le \overline{w}_{i_{h^*}}(\alpha)$. Then

$$\overline{u}^N(\alpha) = \sum_{j=1}^{h^*-1} \overline{w}_{i_j}(\alpha) \cdot \overline{u}_{i_j}(\alpha) + w_{i_{h^*}}(\alpha) \cdot \overline{u}_{i_{h^*}}(\alpha) + \sum_{j=h^*+1}^{m} \underline{w}_{i_j}(\alpha) \cdot \overline{u}_{i_j}(\alpha). \qquad (29)$$

Example 4 Let us consider the fuzzy vectors of normalized weights $\mathbf{W}$ from Example 1, $\mathbf{T}$ from Example 2 and $\mathbf{W}_T$ from Example 3. Let the weighted values be, for simplicity, given by real numbers $u_1 = 0.3$, $u_2 = 0.1$ and $u_3 = 0.9$. Let us denote $U_W = a_F(\mathbf{W}, u_1, u_2, u_3)$, $U_T = a_F(\mathbf{T}, u_1, u_2, u_3)$ and $U_{W_T} = a_F(\mathbf{W}_T, u_1, u_2, u_3)$.

Since $\mathbf{W} = (W_1 \times W_2 \times W_3) \cap \mathcal{S}_3$, where W_1, W_2, W_3 are normalized fuzzy weights, by the special algorithm mentioned above we obtain that $U_W = \langle 0.22, 0.32, 0.44, 0.54\rangle$.

As $\mathbf{T} = \{(w_1, w_2, w_3) \in \mathcal{S}_3 \mid w_1 \ge w_2 \ge w_3\}$ is a crisp relation on $\mathcal{S}_3$ and weighted values are real numbers, the mathematical programming problems (24) and (25) does not depend on α. Therefore, the fuzzy weighted average U_T is equal to a closed interval, $U_T = \{[\underline{u}_T, \overline{u}_T]\}_{\alpha\in[0,1]}$. The values $\underline{u}_T = 0.2$ and $\overline{u}_T = 0.433$ were obtained by solving the following linear programming problems

$$\underline{u}_T = \min_{\substack{\sum_{i=1}^3 w_i=1 \\ w_1-w_2\ge 0 \\ w_2-w_3\ge 0 \\ w_3\ge 0}} 0.3w_1 + 0.1w_2 + 0.9w_3, \qquad (30)$$

$$\overline{u}_T = \max_{\substack{\sum_{i=1}^3 w_i=1 \\ w_1-w_2\ge 0 \\ w_2-w_3\ge 0 \\ w_3\ge 0}} 0.3w_1 + 0.1w_2 + 0.9w_3. \qquad (31)$$

The fuzzy weighted average of u_1, u_2 and u_3 with the fuzzy vector of normalized weights $\mathbf{W}_T$, $\mathbf{W}_T = (W_1 \times W_2 \times W_3) \cap T$, is the fuzzy number $U_{W_T} = \{[\underline{u}_{W_T}(\alpha), \overline{u}_{W_T}(\alpha)]\}_{\alpha\in[0,1]}$ where

$$\underline{u}_{W_T} = \min_{\substack{w_i\in W_{i\alpha},\ i\in N_3 \\ \sum_{i=1}^3 w_i=1 \\ w_1-w_2\ge 0 \\ w_2-w_3\ge 0 \\ w_3\ge 0}} 0.3w_1 + 0.1w_2 + 0.9w_3, \qquad (32)$$

$$\overline{u}_{W_T} = \max_{\substack{w_i\in W_{i\alpha},\ i\in N_3 \\ \sum_{i=1}^3 w_i=1 \\ w_1-w_2\ge 0 \\ w_2-w_3\ge 0 \\ w_3\ge 0}} 0.3w_1 + 0.1w_2 + 0.9w_3. \qquad (33)$$

From (32) and (33), we obtain that $\underline{u}_{W_T}(\alpha) = 0.235 + 0.07\alpha$ for $0 \le \alpha < 0.5$, $\underline{u}_{W_T}(\alpha) = 0.22 + 0.1\alpha$ for $0.5 \le \alpha \le 1$, and $\overline{u}_{W_T}(\alpha) = 0.42 - 0.02\alpha$.

Fig. 4 shows the fuzzy weighted averages U_W, U_T and U_{W_T}. □

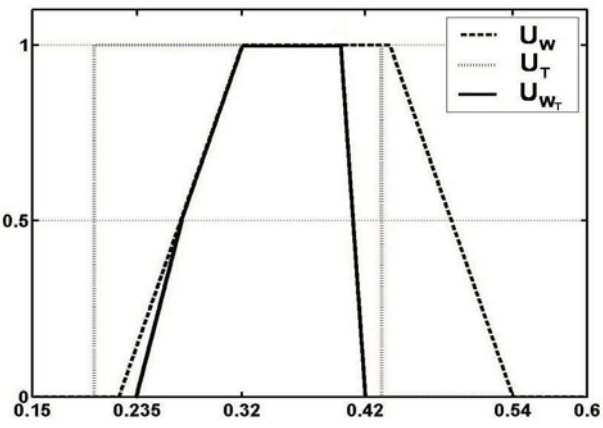

Figure 4: Fuzzy weighted averages U_W, U_T and U_{W_T}.

6 Fuzzy Models of Decision Making Based on the Fuzzy Weighted Average

In this section, a multiple criteria decision making model and a model of decision making under risk, where the fuzzy weighted average of fuzzy numbers with fuzzy vector of normalized weights is applied, will be described.

ISBN: 978-989-95079-6-8

First, let us consider a problem of multiple criteria decision making, where the best of alternatives $x_1, x_2, \ldots, x_n$ is to be chosen. The alternatives are being evaluated with respect to a given overall objective that is partitioned into m partial objectives associated with criteria $C_1, C_2, \ldots, C_m$. Let the uncertain information about the shares of the partial objectives in the overall one be given by an m-dimensional fuzzy vector of normalized weights $\mathbf{W}$. Let uncertain partial fuzzy evaluations of alternatives x_i, $i \in N_n$, with respect to the criteria C_j, $j \in N_m$, be expressed by fuzzy numbers $U_{i,j}$ defined on $[0,1]$ that represent the fuzzy degrees of satisfaction of the corresponding partial objectives of evaluation.

Then the overall fuzzy evaluation U_i of the alternative x_i, $i \in N_n$, can be expressed as follows

$$U_i = a_F(\mathbf{W}, U_{i,1}, U_{i,2}, \ldots, U_{i,m}). \tag{34}$$

The overall fuzzy evaluations $U_1, U_2, \ldots, U_n$ express the fuzzy degrees of satisfaction of the overall objective of evaluation. The best alternative is the first alternative in an ordering of the fuzzy numbers $U_1, U_2, \ldots, U_n$ or the closest to the ideal alternative whose evaluation is equal to 1. For more details on metrics and ordering of fuzzy numbers see e.g. [13]. The overall fuzzy evaluations of alternatives can also be approximated linguistically by linearly ordered elements of a proper linguistic evaluation scale defined on $[0,1]$ (see [1]).

Second, let us consider a problem of decision making under risk that is described by the following fuzzy decision matrix (see Table 1), where $x_1, x_2, \ldots, x_n$ are alternatives, $S_1, S_2, \ldots, S_r$ states of the world, $\mathbf{P}$ is an r-dimensional fuzzy vector of normalized weights that expresses the uncertain probabilities of the states of the world, and for any $i \in N_n$ and $k \in N_r$, $U_{i,k} \in \mathcal{F}_N([0,1])$ denotes the fuzzy degree in which the alternative x_i satisfies a given decision objective if the state S_k occurs.

Table 1: Fuzzy decision matrix.

	S_1	S_2	...	S_r	$\mathbf{P}$
x_1	$U_{1,1}$	$U_{1,2}$	...	$U_{1,r}$	FEU_1
x_2	$U_{2,1}$	$U_{2,2}$	...	$U_{2,r}$	FEU_2
...	...	...	...	...	...
x_n	$U_{n,1}$	$U_{n,2}$	...	$U_{n,r}$	FEU_n

It was shown in [5] that the fuzzy expected value of evaluations of alternatives $x_1, x_2, \ldots, x_n$ are for all $i \in N_n$ expressed by

$$FEU_i = a_F(\mathbf{P}, U_{i,1}, U_{i,2}, \ldots, U_{i,r}). \tag{35}$$

The best alternative is usually determined by the rule of the maximum fuzzy expected value of evaluation. The maximum fuzzy expected value of evaluation is selected from $FEU_1, FEU_2, \ldots, FEU_n$ analogously as it was shown in the case of multiple criteria decision making.

A similar approach can be applied also to multiple criteria decision making under risk (see [14]).

7 Conclusion

In this paper, a new fuzzification of the weighted average operation where uncertain normalized weights are modeled by a general fuzzy vector defined on the probability simplex was presented. Several ways of expert setting the fuzzy vector of normalized weights in fuzzy models were proposed. It was shown that, in comparison with a tuple of normalized fuzzy weights, the fuzzy vector of normalized weights extends the possibilities of modeling the expert's knowledge concerning the weights. Besides the formal definition of the fuzzy weighted average of fuzzy numbers with a fuzzy vector of normalized weights, also a general algorithm for computing the fuzzy weighted average was presented; its three particular forms were illustrated by examples. Finally, applications of the fuzzy weighted average operation in models of multiple criteria decision making and decision making under risk were described.

Integrating Complex User Preferences into a Route Planner: A Fuzzy-Set-Based Approach

Amine Mokhtari Olivier Pivert Allel Hadjali

IRISA/ENSSAT, Université de Rennes 1

Email: {mokhtari, pivert, hadjali}@enssat.fr

Abstract— Route planners are systems which help users select a route between two locations. In such a context, personalization mechanisms notably aim at taking into account user preferences so as to identify the best route(s) among a set of possible answers. In this paper, we present a framework based on fuzzy set theory for modeling complex user preferences. We provide a typology of preferences which make sense in the domain considered and outline a query language integrating such flexible features. The paper also includes a discussion about query evaluation.

Keywords— Route planning, preferences, fuzzy sets.

1 Introduction

During the last century, and particularly the last fifty years, the impact of transportation means on our daily lives has constantly increased. However, it is only recently, with the tremendous development of the Internet, that an alternative solution to the use of paper maps has appeared to help users choose a route. Route planners are systems which aim at computing the "best" route between a location A and a location B, using different types of information about a given road network (structural information, of course, but also, in some cases, real-time data about traffic jams, road conditions, etc).

Even though there now exists a relatively large set of commercially available route planners, these systems have very limited capabilities — if any — when it comes to taking into account sophisticated user preferences.

The need for personalization has been felt for several years in domains such as databases or information retrieval, but not much research effort has been devoted to customizing route planners so far [20]. Currently, in the most "intelligent" commercial systems and research prototypes, only a small set of predefined preferences (e.g., avoid turnpikes, prefer freeways) are made available to the user who can sometimes attach weights to them.

In this paper, we describe a fuzzy-set-based approach to the modeling of sophisticated user preferences concerning a route planning task. Fuzzy set theory has already been used to deal with some transportations problems; in particular route choice[1], where several models based on fuzzy sets have been proposed in order to take into account uncertainty and the subjectivity of the user [17, 12].

[1]For a given origin-destination pair and a given transport mode, the route choice problem (also called traffic assignment) deals with identifying which route a given traveler *would take*. It represents the fourth step in the conventional transportation forecasting model, that aims at estimating the number of vehicles or travelers that will use a specific transportation facility in the future.

The choice of this theoretical framework is motivated by several reasons, in particular:

- the fact that it is very well suited to the interpretation of linguistics terms, which constitute a convenient way for a user to express his/her preferences,
- the fact that fuzzy set theory relies on a commensurability assumption which makes it possible to aggregate several preferences regarding different attributes, thus leading to a complete pre-order.

The remainder of the paper is organized as follows. After a survey of related work in Section 2, we deal with data representation issues in Section 3. In Section 4, we present a typology of user preferences in the context of unimodal point-to-point route planning. The main features of a query language involving such user preferences are presented in Section 5. Query evaluation is discussed in Section 6. The conclusion recalls the main contributions and outlines some perspectives for future work.

2 Related work

Building a personalized route planner is not an easy task, for several reasons. The large size and complexity of modern road networks, and the number of possible preferences present many a difficulty to overcome.

In the last decade, a few propositions have been made to personalize route planners. Some of them exploit a driver's route history to learn individual preferences that can then be used in future planning tasks. Most of the approaches assume that preferences are not given explicitly due to the difficulty of their modeling and elicitation [13].

Liu [14] proposes a route planning system which combines knowledge about the road network with case-based reasoning and brute-force search. He describes how geographical knowledge isolates the search for useful route segments to a local map region. The approach makes the strong assumption that users prefer routes that follow major roads, and the planning algorithm explicitly seeks out major roads to form the plan of a target route.

Rogers and Langley [18] propose a route planning system which can learn preferences from user feedback. During each interactive session, the user is asked to express his/her preferences among recommended routes. The feedback resulting from this interaction is used as the training data for a perceptron-style training algorithm. The authors assume a fixed user preference model which only concern route length,

ISBN: 978-989-95079-6-8

driving time and turn angles. A numeric weight can be associated to the corresponding preferences.

Let us also mention the work by McGinty and Smyth [15] about a case-based route planning approach. The system they describe generates routes which reflect implicit preferences of individual users. The main aspect that distinguishes this system from that proposed by Rogers and Langley [18] is the fact that it does not assume a fixed preference model. Every user preferences are represented as a collection of previous route cases that the user considered satisfactory. Thus, new routes are generated by reusing and combining relevant sections of multiple cases.

Letchner et al. [13] propose a route planner, named TRIP, which produces route plans that more closely match the routes chosen by people who have extensive experience travelling within a region. To do so, it incorporates time-variant road speeds learned from large amounts of driver-collected GPS data. It also exploits a driver's past GPS logs when responding to future route queries in order to provide routes which are more suited to the driver's individual driving preferences.

The work most similar to our proposal is that by Balke et al. [4, 2, 3]. These authors propose a route planning system integrating user preferences over four characteristics of a route: length, traffic jams, road works and weather conditions. To aggregate the scores related to these preferences into an overall degree, a weighted function F is used. The weights are user-defined and express the importance of each of the route characteristics. The user may use a five-level linguistic scale for asserting the importance, and the levels are automatically mapped onto numerical weights w_i. In response to a route planning query, the top k results are delivered to the user.

The main aspect which distinguishes our approach from the works [14, 15, 18] is that we choose — like Balke et al. [4, 2, 3] — to *explicitly* model user preferences. On the other hand, unlike Balke et al., we aim at taking into account a wide range of atomic user preferences, and fuzzy-set theory provides us with a very rich set of connectors for combining such preferences, leading to a highly expressive query language.

3 Representation issues

Modeling user preferences requires a clear representation of concepts, relations and geographic entities which can be involved in a route planning query. Different spatial data models have been proposed in the literature, and road networks can be represented in several ways. This section provides some elements on these topics.

3.1 Road network modeling

A road network is generally modeled as a (directed) graph. Several granularity levels can be considered, according to what the components of the graph (vertices and edges) represent. In the case of an interurban road network, a vertex represents a city, and an edge describes an interurban link (freeway, national roads, etc). However, in a urban road network, a vertex represents an intersection between two or more routes, and an edge corresponds to a street.

In our work, we consider the finest granularity: a vertex represents any intersection/bifurcation between routes or dead ends, and an edge corresponds to a road of any kind.

3.2 Geographic Data Files (GDF)

We assume a *a priori* that any spatial feature may be concerned by a user preference. Thus, interpreting and processing queries involving such a wide range of potential preferences imply to have available a model suited to the representation of these features. Geographic Data Files (GDF) [10] is international standard that specifies the conceptual and logical data model for geographic databases for Intelligent Transportation Systems (ITS) applications. It includes a specification of potential contents of such databases (Features, Attributes and Relationships), a specification of how these contents shall be represented, and of how relevant information about the database itself can be specified (meta data).

3.3 Time and its representation

We consider the following model of time: time is linear (precedence) and dense (for any two time elements there is always a third element between them). We assume time representation based on time points. A time point is represented by a real number.

4 Typology of user preferences

In the context of unimodal, point-to-point, route planning query, we distinguish three families of user preferences:

spatial preferences p_s they express preferences about roads, places or parts of the road network;

spatio-temporal preferences p_{st} they are spatial preferences involving a time component which expresses the moment or period when the spatial preference is relevant.

intrinsic preferences p_{int} they concern some global properties of a route, such as comfort, length, duration or safety.

In the next subsection, we present each family of user preferences in more detail.

4.1 Spatial preferences

Spatial preferences represent the largest class of preference in terms of diversity. Every entity of the road network may be concerned by such a preference.

Definition (Spatial preferences): a preference p is said to be spatial if it concerns a geographic entity, i.e., an entity which has spatial coordinates.

Two categories of spatial preferences may be identified: *i)* preferences on one (or several) specific element(s) of a road network, *ii)* preferences on an induced part of a road network (induced subgraph). The first category corresponds to preferences on one or several vertices/edges of a road network, i.e., on intersection(s) (resp. section(s)) of a road network. This category is used by a user to favour (respectively, disfavour) some specific elements of the network. An example is "avoid turnpikes". The second category corrresponds to preferences which concern an induced part of a road network, that we call a zone in the following. A zone is a geographic area, for instance an administrative area. Preferences on a zone are about the environment that surrounds a route. An example is "prefer a route which passes across Brittany". Two aspects of spatial entities are worthy of discussion. The first one concerns the boundary of a zone. While some zones have clear-cut (crisp)

ISBN: 978-989-95079-6-8

boundaries, as administrative areas, states or regions, others have fuzzy boundaries, such as "a polluted zone". The second aspect concerns the durability of some spatial entities. Depending on what it represents, the definition of a zone can evolve with time. It is the case, for instance, of zones defined in terms of weather conditions such as "a foggy area".

4.1.1 Spatial relationships

Two approaches exist for designating road network elements concerned by spatial user preferences. The explicit approach consists in designating the different entities concerned by the preference by means of their inherent, individual, characteristics. On the other hand, the implicit approach uses references to other spatial entities, by means of spatial relations. An example is "prefer routes which have gas stations along them".

Definition (Spatial relationship): A spatial relationship is relationship between two or more spatial objects.

Several primitive relationships exist. They can be classified into the following non-exhaustive subcategories [16]:

Topological relationships such as *adjacent*, *inside*, *disjoint*, they are invariant under topological transformations like translation, scaling or rotation.

Spatial (strict) order relationships they are based on the definition of an order, either large or strict: *left to/right to*, *above/below*, *behind/in front of*, *near/far*, *inside/outside* or *surround* [11].

Metric relationships they are based on the concept of distance in the considered space.

Directional relationships these relationships are based on an (absolute/relative) frame of reference. Cardinal direction relationships that describe orientation in space (e.g. *north*, *northeast*) are the most commonly used such relationships.

Several mathematical frameworks have been proposed for each type of spatial relations, independently or in association with one another, notably based on fuzzy set theory [5].

In a route planning query with preferences, different spatial relationships may be used. Many of them may be interpreted in a fuzzy manner while some are intrinsically crisp [21].

4.2 Spatio-temporal preferences

Time has an important place in route planning since the duration of a trip is in general a major factor as to the satisfaction of the user. Thus, it is essential to enable the user to express his/her preferences regarding this aspect.

The time dimension may appear with many semantics according to the problem to be represented. As mentioned before, in a spatio-temporal preference, time is used to express the validity period of a spatial preference. An example is "avoid the city center around noon". In other words, a spatio-temporal preference involves both spatial and temporal entities. Thus, a spatio-temporal preference p_{st} can be seen as a complex preference, formed of a spatial preference p_s and a temporal preference p_t. In the following subsections we concentrate on the temporal part of spatio-temporal preferences. We discuss the different types of temporal entities and relations that they may involve.

4.2.1 Temporal entities and representation

Three types of temporal statements may be involved in a route planning query:

- statements referring to a specific point in time, called instant, denoted by i.
- statements which make reference to a continuous time period with duration, called interval, denoted by I.
- statements which make reference to a duration (i.e., the absolute distance between two instants), denoted by d.

A classical numeric representation of time is the set of real numbers $\mathbb{R}$ [1]. Thus, an instant i is considered to be a singleton representing a date/hour (for instance: 8pm). A (time/duration) interval is described by a lower and an upper bound (beginning instant, ending instant) $[i^-, i^+]$ or a beginning instant and a duration) $[i^-, i^- + d]$.

In many cases, users tend to employ linguistic terms such as *around noon*, *early morning*, to express their temporal preferences. Fuzzy set theory provides a suitable symbolic/numeric interface to the representation of such preferences.

4.2.2 Qualitative/Quantitative temporal preferences

A route planning query may contain two types of temporal preferences: quantitative and qualitative ones.

Quantitative preferences express absolute bounds or restrict the temporal distance between two instants [6]. In other terms, they express preferences on the duration of events or their timing. Two types of quantitative preferences can be distinguished:

- unary preferences, which express a constraint on an instant i by means of a set of intervals, and are expressed as: $(i \in I_1) \vee (i \in I_2) \vee \ldots \vee (i \in I_n)$;
- binary preferences, which concern two instants i_1 and i_2 and constrain the distance $i_2 - i_1$: $(i_2 - i_1) \in I_1 \vee (i_2 - i_1) \in I_2 \vee \ldots \vee (i_2 - i_1) \in I_n$.

Example 1. Find a route from Paris to Rennes such that the duration of the trip is less than three hours.□

Qualitative preferences provide a means to specify the relative position of a pair of temporal entities (instants or intervals) t_1 and t_2 [1]. A qualitative temporal preference is expressed as $t_1 \, R \, t_2$, such that: $R \in \Re$ where $\Re$ is a finite set of basic temporal relations. The set $\Re$ contains the following types of relations:

- point-to-point relations: $<$, $\leq$, $=$, $>$, $\geq$.
- interval-to-interval relations between $I = [i^-, i^+]$ and $J = [j^-, j^+]$: *after/before* $(i^+ < j^-)$, *overlaps* $(i^- < j^- < i^+ < j^+)$, *equals* $(i^- = j^- \wedge i^+ = j^+)$.
- point-to-interval and interval-to-point relations between a point i and an interval $I = [i^-, i^+]$: *after/before* $(i < i^-)$, *during/contains* $(i^- < i < i^+)$.

ISBN: 978-989-95079-6-8

Example 2. Find a route from Paris to Berlin, with the preference "to arrive before night". Processing such a query requires to compare the arrival time with the linguistic term *night*.□

Notice that in the framework considered, temporal criteria intervene in spatio-temporal preferences, i.e., are related to a given spatial entity. In the example above, the criterion about the arrival time is related to the spatial entity "Berlin".

Let us also mention the existence of some theoretical work about the fuzzification of temporal relations [7].

4.3 Intrinsic preferences

A route can be seen as a particular geographic entity within the framework we propose. Contrary to spatial and spatio-temporal preferences which can be called *local* inasmuch as they concern a part of a route, intrinsic preferences characterize the route *as a whole*. They involve qualitative criteria such as expensive, fast, safe, and so on. Among the most intuitive properties of a route, let us mention: *rapidity*, *length*, *safety*, *cost* and *comfort*. Other properties may be of interest in some specific contexts, for example: robustness (for military applications or rescue services) or pollution produced.

5 Outline of a query language

In the previous section, we have presented the different kinds of preferences, elementary entities and possible relations involved in a route planning query with preferences. These elements constitute the basic components of a query language dedicated to route planning. In the sequel, we outline the syntax of this language as well as the different semantics that a route query can convey.

5.1 Query formalization

Let $Q^{\delta_d}_{\delta_a}(P)$ be a unimodal point-to-point route planning query with user preferences where: $\delta_d = (s_d,\ t_d)$ represents departure parameters (departure place s_d and departure time t_d), $\delta_a = (s_a,\ t_a)$ represents arrival parameters, and $P = p_1 \otimes p_2 \otimes \ldots \otimes p_n$ is a compound preference where $\otimes$ stands for a fuzzy connector (conjunction, mean, etc) and p_i is an atomic user preference. Two types of atomic preferences may be distinguished: those which concern the route as a whole, and those which concern the segment of a route. The first type takes the forms:

- $attribute\ \theta\ constant$, where θ is a crisp or fuzzy comparator, e.g., duration $\approx$ 5 hours.
- $attribute\ is\ fuzzy\_term$, e.g., cost is *high*.

The second type may take the following forms:

- $[\exists \mid \forall]$ RoadElement $R\ Entity\ \{temporal\ constraint\}$ where R is a spatial relation. An example is: prefer a route passing next to at least one gas station: $\exists$ RoadElement near gas_station. Another example is: avoid the city center between 11am and 2pm: $\forall$ RoadElement outside city_center when $t \in$ [11am, 2pm].
- $[\exists \mid \forall]$ RoadElement.attribute $\theta\ value$ where θ is a comparator and $value$ is a (linguistic or numeric) constant. For instance, avoid highways: $\forall$ RoadElement.type $\neq$ 'highway'. Another example is: prefer a route with no portion with a speed limit under 60mph: $\forall$ RoadElement.speedlimit ≥ 60.

A first query representation that could be envisaged is:

GO	**FROM**	δ_d
	TO	δ_a
	PREFERENCES	P

Example 3. Find a fast, comfortable, and inexpensive route from Rennes to Paris, with a departure at 16:00, and with the constraint that the cost of the trip must be low. This query may be formulated as follows:

GO	**FROM**	Rennes, 16:00
	TO	Paris
	PREFERENCES	duration is short **and** comfort is high **and** cost is low□

However, this representation does not distinguish between constraints and wishes (in the spirit of the concept of bipolarity [8]). Consequently, in the example above, a route can be selected even though its cost is almost not low at all, as soon as it has a very short duration and a very high level of comfort. To avoid this, user preferences may be partitioned into two sets representing two distinct components of user requirements. The first one, introduced by the keyword *preferring*, gathers the preferences, denoted by P^+, which describe the wishes of the user. The second component, introduced by the keyword *avoiding*, denoted by P^-, specifies the constraints, i.e., the characteristics of routes considered as unacceptable or undesirable by the user. The following formulation makes explicit the bipolar nature of route planning queries:

GO	**FROM**	δ_d
	TO	δ_a
	PREFERRING	P^+
	AVOIDING	P^-

Thus, the previous route query can be expressed as:

GO	**FROM**	Rennes, 16:00
	TO	Paris
	PREFERRING	duration is short **and** comfort is high
	AVOIDING	cost is high.

5.2 Route query semantics

Let $Q^{\delta_d}_{\delta_a}(P)$ be a route query. The parameter t_d (resp. t_a) may be an instant or an interval. Depending on the value of t_d (resp. t_a), such a query may take two different interpretations: static or dynamic.

Static queries (SQ): consist in computing the relevant routes between s_d and s_a for a set of preferences P, at a given instant t_d (resp. t_a). Such a query involves either t_d or t_a or none of them, but not both. If the query includes t_a, an answer will provide t_d, and reciprocally.

Dynamic queries (DQ): the parameter t_d (resp. t_a) is an interval. Such a query specifies either t_a or t_d. The objective is not only to return the relevant routes, but also to determine the best moment for the trip. An answer is thus a triple (departure time, arrival time, route). Here, the satisfaction degree associated with an answer depends on the state of the network at the moment considered (traffic jams, construction works, etc) thus takes into account dynamic data.

From a processing point of view, a dynamic query $Q^{\delta_d}_{\delta_a}(P)$ boils down to a set of static ones. Assuming a discrete time

ISBN: 978-989-95079-6-8

representation, an interval t_d (resp. t_a) corresponds to a finite set of instants $\{i_1, \ldots, i_n\}$ (resp. $\{i'_1, \ldots, i'_m\}$). Evaluating Q with $\delta_d = (s_d,\ t_d)$ (resp. $\delta_a = (s_a,\ t_a)$) comes down to evaluate $Q^{\delta'_d}_{\delta'_a}(P)$ with $\delta'_d = (s_d, t_i)$ for $i = 1..n$, (resp. with $\delta'_a = (s_a, t_{i'})$ for $i' = 1..m$), and to keep the best answer(s).

6 Route query processing

In this section, we describe the evaluation procedure of a route query with preferences. Two aspects are tackled: *i)* how to define the semantics (in terms of trapezoidal membership functions, t.m.f.[2]) of the fuzzy sets which model preferences; *ii)* how to proceed for finding the best k answers. For the former, two cases are considered:

Absolute predicates The semantics of such predicates is explicitly given by the user. It is assumed that a route planning system is endowed with an interface that allows the user to define the t.m.f. of such fuzzy terms in a convenient way. Examples of conditions involving absolute predicates are: departure time is $around\_2pm$, RoadElement is $close\_to$ seashore.

Relative predicates Examples of such predicates are: *as fast as possible*, *as short as possible*. The definition of relative predicates (i.e., their t.m.f.) is automatically computed by the system on the basis of a set of values (that we call the *context*) returned by another query (for example, the context of the relative predicates present in a user query $Q = (\delta_d,\ \delta_a,\ P)$ may be defined as the result of the query which returns the top-k' shortest routes between δ_d and δ_a without taking into account the preferences P). The idea is to define the t.m.f. of a relative predicate using the minimum, average and maximum values of the context, as illustrated in the example given further.

As to query evaluation, finding a best path in a graph w.r.t. a set of preferences is known as a multi-objective shortest path problem, where preferences represent the set of objectives to optimize. Depending on the preference model used, the goal can then be either to compute the set of non dominated routes (preference model based on Pareto order where the preferences are not commensurable) or the k best answers (as in the fuzzy-set-based preference model used here). In any case, computing the answer $\mathcal{R}$ to such a query is an NP-hard problem [19]. In the following, we propose a method which leads to an approximation of $\mathcal{R}$ in an acceptable time.

Let us consider a route planning query $Q^{\delta_d}_{\delta_a}(P)$ and assume that the user is interested in the k best route plans. The evaluation procedure proposed involves four steps:

Step 1 compute the k' shortest paths ($k' > k$) from departure place δ_d to arrival place δ_a. This can be done using one of the classical algorithms from the literature [9]. Let $\mathcal{R}_{k'}$ be the set of resulting routes;

Step 2 build the t.m.f. of the relative predicates involved in $Q^{\delta_d}_{\delta_a}(P)$ using $\mathcal{R}_{k'}$ as their context; it is assumed that "length is short" is an implicit constraint present in every query. So, the list of relative predicates always includes $short_d$ (related to the length of the route);

[2] A t.m.f is expressed by a quadruplet (A, B, a, b), where $[A, B]$ defines the core of the fuzzy set and $[A - a, B + b]$ its support.

Step 3 evaluate each route $r \in S_{k'}$ w.r.t. each atomic user preference present in $Q^{\delta_d}_{\delta_a}(P)$;

Step 4 aggregate the preference degrees into a single score (or two: one for the constraints, one for the wishes, depending on how bipolarity is handled), sort $\mathcal{R}_{k'}$ according to this score (or these two scores) and return the k best answers.

Example 4. Let us consider a person who wants to go from city A to city B, with a departure at 16:00 and an arrival around 21:00 (wish), preferably by a route which is fast (wish) and not expensive (constraint). The route query Q is:

GO	**FROM**	A, 16:00
	TO	B, around_21h
	PREFERRING	duration is short
	AVOIDING	cost is high

The fuzzy predicates involved in this query are:

- $around\_21h$: It is a user-defined (absolute) predicate. Its semantics may be given by the following trapezoidal membership function (t.m.f.): (20:30, 21:30, 1:00, 1:00).
- $short_t$: It is a relative predicate. Its t.m.f. is obtained the following way: *i)* one computes the duration of each route plan in $\mathcal{R}_{k'}$; *ii)* denoting by d_{min} and d_{avg} the minimum and the average duration respectively, then the t.m.f. associated with the predicate $short_t$ is $(d_{min}, d_{min}, 0, d_{avg} - d_{min})$.
- $high$: It is also a relative predicate. Its t.m.f. is built as follows: *i)* for each route $r \in \mathcal{R}_{k'}$, one computes the cost of the trip; *ii)* denoting by c_{avg} and c_{max} the average and the maximum of the computed costs, then the t.m.f. associated to the predicate "*high*" is $(c_{max}, \infty, c_{max} - c_{avg}, 0)$.
- implicit relative predicate $short_d$ (about length) is defined the same way as $short_t$ using the length instead of the duration.□

So as to obtain a unique scalar index for rank-ordering the routes from $\mathcal{R}_{k'}$ according to their overall satisfaction degrees w.r.t. Q, one may merge the satisfaction degree μ_{Pos} coming from the positive preferences (i.e., the wishes) with the degree μ_{Neg} related to the negative preferences (i.e., the constraints) the following way [8]:

$$\mu_Q(r) = min(\mu_{Neg}(r),\ \lambda.\mu_{Neg}(r) + (1 - \lambda).\mu_{Pos}(r))$$

where $\lambda \in]0, 1]$ is a parameter expressing some trade-off between μ_{Pos} and μ_{Neg}. In the case of our example, we have:

$$\mu_{Neg}(r) = min(1 - \mu_{high}(r.cost),\ \mu_{short_d}(r.length)),$$
$$\mu_{Pos}(r) = max(\mu_{short_t}(r.duration),\ \mu_{around\_21h}(r.t_a)).$$

In case two degrees are kept, one may rank the answers using the lexicographic order (with a priority given to the constraints, which means that the wishes are only used to break ties).

One may think that in general the value k specified by the user will be ≤ 5. A choice that we think *a priori* reasonable for k' is $4 \times k$, but experimentations will have to be performed

ISBN: 978-989-95079-6-8

so as to determine which is the "best" choice for k'. The value of k' should be big enough to include the most interesting routes, and small enough to have a reasonable computational cost.

7 Conclusion

In this paper, we have outlined a fuzzy-set-based approach to the modeling and handling of complex user preferences in the context of route planning. A typology of preferences covering a variety of intuitive preferences has been proposed and discussed. We have also provided the basis of a query language dedicated to route planning on the one hand, and described the main steps of the evaluation of a route query, on the other hand.

This is still a preliminary work, and many perspectives exist for future research. First, we intend to provide a more detailed specification of the formal query language which was just outlined here. An aspect strongly connected with this aspect, and which is worthy of investigation, is that of a user-friendly interface, which is all the more crucial as fuzzy predicates are to be handled. Also, a user study is necessary to determine the preferences which really make sense in practice (i.e the most relevant ones). As to query evaluation, it would be of interest to devise optimization mechanisms aimed at reducing the search space further. In particular, it is worth investigating whether some pruning criteria could be infered from non-intrinsic preferences, which would enable computing $\mathcal{R}_{k'}$ more efficiently. Our final objective, of course, is to implement a prototype based on the principles described here and to assess its performances by means of experimentations.

Abstract— The aim of this paper is to study monadic **L**-fuzzy quantifiers of the type $\langle 1 \rangle$ determined by fuzzy measures. These fuzzy quantifiers are defined using a novel notion of $\otimes$-fuzzy integral. Several semantic properties of these **L**-fuzzy quantifiers are studied.

Keywords— fuzzy integral, fuzzy logic, fuzzy measure, fuzzy quantifier, generalized quantifier

1 Introduction

This paper studies semantic properties of one class of monadic **L**-fuzzy quantifiers [1, 2] by studying one specific but important class of them, namely fuzzy quantifiers of the type $\langle 1 \rangle$ determined by fuzzy measures.

Quantifiers of the type $\langle 1 \rangle$ are denotations of important noun phrases of natural language, e.g. "something" in "Something is broken.", "everyone" in "Everyone likes Bob.", "nobody" in "Nobody knows everything.", etc. Moreover, classical logical quantifiers "for all" and "there exists" also belong to this type. It is claimed (e.g. in [3]) that from the point of view of natural language semantics, quantifiers of the type $\langle 1, 1 \rangle$ (e.g. "every" in "Every book has leaves.", "most" in "Most birds fly.") are more basic and more important. However, it is usual and advantageous to start with the type $\langle 1 \rangle$ quantifiers, because they are simpler and there are important relationships between them and quantifiers of the type $\langle 1, 1 \rangle$.

Generalized quantifiers evolved, from pioneering works of Mostowski [4], Lindström [5], Barwise and Cooper [6], into quite large research field with deep results. For overview as well as new results see a recent monograph [3]. A quantifier of the type $\langle 1 \rangle$ is usually modeled, given a universe M, as a mapping $Q_M : \mathcal{P}_M \longrightarrow \{true, false\}$ (or, equivalently, as subsets of the power set $\mathcal{P}_M$). It is possible to introduce many properties of (models of) quantifiers, characterizing their behavior from various points of view, for example permutation invariance (PI), isomorphism invariance (ISOM), extension (EXT), and others, see Section 4.

When we think about a definition and properties of generalized quantifiers (like e.g. *many*, *a few* and others), we feel that their truth values should not change abruptly if we gradually change cardinalities of corresponding sets of objects. Consider for example a sentence "Many people read books." If the number of people who read books increase by 1, it would be very strange if the truth value of this sentence changes from false to true. Therefore, it was inevitable that researchers started to consider more than two truth values in this context, and so-called *fuzzy quantifiers* emerged, starting from a generalization of definition from the previous paragraph, where instead of $\{true, false\}$ we consider some other structure of truth values, notably the interval $[0, 1]$.

Research in the field of fuzzy quantifiers started with works of Zadeh [7], Thiele [8], Ralescu [9] and others, see also [10, 11, 12]. An important contribution was made by Hájek in [13]. A comprehensive study of fuzzy quantifiers was undertaken by Glöckner [1] (see also [14]). In the recent paper [15], Novák studies so-called intermediate quantifiers, mainly from the syntactic point of view in the frame of fuzzy type theory [16]. An attempt to model linguistic quantifiers by fuzzy (Sugeno) integral was presented by Ying in [17].

The semantic interpretation of many generalized quantifiers is connected to measurement of "size" of sets in concern. Consider e.g. quantifier "many". The truth value of a proposition "many books have red cover" clearly depends on the "size" of the set of red books. Therefore, it is natural to consider measures (and integrals) of (fuzzy) sets as natural tools for the modeling of important classes of monotonically non-decreasing and monotonically non-increasing generalized quantifiers.

Fuzzy measures and integrals ([18], see also [19, 20]) are important tools allowing us to compare sets with respect to their size. Standardly, fuzzy measures are set functions defined on some algebra of sets which are monotone with respect to inclusion and they assign zero to the empty set. In our approach, fuzzy measures are defined on algebras of fuzzy sets (fuzzy measure spaces) and, generally, they attain values from a complete residuated lattice **L**. Details can be found in [21] in these proceedings, here we present only basic ideas.

Two types of fuzzy integral, namely the $\otimes$-fuzzy integral and the $\rightarrow$-fuzzy integral, are defined on an arbitrary fuzzy measure space. Integrals of $\otimes$ type will be used as models of quantifiers like *all* and *some*, while integrals of $\rightarrow$ type as models of *no* and *not all*, etc. However, in this contribution we will concentrate only on $\otimes$-fuzzy integrals and quantifiers defined by means of them. Nevertheless, if the structure of truth values **L** is a complete MV-algebra, then it is possible to define the $\rightarrow$-fuzzy integral from the $\otimes$-fuzzy integral [21].

2 Preliminaries

For details we refer to our contribution [21] in this volume, here we review only a few necessary notions.

2.1 Structures of truth values

In this paper, we suppose that the structure of truth values is a *complete residuated lattice* (see e.g. [22]), i.e., an algebra $\mathbf{L} = \langle L, \wedge, \vee, \rightarrow, \otimes, \bot, \top \rangle$ with four binary operations and

ISBN: 978-989-95079-6-8

two constants such that $\langle L, \wedge, \vee, \bot, \top\rangle$ is a complete lattice, where $\bot$ is the least element and $\top$ is the greatest element of L, respectively, $\langle L, \otimes, \top\rangle$ is a commutative monoid (i.e., $\otimes$ is associative, commutative and the identity $a \otimes \top = a$ holds for any $a \in L$) and the adjointness property is satisfied, i.e.,

$$a \leq b \to c \quad \text{iff} \quad a \otimes b \leq c \tag{1}$$

holds for each $a, b, c \in L$, where $\leq$ denotes the corresponding lattice ordering. The operations $\otimes$ and $\to$ are usually called multiplication and residuum, respectively.

2.2 L-fuzzy sets

Let $\mathbf{L} = \langle L, \wedge, \vee, \to, \otimes, \bot, \top\rangle$ be a complete residuated lattice and M be a universe of discourse (possibly empty). A mapping $A : M \to L$ is called an **L**-*fuzzy set on* M. A value $A(m)$ is called a *membership degree of* m *in the* **L**-*fuzzy set* A. The set of all **L**-fuzzy sets on M is denoted by $\mathcal{F}_{\mathbf{L}}(M)$. Obviously, if $M = \emptyset$, then the empty mapping $\emptyset$ is the unique **L**-fuzzy set on $\emptyset$ and thus $\mathcal{F}(\emptyset) = \{\emptyset\}$. An **L**-fuzzy set A on M is called *crisp*, if there is a subset X of M such that $A = 1_X$, where 1_X denotes the characteristic function of X. Particularly, $1_\emptyset$ denotes the empty **L**-fuzzy set on M, i.e., $1_\emptyset(m) = \bot$ for any $m \in M$. This convention will be also kept for $M = \emptyset$. The set of all crisp **L**-fuzzy sets on M is denoted by $\mathcal{P}_{\mathbf{L}}(M)$. An **L**-fuzzy set A is *constant*, if there is $c \in L$ such that $A(m) = c$ for any $m \in M$. For simplicity, a constant **L**-fuzzy set is denoted by the corresponding element of L, e.g., a, b, c.[1]

Let A be an **L**-fuzzy set on M. The *complement* of A is an **L**-fuzzy set $\overline{A}$ on M defined by $\overline{A}(m) = \neg A(m)$ for any $m \in M$. Finally, an extension of the operations $\otimes$ and $\to$ on L to the operations on $\mathcal{F}_{\mathbf{L}}(M)$ is given by

$$(A \otimes B)(m) = A(m) \otimes B(m) \tag{2}$$

$$(A \to B)(m) = A(m) \to B(m) \tag{3}$$

for any $A, B \in \mathcal{F}_{\mathbf{L}}(M)$ and $m \in M$, respectively. A mapping $f^{\to} : \mathcal{F}_{\mathbf{L}}(M) \to \mathcal{F}_{\mathbf{L}}(M')$ defined by $f^{\to}(A)(m) = \bigvee_{m' \in f^{-1}(m)} A(m')$ is called a *fuzzy extension* of the mapping f. Obviously, if f is a bijective mapping, then $f^{\to}(A)(f(m)) = A(m)$ for any $m \in M$.

3 Fuzzy measures and integrals

In this section, we will review a notion of a fuzzy measure of **L**-fuzzy sets and of a $\otimes$-fuzzy integral that will be used to define **L**-fuzzy quantifiers. For details and examples see [21], where also definitions of a complementary fuzzy measure and a $\to$-fuzzy integral can be found. For more information about fuzzy integrals, we refer to [18, 19].

3.1 Fuzzy measures of L-fuzzy sets

For our purposes we will consider algebras of **L**-fuzzy sets as a base for defining fuzzy measures of **L**-fuzzy sets.

Definition 3.1 ([18])**.** Let M be a non-empty universe of discourse. A subset $\mathcal{M}$ of $\mathcal{F}_{\mathbf{L}}(M)$ is an *algebra of* **L**-*fuzzy sets on* M, if the following conditions are satisfied

(i) $1_\emptyset, 1_M \in \mathcal{M}$,

(ii) if $A \in \mathcal{M}$, then $\overline{A} \in \mathcal{M}$,

(iii) if $A, B \in \mathcal{M}$, then $A \cup B \in \mathcal{M}$.

A couple $(M, \mathcal{M})$ is called a *fuzzy measurable space*, if $\mathcal{M}$ is an algebra of **L**-fuzzy sets on M.

Let us introduce the concept of fuzzy measure as follows. The first definition is a modification of the definition of a normed measure with respect to truth values (see e.g. [19, 20]).

Definition 3.2. Let $(M, \mathcal{M})$ be a fuzzy measurable space. A mapping $\mu : \mathcal{M} \to L$ is called a *fuzzy measure* on $(M, \mathcal{M})$, if

(i) $\mu(1_\emptyset) = \bot$ and $\mu(1_M) = \top$,

(ii) if $A, B \in \mathcal{M}$ such that $A \subseteq B$, then $\mu(A) \leq \mu(B)$.

A triplet $(M, \mathcal{M}, \mu)$ is called the *fuzzy measure space*, if $(M, \mathcal{M})$ is a fuzzy measurable space and μ is a fuzzy measure on $(M, \mathcal{M})$.

Example 3.1. Let **L** be a complete residuated lattice with the support $[0, 1]$ and $\mathbb{N}$ be the set of natural numbers with 0. For any non-empty countable (finite or denumerable) universe M, injective mapping $f : M \to \mathbb{N}$, $n \in \mathbb{N}$ and $A \in \mathcal{F}_{\mathbf{L}}(M)$, denote

$$A_{f,n}(m) = \begin{cases} A(m), & \text{if } f(m) \leq n; \\ 0, & \text{otherwise.} \end{cases} \tag{4}$$

Further, for any injective mapping $f : M \to \mathbb{N}$ and $n \in \mathbb{N}$, define $\mu_{f,n} : \mathcal{F}_{\mathbf{L}}(M) \to [0, 1]$ as follows

$$\mu_{f,n}(A) = \frac{\sum_{m \in \mathrm{Supp}(A_{f,n})} A_{f,n}(m)}{|\mathrm{Supp}(1_{M_{f,n}})|} \tag{5}$$

and, finally, define $\underline{\mu}_f, \overline{\mu}_f : \mathcal{F}_{\mathbf{L}}(M) \to [0, 1]$ as follows

$$\underline{\mu}_f = \liminf_{n \to \infty} \mu_{f,n}(A), \tag{6}$$

$$\overline{\mu}_f = \limsup_{n \to \infty} \mu_{f,n}(A). \tag{7}$$

It is easy to see that $\mu_{f,n}$, $\underline{\mu}_f$ and $\overline{\mu}_f$ are fuzzy measures on $(M, \mathcal{F}_{\mathbf{L}}(M))$ determined by an injective mapping f. If, for example, $M = \mathbb{N}$ and $f = \mathrm{id}$, then $\underline{\mu}_f(A) = \overline{\mu}_f(A) = \bot$ for any **L**-fuzzy set on a finite universe. For the set of all even or odd numbers, both fuzzy measures give $\frac{1}{2}$ and, for the set of all prime numbers, we obtain 0.

If M is finite, then $\underline{\mu}_f = \underline{\mu}_g = \overline{\mu}_f = \overline{\mu}_g$ for any injective mappings $f, g : M \to \mathbb{N}$ and

$$\underline{\mu}_f(A) = \overline{\mu}_f(A) = \frac{\sum_{m \in M} A(m)}{|M|}. \tag{8}$$

Let $(M, \mathcal{M})$ be a fuzzy measurable space and $X \in \mathcal{F}_{\mathbf{L}}(M)$. Denote $\mathcal{M}_X$ the set of all $\mathcal{M}$-measurable sets which are contained in X, i.e.,

$$\mathcal{M}_X = \{A \mid A \in \mathcal{M} \text{ and } A \subseteq X\}. \tag{9}$$

Note that $1_\emptyset \in \mathcal{M}_X$ for each $X \in \mathcal{F}_{\mathbf{L}}(M)$ and if X is $\mathcal{M}$-measurable set, then also $X \in \mathcal{M}_X$. If $X = M$, then we will write only $\mathcal{M}$ instead of $\mathcal{M}_M$.

In the following part we will define an isomorphism between fuzzy measure spaces.

[1] We suppose that the meaning of this symbol will be unmistakable from the context, that is, it should be clear when an element of L is considered and when a constant **L**-fuzzy set is assumed.

ISBN: 978-989-95079-6-8

Definition 3.3. Let $(M, \mathcal{M})$ and $(M', \mathcal{M}')$ be fuzzy measurable spaces. We say that a mapping $g : \mathcal{M} \to \mathcal{M}'$ is an *isomorphism between* $(M, \mathcal{M})$ *and* $(M', \mathcal{M}')$, if

(i) g is a bijective mapping with $g(1_\emptyset) = 1_\emptyset$,

(ii) $g(A \cup B) = g(A) \cup g(B)$ and $g(\overline{A}) = \overline{g(A)}$ hold for any $A, B \in \mathcal{M}$,

(iii) there exists a bijective mapping $f : M \to M'$ with $A(m) = g(A)(f(m))$ for any $A \in \mathcal{M}$ and $m \in M$.

Definition 3.4. Let $(M, \mathcal{M})$ and $(M', \mathcal{M}')$ be fuzzy measurable spaces. We say that a mapping $g : \mathcal{M} \to \mathcal{M}'$ is an *isomorphism between* $(M, \mathcal{M}, \mu)$ *and* $(M', \mathcal{M}', \mu')$, if

(i) g is an isomorphism between $(M, \mathcal{M})$ and $(M', \mathcal{M}')$,

(ii) $\mu(A) = \mu'(g(A))$.

If g is an isomorphism between fuzzy measure spaces $(M, \mathcal{M}, \mu)$ and $(M', \mathcal{M}', \mu')$, then we write $g(M, \mathcal{M}, \mu) = (M', \mathcal{M}', \mu')$.

Let $[(M, \mathcal{M}, \mu)]$ denote the class of all fuzzy measure spaces defined on M that are isomorphic with $(M, \mathcal{M}, \mu)$. Obviously, we can write

$$[(M, \mathcal{M}, \mu)] = \{(M, f^{\rightarrow}(\mathcal{M}), \mu_{f^{\rightarrow}}) \mid \\ \mid f : M \to M \text{ is a bijective mapping}\}.$$

3.2 $\otimes$-fuzzy integral

Definition 3.5. Let $(M, \mathcal{M}, \mu)$ be a fuzzy measure space, $A \in \mathcal{F}_{\mathbf{L}}(M)$ and $X \in \mathcal{M}$. The *$\otimes$-fuzzy integral of A on X* is given by

$$\int_X^{\otimes} A \, d\mu = \bigvee_{Y \in \mathcal{M}_X \setminus \{1_\emptyset\}} \bigwedge_{m \in \mathrm{Supp}(Y)} (A(m) \otimes \mu(Y)). \quad (10)$$

If $X = 1_M$, then we write $\int^{\otimes} A \, d\mu$.

Theorem 3.1. *Let $(M, \mathcal{M}, \mu)$ be a fuzzy measure space. If $X \in \mathcal{M}$ is such that $1_{\mathrm{Supp}(Y)} \in \mathcal{M}_X$ for any $Y \in \mathcal{M}_X$, then for any $A \in \mathcal{F}_{\mathbf{L}}(M)$*

$$\int_X^{\otimes} A \, d\mu = \bigvee_{1_Y \in \mathcal{P}_X \setminus \{1_\emptyset\}} \bigwedge_{m \in Y} (A(m) \otimes \mu(1_Y)), \quad (11)$$

where $\mathcal{P}_X = \{1_{\mathrm{Supp}(Z)} \mid Z \in \mathcal{M}_X\}$.

Theorem 3.2. *Let $\mathbf{L}$ be a complete MV-algebra, $(M, \mathcal{M}, \mu)$ be a fuzzy measure space, $A \in \mathcal{F}_{\mathbf{L}}(M)$ and $X \in \mathcal{M}$. Then*

$$\int_X^{\otimes} A \, d\mu = \bigvee_{Y \in \mathcal{M}_X \setminus \{1_\emptyset\}} \big(\mu(Y) \otimes \bigwedge_{m \in \mathrm{Supp}(Y)} A(m)\big). \quad (12)$$

Moreover,

$$\int_X^{\otimes} (c \otimes A) \, d\mu = c \otimes \int_X^{\otimes} A \, d\mu \quad (13)$$

for any $c \in L$.

Theorem 3.3. *Let g be an isomorphism between fuzzy measure spaces $(M, \mathcal{M}, \mu)$ and $(M', \mathcal{M}', \mu')$ and $X \in \mathcal{M}$. Then*

$$\int_X^{\otimes} A \, d\mu = \int_{g(X)}^{\otimes} g(A) \, d\mu' \quad (14)$$

for any $A \in \mathcal{F}_{\mathbf{L}}(M)$.

In the end of this part we will show that the Sugeno integral is a special case of our proposed integral. Let $\mathbf{L}$ be a complete residuated lattice and $(M, \mathcal{M})$ be a fuzzy measurable space such that $A \cap B \in \mathcal{M}$ for any $A, B \in \mathcal{M}$. Denote $A_a = \{m \mid m \in M \ \& \ A(m) \geq a\}$. We say that an $\mathbf{L}$-fuzzy set A is *$\mathcal{M}$-Sugeno measurable*, if $1_{A_a} \in \mathcal{M}$ for any $a \in L$. The *Sugeno integral* is given, for any fuzzy measure space $(M, \mathcal{M}, \mu)$ with $A \cap B \in \mathcal{M}$ for any $A, B \in \mathcal{M}$, for any $\mathcal{M}$-Sugeno measurable $\mathbf{L}$-fuzzy set A and for any $X \in \mathcal{M}$, by

$$\int_X A \, d\mu = \bigvee_{a \in L} (a \wedge \mu(1_{A_a} \cap X)). \quad (15)$$

Theorem 3.4. *Let $\mathbf{L}$ be a complete Heyting algebra, $(M, \mathcal{M}, \mu)$ be a fuzzy measure space with $A \cap B \in \mathcal{M}$ for any $A, B \in \mathcal{M}$, A be an $\mathcal{M}$-Sugeno measurable $\mathbf{L}$-fuzzy set and $X \in \mathcal{M}$. Then $\int_X A \, d\mu = \int_X^{\otimes} A \, d\mu$.*

For a definition and properties of $\rightarrow$-fuzzy integral we refer to [21].

4 L-fuzzy quantifiers of the type $\langle 1 \rangle$

In [2], we defined the monadic $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1^n, 1 \rangle$. Here, we restrict ourselves to their special subclass, namely, to the monadic $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1 \rangle$ that can be defined as follows.

Definition 4.1. Let $\mathbf{L}$ be a complete residuated lattice, M be a universe (possibly empty[2]). A mapping $Q_M : \mathcal{F}_{\mathbf{L}}(M) \to L$ is called a *monadic $\mathbf{L}$-fuzzy quantifier of the type $\langle 1 \rangle$ limited to M*.

Definition 4.2. An *unlimited (finite, countable) monadic $\mathbf{L}$-fuzzy quantifier of the type $\langle 1 \rangle$* is a functional Q assigning to each (finite, countable) universe M a monadic $\mathbf{L}$-fuzzy quantifier Q_M of the type $\langle 1 \rangle$ limited to M.

In the following text, we will usually omit the terms "unlimited", "monadic" and "of the type $\langle 1 \rangle$" and we will say only "$\mathbf{L}$-fuzzy quantifier". Let us demonstrate several examples of unlimited $\mathbf{L}$-fuzzy quantifiers that are interpretations of well-known quantifiers in natural language (see [2]). We will use expressions all, some, not all and no as generic expressions which stand for natural language quantifiers of the type $\langle 1 \rangle$, e.g. "everything", "someone", "not everyone" and "nothing", respectively.

[2] To define the behavior of generalized quantifiers for the empty universe is important in some situations. It happens, for example, when we study type $\langle 1, 1 \rangle$ quantifiers which are obtained from type $\langle 1 \rangle$ quantifiers by means of *relativization*. Then it is vital to have values of e.g. $\mathsf{some}_\emptyset(1_\emptyset)$ defined, see discussion in [3], p. 137.

ISBN: 978-989-95079-6-8

Example 4.1. Let $\mathbf{L}$ be a complete residuated lattice. Then

$$(\mathsf{all})_M(A) = \bigwedge_{m\in M} A(m),$$
$$(\mathsf{some})_M(A) = \bigvee_{m\in M} A(m),$$
$$(\mathsf{not\ all})_M(A) = \bigvee_{m\in M} \neg A(m),$$
$$(\mathsf{no})_M(A) = \bigwedge_{m\in M} \neg A(m),$$

where M is an arbitrary universe and $A \in \mathcal{F}_{\mathbf{L}}(M)$, define unlimited $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1\rangle$. Obviously, the definitions of all and some (interpretations of quantifiers *all* and *some*) are the same as the interpretations of $\forall$ and $\exists$ in fuzzy logic, respectively. The others are negations of the previous ones. Notice that $(\mathsf{all})_\emptyset(\emptyset) = (\mathsf{no})_\emptyset(\emptyset) = \top$ and $(\mathsf{some})_\emptyset(\emptyset) = (\mathsf{not\ all})_\emptyset(\emptyset) = \bot$.

Now, let us recall some well-known semantics properties that are usually investigated in the case of the $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1\rangle$. For more information as well as examples we refer to [1, 2].

Definition 4.3. Let Q, P be $\mathbf{L}$-fuzzy quantifiers. Then we say that Q *is less than or equal to* P and denote it by $Q \le P$, if, for any non-empty universe M and $A \in \mathcal{F}_{\mathbf{L}}(M)$,

$$Q_M(A) \le P_M(A). \tag{16}$$

Further, we say that Q *is equal to* P and denote it by $Q = P$, if $Q \le P$ and $P \le Q$.

Definition 4.4. Let Q, P be $\mathbf{L}$-fuzzy quantifiers. We say that Q *is identical to* P and denote it by $Q \equiv P$, if for any (possibly empty) universe M and $A \in \mathcal{F}_{\mathbf{L}}(M)$,

$$Q_M(A) = P_M(A). \tag{17}$$

Remark 4.2. Note that the behavior of $\mathbf{L}$-fuzzy quantifiers for the empty universe is often unpredictable (e.g., $\mathsf{all}_M(A) \le \mathsf{some}_M(A)$ for all $M \neq \emptyset$, but $\mathsf{some}_\emptyset(1_\emptyset) \le \mathsf{all}_\emptyset(1_\emptyset)$), therefore, we require only non-empty universes for their comparison in the first definition. Moreover, this restriction seems to be insignificant from the practical point of view. The second definition of identity of $\mathbf{L}$-fuzzy quantifiers gives useful denotation.

Definition 4.5. An $\mathbf{L}$-fuzzy quantifier Q is *permutation-invariant*, if for arbitrary universe M, bijective mapping $f : M \to M$ and $A \in \mathcal{F}_{\mathbf{L}}(M)$

$$Q_M(A) = Q_M(f^{\rightarrow}(A)). \tag{18}$$

The set of all permutation-invariant $\mathbf{L}$-fuzzy quantifiers is denoted by PI.

Definition 4.6. An $\mathbf{L}$-fuzzy quantifier Q is *isomorphism-invariant*, if for arbitrary universe M, bijective mapping $f : M \to M'$ and $A \in \mathcal{F}_{\mathbf{L}}(M)$,

$$Q_M(A) = Q_{M'}(f^{\rightarrow}(A)). \tag{19}$$

The set of all isomorphism-invariant $\mathbf{L}$-fuzzy quantifiers is denoted by ISOM.

Definition 4.7. An $\mathbf{L}$-fuzzy quantifier Q satisfies *extension*, if for arbitrary universes M, M' with $M \subseteq M'$ and $A \in \mathcal{F}_{\mathbf{L}}(M)$,

$$Q_M(A) = Q_{M'}(A). \tag{20}$$

The set of all $\mathbf{L}$-fuzzy quantifiers satisfying extension is denoted by EXT.

Definition 4.8. Let Q be an $\mathbf{L}$-fuzzy quantifier. We say that Q is *monotonically non-decreasing*, if for arbitrary universe M and $A \in \mathcal{F}_{\mathbf{L}}(M)$ and $A' \in \mathcal{F}_{\mathbf{L}}(M)$ with $A \subseteq A'$,

$$Q_M(A) \le Q_M(A') \tag{21}$$

and Q is *monotonically non-increasing*, if for arbitrary universe M and $A \in \mathcal{F}_{\mathbf{L}}(M)$ and $A' \in \mathcal{F}_{\mathbf{L}}(M)$ with $A' \subseteq A$,

$$Q_M(A) \le Q_M(A'). \tag{22}$$

For our purpose we will consider the following stronger definition of $\mathbf{L}$-similarity of fuzzy sets. Recall that a mapping $R : \mathcal{F}_{\mathbf{L}}(M) \times \mathcal{F}_{\mathbf{L}}(M) \to L$ is called an $\mathbf{L}$-*fuzzy relation on* $\mathcal{F}_{\mathbf{L}}(M)$. Let $[A\ R\ B]$ denote the degree in which $\mathbf{L}$-fuzzy sets A and B belongs to $\mathbf{L}$-fuzzy relation, i.e., $[A\ R\ B] = R(A, B)$. Let us define an $\mathbf{L}$-fuzzy relation $\equiv_M$: $\mathcal{F}_{\mathbf{L}}(M) \times \mathcal{F}_{\mathbf{L}}(M) \to L$ by $[A \equiv_M B] = \top$, if there is a bijective mapping f of M onto M such that $f^{\rightarrow}(A) = B$, and $[A \equiv_M B] = \bot$, otherwise. The following definition generalizes $\equiv_M$.

Definition 4.9. An $\mathbf{L}$-fuzzy relation $\approx_M$: $\mathcal{F}_{\mathbf{L}}(M) \times \mathcal{F}_{\mathbf{L}}(M) \to L$ is called an $\mathbf{L}$-*permutation equivalence* on $\mathcal{F}_{\mathbf{L}}(M)$, if

$$[A \approx_M B] \ge [A \equiv_M B] \tag{23}$$
$$[A \approx_M B] = [B \approx_M A] \tag{24}$$
$$[A \approx_M B] \le [\overline{A} \approx_M \overline{B}] \tag{25}$$
$$[A \approx_M B] \otimes [B \approx_M C] \le [A \approx_M C] \tag{26}$$

hold for arbitrary $A, B, C \in \mathcal{F}_{\mathbf{L}}(M)$.

Obviously, (24) and (26) are the common axioms of symmetry and transitivity, respectively. Let $A, B \subseteq M$ are $\mathbf{L}$-fuzzy sets which are similar. Then one could wish that the complements of A and B are also similar (at least in the degree in which A and B are $\mathbf{L}$-equivalent). This idea is expressed in (25).

Example 4.3 (see [2])**.** Let $\mathbf{L}$ be a complete residuated lattice, M be any universe and $\mathrm{Perm}(M)$ denote the set of all bijective mappings of M onto M. Then

$$[A \approx^{\wedge}_M B] = \bigvee_{f\in \mathrm{Perm}(M)} \bigwedge_{m\in M} (A(m) \leftrightarrow B(m)) \tag{27}$$

defines the $\mathbf{L}$-permutation equivalence $\approx^{\wedge}_M$ on $\mathcal{F}_{\mathbf{L}}(M)$.

Definition 4.10. Let $\approx$ be a class of $\mathbf{L}$-permutation equivalences such that for each (finite, countable) universe M there is a unique $\approx_M$ from $\approx$ defined on $\mathcal{F}_{\mathbf{L}}(M)$. A (finite, countable) $\mathbf{L}$-fuzzy quantifier Q of the type $\langle 1\rangle$ is *extensional with respect to* $\approx$, if

$$[A \approx_M A'] \le Q_M(A) \leftrightarrow Q_M(A') \tag{28}$$

for each (finite, countable) universe M and $A, A' \in \mathcal{F}_{\mathbf{L}}(M)$. The set of all extensional $\mathbf{L}$-fuzzy quantifiers with respect to $\approx$ is denoted by $\mathrm{EXTENS}(\approx)$.

5 L-fuzzy quantifiers of the type $\langle 1\rangle$ determined by fuzzy measures

Let $\mathcal{S}(M)$ denote a set of fuzzy measure spaces defined on M. For better readability, we will denote by

$$\int_{(M,\mathcal{M})}^{\otimes} A\, d\mu \tag{29}$$

the $\otimes$-fuzzy integral $\int^{\otimes} A\, d\mu$ defined over a fuzzy measure space $(M,\mathcal{M},\mu)$. Now we can define $\mathbf{L}$-fuzzy quantifiers limited to M using fuzzy measure spaces from a set $\mathcal{S}(M)$ as follows.

Definition 5.1. Let $\mathcal{S}(M)$ be a (possibly empty) set of fuzzy measure spaces defined on a non-empty universe M. An $\mathbf{L}$-*fuzzy quantifier of the type* $\langle 1\rangle$ *limited to* M *determined by the fuzzy measure spaces from* $\mathcal{S}(M)$ is a mapping $Q_{\mathcal{S}(M)} : \mathcal{F}_{\mathbf{L}}(M) \to L$ defined by

$$Q_{\mathcal{S}(M)}(A) = \bigvee_{(M,\mathcal{M},\mu)\in\mathcal{S}(M)} \int_{(M,\mathcal{M})}^{\otimes} A\, d\mu. \tag{30}$$

Remark 5.1. It is easy to see that if $\mathcal{S}(M) = \emptyset$ for some (possibly non-empty) set M, then $Q_{\mathcal{S}(M)}(A) = \bot$ for any $A \in \mathcal{F}_{\mathbf{L}}(M)$.

It is easy to see that $\mathcal{S}(\emptyset) = \emptyset$ (there is no fuzzy measure space with $M = \emptyset$). Hence, each unlimited fuzzy quantifier Q based only on the formula (30) has $Q_\emptyset(1_\emptyset) = Q_{\mathcal{S}(\emptyset)}(1_\emptyset) = \bot$. However, for example, it holds that $(\mathsf{all})_\emptyset(1_\emptyset) = \top$. This motivates us to exclude the determination of $Q_\emptyset(1_\emptyset)$ by (30) in the following definition of unlimited $\mathbf{L}$-fuzzy quantifier.

Definition 5.2. Let $\mathcal{S}$ be a functional assigning to each universe M a set $\mathcal{S}(M)$ of fuzzy measure spaces defined on M. An *unlimited* $\mathbf{L}$-*fuzzy quantifier of the type* $\langle 1\rangle$ *determined by fuzzy measures over* $\mathcal{S}$ is an unlimited $\mathbf{L}$-fuzzy quantifier of the type $\langle 1\rangle$ assigning an $\mathbf{L}$-fuzzy quantifier $Q_{\mathcal{S}(M)}$ determined by the fuzzy measure spaces from $\mathcal{S}(M)$ to each *non-empty* universe M.

Example 5.2. Let M be a non-empty universe and $\mathcal{S}(M)_i = \{(M,\mathcal{F}_{\mathbf{L}}(M),\mu_i)\}$, where, for $i = 1, 2$,

$$\mu_1(A) = \begin{cases} \bot, & \text{if } A = 1_\emptyset, \\ \top, & \text{otherwise} \end{cases} \tag{31}$$

and

$$\mu_2(A) = \begin{cases} \top, & \text{if } A = 1_M, \\ \bot, & \text{otherwise.} \end{cases} \tag{32}$$

If Q is determined by fuzzy measures from $Q_{\mathcal{S}(M)_1}$ for all $M \neq \emptyset$, then $Q = \mathsf{some}$. In fact, if $M \neq \emptyset$ and $A \in \mathcal{F}_{\mathbf{L}}(M)$, then

$$Q_M(A) = Q_{\mathcal{S}(M)_1}(A) = \int_{(M,\mathcal{F}_{\mathbf{L}}(M))}^{\otimes} A\, d\mu_1 =$$
$$= \bigvee_{m\in M} \mu_1(\{m\}) \otimes A(m) =$$
$$= \bigvee_{m\in M} \top \otimes A(m) = \bigvee_{m\in M} A(m) = (\mathsf{some})_M(A).$$

According to Definition 4.3, $Q = \mathsf{some}$. One checks easily that Q determined by $Q_{\mathcal{S}(M)_2}$ for all $M \neq \emptyset$ is equal to all.

Example 5.3. Let $\mathbf{L}$ be the standard Gödel algebra and

$$\mathcal{S}(M) = \{(M,\mathcal{F}_{\mathbf{L}}(M),\mu)\}.$$

One checks easily, using Theorem 3.1, that

$$Q_{\mathcal{S}(M)}(A) = \bigvee_{1_Y\in\mathcal{P}_{\mathbf{L}}(M)\setminus\{1_\emptyset\}} \Big(\mu(1_Y) \wedge \bigwedge_{m\in Y} A(m)\Big),$$

because $\otimes$ coincides with $\wedge$ in Gödel algebras. Notice that because $\mathbf{L}$ is the Gödel algebra, it is also a Heyting algebra and, according to Theorem 3.4, the $\otimes$-fuzzy integral coincides with the Sugeno integral in this case.

Let M be a non-empty countable universe and μ_f denote one of the fuzzy measures on $(M,\mathcal{F}_{\mathbf{L}}(M))$ defined by (6) and (7) in Example 3.1. Putting

$$Q_{\mathcal{S}(M)}(A) = \bigvee_{1_Y\in\mathcal{P}_{\mathbf{L}}(M)\setminus\{1_\emptyset\}} \Big(\mu_f(1_Y) \wedge \bigwedge_{m\in Y} A(m)\Big)$$

for any non-empty countable universe M and $Q_\emptyset(1_\emptyset) = \top$, we obtain a countable $\mathbf{L}$-fuzzy quantifier which is an interpretation of the quantifier *many things*. Define

$$\mu_f^{1/2}(A) = \begin{cases} \top, & \text{if } \mu_f(A) \geq \frac{1}{2}, \\ \bot, & \text{otherwise,} \end{cases}$$

for any $A \in \mathcal{F}_{\mathbf{L}}(M)$. Then putting

$$Q_{\mathcal{S}(M)}(A) = \bigvee_{1_Y\in\mathcal{P}_{\mathbf{L}}(M)\setminus\{1_\emptyset\}} \Big(\mu_f^{1/2}(1_Y) \wedge \bigwedge_{m\in Y} A(m)\Big)$$

for any non-empty countable universe M and $Q_\emptyset(1_\emptyset) = \top$, we obtain a countable $\mathbf{L}$-fuzzy quantifier which is an interpretation of the quantifier *at least half things*. If we restrict ourselves to the class of all finite $\mathbf{L}$-fuzzy quantifiers, then one checks easily (using the equality $\mu_f(A) = \mu_f(h^{\rightarrow}(A))$ from Example 3.1) that both defined quantifiers are PI and ISOM. Moreover, they are $\mathrm{EXTENS}(\approx^{\wedge})$ (see Theorem 5.6).

Intuitively, it is obvious that all is the smallest and some the greatest $\mathbf{L}$-fuzzy quantifier Q determined by fuzzy measures with respect to the ordering from Definition 4.3.

Theorem 5.1. *For each* $\mathbf{L}$*-fuzzy quantifier* Q *determined by fuzzy measures over* $\mathcal{S}$*, it holds that*

$$\mathsf{all} \leq Q \leq \mathsf{some}. \tag{33}$$

In the following part, we will present some results on the semantic properties of $\mathbf{L}$-fuzzy quantifiers determined by fuzzy measures. The following theorem states a sufficient condition for $\mathbf{L}$-fuzzy quantifiers to be permutation invariant.

Theorem 5.2. *Let* Q *be an unlimited* $\mathbf{L}$*-fuzzy quantifier of the type* $\langle 1\rangle$ *determined by fuzzy measures over* $\mathcal{S}$ *such that for each non-empty universe* M *it holds that* $\mathcal{S}(M) = [(M,\mathcal{M},\mu)]$*. Then* $Q \in \mathrm{PI}$.

Note that the specification of a necessary condition for $\mathbf{L}$-fuzzy quantifiers being permutation invariant seems to be immensely complicated and it is still an open problem. In the following theorem, let us denote fuzzy measure spaces $(M,\mathcal{M},\mu)$ and $(M',\mathcal{M}',\mu')$ by $\mathbf{M}$ and $\mathbf{M}'$, respectively.

ISBN: 978-989-95079-6-8

Theorem 5.3. *Let Q be an unlimited* $\mathbf{L}$*-fuzzy quantifier of the type $\langle 1\rangle$ determined by fuzzy measures over $\mathcal{S}$ such that, for any universes M, M' with the same cardinality,*

(i) if $\mathbf{M} \in \mathcal{S}(M)$ and $f : M \to M'$ is a bijection, then $f^{\to}(\mathbf{M}) \in \mathcal{S}(M')$,

(ii) if $\mathbf{M} \in \mathcal{S}(M)$ and $\mathbf{M}' \in \mathcal{S}(M')$, then $\mathbf{M}$ and $\mathbf{M}'$ are isomorphic.

Then $Q \in$ ISOM.

From the definition of $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1\rangle$ determined by fuzzy measures it should be clear that they possess non-decreasing behavior, which is expressed by the following theorem. Naturally, if we base $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1\rangle$ on complementary fuzzy measures and $\to$-fuzzy integrals [21], they will be non-increasing.

Theorem 5.4. *Let Q be an unlimited* $\mathbf{L}$*-fuzzy quantifier of the type $\langle 1\rangle$ determined by fuzzy measures over $\mathcal{S}$. Then Q is a non-decreasing* $\mathbf{L}$*-fuzzy quantifier.*

The following theorem shows that some is the only type $\langle 1\rangle$ quantifier with the extension (EXT) property which can be successfully modeled by our $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1\rangle$ determined by fuzzy measures. However, the quantifier all and quantifiers which are interesting from the point of view of fuzzy logic, for example "at least half things", "many things", "most things" do not possess the extension property, and we can model them, see Examples 5.2 and 5.3. Nevertheless, quantifiers which refer to absolute cardinalities, e.g. "at least three things", possess the extension property, therefore they cannot be successfully modeled by our quantifiers.

Theorem 5.5. *Let Q be an unlimited* $\mathbf{L}$*-fuzzy quantifier of the type $\langle 1\rangle$ determined by fuzzy measures over $\mathcal{S}$. Then $Q \in$* EXT *if and only if $Q \equiv$* some.

Finally, we show that fuzzy quantifiers of type $\langle 1\rangle$ determined by fuzzy measures are behaving well with respect to extensionality (see Definition 4.10).

Theorem 5.6. *Let Q be an unlimited* $\mathbf{L}$*-fuzzy quantifier of the type $\langle 1\rangle$ determined by fuzzy measures over $\mathcal{S}$ such that $\mathcal{S}(M) = [(M, \mathcal{M}, \mu)]$ for each non-empty universe M. Then $Q \in$* EXTENS($\approx^{\wedge}$).

6 Conclusion

In the future we will concentrate on studying of $\mathbf{L}$-fuzzy quantifiers of the type $\langle 1, 1\rangle$ (and possibly also of the type $\langle 1^n, 1\rangle$) generated by fuzzy measures. Quantifiers of the type $\langle 1, 1\rangle$ serve as models of very important class of natural language determiners (cf. e.g. [3]), for example "a few X are Y", "almost all X are Y", etc. Our definitions of $\otimes$-fuzzy integral and $\to$-fuzzy integral allow us to define these quantifiers, and we believe that they provide an important class of models with interesting properties.

Abstract— *Fuzzy queries addressed to a relational database management system are based on the expression of user preferences which leads to obtain more appropriate answers. Fuzzy set theory provides powerful tools to define such conditions (fuzzy conditions). In this context, it is possible to consider fuzzy bipolar conditions which are made of two fuzzy sets to describe user's preferences: i) a fuzzy constraint to represent a mandatory requirement, ii) a fuzzy wish to represent an optional requirement. A Fuzzy constraint is mandatory in the sense that it* ***must*** *be fulfilled (and it can be used to discard elements). A fuzzy wish is optional since it cannot be used to discard elements (but its satisfaction brings a bonification). This paper is devoted to the aggregation of fuzzy bipolar conditions and to the definition of extended norms and co-norms.*

Keywords— *flexible querying, fuzzy bipolar condition, relational database.*

1 Introduction

When querying a relational database management system (DBMS), the expression of user preferences is a manner to integrate the personalized needs of the user. As a consequence, it leads to obtain more appropriate answers, since they can be ranked from the more relevant (the more preferred) to the less relevant (a set of discriminated answers being obtained). The problem of expressing and managing user preferences in the relational model of data has received more and more attention in the last few years [1, 2, 3, 4, 5, 6, 7] and we consider the study of bipolar conditions [8, 9, 10, 11, 12]. Such conditions are made of two components: a mandatory condition (also called a constraint) and an optional condition (also called a wish). More precisely, we consider fuzzy bipolar conditions where the constraint and the wish express user preferences and are defined by fuzzy sets.

The main interrogation systems proposed to integrate user preferences do not take into account such bipolar conditions. The SQLf language considers preferences defined by fuzzy sets and proposes a commensurable approach without bipolarity. It does not distinguish between constraints and wishes, each atomic fuzzy condition being a commensurable constraint. On the contrary, PreferenceSQL deals with a particular case of bipolarity where constraints are Boolean while wishes are not commensurable preferences. The preferences being not commensurable in PreferenceSQL, this proposition leads to a partial order of answers while SQLf language delivers a total order (the preferences being commensurable). One of the main differences [10] between these two approaches is that SQLf is set in the algebraic framework while it is not the case for PreferenceSQL. As a consequence, this article is a contribution to the extension of the relational algebra (and SQL) to fuzzy bipolar conditions. Our final aim is to propose an SQL-like query language where fuzzy bipolar conditions can be defined as an extension of fuzzy conditions. As a consequence, a total order of answers is expected.

Fuzzy bipolar conditions are introduced in section 2 and it is shown that a fuzzy condition defined by a fuzzy set is a particular case of a fuzzy bipolar condition. Section 3 is interested in extending logical operators to define more complex fuzzy bipolar conditions. These operators are soundness from an user's point of view but they cannot be considered as extended norms and co-norms. Section 4 proposes definition for an extended norm and an extended co-norm to aggregate fuzzy bipolar conditions.

2 Fuzzy bipolar conditions

Bipolarity can be defined as the human capability to evaluate situations in terms of pros and cons or positive and negative aspects. Depending of the relationship between these two aspects, Dubois and Prade [8, 9] distinguish between three categories of bipolarity, called types I, II and III.

The type I is called *symmetric univariate bipolarity*. It corresponds to the case where the scale to evaluate situations is bipolar which means defined by an ordered set (total order) with a neutral elements to separate positive and negative information (*symmetric bipolarity*). As a consequence a single value (*univariate*) from this scale expresses, at the same time the positive and negative aspects since the opposite evaluation is obtained by symmetry. An example of type I bipolarity is provided by probability measures, the neutral element being 0.5. The type II is called *symmetric bivariate unipolarity*. In this case, the scale to evaluate situations is unipolar which means that the neutral element is at one end of the scale and two dual values (symmetric bivariate) is necessary to judge a situation. Unlike the symmetric univariate bipolarity, it is possible for a situation to be evaluated positive and negative at the same time. An example of type II bipolarity is provided by possibility theory where a couple of dual unipolar indexes (possibility and possibility of opposite event) is used to evaluate a situation. The type III is called *asymmetric bipolarity*. In this case two bipolar scales are used to evaluate a situation, one expressing the positive, the other one the negative aspects. As a consequence, positive and negative evaluations are of different nature and can be provided by different kind of sources.

ISBN: 978-989-95079-6-8

A bipolar condition is made of two components: a *constraint* (a condition denoted C) whose negation defines not acceptable values (negative evaluation) and a *wish* (a condition denoted W) to define desired values (positive evaluation). The satisfaction to the constraint and the wish are based on two different bipolar scales, the two extremum being the total satisfaction 1 and the total non satisfaction 0. In addition, constraints and wishes are neither dual nor symmetric. As a consequence, a bipolar condition expresses a type III bipolarity.

This paper considers that a bipolar condition denoted (C, W) means "to satisfy C and, if possible, to satisfy W" and this meaning has two important consequences. Firstly, it implies that the satisfaction with respect to the constraint is mandatory while the satisfaction with respect to the wish is optional. Secondly, the set of wished values must be a subset of that of mandatory values (W $\subseteq$ C). This property states that it is incoherent to wish non-acceptable values.

In the context of database querying with such conditions, tuples which do not satisfy the constraint are discarded (since this condition is mandatory), while tuples which do not satisfy the wish can be proposed to the user (the wish being optional). When C and W are Boolean conditions, the satisfaction with respect to the bipolar condition (C,W) is a couple (c, w) where c and w are values in {0, 1}. Tuples satisfying the constraint and the wish are returned in priority to the user. If such answers do not exist, the tuples satisfying only the constraint are delivered. When the two components express preferences and are defined by fuzzy sets, their satisfactions are sets in [0,1]. As a consequence, the satisfaction of a given element x with respect to a fuzzy bipolar condition is a couple of degrees ($\mu_C(x)$, $\mu_W(x)$), and their processing is more tricky. These two degrees are not commensurable (due to the chosen meaning for the fuzzy bipolar conditions) and, consequently, they cannot be aggregated to compute an overall degree of satisfaction. In addition, the constraint being mandatory, its satisfaction is firstly used to discriminate among answers. The satisfactions with respect to the wish being not mandatory, they can only be used to discriminate among answers having same evaluation with respect to the constraint. Thus, the wishes allow to differentiate between tuples which are equal with respect to their constraints and a *total order* is obtained on C and W (with (1, 1) as greatest element and (0, 0) as least element). In other words, it is possible to rank the tuples by using a *lexicographical* order on the constraints and the wishes:

a tuple t_i is preferred to a tuple t_j
if ($\mu_C(t_i) > \mu_C(t_j)$)
or (($\mu_C(t_i) = \mu_C(t_j)$) and ($\mu_W(t_i) > \mu_W(t_j)$)),

Obviously, a tuple t_i is similar to a tuple t_j (they have same level of preference) if and only if $\mu_C(t_i) = \mu_C(t_j)$ and $\mu_W(t_i) = \mu_W(t_j)$.

For the sake of simplicity, "t_i is preferred to t_j" is denoted $t_i > t_j$ while "t_i is similar to t_j" is denoted $t_i = t_j$.

Example 1. We consider relation Sales from Table 1 where attributes #Sale, Date, Town, Benefit are respectively the identification of a sale, the date and place where it has been concluded and the percentage of benefit for the salesman.

A salesman wants to know the town where a sale has occurred with a *high* benefit and, if possible, a benefit *around 100%*. A *high* benefit is a mandatory condition while condition *around 100%* is optional. These two fuzzy conditions are given by Figure 1 and define the fuzzy bipolar condition (C, W) where C is "*high* benefit" and W is "benefit *around 100%*".

Table 1 : Relation Sales.

#Sale	Date	Town	Benefit
#1	01-05-07	Paris	82%
#2	04-06-07	Paris	85%
#3	08-09-07	Londres	59%
#4	15-06-07	Nice	94%
#5	17-07-07	Londres	97%
#6	08-09-07	Madrid	56%

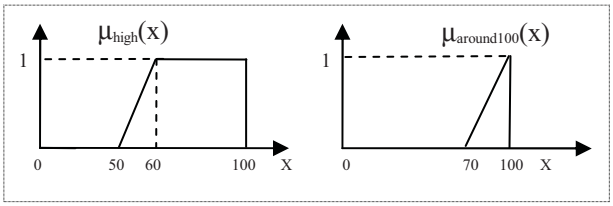

Figure 1 : *high* benefit and benefit *around 100%*.

The satisfactions with respect to the constraint C and the wish W are given by Table 2.

Table 2 : Satisfactions with respect to the fuzzy bipolar condition : "*high* benefit" and if possible "*around 100%*".

#Sale	*(high* benefit, benefit *around 100%*) (μ_C(#Sale), μ_W(#Sale)),
#1	(1, 0.4)
#2	(1, 0.5)
#3	(0.9, 0)
#4	(1, 0.8)
#5	(1, 0.9)
#6	(0.6, 0)

The lexicographical order gives :

#5 > #4 > #2 > #1 > #3 > #6.

Sale #5 is the best sale with respect to the bipolar condition (C, W) because, among the best sales according to the constraint (at degree 1), it is the best one according to the wish. ◆

The property of constraints and wishes expressed on a same universe is that the set of wished values must be a subset of that of mandatory values (W $\subseteq$ C). In case of fuzzy sets, this property of inclusion is rewritten :

for each value x in X, $\mu_W(x) \leq \mu_C(x)$,

ISBN: 978-989-95079-6-8

such that X is the domain set where the fuzzy bipolar condition applies. Such a property can be checked on the fuzzy bipolar condition provided by example 1. This property is natural and is always implicit in the formulation of fuzzy bipolar conditions. As a consequence, a condition formulated as "a *cheap* and, if possible, a *low* consuming car" should be rewritten : "a *cheap* car and, if possible, a *cheap* and *low* consuming car".
An important particular case arises when a fuzzy bipolar condition is a fuzzy predicate (a pure constraint). Since a fuzzy predicate C can be rewritten "C and, if possible, C", a pure constraint is defined by a fuzzy bipolar condition where the constraint equals the wish ((C, C)). As a consequence, a fuzzy bipolar condition is a generalization of a fuzzy condition.

3 Logical operators and fuzzy bipolar conditions

In this section, we consider several fuzzy bipolar conditions and their aggregation using conjunction and disjunction operators.
A first idea to define the conjunction of two fuzzy bipolar conditions (C_1, W_1) and (C_2, W_2) is to compute the minimum of both the satisfactions to the constraints and to the wishes. In this case "(C_1, W_1) and (C_2, W_2)" is the fuzzy bipolar condition "to satisfy (C_1 and C_2) and if possible to satisfy (W_1 and W_2)". Since the minimum is a triangular norm, this operation can be generalized to define parameterized operators $O_{op1,op2}$ using various norms and conorms :

$$(C_1,W_1)\ O_{op1,\,op2}\ (C_2,W_2) \equiv (op_1(C_1, C_2), op_2(W_1,W_2)), \quad (1)$$

where op_1 and op_2 are either a norm or a co-norm. Depending on the choice for op_1 and op_2 , different meanings can be obtained for the operator (as shown by Table 3).

Table 3 : Different meanings for $O_{op1,op2}$.

	op_1 is a norm	op_1 is a co-norm
op_2 is a norm	$(C_1,W_1)\ O_{op1,op2}\ (C_2,W_2)$ ≡ (C_1 and C_2) and if possible (W_1 and W_2)	$(C_1,W_1)\ O_{op1,\,op2}\ (C_2,W_2)$ ≡ (C_1 or C_2) and if possible (W_1 and W_2)
op_2 is a co-norm	$(C_1,W_1)\ O_{op1,op2}\ (C_2, W_2)$ ≡ (C_1 and C_2) and if possible (W_1 or W_2)	$(C_1,W_1)\ O_{op1,op2}\ (C_2,W_2)$ ≡ (C_1 or C_2) and if possible (W_1 or W_2)

Example 2. A client looks for a trip in a travel agency. His request is expressed as: "a *cheap* journey, if possible with a *small* flight time, and an hotel in a *small* town, if possible located *in the countryside*". This query is a selection R:Θ where relation R describes trips proposed by the agency and condition Θ is the conjunction between two fuzzy bipolar conditions "(C_1,W_1) and (C_2,W_2)". Constraint C_1 is the fuzzy condition "a *cheap* journey", W_1 is the fuzzy wish "a *cheap* journey with a *small* flight time" and C_2 is the fuzzy constraint "hotel in a *small* town" while W_2 is the fuzzy wish "hotel in a *small* town and *in the countryside*". Each one of these two atomic bipolar fuzzy conditions is defined on several attributes (on the Cartesian product of their respective domains). The different satisfactions with respect to the constraints and wishes are given by Table 4. Obviously, the result depends on the chosen operator to represent the conjunction. We propose the two different conjunction operators $O_{min,\,min}$ and $O_{min,\,max}$.

Table 4 : Satisfactions with respect to (C_1,W_1) and (C_2,W_2)

#Trip	C_1 "a *cheap* journey"	W_1 "a *cheap* journey and a *small* flight time"	C_2 "*small* town"	W_2 "a *small* town and *in the countryside*"
#1	0.9	0.7	1	0.1
#2	1	0.5	0.9	0.5
#3	0.9	0.3	1	1
#4	0.7	0.6	0.6	0.5
#5	0.8	0.2	0.6	0.5

When the operator $O_{min,\,min}$ is chosen, the meaning of the query becomes:

"a *cheap* journey with an hotel in a *small* town, if possible with a *small* flight time ***and*** an hotel located *in the countryside*".

The results are given by Table 5.

Table 5 : Results provided by $O_{min,\,min}$

#Trip	μ_C(#Trip)	μ_W(#Trip)
#2	0.9	0.5
#3	0.9	0.3
#1	0.9	0.1
#4	0.6	0.5
#5	0.6	0.2

We obtain the order : #2 > #3 > #1 > #4 > #5.

When the operator $O_{min,\,max}$ is chosen, the meaning of the query becomes:

"a *cheap* journey with an hotel in a *small* town, if possible with a *small* flight time ***or*** an hotel located *in the countryside*".

The results are given by Table 6:

Table 6 : Results provided by $O_{min,\,max}$

#Trip	μ_C(#Trip)	μ_W(#Trip)
#3	0.9	1
#1	0.9	0.7
#2	0.9	0.5
#4	0.6	0.6
#5	0.6	0.5

ISBN: 978-989-95079-6-8

We obtain the order : #3 > #1 > #2 > #4 > #5.

The obtained order is different from the ones provided by $O_{min, min}$ (the meanings of the operator being different).
This example shows that the two different operators considered here lead to two different results since they have two different meanings ($O_{min, min}$ means "*all* the constraints and *all* the wishes", while $O_{min, max}$ means "*all* the constraints and *at least one* wish"). ♦

Last example has shown that, when $O_{min, min}$ and $O_{min, max}$ are used, the fundamental property of constraints and wishes ($W \subseteq C$) is lost (since the result are based on ad-hoc operators). However, we think that this loss is not an issue since it reflects the user's attitude with respect to the aggregation of wishes (either all, either at least one). However, it stresses the need for other operators (as extended norms and co-norms).

4 Extended norms and co-norms

This section is interested in defining operators acting as extended norms and co-norms for fuzzy bipolar conditions. Subsection 4.1 shows that it is not possible to define an extended norm (and an extended co-norm) using any operator $O_{op1, op2}$ where op_1 and op_2 are either a norm or a co-norm (cf. section 3). Section 4.2 defines a couple of extended norm and co-norm (and their associated negation).

4.1 Extended norms, co-norms and $O_{op1, op2}$

The different properties bring by norms and co-norms are necessary conditions to keep the algebraic framework of computations (or at least to achieve computations in an human-consistent framework). The operator $O_{min,min}$ is a rather rational candidate for an extended norm but next example shows that it does not respect the monotonicity property of norms and it concludes that this loss is very damageable.

Example 3. The property of monotonicity of a given norm $\wedge$ is defined by:

$$a \geq b \text{ and } c \geq d \Rightarrow (a \wedge c) \geq (b \wedge d)$$

The following counter example shows it is not respected by $O_{min,min}$:

Let x and y be two elements and two fuzzy bipolar conditions FBC1 and FBC2. The respective satisfaction of x and y to these two fuzzy bipolar conditions are shown by Figure 2.

	FBC1	FBC2
x	(0.7, 0.7)	(0.9, 0.4)
y	(0.7, 0.6)	(0.8, 0.5)

Figure 2 : Satisfactions of x and y to FBC1, FBC2.

The property of monotonicity does not hold in this case since:

$$(0.7, 0.7) \geq (0.7, 0.6) \text{ and } (0.9 , 0.4) \geq (0.8, 0.5)$$

while :

$$(0.7, 0.7)\ O_{min,min}\ (0.9, 0.4)$$

$$< (0.7, 0.6)\ O_{min,min}\ (0.8, 0.5).$$

This behaviour is not acceptable for a conjunction since x is preferred to y when considering criteria FBC1 and when considering criteria FBC2, but x is not preferred to y when considering the conjunction "FBC1 and FBC2". ♦

More generally, an extended norm (or co-norm) cannot be defined by any operator $O_{op1,op2}$ as demonstrated hereafter (the demonstration is only provided for the norm and it can be easily adapted for a co-norm).

Demonstration. We assume an extended norm defined as $O_{op1,op2}$:

$$(C_1,W_1)\ O_{op1, op2}\ (C_2,W_2) \equiv (op_1(C_1, C_2), op_2(W_1,W_2)),$$

where op_1 and op_2 are either a norm or a co-norm. The demonstration is based on two steps. At first, two properties which are necessarily satisfied by such an operator are pointed out. Secondly, it is shown that these properties are not compatible with an extended norm since the property of monotonicity does not hold.

First step: Since a fuzzy condition (a fuzzy set) is a particular case of a fuzzy bipolar condition, an extended norm for fuzzy bipolar conditions should revert to a norm in case of a fuzzy set. A fuzzy set being defined as a fuzzy bipolar condition where the constraint equals the wish, the application of an extended norm $O_{op1,op2}$ can be rewritten (in case of fuzzy sets):

$$(C_1,C_1)\ O_{op1, op2}\ (C_2,C_2) \equiv (op_1(C_1, C_2), op_2(C_1,C_2)),$$

In addition $(op_1(C_1, C_2), op_2(C_1,C_2))$ is nothing but the expression of a norm $\wedge$ between C_1 and C_2 . Since $\wedge (C_1, C_2)$ can be represented by $(\wedge (C_1, C_2), \wedge (C_1,C_2))$ we immediately get two properties:

P1) op1 equals op2,
P2) op1 is a norm (denoted $\wedge$).

Second step: Due to the previous result, any $O_{op1,op2}$ operator defining an extended norm is rewritten $O_{\wedge,\wedge}$ where $\wedge$ is a norm. As a consequence, the property of monotonicity does not hold since:

$$(0, 1) \geq (0, 1)$$

and $(1, 0) \geq (0, 1)$

while:

$$(0, 1)\ O_{\wedge,\wedge}\ (1, 0) < (0, 1)\ O_{\wedge,\wedge}\ (0, 1)$$

(since $(0, 1)\ O_{\wedge,\wedge}\ (1, 0) = (0 \wedge 1, 1 \wedge 0) = (0, 0)$
and $(0, 1)\ O_{\wedge,\wedge}\ (0, 1) = (0 \wedge 0, 1 \wedge 1) = (0, 1)$). ♦

ISBN: 978-989-95079-6-8

This subsection has shown that it is necessary to define operators satisfying the properties of norms and co-norms (we recall that the total order considered here is the lexicographical order with (1, 1) as greatest element and (0, 0) as least element).

4.2 Definition for a couple of extended norm and co-norm

An extended norm $\wedge$ and an extended co-norm $\vee$ can be defined by the minimum and maximum with respect to the lexicographical order (which provides a total order):

$$(x, y) \wedge (x', y') = \min((x, y), (x', y')), \quad (2)$$

$$(x, y) \vee (x', y') = \max((x, y), (x', y')). \quad (3)$$

Due to the total order, it is easy to prove that $\wedge$ and $\vee$ are respectively an extended norm and an extended co-norm.

Similarly, a negation operator $\neg$ can be defined by:

$$\neg(x, y) = (1-x, 1-y). \quad (4)$$

Next proof shows that the De Morgan laws are preserved:

$$\neg(x, y) \vee \neg(x', y') = \neg[(x, y) \wedge (x', y')]$$

$$\neg(x, y) \wedge \neg(x', y') = \neg[(x, y) \vee (x', y')].$$

Proof. We consider $(x, y) \wedge (x', y') = \min((x, y), (x', y')) = (x, y)$. The properties to demonstrate obviously hold when ($x = x'$) and ($y = y'$). When ($x \neq x'$) or ($y \neq y'$), we get ($x < x'$ or (($x = x'$) and ($y < y'$)). The complementation to one gives : ($1-x > 1-x'$) or ((1- x = 1-x') and ($1-y > 1-y'$)). As a consequence $(1 - x, 1 -y) \vee (1-x', 1-y') = (1-x, 1-y)$ which can be rewritten $\neg(x, y) \vee \neg(x', y') = \neg(x, y)$. Then we get $\neg(x, y) \vee \neg(x', y') = \neg(x, y) = \neg[(x, y) \wedge (x', y')]$. The first law is then demonstrated and the second one is valid .♦

Example 4. We consider the framework and the query of example 2 ("a *cheap* journey, if possible with a *small* flight time, and an hotel in a *small* town, if possible located *in the countryside*). Constraint C_1 is the fuzzy condition "a *cheap* journey", W_1 is the fuzzy wish "a *cheap* journey with a *small* flight time" and C_2 is the fuzzy constraint "hotel in a *small* town" while W_2 is the fuzzy wish "hotel in a *small* town and *in the countryside*".
When the norm $\wedge$ is chosen, the conjunction returns the worst case between (C_1,W_1) and (C_2,W_2) and the meaning of the query is a pure conjunction (the worst evaluation being retained). We get the results provided by Table 7.

Table 7 : Results provided by norm $\wedge$

#Trip	μ_C(#Trip)	μ_W(#Trip)
#1	0.9	0.7
#2	0.9	0.5
#3	0.9	0.3
#4	0.6	0.5
#5	0.6	0.5

We obtain the order : #1 > #2 > #3 > #4 = #5.

Here again, the obtained order is different from the ones provided by $O_{min,\ max}$ and $O_{min,\ min}$ (the meanings of the operator being different, cf example 3). In addition, one may remark that the fundamental property of fuzzy wish and constraint ($W \subseteq C$) holds in this case (since $\mu_W(\#Trip) \leq \mu_C(\#Trip)$ for any trip). ♦

5 Particular case of fuzzy conditions

This subsection shows the behaviours of the operators defined in the previous sections in the particular case where the fuzzy bipolar conditions are pure constraints ($W = C$).
When dealing with pure constraints, the extended norm $\wedge$ and co-norm $\vee$ are nothing but the norm min and the co-norm max of fuzzy sets.

Proof. We consider $(x, x) \wedge (y, y) = (x, x)$. It means (x, x) is the minimum when the lexicographical order is used which can be rewritten ($x < y$) or ($x = y$) and then:

$$(x, x) \wedge (y, y) = (x, x) = (\min(x, y), \min(x, y)).$$

The expression $(\min(x, y), \min(x, y))$ is the representation (in terms of constraints and wishes) of the minimum of the two degrees x and y which demonstrate that $(x, x) \wedge (y, y)$ represents the norm min. A similar proof holds for $\vee$ and the co-norm max.♦

The extended norm $\wedge$ and co-norm $\vee$ can also be defined by the parameterized operator $O_{op1,op2}$ where op_1 equals op_2 and is either the minimum or the maximum (it is not the case in general since $\wedge$ and $\vee$ cannot be expressed by $O_{op1,op2}$, as example $(0.6, 0.8) \wedge (0.5, 1) = (0.5, 1)$ while $(0.6, 0.8)\ O_{min,\ min}\ (0.5, 1) = (0.5, 0.8)$).

Proof. We consider $(x, x) \wedge (y, y) = (x, x)$ and $(x, x) \vee (y, y) = (y, y)$. It means ($x < y$) or ($x = y$) and then :

$$(x, x) \wedge (y, y) = (x, x) = (\min(x, y), \min(x, y))$$
$$= (x, x)\ O_{min,\ min}\ (y, y),$$
$$(x, x) \vee (y, y) = (y, y) = (\max(x, y), \max(x, y))$$
$$= (x, x)\ O_{max,\ max}\ (y, y).\ ♦$$

More generally, when op_1 equals op_2 the parameterized operator $O_{op1,op2}$ is either a norm or a co-norm between two fuzzy sets (the one chosen to implement op_1 and op_2).
The main question is about the meaning of $O_{op1,op2}$ when op_1 and op_2 differs. First of all, for a sake of simplicity, we assume that op_1 is a norm. Since the lexicographical order is used, it is possible to claim that $O_{op1,op2}$ allows for a refinement of norm op_1 since results are firstly ranked on the degree provided by op1, op_2 being only used to discriminate among elements having same degrees for the norm op_1. Similarly, when op1 is a co-norm, the lexicographical order provides a refinement of this co-norm.

ISBN: 978-989-95079-6-8

Example 5. We consider four items x,y,z and t which are valuated using a conjunction between the satisfactions of two fuzzy bipolar conditions FBC1 and FBC2 (cf. Table 8).

Table 8 : Satisfactions with respect to FBC1 and FBC2

item	FBC1	FBC2
x	(0.7, 0.7)	(0.8,0.8)
y	(0.5, 0.5)	(1, 1)
z	(0.5, 0.5)	(0.8, 0.8)
t	(0.3, 0.3)	(1, 1)

The satisfactions with respect to the conjunction are given by Table 9.

Table 9 : Satisfactions with respect to the conjunction

item	FBC1 $O_{min, min}$ FBC2	FBC1 $O_{min, max}$ FBC2
x	(0.7, 0.7)	(0.7,0.8)
y	(0.5, 0.5)	(0.5, 1)
z	(0.5, 0.5)	(0.5, 0.8)
t	(0.3, 0.3)	(0.3, 1)

When the minimum ($O_{min, min}$) is considered we get $x > y = z > t$, while $O_{min, max}$ gives $x > y > z > t$. The operator $O_{min, max}$ allows to discriminate elements y and z which are undistinguishable when $O_{min, min}$ is considered. ♦

6 Conclusion

This paper has dealt with the evaluation of fuzzy bipolar conditions into fuzzy queries addressed to a regular relational database (where the stored data are precisely known). Such conditions are made of two components: a mandatory condition (also called a constraint) and an optional condition (also called a wish). More precisely, we have considered fuzzy bipolar conditions where the constraint and the wish express user preferences and are defined by fuzzy sets. In particular, we have shown that a fuzzy bipolar condition is a generalization of a fuzzy condition (defined by a fuzzy set) and several operators to aggregate fuzzy bipolar conditions have been defined.

This paper has pointed out the importance to define an extended norm and an extended co-norm for fuzzy bipolar conditions. It proposes a couple of extended norm and co-norm which is a generalization of the couple (min, max) of fuzzy sets. In the particular case where fuzzy bipolar conditions are fuzzy conditions, some proposed operators leads to a refinement of norm and conorm as it is the case for the leximin and discrimin orders [13].

Abstract— This paper presents a new abstract framework to deal in a uniform way with the increasing variety of fuzzy logics studied in the literature. By means of notions and techniques from Abstract Algebraic Logic, we perform a study of non-classical logics based on the kind of generalized implication connectives they possess. It yields the new *hierarchy of implicational logics*. In this framework the notion of *implicational semilinear logic* can be naturally introduced as a property of the implication, namely a logic L is an implicational semilinear logic iff it has an implication such that L is complete w.r.t. the matrices where the implication induces a linear order, a property which is typically satisfied by well-known systems of fuzzy logic. The hierarchy of implicational logics is then restricted to the semilinear case obtaining a classification of implicational semilinear logics that encompasses almost all the known examples of fuzzy logics and suggests new directions for research in the field.

Keywords— Abstract Algebraic Logic, Implicative logics, Leibniz Hierarchy, Mathematical Fuzzy Logic, Semilinear logics.

1 Introduction

Mathematical Fuzzy Logic is the subdiscipline of Mathematical Logic which studies the logical systems that, since the inception of the theory of fuzzy sets, have been proposed to deal with the reasoning with predicates that can be modelled by fuzzy sets. The first ones, coming from the many-valued logic tradition, were Łukasiewicz and Gödel-Dummett logics, both complete w.r.t. the semantics given by a continuous t-norm. Later, a third system with this feature was introduced: product logic. Starting from these three main examples, the area has followed a long process of increasing generalization that has led to wider and wider classes of fuzzy logics. The first step was taken by Hájek [14] when he proposed the Basic fuzzy Logic BL, which turn out to be complete w.r.t. the semantics of all continuous t-norms. Later on, to put it in Hájek's words, scholars kept *removing legs from the flea* by considering weaker notions of fuzzy logic: divisibility was removed in the logic MTL [8] which is complete w.r.t. the semantics of all left-continuous t-norms, negation was removed when considering fuzzy logics based on hoops [9], commutativity of t-norms was disregarded in [13], and t-norms were replaced by *uninorms* in [16]. On the other hand, logics with a higher expressive power were introduced by considering expanded real-valued algebras (with projection Δ, involution $\sim$, truth-constants, etc.), and in recent works fuzzy logics have started emancipating from the real-valued algebras as the only intended semantics by considering systems complete w.r.t. rational, finite or hyperreal linearly ordered algebras [5].

When dealing with this huge variety of fuzzy logics one may want to have some tools to prove general results that apply not only to a particular logic, but to a class of logics. To some extent this has been achieved by means of the notions of core and Δ-core fuzzy logics [15] and results for these classes can be already found in a number of papers. However, those classes contain roughly just expansions of MTL and $\mathrm{MTL}_\triangle$ logics, so they do not cover weaker systems such as those from [16]. This shows that general notions of fuzzy logics are very useful, but we need to look for a more abstract framework to cope with all known examples and with other new logics that may arise in the near future.

In doing so, one certainly needs some intuition about the class of objects he would like to mathematically determine, namely some intuition of what are the minimal properties that should be required for a logic to be fuzzy. The evolution outlined above shows that almost no property of these systems was essential as they were step-by-step disregarded. Nevertheless, there is one that has remained untouched so far: *completeness w.r.t. a semantics based on linearly ordered algebras*. It actually corresponds to the main thesis of [1] that defends that *fuzzy logics are the logics of chains*. Such a claim must be read as a methodological statement, pointing at a roughly defined class of logics, rather than a precise mathematical description of what fuzzy logics are, since there could be many different ways in which a logic might enjoy a complete semantics based on chains. The aim of the present paper is to use some notions and techniques from Abstract Algebraic Logic (AAL) to provide a new framework where we can develop in a natural way a particular technical notion corresponding to the intuition of fuzzy logics as the logics of chains. Namely, we will present the *hierarchy of implicational logics* as a new classification of non-classical logics extending the well-known *Leibniz hierarchy* and encompassing other important classes such as implicative logics [18] and weakly implicative logics [4]. Inside this new hierarchy we will build a very general class of fuzzy logics that we will call *implicational semilinear logics*.

The technical aspects of this paper are based on the submitted work [6] however it concentrates on presenting the justification of our new framework from the point of view of Mathematical Fuzzy Logic. Section 2 describes our general setting and Section 3 informally summarizes our arguments. The remaining sections present samples of technical arguments supporting our thesis. Finally, Appendix A recalls crucial preliminary notions from the theory of logical calculi.

2 The hierarchy of implicational logics

Although implication in the vast majority of existing fuzzy logics is given by a single (primitive or derived) connective, we follow a long-established tradition of Abstract Algebraic Logic and consider that implication could be given by a (possibly parameterized) set of formulae. However the following convention will allow us to hide this feature of our approach, providing a high level of abstraction without any apparent increase of complexity. Let $\Rightarrow(p, q, \overrightarrow{r})$ be a set of $\mathcal{L}$-formulae in two variables and, possibly, with a sequence of parameters $\overrightarrow{r}$. Given formulae φ, ψ and a sequence of formulae $\overrightarrow{\alpha}$, $\Rightarrow(\varphi, \psi, \overrightarrow{\alpha})$ denotes the set obtained by substituting the variables in $\Rightarrow(p, q, \overrightarrow{r})$ by the corresponding formulae, and $\varphi \Rightarrow \psi$ denotes the set $\bigcup\{\Rightarrow(\varphi, \psi, \overrightarrow{\alpha}) \mid \overrightarrow{\alpha} \in \mathrm{Fm}_{\mathcal{L}}^{<\omega}\}$.

We generalize the following properties, typically satisfied by an implication, to sets of (parameterized) formulae. However a reader can always understand these conditions as if $\Rightarrow$ would be just a single binary connective.

Definition 1. *Let* L *be a logic and* $\Rightarrow(p, q, \overrightarrow{r}) \subseteq \mathrm{Fm}_{\mathcal{L}}$ *be a parameterized set of formulae. We say that* $\Rightarrow$ *is a* weak p-implication *in* L *if:*

$$
\begin{array}{ll}
\text{(R)} & \vdash_{\mathrm{L}} \varphi \Rightarrow \varphi \\
\text{(MP)} & \varphi, \varphi \Rightarrow \psi \vdash_{\mathrm{L}} \psi \\
\text{(T)} & \varphi \Rightarrow \psi, \psi \Rightarrow \chi \vdash_{\mathrm{L}} \varphi \Rightarrow \chi \\
\text{(sCng)} & \varphi \Rightarrow \psi, \psi \Rightarrow \varphi \vdash_{\mathrm{L}} c(\chi_1, \ldots, \chi_i, \varphi, \ldots, \chi_n) \\
 & \Rightarrow c(\chi_1, \ldots, \chi_i, \psi, \ldots, \chi_n) \\
 & \text{for each } \langle c, n\rangle \in \mathcal{L} \text{ and each } i < n
\end{array}
$$

We change the prefix 'weak' to 'algebraic' if there is a set $\mathcal{E}(p)$ *of equations in one variable such that*

$$\text{(Alg)} \quad p \dashv\vdash_{\mathrm{L}} E[\mathcal{E}(p)],$$

where $E(p, q, \overrightarrow{r}) = \Rightarrow(p, q, \overrightarrow{r}) \cup \Rightarrow(q, p, \overrightarrow{r})$
We change the prefix 'weak' to 'regular' if:

$$\text{(Reg)} \quad \varphi, \psi \vdash_{\mathrm{L}} \psi \Rightarrow \varphi$$

We change the prefix 'weak' to 'Rasiowa' if:

$$\text{(W)} \quad \varphi \vdash_{\mathrm{L}} \psi \Rightarrow \varphi$$

Finally, if $\Rightarrow$ *is parameter-free we drop the prefix 'p-'.*

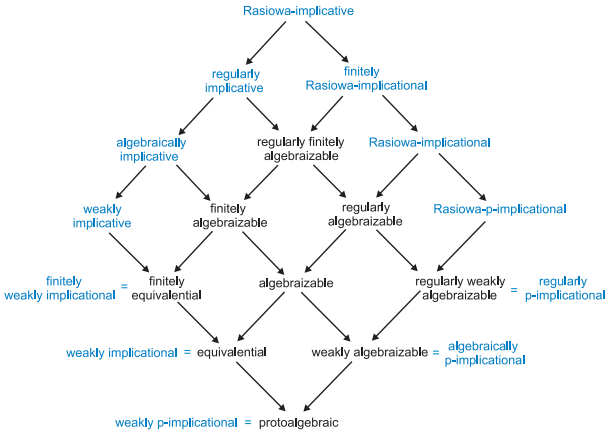
We can easily show the relative strength of defined notions: each Rasiowa p-implication is a regular p-implication and each regular p-implication is an algebraic p-implication.

Definition 2. *We say that a logic* L *is a* weakly/algebraically/regularly/Rasiowa- (p-)implicational logic *if there is a (parameterized) set of formulae* $\Rightarrow$ *which is a weak/algebraic/regular/Rasiowa (p-)implication in* L. *We add the prefix* 'finitely' *if* $\Rightarrow$ *is finite and we use the adjective* 'implicative' *instead of* 'implicational' *if* $\Rightarrow$ *is a* parameter-free singleton.

Each class of the well-known Leibniz hierarchy [7] coincides with some of our newly defined classes. In fact, our new taxonomy extends it, incorporates other already existing classes of logics,[1] and offers a more systematic way of classification: in one axis we go from p-implicational, implicational, finitely implicational to implicative (depending on the form of the implication set); in the second one we use prefixes 'weakly', 'algebraically', 'regularly', or 'Rasiowa-' (depending on extra properties fulfilled by that set). The translation table is:

Classes of Leibniz hierachy	*Our systematic names*
protoalgebraic	weakly p-implicational
(finitely) equivalential	(finitely) weakly impl.
weakly algebraizable	algebraically p-impl.
regularly weakly algebraizable	regularly p-implicational
(finitely) algebraizable	(finitely) algebraically impl.
(finitely) regularly algebraizable	(finitely) regularly impl.

Our new classification of logics, *the hierarchy of implicational logics* is depicted below (the arrows correspond to the class subsumption relation). We can show that almost all classes of logics in this hierarchy are mutually different; only the difference between Rasiowa-implicational and Rasiowa-p-implicational logics remains to be shown.



The syntactical notion of weak p-implication that we have introduced has a natural semantical counterpart: a preorder in the models that becomes an order in reduced models.

Definition 3. *Let* $\Rightarrow$ *be a parameterized set of formulae and* $\mathbf{A} = \langle \mathcal{A}, F\rangle$ *a matrix. We define a binary relation* $\leq_{\mathbf{A}}^{\Rightarrow}$ *on* A*:*

$$a \leq_{\mathbf{A}}^{\Rightarrow} b \qquad \textit{iff} \qquad a \Rightarrow^{\mathcal{A}} b \subseteq F.$$

Proposition 1. *Let* L *be a logic and* $\mathbf{A} \in \mathbf{MOD}(\mathrm{L})$*. Then a parameterized set* $\Rightarrow$ *is a weak p-implication in* L *iff* $\leq_{\mathbf{A}}^{\Rightarrow}$ *is a preorder and its symmetrization of* $\leq_{\mathbf{A}}^{\Rightarrow}$ *is the Leibniz congruence of* $\mathbf{A}$.

Clearly $\leq_{\mathbf{A}}^{\Rightarrow}$ is an order iff $\mathbf{A}$ is reduced. Thus (by virtue of Theorem 10) we can say that a L is complete w.r.t. the class of ordered matrices. Our main interest are the logics complete w.r.t. linearly ordered matrices in the following sense:

Definition 4. *Let* L *be a logic and* $\mathbf{A} = \mathbf{MOD}(\mathrm{L})$*. We say that* $\mathbf{A}$ *is a* linear model *w.r.t.* $\Rightarrow$ *if* $\leq_{\mathbf{A}}^{\Rightarrow}$ *is a linear order. The class of linear models of* L *is denoted by* $\mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$.

Observe that the class of linear models is not intrinsically defined for a given logic as it depends on the chosen implication. However, we will see later that in a reasonably wide class of logics all *semilinear implications* define the same linear models. But even in a general case we can prove:

Theorem 1. *Let* L *be a protoalgebraic logic. Then, for any weak p-implication* $\Rightarrow$*,* $\mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L}) \subseteq \mathbf{MOD}^{*}(\mathrm{L})_{\mathrm{RFSI}}$.

[1] Rasiowa-implicative logics were already defined in 1974 by Rasiowa [18] and weakly implicative logics in 2006 by Cintula [4].

3 Semilinear implications and logics

Given a logic L and a weak p-implication $\Rightarrow$, we say that $\Rightarrow$ is a weak *semilinear* p-implication if the logic is complete w.r.t. the class of its corresponding linear models. Formally:

Definition 5. *Let* L *be a logic and* $\Rightarrow$ *a weak p-implication. We say that* $\Rightarrow$ *is a weak* semilinear *p-implication if*

$$\vdash_{\mathrm{L}} \;=\; \models_{\mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})}.$$

Later we define *implicational semilinear logics* as those possessing some weak semilinear p-implication. Obviously, they will be fuzzy logics in the sense of [1]. However, we choose the term 'semilinear' instead of 'fuzzy' in spite of the fact that a first step towards the general definition we are offering here had been done by the first author in [4], when he defined the class of *weakly implicative fuzzy logics* (in our new framework: logics with a weak semilinear implication given a single binary connective). We have realized that the attempt of [4] of using the term 'fuzzy' to formally define a class of logics was rather futile as such word is heavily charged with many conflicting potential meanings.

Therefore, we have opted now for the new neutral name 'semilinear'. The term was first used by Olson and Raftery in [17] in the context of residuated lattices; it refers to the Universal Algebra tradition of calling a class of algebras 'semi$X$' whenever its subdirectly irreducible members have the property X (how this is related to our case will be apparent after Theorem 3). Despite using a new neutral name our intention remains the same: to formally delimit the class of fuzzy logics inside some existing abstract class of formal non-classical logics (originally, among weakly implicative ones now among the protoalgebraic ones). Of course it should include almost all the prominent examples of fuzzy logics known so far and exclude non-classical logics which are usually not recognized as fuzzy logics in the Logic community.

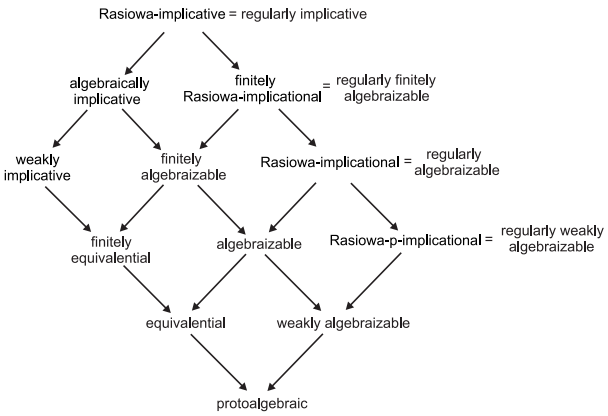
However let us stress that we *do not* expect to capture in a mathematical definition *the whole* intuitive notion of *arbitrary* fuzzy logic. Even if we would agree that linearity of semantics is crucial for a formal logic to be *fuzzy* there could be several other ways in which a logic might have a complete semantics somehow based on chains (see e.g. [2] or some recent work on modal fuzzy logics).

We formally define classes of implicational semilinear logics based on the form of semilinear implication they possess.

Definition 6. *We say that* L *is a* weakly/algebraically/ Rasiowa- (p-)implicational semilinear logic *if there is a (parameterized) set of formulae* $\Rightarrow$ *such that it is a weak/algebraic/Rasiowa semilinear (p-)implication in* L. *We add the* 'finitely' *if the set* $\Rightarrow$ *is finite and we use* 'implicative' *instead of* 'implicational' *if* $\Rightarrow$ *is a parameter-free singleton.*

We have not defined the class of *regularly* (p-)implicational (implicative) semilinear logics, because (as we will see in Corollary 2) we would obtain that each regularly p-implicational semilinear logic is a Rasiowa-p-implicational semilinear logic (and analogously for the other three Rasiowa-classes in the hierarchy of implicational logics). See all the classes and their inclusions in the next figure.

We can prove the mutual difference of many classes, but three differences remain to be seen: Rasiowa-implicational



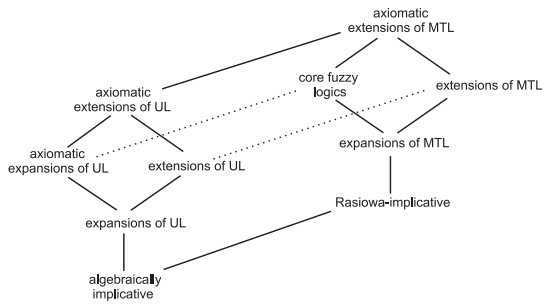
semilinear logics $\neq$ Rasiowa-p-implicational semilinear logics, algebraizable semilinear logics $\neq$ weakly algebraizable semilinear logics, and equivalential semilinear logics $\neq$ protoalgebraic semilinear logics.

Proposition 2. *Let* $\mathcal{X}$ *be any class in the hierarchy of implicational logics. Then, there is an* $\mathcal{X}$ *logic which is not an* $\mathcal{X}$ *semilinear logic.*

The three main logics based on continuous t-norms (Łukasiewicz, Gödel-Dummett, and Product logics) as well as the logic of all continuous t-norms BL are clearly Rasiowa-implicative semilinear logics. The same can be said in general as regards to left-continuous t-norm-based logics such as MTL and its t-norm based axiomatic extensions, and even for all *axiomatic extensions of MTL* (even those which are not complete w.r.t. a semantics of t-norms) as all of them are complete w.r.t. a subvariety of MTL-algebras generated by its linearly ordered members. Two incomparable superclasses of this one have been considered in the literature. On one hand, we have the so-called *core fuzzy logics* introduced in [15] as finitary logics expanding MTL or $\mathrm{MTL}_{\triangle}$, satisfying (sCng) for $\rightarrow$, and one of the following forms of Deduction Theorem: (i) $T, \varphi \vdash_{\mathrm{MTL}_{\triangle}} \psi$ iff $T \vdash_{\mathrm{MTL}_{\triangle}} \Delta\varphi \rightarrow \psi$, for expansions of $\mathrm{MTL}_{\triangle}$, or (ii) $T, \varphi \vdash_{\mathrm{MTL}} \psi$ iff there is $n \in \mathbb{N}$ such that $T \vdash_{\mathrm{MTL}} \varphi^n \rightarrow \psi$, for expansions of MTL. On the other hand, we can consider the class of all *semilinear finitary extensions of MTL*. Their equivalent quasivariety semantics are the subquasivarieties of MTL-algebras generated by chains. Since there are such quasivarieties that are not varieties, we have that this class is strictly bigger than that of axiomatic extensions of MTL. Both incomparable classes are included in the class of *semilinear expansions of MTL*, and finally this one is included in the Rasiowa-implicative semilinear logics. In the recent paper [16] the fuzzy logic UL based on uninorms instead of t-norms has been studied. It is an algebraizable logic without weakening, so it belongs to the class of algebraically implicative semilinear logics. We can consider the same structure of classes as above without weakening by replacing MTL for UL. See the resulting hierarchy of classes of semilinear logics in the next figure. We realize that all of them lie on the top of our classification, above Rasiowa-implicative or algebraically implicative semilinear logics. But if, by means of our definition of semilinear implication presented in this paper, we have succeeded in capturing an interesting way by which a logic can be fuzzy this means that fuzzy logics are a much wider class than those studied so far. Thus,

ISBN: 978-989-95079-6-8

future research in the field will probably bring new significant examples of fuzzy logics throughout the whole hierarchy of implicational semilinear logics.



4 Characterizations of semilinearity

This section provides some useful mathematical characterization of semilinear implications. First we define:

Definition 7. *Let* $\mathbf{A} = \langle \mathcal{A}, F \rangle \in \mathbf{MOD}(\mathrm{L})$. *The filter* F *is called* $\Rightarrow$-linear *if* $\leq^{\Rightarrow}_{\mathbf{A}}$ *is a total preorder.*

We say that L *has the* Linear Extension Property (LEP) *w.r.t.* $\Rightarrow$ *if for every theory* $T \in Th(\mathrm{L})$ *and every formula* $\varphi \in \mathrm{Fm}_{\mathcal{L}} \setminus T$, *there is a* $\Rightarrow$*-linear theory* $T' \supseteq T$ *s.t.* $\varphi \notin T'$.

Notice that a matrix $\langle \mathcal{A}, F \rangle \in \mathbf{MOD}(\mathrm{L})$ is in $\mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$ iff it is reduced and F is $\Rightarrow$-linear. Clearly the (LEP) says that the $\Rightarrow$-linear theories form a basis of the closure system $Th(\mathrm{L})$. Next theorem shows that an analogous statement holds for other than Lindenbaum matrices, as one of the so-called 'transfer principles' from AAL.

Theorem 2. *Let* L *be a finitary logic with* (LEP) *w.r.t.* $\Rightarrow$ *and* $\mathcal{A} \in \mathbf{ALG}^{*}(\mathrm{L})$. *Then* $\Rightarrow$*-linear filters form a basis of* $\mathcal{F}i_{\mathrm{L}}(\mathcal{A})$.

Next we generalize the 'Prelinearity property' from [4]. However, here we prefer the new name 'Semilinearity Property' following our new terminology.

Definition 8. *We say that* L *has the* Semilinearity Property (SLP) *w.r.t.* $\Rightarrow$ *if the following meta rule is valid:*

$$\frac{\Gamma, \varphi \Rightarrow \psi \vdash_{\mathrm{L}} \chi \qquad \Gamma, \psi \Rightarrow \varphi \vdash_{\mathrm{L}} \chi}{\Gamma \vdash_{\mathrm{L}} \chi}$$

Theorem 3 (Characterization of semilinear implications). *The following are equivalent:*

1. $\Rightarrow$ *is semilinear in* L,
2. L *has the* (LEP) *w.r.t.* $\Rightarrow$.

Furthermore, if L *is finitary we can add:*

3. L *has the* (SLP) *w.r.t.* $\Rightarrow$,
4. $\mathbf{MOD}^{*}(\mathrm{L})_{\mathrm{RSI}} \subseteq \mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$.

Moreover, if $\Rightarrow$ *is finite we can add:*

5. $\mathbf{MOD}^{*}(\mathrm{L})_{\mathrm{RFSI}} \subseteq \mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$.

The previous theorem has several important corollaries. Using Theorem 1 we obtain that, at least in a reasonably wide class of logics, being the class of linear models w.r.t. any finite semilinear implication is an intrinsic property of a logic.

Corollary 1. *Let* L *be a finitary protoalgebraic logic and* $\Rightarrow$ *a finite weak semilinear p-implication. Then* $\mathbf{MOD}^{*}(\mathrm{L})_{\mathrm{RFSI}} = \mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$.

Corollary 2. *Each regular semilinear p-implication is a Rasiowa p-implication.*

Corollary 3. *Let* $\Rightarrow$ *a weak semilinear p-implication in* L. *Then,* $\Rightarrow$ *is semilinear in all axiomatic extensions of* L.

This last corollary will be particulary useful for showing that some logic has *no* semilinear implication. It is quite easy to show that an implication in some logic is not semilinear, consider e.g. the normal implication of the intuitionistic logic; the well-know fact that the linear Heyting algebras do not generate the variety of Heyting algebras does the job. However using part 5. of the characterization theorem we can show much more: there is *no weak semilinear p-implication definable* in the intuitionistic logic, i.e. not only the standard nice Rasiowa implication given by a single formula is not semilinear but even using an infinite set with parameters we could never obtain an implication whose linearly ordered Heyting algebras would generate the variety of Heyting algebras.

Proposition 3. *Let* L *be the logic of a quasivariety of pointed residuated lattices containing the variety of Heyting algebras. Then,* L *is not weakly semilinear p-implicational logic.*

Many well-known logics fall under the scope of the previous proposition: Full Lambek logic (possibly extended with structural rules), multiplicative-additive fragment of (Affine) Intuitionistic Linear logic, Relevance logic R, etc.

Corollary 4. *Let* L *be a logic and* $\Rightarrow$ *a weak p-implication. Then, there is the weakest logic extending* L *where* $\Rightarrow$ *is semilinear. Let us denote this logic as* $\mathrm{L}^{\ell}_{\Rightarrow}$.

In Section 6 we will show how to axiomatize $\mathrm{L}^{\ell}_{\Rightarrow}$. However, to determine a complete semantics is simple:

Proposition 4. *Let* $\Rightarrow$ *be a weak p-implication in* L. *Then,* $\mathrm{L}^{\ell}_{\Rightarrow} = \models_{\mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})}$ *and* $\mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L}^{\ell}_{\Rightarrow}) = \mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$.

5 Disjunctions

In order to provide additional characterizations of semilinearity (and to fill the gap between our abstract setting and real-life logics) we need to study a generalized notion of disjunction. As in the case of implication, given a parameterized set of formulae $\nabla(p, q, \overrightarrow{r})$ and formulae φ and ψ we define $\varphi \nabla \psi$.

Definition 9. *Given a logic* L *and a parameterized set of formulae* ∇, *we define the following properties:*

(PD)	$\varphi \vdash_{\mathrm{L}} \varphi \nabla \psi \quad$ *and* $\quad \psi \vdash_{\mathrm{L}} \varphi \nabla \psi$
(C)	$\varphi \nabla \psi \vdash_{\mathrm{L}} \psi \nabla \varphi$
(I)	$\varphi \nabla \varphi \vdash_{\mathrm{L}} \varphi$
(A)	$\varphi \nabla (\psi \nabla \chi) \dashv\vdash_{\mathrm{L}} (\varphi \nabla \psi) \nabla \chi$
(PCP)	*If* $\Gamma, \varphi \vdash_{\mathrm{L}} \chi$ *and* $\Gamma, \psi \vdash_{\mathrm{L}} \chi$, *then* $\Gamma, \varphi \nabla \psi \vdash_{\mathrm{L}} \chi$.

They correspond to well known usual properties of disjunction connectives. (C), (I) and (A) are respectively commutativity, idempotency and associativity, which are typically also satisfied by conjunction connectives. In contrast, the (PCP) is typically satisfied only by disjunction connectives. In [6] we also study a weaker variant of (PCP) for $\Gamma = \emptyset$.

ISBN: 978-989-95079-6-8

Definition 10. *Given a logic* L *and a parameterized set of formulae* $\nabla(p, q, \overrightarrow{r})$ *and a set of properties* $\sigma \subseteq \{(\mathrm{C}), (\mathrm{I}), (\mathrm{A})\}$*, we say that* ∇ *is a* σ-p-protodisjunction *in* L *if* (PD) *and the properties of* σ *are satisfied. Furthermore a p-protodisjunction* ∇ *is a* p-disjunction *if it satisfies* (PCP)*. Finally, if* ∇ *has no parameters we drop the prefix 'p-'.*

All these defined notions are mutually distinct and any p-disjunction is in fact a $\{(\mathrm{C}), (\mathrm{I}), (\mathrm{A})\}$-p-protodisjunction. Moreover, the notion of p-disjunction is intrinsic as any two p-disjunctions are mutually interderivable.

Definition 11. *We call a logic* (p-)disjunctional *if it has a (p-)disjunction. Furthermore, we call a logic* disjunctive *if it has a disjunction given by a single parameter-free formula.*

The classes of disjunctive and disjunctional logics are mutually different. E.g. the implication fragment of Gödel logic is not disjunctive but the set $\{(p \to q) \to q, (q \to p) \to p\}$ is its disjunction.

Definition 12. *Let* L *be a logic,* ∇ *a parameterized set of formulae,* $\mathcal{A} \in \mathbf{ALG}^*(\mathrm{L})$*, and* $F \in \mathcal{F}i_{\mathrm{L}}(\mathcal{A})$*. F is called* ∇-prime *if for every* $a, b \in A$*,* $a\nabla^{\mathcal{A}}b \subseteq F$ *iff* $a \in F$ *or* $b \in F$*.*

The *prime extension property* (PEP) is defined as the (LEP) by substituting the notion of $\Rightarrow$-linear filter for that of ∇-prime filter. Then we can prove:

Theorem 4. *Let* L *be a finitary logic and* ∇ *a p-protodisjunction. Then* L *has the* (PEP) *iff* ∇ *is p-disjunction.*

Theorem 5. *Let* L *be a finitary p-disjunctional logic. Then* ∇*-prime filters form a basis of* $\mathcal{F}i_{\mathrm{L}}(\mathcal{A})$ *for any* $\mathcal{A} \in \mathbf{ALG}^*(\mathrm{L})$*.*

Now we provide a syntactical characterization of (PCP). Let us by R^{∇} (for an $\mathcal{L}$-consecution $R = \Gamma \rhd \varphi$) denote the set $\{\Gamma\nabla\chi \rhd \delta \mid \chi \in \mathrm{Fm}_{\mathcal{L}}$ and $\delta \in \varphi\nabla\chi\}$.

Theorem 6. *Let* L *be a finitary logic with a presentation* $\mathcal{AS}$ *and* ∇ *a* $\{(\mathrm{C}), (\mathrm{I})\}$*-p-protodisjunction. Then, the following are equivalent:*

1. ∇ *is a p-disjunction,*
2. $R^{\nabla} \subseteq \mathrm{L}$ *for each (finitary)* $R \in \mathrm{L}$*,*
3. $R^{\nabla} \subseteq \mathrm{L}$ *for each* $R \in \mathcal{AS}$*.*

Corollary 5. *Let* ∇ *be a p-disjunction in a finitary logic* L_1 *and* L_2 *an expansion of* L_1 *by a set of consecutions* $\mathcal{C}$*. Then:*

- ∇ *is a p-disjunction in* L_2 *if* $R^{\nabla} \subseteq \mathrm{L}_2$ *for each* $R \in \mathcal{C}$*.*
- *If all the consecutions from* $\mathcal{C}$ *are finitary, then* $R^{\nabla} \subseteq \mathrm{L}_2$ *for each* $R \in \mathcal{C}$ *iff* ∇ *is a p-disjunction in* L_2*.*
- *If all the consecutions from* $\mathcal{C}$ *are axioms, then* ∇ *is a p-disjunction.*

Definition 13. *Let* L *be a logic and* ∇ *a parameterized set of formulae. We denote by* L^{∇} *the least logic extending* L *where* ∇ *is a p-disjunction.*

Theorem 7. *Let* L *be a finitary logic with a finitary presentation* $\mathcal{AS}$ *and* ∇ *a* $\{(\mathrm{C}), (\mathrm{I}), (\mathrm{A})\}$*-p-protodisjunction. Then,* L^{∇} *is axiomatized by* $\mathcal{AS} \cup \bigcup\{R^{\nabla} \mid R \in \mathcal{AS}\}$*.*

6 Disjunctions and semilinearity

In this section we consider the interesting relationships between the several kinds of disjunctions and implications we have defined and their corresponding properties. First, we introduce two natural syntactical conditions: a version of Modus Ponens with disjunction (DMP): $\varphi \Rightarrow \psi, \varphi\nabla\psi \vdash_{\mathrm{L}} \psi$ and $\varphi \Rightarrow \psi, \psi\nabla\varphi \vdash_{\mathrm{L}} \psi$, and a generalization of the prelinearity axiom used in fuzzy logics (P): $\vdash_{\mathrm{L}} (\varphi \Rightarrow \psi)\nabla(\psi \Rightarrow \varphi)$.

Theorem 8. *Let* L *be a logic,* ∇ *a p-protodisjunction, and* $\Rightarrow$ *a weak p-implication.*

- *If* L *fulfills* (DMP)*, we have:*
  1. *each* $\Rightarrow$*-linear theory is* ∇*-prime,*
  2. *if* $\Rightarrow$ *has the* (LEP)*, then* ∇ *has the* (PEP)*,*
  3. *if* $\Rightarrow$ *has the* (SLP)*, then* ∇ *has the* (PCP)*.*
- *If* L *fulfills* (P)*, we have:*
  4. *each* ∇*-prime theory is* $\Rightarrow$*-linear,*
  5. *if* ∇ *has the* (PEP)*, then* $\Rightarrow$ *has the* (LEP)*.*
- *If* L *fulfills* (P) *and either it is finitary or* $\Rightarrow$ *is finite and parameter-free, we have:*
  6. *if* ∇ *has the* (PCP)*, then* $\Rightarrow$ *has the* (SLP)*.*

This theorem together with known relations of the properties (SLP), (PCP), (PEP), (LEP) and semilinearity (Theorems 3 and 4) allows us to formulate numerous corollaries about their mutual relationships.

Corollary 6. *If* L *is finitary,* ∇ *is a p-protodisjunction, and* $\Rightarrow$ *a weak p-implication, the following are equivalent:*

1. L *satisfies* (DMP) *and* $\Rightarrow$ *is semilinear.*
2. L *satisfies* (DMP) *and* $\Rightarrow$ *has the* (SLP)*.*
3. L *satisfies* (DMP) *and* $\Rightarrow$ *has the* (LEP)*.*
4. L *satisfies* (P) *and* ∇ *has the* (PEP)*.*
5. L *satisfies* (P) *and* ∇ *has the* (PCP)*.*

Thus e.g. a weak p-implication in a finitary p-disjunctional logic L is semilinear iff L satisfies (P). In p-disjunctional logic we can strengthen two important results from the previous section. First, we can remove the precondition of finiteness of implication in Part 5. of Theorem 3.

Corollary 7. *Let* L *be a finitary p-disjunctional logic and* $\Rightarrow$ *a weak p-implication. Then the following are equivalent:*

1. $\Rightarrow$ *is semilinear in* L*,*
2. $\mathbf{MOD}^*(\mathrm{L})_{\mathrm{RFSI}} \subseteq \mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$*.*

Furthermore, in any finitary p-disjunctional protoalgebraic logic it holds that: $\mathbf{MOD}^*(\mathrm{L})_{\mathrm{RFSI}} = \mathbf{MOD}^{\ell}_{\Rightarrow}(\mathrm{L})$ *for any semilinear p-implication* $\Rightarrow$*.*

Theorem 9. *If* L *is finitary,* ∇ *is a* $\{(\mathrm{C}),(\mathrm{I}),(\mathrm{A})\}$*-p-protodisjunction,* $\Rightarrow$ *is a weak p-implication and* L *satisfies* (DMP)*, then* $\mathrm{L}^{\ell}_{\Rightarrow}$ *is the extension of* L^{∇} *by* (P)*.*

Corollary 8. *Let* L *be a finitary p-disjunctional logic and* $\Rightarrow$ *a weak p-implication. Then,* $\mathrm{L}^{\ell}_{\Rightarrow}$ *is extension of* L *by* (P)*.*

A Bits of the theory of logical calculi

We recall some basic definitions and results of Abstract Algebraic Logic.[2] The notion of *propositional language* $\mathcal{L}$ is defined in the usual way (a set of connectives with finite arity). By $\mathbf{Fm}_{\mathcal{L}}$ we denote the free term algebra over a denumerable set of variables in the language $\mathcal{L}$, by $\mathrm{Fm}_{\mathcal{L}}$ we denote its universe and we call its elements $\mathcal{L}$*-formulae*.

A $\mathcal{L}$*-consecution* is a pair $\Gamma \rhd \varphi$, where $\Gamma \subseteq \mathrm{Fm}_{\mathcal{L}}$ and $\varphi \in \mathrm{Fm}_{\mathcal{L}}$. A consecution $\Gamma \rhd \varphi$ is *finitary* if Γ is finite. For a set of consecutions L we write $\Gamma \vdash_{\mathrm{L}} \varphi$ rather than $\Gamma \rhd \varphi \in \mathrm{L}$. A *propositional logic* is a pair $\mathrm{L} = \langle \mathcal{L}, \vdash_{\mathrm{L}} \rangle$ where $\vdash_{\mathrm{L}}$ is a structural consequence relation.

A logic L is *finitary* if for every $\Gamma \cup \{\varphi\} \subseteq \mathrm{Fm}_{\mathcal{L}}$ such that $\Gamma \vdash_{\mathrm{L}} \varphi$ there is a finite $\Gamma_0 \subseteq \Gamma$ such that $\Gamma_0 \vdash_{\mathrm{L}} \varphi$. We write $\Gamma \vdash_{\mathrm{L}} \Delta$ when $\Gamma \vdash_{\mathrm{L}} \varphi$ for every $\varphi \in \Delta$. A *theory* of a logic L is a set of formulae T such that if $T \vdash_{\mathrm{L}} \varphi$ then $\varphi \in T$. By $Th(\mathrm{L})$ we denote the set of all theories of L.

Given a *finitary* logic $\mathrm{L} = \langle \mathcal{L}, \vdash_{\mathrm{L}} \rangle$, we say that a set $\mathcal{AS}$ of $\mathcal{L}$-consecutions whose left member is finite is a *presentation* of L if the relation $\vdash_{\mathrm{L}}$ coincides with the provability relation given by $\mathcal{AS}$ as a Hilbert-style axiomatic system.

Given a language $\mathcal{L}$, an $\mathcal{L}$*-matrix* is a pair $\mathbf{A} = \langle \mathcal{A}, F \rangle$ where $\mathcal{A}$ is an $\mathcal{L}$-algebra and F is a subset of A called the *filter* of $\mathbf{A}$. A homomorphism from $\mathbf{Fm}_{\mathcal{L}}$ to $\mathcal{A}$ is called an $\mathbf{A}$*-evaluation*. The semantical consequence w.r.t. a class of matrices $\mathbb{K}$ is defined as: $\Gamma \models_{\mathbb{K}} \varphi$ iff for each $\mathbf{A} \in \mathbb{K}$ and each $\mathbf{A}$-evaluation e we obtain $e(\varphi) \in F$ whenever $e[\Gamma] \subseteq F$. Clearly, $\langle \mathcal{L}, \models_{\mathbb{K}} \rangle$ is a logic. We say that a matrix $\mathbf{A}$ is a *model* of L if $\vdash_{\mathrm{L}} \subseteq \models_{\mathbf{A}}$ and write $\mathbf{A} \in \mathbf{MOD}(\mathrm{L})$.

Given an $\mathcal{L}$-algebra $\mathcal{A}$, a subset $F \subseteq A$ is an L*-filter* if $\langle \mathcal{A}, F \rangle \in \mathbf{MOD}(\mathrm{L})$. Let $\mathcal{F}i_{\mathrm{L}}(\mathcal{A})$ be the set of all L-filters over $\mathcal{A}$. Observe that for every set of formulae T, we have $T \in Th(\mathrm{L})$ iff $\langle \mathbf{Fm}_{\mathcal{L}}, T \rangle \in \mathbf{MOD}(\mathrm{L})$; these models are called the *Lindenbaum matrices* for L.

It is straightforward to check that $\mathcal{F}i_{\mathrm{L}}(\mathcal{A})$ is closed under arbitrary intersections and hence it is a closure system. Recall that a family $\mathcal{B} \subseteq \mathcal{C}$ is a *basis* of a closure system $\mathcal{C}$ if for every $X \in \mathcal{C}$ there is a $\mathcal{D} \subseteq \mathcal{C}$ such that $X = \bigcap \mathcal{D}$ (which can be equivalent formulated as: for every $Y \in \mathcal{C}$ and every $a \in A \setminus Y$ there is $Z \in \mathcal{B}$ such that $Y \subseteq Z$ and $a \notin Z$).

Given a matrix $\mathbf{A} = \langle \mathcal{A}, F \rangle$, a binary relation $\Omega_{\mathcal{A}}(F)$ is defined as $\langle a, b \rangle \in \Omega_{\mathcal{A}}(F)$ if, and only if, for every sequence of parameters $\overrightarrow{z}$, $\mathcal{L}$-formula $\varphi(x, \overrightarrow{z})$, and $\overrightarrow{c} \in A^{<\omega}$ we have $\varphi^{\mathcal{A}}(a, \overrightarrow{c}) \in F$ iff $\varphi^{\mathcal{A}}(b, \overrightarrow{c}) \in F$. Inspired by the famous Leibniz's identity of indiscernibles principle, $\Omega_{\mathcal{A}}(F)$ is called the *Leibniz congruence* of $\langle \mathcal{A}, F \rangle$.

A matrix is said to be *reduced* if its Leibniz congruence is the identity relation. Given a logic L, the class of its reduced models is denoted by $\mathbf{MOD}^*(\mathrm{L})$, and the class of algebraic reducts of $\mathbf{MOD}^*(\mathrm{L})$ is denoted by $\mathbf{ALG}^*(\mathrm{L})$. They are enough to provide a complete semantics for the logic:

Theorem 10. *Let* L *be a logic. Then* $\Gamma \vdash_{\mathrm{L}} \varphi$ *if, and only if,* $\Gamma \models_{\mathbf{MOD}^*(\mathrm{L})} \varphi$*, for every set of formulae* $\Gamma \cup \{\varphi\}$.

A matrix $\mathbf{A} \in \mathbf{MOD}^*(\mathrm{L})$ is called *(finitely) subdirectly irreducible* if it is not a non-trivial (finite) subdirect product of reduced matrices. The corresponding classes of matrices are denoted as $\mathbf{MOD}^*(\mathrm{L})_{\mathrm{RSI}}$ and $\mathbf{MOD}^*(\mathrm{L})_{\mathrm{RFSI}}$ respectively.

Abstract— *We are interested in representations and characterizations of lattice polynomial functions $f : L^n \to L$, where L is a given bounded distributive lattice. In an earlier paper [4, 5], we investigated certain representations and provided various characterizations of these functions both as solutions of certain functional equations and in terms of necessary and sufficient conditions. In the present paper, we investigate these representations and characterizations in the special case when L is a chain, i.e., a totally ordered lattice. More precisely, we discuss representations of lattice polynomial functions given in terms of standard simplices and we present new axiomatizations of these functions by relaxing some of the conditions given in [4, 5] and by considering further conditions, namely comonotonic minitivity and maxitivity.*

Keywords— Lattice polynomial function, discrete Sugeno integral, normal form, homogeneity, strong idempotency, median decomposability, comonotonicity.

1 Introduction

In [5], the class of (*lattice*) *polynomial functions*, i.e., functions representable by combinations of variables and constants using the lattice operations $\wedge$ and $\vee$, was considered and characterized both as solutions of certain functional equations and in terms of necessary and sufficient conditions rooted in aggregation theory.

Formally, let L be a bounded distributive lattice with operations $\wedge$ and $\vee$, and with least and greatest elements 0 and 1, respectively. An *n-ary polynomial function* on L is any function $f : L^n \to L$ which can be obtained by finitely many applications of the following rules:

(i) For each $i \in [n] = \{1, \ldots, n\}$ and each $c \in L$, the projection $\mathbf{x} \mapsto x_i$ and the constant function $\mathbf{x} \mapsto c$ are polynomial functions from L^n to L.

(ii) If f and g are polynomial functions from L^n to L, then $f \vee g$ and $f \wedge g$ are polynomial functions from L^n to L.

Polynomial functions are also called lattice functions (Goodstein [9]), algebraic functions (Burris and Sankappanavar [3]) or weighted lattice polynomial functions (Marichal [15]). Polynomial functions obtained from projections by finitely many applications of (ii) are referred to as *lattice term functions*.

The recent interest by aggregation theorists in this class of polynomial functions is partially motivated by its connection to noteworthy aggregation functions such as the (*discrete*) *Sugeno integral*, which was introduced by Sugeno [18, 19] and widely investigated in aggregation theory, due to the many applications in fuzzy set theory, data fusion, decision making, image analysis, etc. As shown in [15], the discrete Sugeno integrals are nothing other than those polynomial functions $f : L^n \to L$ which are idempotent, that is, satisfying $f(x, \ldots, x) = x$. For general background on aggregation theory, see [1, 11] and for a recent reference, see [10].

In this paper, we refine our previous results in the particular case when L is a chain, by relaxing our conditions and proposing weak analogues of those properties used in [4, 5], and then providing characterizations of polynomial functions, accordingly. Moreover, and motivated by the axiomatizations of the discrete Sugeno integrals established by de Campos and Bolaños [6] (in the case when $L = [0, 1]$ is the unit real interval), we present further and alternative characterizations of polynomial functions given in terms of comonotonic minitivity and maxitivity. As particular cases, we consider the subclass of discrete Sugeno integrals.

The current paper is organized as follows. We start in §2 by introducing the basic notions needed in this paper and presenting the characterizations of lattice polynomial functions on arbitrary (possibly infinite) bounded distributive lattices, established in [4, 5]. Those characterizations are reassembled in Theorem 1. We discuss representations of polynomial functions in normal form (such as the classical disjunctive and conjunctive normal forms) and introduce variant representations in the case of chains and given in terms of standard simplices in §3. In §4, we present characterizations of polynomial functions on chains given in terms of weak analogues of the properties used in Theorem 1 as well as in terms of comonotonic minitivity and maxitivity. Axiomatizations for the subclass of discrete Sugeno integrals are then presented in §5.

2 Basic notions and terminology

Throughout this paper, let L be a bounded chain with operations $\wedge$ and $\vee$, and with least and greatest elements 0 and 1, respectively. A subset S of a chain L is said to be *convex* if for every $a, b \in S$ and every $c \in L$ such that $a \leqslant c \leqslant b$, we have $c \in S$. For any subset $S \subseteq L$, we denote by $\overline{S}$ the convex hull of S, that is, the smallest convex subset of L containing S. For every $a, b \in S$ such that $a \leqslant b$, the *interval* $[a, b]$ is the set $[a, b] = \{c \in L : a \leqslant c \leqslant b\}$. For any integer $n \geqslant 1$, let $[n] = \{1, \ldots, n\}$.

For any bounded chain L, we regard the Cartesian product L^n, $n \geqslant 1$, as a distributive lattice endowed with the operations $\wedge$ and $\vee$ given by

$$\begin{aligned}(a_1, \ldots, a_n) \wedge (b_1, \ldots, b_n) &= (a_1 \wedge b_1, \ldots, a_n \wedge b_n),\\ (a_1, \ldots, a_n) \vee (b_1, \ldots, b_n) &= (a_1 \vee b_1, \ldots, a_n \vee b_n).\end{aligned}$$

The elements of L are denoted by lower case letters $a, b, c, \ldots$, and the elements of L^n, $n > 1$, by bold face letters $\mathbf{a}, \mathbf{b}, \mathbf{c}, \ldots$.

ISBN: 978-989-95079-6-8

We also use $\mathbf{0}$ and $\mathbf{1}$ to denote the least element and greatest element, respectively, of L^n. For $c \in L$ and $\mathbf{x} = (x_1, \ldots, x_n) \in L^n$, set

$$\mathbf{x} \wedge c = (x_1 \wedge c, \ldots, x_n \wedge c) \quad \text{and} \quad \mathbf{x} \vee c = (x_1 \vee c, \ldots, x_n \vee c).$$

The *range* of a function $f\colon L^n \to L$ is defined by $\mathcal{R}_f = \{f(\mathbf{x}) : \mathbf{x} \in L^n\}$. A function $f\colon L^n \to L$ is said to be *nondecreasing* (*in each variable*) if, for every $\mathbf{a}, \mathbf{b} \in L^n$ such that $\mathbf{a} \leqslant \mathbf{b}$, we have $f(\mathbf{a}) \leqslant f(\mathbf{b})$. Note that if f is nondecreasing, then $\overline{\mathcal{R}}_f = [f(\mathbf{0}), f(\mathbf{1})]$.

Let S be a nonempty subset of L. A function $f\colon L^n \to L$ is said to be

- *S-idempotent* if for every $c \in S$, we have $f(c, ..., c) = c$.
- *S-min homogeneous* if for every $\mathbf{x} \in L^n$ and $c \in S$,
$$f(\mathbf{x} \wedge c) = f(\mathbf{x}) \wedge c. \tag{1}$$
- *S-max homogeneous* if for every $\mathbf{x} \in L^n$ and $c \in S$,
$$f(\mathbf{x} \vee c) = f(\mathbf{x}) \vee c. \tag{2}$$
- *horizontally S-minitive* if for every $\mathbf{x} \in L^n$ and $c \in S$,
$$f(\mathbf{x}) = f(\mathbf{x} \vee c) \wedge f([\mathbf{x}]^c), \tag{3}$$
where $[\mathbf{x}]^c$ is the n-tuple whose ith component is 1, if $x_i \geqslant c$, and x_i, otherwise.
- *horizontally S-maxitive* if for every $\mathbf{x} \in L^n$ and $c \in S$,
$$f(\mathbf{x}) = f(\mathbf{x} \wedge c) \vee f([\mathbf{x}]_c), \tag{4}$$
where $[\mathbf{x}]_c$ is the n-tuple whose ith component is 0, if $x_i \leqslant c$, and x_i, otherwise.
- *median decomposable* if, for every $\mathbf{x} \in L^n$ and $k \in [n]$,
$$f(\mathbf{x}) = \operatorname{median}\big(f(\mathbf{x}_k^0), x_k, f(\mathbf{x}_k^1)\big), \tag{5}$$
where $\operatorname{median}(x, y, z) = (x \wedge y) \vee (y \wedge z) \vee (z \wedge x)$ and $\mathbf{x}_k^c = (x_1, \ldots, x_{k-1}, c, x_{k+1}, \ldots, x_n)$ for $c \in L$.
- *strongly idempotent* if, for every $\mathbf{x} \in L^n$ and $k \in [n]$,
$$f(x_1, \ldots, x_{k-1}, f(\mathbf{x}), x_{k+1}, \ldots, x_n) = f(\mathbf{x}).$$

Remark 1. In the case when $S = L$ is the real interval $[0, 1]$, the concepts of S-min and S-max homogeneity were introduced by Fodor and Roubens [8] to specify certain classes of aggregation functions, and the concept of horizontal S-maxitivity was introduced by Benvenuti et al. [2] as a general property of the Sugeno integral. The concept of median decomposability was introduced in [15] and that of strong idempotency in [4, 5] as properties of polynomial functions.

We say that a function $f\colon L^n \to L$ has a *componentwise convex range* if either $n = 1$ and f has a convex range, or $n > 1$ and for every $\mathbf{a} = (a_1, \ldots, a_n) \in L^n$ and every $k \in [n]$, the unary function $f_{\mathbf{a}}^k\colon L \to L$, given by $f_{\mathbf{a}}^k(x) = f(\mathbf{a}_k^x)$ has a convex range.

The following theorem reassembles the various characterizations of polynomial functions, established in [4], in the particular case when L is a bounded chain.

Theorem 1. *Let $f\colon L^n \to L$ be a function. The following conditions are equivalent:*

(i) *f is a polynomial function.*

(ii) *f is median decomposable.*

(iii) *f is nondecreasing, strongly idempotent, has a convex range and a componentwise convex range.*

(iv) *f is nondecreasing, $\overline{\mathcal{R}}_f$-min homogeneous, and $\overline{\mathcal{R}}_f$-max homogeneous.*

(v) *f is nondecreasing, $\overline{\mathcal{R}}_f$-min homogeneous, and horizontally $\overline{\mathcal{R}}_f$-maxitive.*

(vi) *f is nondecreasing, horizontally $\overline{\mathcal{R}}_f$-minitive, and $\overline{\mathcal{R}}_f$-max homogeneous.*

(vii) *f is nondecreasing, $\overline{\mathcal{R}}_f$-idempotent, horizontally $\overline{\mathcal{R}}_f$-minitive, and horizontally $\overline{\mathcal{R}}_f$-maxitive.*

3 Representations of polynomial functions

Polynomial functions are known to be exactly those functions which can be represented by formulas in disjunctive and conjunctive normal forms. This fact was first observed by Goodstein [9] who, in fact, showed that each polynomial function $f\colon L^n \to L$ is uniquely determined by its restriction to $\{0, 1\}^n$. For a recent reference, see Rudeanu [17].

In this section we recall and refine some known results concerning normal forms of polynomial functions and, in the special case when L is a chain, we present variant representations given in terms of standard simplices of L^n.

The following three results are due to Goodstein [9].

Corollary 2. *Every polynomial function is completely determined by its restriction to $\{0, 1\}^n$.*

Corollary 3. *A function $g\colon \{0, 1\}^n \to L$ can be extended to a polynomial function $f\colon L^n \to L$ if and only if it is nondecreasing. In this case, the extension is unique.*

Proposition 4. *Let $f\colon L^n \to L$ be a function. The following conditions are equivalent:*

(i) *f is a polynomial function.*

(ii) *There exists $\alpha\colon 2^{[n]} \to L$ such that*
$$f(\mathbf{x}) = \bigvee_{I \subseteq [n]} \big(\alpha(I) \wedge \bigwedge_{i \in I} x_i\big).$$

(iii) *There exists $\beta\colon 2^{[n]} \to L$ such that*
$$f(\mathbf{x}) = \bigwedge_{I \subseteq [n]} \big(\beta(I) \vee \bigvee_{i \in I} x_i\big).$$

We shall refer to the expressions given in (ii) and (iii) of Proposition 4 as the *disjunctive normal form* (DNF) representation and the *conjunctive normal form* (CNF) representation, respectively, of the polynomial function f.

Remark 2. By requiring α and β to be nonconstant functions from $2^{[n]}$ to $\{0, 1\}$ and satisfying $\alpha(\varnothing) = 0$ and $\beta(\varnothing) = 1$, respectively, we obtain the analogue of Proposition 4 for term functions.

ISBN: 978-989-95079-6-8

For each polynomial function $f\colon L^n \to L$, set

$$\mathrm{DNF}(f) = \Big\{\alpha \in L^{2^{[n]}} : f(\mathbf{x}) = \bigvee_{I\subseteq[n]} \big(\alpha(I) \wedge \bigwedge_{i\in I} x_i\big)\Big\},$$

$$\mathrm{CNF}(f) = \Big\{\beta \in L^{2^{[n]}} : f(\mathbf{x}) = \bigwedge_{I\subseteq[n]} \big(\beta(I) \vee \bigvee_{i\in I} x_i\big)\Big\}.$$

A complete description of the sets $\mathrm{DNF}(f)$ and $\mathrm{CNF}(f)$ can be found in [5, §3.1]. As we are concerned by the case when L is a chain, we recall the description only in this special case; see [15, §3].

For each $I \subseteq [n]$, let $\mathbf{e}_I$ be the element of L^n whose ith component is 1, if $i \in I$, and 0, otherwise. Let $\alpha_f\colon 2^{[n]} \to L$ be the function given by $\alpha_f(I) = f(\mathbf{e}_I)$ and consider the function $\alpha_f^*\colon 2^{[n]} \to L$ defined by

$$\alpha_f^*(I) = \begin{cases} \alpha_f(I), & \text{if } \bigvee_{J\subsetneq I} \alpha_f(J) < \alpha_f(I),\\ 0, & \text{otherwise.}\end{cases}$$

Dually, Let $\beta_f\colon 2^{[n]} \to L$ be the function given by $\beta_f(I) = f(\mathbf{e}_{[n]\setminus I})$ and consider the function $\beta_f^*\colon 2^{[n]} \to L$ defined by

$$\beta_f^*(I) = \begin{cases} \beta_f(I), & \text{if } \bigwedge_{J\subsetneq I} \beta_f(J) > \beta_f(I),\\ 1, & \text{otherwise.}\end{cases}$$

Proposition 5. *Let $f\colon L^n \to L$ be a polynomial function. Then*

(i) $\mathrm{DNF}(f) = [\alpha_f^*, \alpha_f]$ and f has a unique DNF representation if and only if $\bigvee_{J\subsetneq I} \alpha_f(J) < \alpha_f(I)$ for every $I \subseteq [n]$,

(ii) $\mathrm{CNF}(f) = [\beta_f, \beta_f^*]$ and f has a unique CNF representation if and only if $\bigwedge_{J\subsetneq I} \beta_f(J) > \beta_f(I)$ for every $I \subseteq [n]$.

In particular, α_f and β_f are the unique isotone and antitone, respectively, maps in $\mathrm{DNF}(f)$ and $\mathrm{CNF}(f)$, respectively.

In the case of chains, the DNF and CNF representations of polynomial functions $f\colon L^n \to L$ can be refined and given in terms of standard simplices of L^n (see Proposition 6 below). Recall that

$$\mathrm{median}(x_1, \ldots, x_{2n+1}) = \bigvee_{\substack{I\subseteq[2n+1]\\ |I|=n+1}} \bigwedge_{i\in I} x_i.$$

Let σ be a permutation on $[n]$. The *standard simplex* of L^n associated with σ is the subset $L_\sigma^n \subset L^n$ defined by

$$L_\sigma^n = \{(x_1, \ldots, x_n) \in L^n : x_{\sigma(1)} \leqslant \cdots \leqslant x_{\sigma(n)}\}.$$

For each $i \in [n]$, define $S_\sigma^{\uparrow}(i) = \{\sigma(i), \ldots, \sigma(n)\}$ and $S_\sigma^{\downarrow}(i) = \{\sigma(1), \ldots, \sigma(i)\}$. As a matter of convenience, set $S_\sigma^{\uparrow}(n+1) = S_\sigma^{\downarrow}(0) = \varnothing$.

Proposition 6. *Let $f\colon L^n \to L$ be a function. The following conditions are equivalent:*

(i) f is a polynomial function.

(ii) For any permutation σ on $[n]$ and every $\mathbf{x} \in L_\sigma^n$, we have

$$\begin{aligned} f(\mathbf{x}) &= \bigvee_{i\in[n+1]} \big(\alpha_f(S_\sigma^{\uparrow}(i)) \wedge x_{\sigma(i)}\big)\\ &= \bigwedge_{i\in[n+1]} \big(\alpha_f(S_\sigma^{\uparrow}(i)) \vee x_{\sigma(i-1)}\big)\\ &= \mathrm{median}\big(x_1, ..., x_n, \alpha_f(S_\sigma^{\uparrow}(1)), ..., \alpha_f(S_\sigma^{\uparrow}(n+1))\big),\end{aligned}$$

where $x_{\sigma(0)} = 0$ and $x_{\sigma(n+1)} = 1$.

(iii) For any permutation σ on $[n]$ and every $\mathbf{x} \in L_\sigma^n$, we have

$$\begin{aligned} f(\mathbf{x}) &= \bigvee_{i\in[n+1]} \big(\beta_f(S_\sigma^{\downarrow}(i-1)) \wedge x_{\sigma(i)}\big)\\ &= \bigwedge_{i\in[n+1]} \big(\beta_f(S_\sigma^{\downarrow}(i-1)) \wedge x_{\sigma(i-1)}\big)\\ &= \mathrm{median}\big(x_1, \ldots, x_n, \beta_f(S_\sigma^{\downarrow}(0)), \ldots, \beta_f(S_\sigma^{\downarrow}(n))\big),\end{aligned}$$

where $x_{\sigma(0)} = 0$ and $x_{\sigma(n+1)} = 1$.

Remark 3. The equivalence between (i) and (ii) of Proposition 6 was already observed in [15, §5]. Prior to this, Propositions 5 and 6 were already established in [14] for idempotent polynomial functions (discrete Sugeno integrals) in the case when L is the unit real interval $[0, 1]$; see also [13, §4.3].

4 Characterizations of polynomial functions

In this section, we propose weak analogues of the properties used in Theorem 1 and provide characterizations of polynomial functions on chains, accordingly. Moreover, we introduce further properties, namely, comonotonic minitivity and maxitivity, which we then use to provide further characterizations of polynomial functions.

For integers $0 \leqslant p \leqslant q \leqslant n$, define $L_n^{(p,q)} = \{\mathbf{x} \in L^n : |\{x_1, \ldots, x_n\} \cap \{0, 1\}| \geqslant p \text{ and } |\{x_1, \ldots, x_n\}| \leqslant q\}$. For instance, $L_n^{(0,2)}$ is the set of Boolean vectors of L^n that are two-sided trimmed by constant vectors, that is

$$L_n^{(0,2)} = \bigcup_{\substack{\mathbf{e}\in\{0,1\}^n\\ c,d\in L}} \{\mathrm{median}(c, \mathbf{e}, d)\},$$

where the median is taken componentwise.

4.1 Weak homogeneity

Let S be a nonempty subset of L. We say that a function $f\colon L^n \to L$ is *weakly S-min homogeneous* (resp. *weakly S-max homogeneous*) if (1) (resp. (2)) holds for every $\mathbf{x} \in L_n^{(0,2)}$ and every $c \in S$.

For every integer $m \geqslant 1$, every $\mathbf{x} \in L^m$, and every $f\colon L^n \to L$, we define $\langle \mathbf{x} \rangle_f \in L^m$ as the m-tuple

$$\langle \mathbf{x} \rangle_f = \mathrm{median}(f(\mathbf{0}), \mathbf{x}, f(\mathbf{1})),$$

where the right-hand side median is taken componentwise. As observed in [5], for every nonempty subset $S \subseteq L$, we have that f is S-min homogeneous and S-max homogeneous if and only if it satisfies

$$f(\mathrm{median}(r, \mathbf{x}, s)) = \mathrm{median}(r, f(\mathbf{x}), s)$$

ISBN: 978-989-95079-6-8

for every $\mathbf{x} \in L^n$ and every $r, s \in S$. In particular, if $f(\mathbf{0}), f(\mathbf{1}) \in S$ then, for any $\mathbf{x} \in L^n$ such that $f(\mathbf{0}) \leqslant f(\mathbf{x}) \leqslant f(\mathbf{1})$, we have $f(\mathbf{x}) = f(\langle \mathbf{x} \rangle_f)$.

It was also shown in [5] that, for every nonempty subset $S \subseteq L$, if f is S-min homogeneous and S-max homogeneous, then it is S-idempotent. The following lemma shows that the weak analogue also holds.

Lemma 7. *Let S be a nonempty subset of L. If $f\colon L^n \to L$ is weakly S-min homogeneous and weakly S-max homogeneous, then it is S-idempotent. Moreover, if $f(\mathbf{0}), f(\mathbf{1}) \in S$ then, for any $\mathbf{x} \in L_n^{(0,2)}$ such that $f(\mathbf{0}) \leqslant f(\mathbf{x}) \leqslant f(\mathbf{1})$, we have $f(\mathbf{x}) = f(\langle \mathbf{x} \rangle_f)$.*

As we are going to see, of particular interest is when $S = \overline{\mathcal{R}}_f$. The following result characterizing the class of polynomial functions shows that, in the case of chains, the conditions in (iv) of Theorem 1 can be replaced with their weak analogues.

Theorem 8. *A function $f\colon L^n \to L$ is a polynomial function if and only if it is nondecreasing, weakly $\overline{\mathcal{R}}_f$-min homogeneous, and weakly $\overline{\mathcal{R}}_f$-max homogeneous.*

Remark 4. Note that Theorem 8 does not generally hold in the case of bounded distributive lattices. To see this, let $L = \{0, a, b, 1\}$ where $a \wedge b = 0$ and $a \vee b = 1$, and consider the binary function $f\colon L^2 \to L$ defined by

$$f(x_1, x_2) = \begin{cases} 1, & \text{if } x_1 = 1 \text{ or } x_2 = 1, \\ 1, & \text{if } x_1 = x_2 = b, \\ a, & \text{if } (x_1 = a \text{ and } x_2 \neq 1) \\ & \text{or } (x_2 = a \text{ and } x_1 \neq 1), \\ 0, & \text{otherwise.} \end{cases}$$

It is easy to verify that f is nondecreasing and both weakly $\overline{\mathcal{R}}_f$-min homogeneous and weakly $\overline{\mathcal{R}}_f$-max homogeneous, but it is not $\overline{\mathcal{R}}_f$-max homogeneous. For instance, $f(a \vee a, b \vee a) = f(a, 1) = 1 \neq a = f(a, b) \vee a$. Thus, f is not a polynomial function by Theorem 1.

4.2 Weak horizontal minitivity and maxitivity

Let S be a nonempty subset of L. We say that a function $f\colon L^n \to L$ is *weakly horizontally S-minitive* (resp. *weakly horizontally S-maxitive*) if (3) (resp. (4)) holds for every $\mathbf{x} \in L_n^{(0,2)}$ and every $c \in S$.

The following result provides characterizations of the n-ary polynomial functions on a chain L, given in terms of weak homogeneity and weak horizontal minitivity and maxitivity.

Theorem 9. *Let $f\colon L^n \to L$ be a function. The following conditions are equivalent:*

(i) *f is a polynomial function.*

(ii) *f is nondecreasing, weakly $\overline{\mathcal{R}}_f$-min homogeneous, and weakly $\overline{\mathcal{R}}_f$-max homogeneous.*

(iii) *f is nondecreasing, weakly $\overline{\mathcal{R}}_f$-min homogeneous, and weakly horizontally $\overline{\mathcal{R}}_f$-maxitive.*

(iv) *f is nondecreasing, weakly horizontally $\overline{\mathcal{R}}_f$-minitive, and weakly $\overline{\mathcal{R}}_f$-max homogeneous.*

(v) *f is nondecreasing, $\overline{\mathcal{R}}_f$-idempotent, weakly horizontally $\overline{\mathcal{R}}_f$-minitive, and weakly horizontally $\overline{\mathcal{R}}_f$-maxitive.*

4.3 Weak median decomposability

As we saw in Theorem 1, in the case of distributive lattices L, the n-ary polynomial functions on L are exactly those which satisfy the median decomposition formula (5). As we are going to see, in the case of chains, this condition can be relaxed by restricting the satisfaction of (5) by a function $f : L^n \to L$ to the vectors of $L_n^{(0,2)} \cup L_n^{(1,3)}$. In the latter case, we say that $f : L^n \to L$ is *weakly median decomposable*.

Lemma 10. *Let $f\colon L^n \to L$ be a nondecreasing function. If f is weakly median decomposable, then it is $\overline{\mathcal{R}}_f$-idempotent.*

Proposition 11. *Let $f\colon L^n \to L$ be a nondecreasing function. The following conditions are equivalent:*

(i) *f is weakly median decomposable.*

(ii) *f weakly $\overline{\mathcal{R}}_f$-min homogeneous and weakly $\overline{\mathcal{R}}_f$-max homogeneous.*

Remark 5. Using the binary function f given in Remark 4, we can see that Proposition 11 does not hold in the general case of bounded distributive lattices. Indeed, as observed, f is nondecreasing and both weakly $\overline{\mathcal{R}}_f$-min homogeneous and weakly $\overline{\mathcal{R}}_f$-max homogeneous, but $f(b, b) = 1 \neq b = \operatorname{median}(f(0, b), b, f(1, b))$ which shows that f is not weakly median decomposable.

From Proposition 11 and Theorem 8, we obtain the following description of polynomial functions given in terms of weak median decomposability.

Theorem 12. *A nondecreasing function $f\colon L^n \to L$ is a polynomial function if and only if it is weakly median decomposable.*

Remark 6. Note that Theorem 12 does not hold if weak median decomposability would have been defined in terms of vectors in $L_n^{(0,2)}$ only. To see this, let $L = \{0, c, 1\}$ and consider the following nondecreasing function $f : L^3 \to L$, defined by

$$f(x_1, x_2, x_3) = \begin{cases} 1, & \text{if } \operatorname{median}(x_1, x_2, x_3) = 1, \\ c, & \text{if } \operatorname{median}(x_1, x_2, x_3) \\ & = x_1 \wedge x_2 \wedge x_3 = c, \\ 0, & \text{otherwise.} \end{cases}$$

It is easy to this that f is median decomposable for vectors in $L_n^{(0,2)}$, but it is not a polynomial function, e.g., we have $f(0, c, c) = 0$ but $f(0, 1, 1) \wedge c = c$.

4.4 Strong idempotency and componentwise range convexity

By Theorem 1, a nondecreasing function $f\colon L^n \to L$ is a polynomial function if and only if it is strongly idempotent, has a convex range, and a componentwise convex range. In the case of chains, the condition requiring a convex range becomes redundant, since it becomes a consequence of componentwise range convexity. Thus, we obtain the following characterization, which weakens condition (iii) of Theorem 1 when L is a chain.

ISBN: 978-989-95079-6-8

Theorem 13. *A function $f\colon L^n \to L$ is a polynomial function if and only if it is nondecreasing, strongly idempotent, and has a componentwise convex range.*

Remark 7. None of the conditions provided in Theorem 13 can be dropped off. For instance, let L be the real interval $[0,1]$. Clearly, the unary function $f(x) = x^2$ is nondecreasing and has a componentwise convex range, but it is not strongly idempotent. On the other hand, the function $f\colon L^2 \to L$ defined by

$$f(x_1, x_2) = \begin{cases} 1, & \text{if } x_1 = x_2 = 1, \\ 0, & \text{otherwise,} \end{cases}$$

is nondecreasing and strongly idempotent but it does not have a componentwise convex range, e.g., both $f^1_{\mathbf{1}}$ and $f^2_{\mathbf{1}}$ do not have convex ranges.

In the special case of real interval lattices, i.e., where $L = [a,b]$ for reals $a \leqslant b$, the property of having a convex range, as well as the property of having a componentwise convex range, are consequences of continuity. More precisely, for nondecreasing functions $f : [a,b]^n \to \mathbb{R}$, being continuous reduces to being continuous in each variable, and this latter property is equivalent to having a componentwise convex range. In fact, since polynomial functions are continuous, the condition of having a componentwise convex range can be replaced in Theorem 13 by continuity in each variable. Also, we can add continuity and replace $\overline{\mathcal{R}}_f$ by $\mathcal{R}_f$ in Theorems 8 and 9.

Corollary 14. *Assume that L is a bounded real interval $[a,b]$. A function $f\colon L^n \to L$ is a polynomial function if and only if it is nondecreasing, strongly idempotent, and continuous (in each variable).*

4.5 Comonotonic maxitivity and minitivity

Two vectors $\mathbf{x}$ and $\mathbf{x}'$ in L^n are said to be *comonotonic* if $\mathbf{x}, \mathbf{x}' \in L^n_\sigma$ for some permutation σ on $[n]$. A function $f\colon L^n \to L$ is said to be

- *comonotonic minitive* if, for any two comonotonic vectors $\mathbf{x}, \mathbf{x}' \in L^n$, we have
$$f(\mathbf{x} \wedge \mathbf{x}') = f(\mathbf{x}) \wedge f(\mathbf{x}').$$
- *comonotonic maxitive* if, for any two comonotonic vectors $\mathbf{x}, \mathbf{x}' \in L^n$, we have
$$f(\mathbf{x} \vee \mathbf{x}') = f(\mathbf{x}) \vee f(\mathbf{x}').$$

Note that for any $\mathbf{x} \in L^n$ and any $c \in L$, we have that $\mathbf{x}$ and $(c, \ldots, c)$ are comonotonic and that $\mathbf{x} \vee c$ and $[\mathbf{x}]^c$ are comonotonic. These facts lead to the following result.

Lemma 15. *Let S be a nonempty subset of L. If a function $f\colon L^n \to L$ is comonotonic minitive (resp. comonotonic maxitive), then it is horizontally S-minitive (resp. horizontally S-maxitive). Moreover, if f is S-idempotent, then it is S-min homogeneous (resp. S-max homogeneous).*

Let σ be a permutation on $[n]$. Clearly, every comonotonic minitive (or comonotonic maxitive) function $f\colon L^n \to L$ is nondecreasing on the standard simplex L^n_σ. The following lemma shows that this fact can be extended to the whole domain L^n.

Lemma 16. *If $f\colon L^n \to L$ is comonotonic minitive or comonotonic maxitive, then it is nondecreasing. Furthermore, every nondecreasing unary function is comonotonic minitive and comonotonic maxitive.*

We now have the following characterization of polynomial functions.

Theorem 17. *Let $f\colon L^n \to L$ be a function. The following conditions are equivalent:*

(i) *f is a polynomial function.*

(ii) *f is weakly $\overline{\mathcal{R}}_f$-min homogeneous and comonotonic maxitive.*

(iii) *f is comonotonic minitive and weakly $\overline{\mathcal{R}}_f$-max homogeneous.*

(iv) *f is $\overline{\mathcal{R}}_f$-idempotent, weakly horizontally $\overline{\mathcal{R}}_f$-minitive, and comonotonic maxitive.*

(v) *f is $\overline{\mathcal{R}}_f$-idempotent, comonotonic minitive, and weakly horizontally $\overline{\mathcal{R}}_f$-maxitive.*

(vi) *f is $\overline{\mathcal{R}}_f$-idempotent, comonotonic minitive, and comonotonic maxitive.*

Remark 8. (i) As already observed in the remark following Theorem 9, the weak horizontal $\overline{\mathcal{R}}_f$-minitivity (resp. weak horizontal $\overline{\mathcal{R}}_f$-maxitivity) can be replaced with weak horizontal L-minitivity (resp. weak horizontal L-maxitivity) in the assertions (iv)–(v) of Theorem 17.

(ii) The condition requiring $\overline{\mathcal{R}}_f$-idempotency is necessary in conditions (iv)–(vi) of Theorem 17. For instance, let L be the unit interval $[0,1]$. Clearly, the unary function $f(x) = x^2$ is nondecreasing and thus comonotonic minitive and comonotonic maxitive. By Lemma 15, it is also horizontally $\overline{\mathcal{R}}_f$-minitive and horizontally $\overline{\mathcal{R}}_f$-maxitive. However, it is not a polynomial function.

(iii) The concept of comonotonic vectors appeared as early as 1952 in Hardy et al. [12]. Comonotonic minitivity and maxitivity were introduced in the context of Sugeno integrals in de Campos et al. [7]. An interpretation of these properties was given by Ralescu and Ralescu [16] in the framework of aggregation of fuzzy subsets.

5 Discrete Sugeno integrals

In this final section, we consider a noteworthy subclass of polynomial functions, namely, that of discrete Sugeno integrals, and provide its characterizations.

A function $f\colon L^n \to L$ is said to be *idempotent* if it is L-idempotent.

Fact 18. *A polynomial function is $\{0,1\}$-idempotent if and only if it is idempotent.*

In [15, §4], $\{0,1\}$-idempotent polynomial functions are referred to as *discrete Sugeno integrals*. They coincide exactly with those functions $\mathcal{S}_\mu\colon L^n \to L$ for which there is a fuzzy measure μ such that

$$\mathcal{S}_\mu(\mathbf{x}) = \bigvee_{I \subseteq [n]} \big(\mu(I) \wedge \bigwedge_{i \in I} x_i\big).$$

ISBN: 978-989-95079-6-8

(A *fuzzy measure* μ is simply a set function $\mu\colon 2^{[n]} \to L$ satisfying $\mu(I) \leqslant \mu(I')$ whenever $I \subseteq I'$, and $\mu(\varnothing) = 0$ and $\mu([n]) = 1$.)

The following proposition shows how polynomial functions relate to Sugeno integrals; see [15, Proposition 12].

Proposition 19. *For any polynomial function $f\colon L^n \to L$ there is a fuzzy measure $\mu\colon 2^{[n]} \to L$ such that $f(\mathbf{x}) = \langle \mathcal{S}_\mu(\mathbf{x}) \rangle_f$.*

We say that a function $f\colon L^n \to L$ is *Boolean min homogeneous* (resp. *Boolean max homogeneous*) if (1) (resp. (2)) holds for every $\mathbf{x} \in \{0,1\}^n$ and every $c \in L$. Note that every weakly L-min homogeneous (resp. weakly L-max homogeneous) function is Boolean min homogeneous (resp. Boolean max homogeneous). The following result provides a variant of Theorem 8.

Theorem 20. *A function $f\colon L^n \to L$ is a discrete Sugeno integral if and only if it is nondecreasing, Boolean min homogeneous, and Boolean max homogeneous.*

Remark 9. (i) Theorem 20 as well as the characterization of the discrete Sugeno integrals obtained by combining $\{0,1\}$-idempotency with (vi) in Theorem 17 were presented in the case of real variables by [13, §4.3]; see also [14].

(ii) Even though Theorem 20 can be derived from condition (ii) of Theorem 9 by simply modifying the two homogeneity properties, to proceed similarly with conditions (iii) and (iv), it is necessary to add the conditions of $\{1\}$-idempotency and $\{0\}$-idempotency, respectively (and similarly with conditions (ii) and (iii) of Theorem 17). To see this, let L be a bounded chain with at least three elements and consider the unary functions $f(x) = x \wedge d$ and $g(x) = x \vee d$, where $d \in L \setminus \{0,1\}$. Clearly, f is L-min homogeneous and horizontally L-maxitive and g is L-max homogeneous and horizontally L-minitive. However, neither f nor g is a discrete Sugeno integral. To see that these additions are sufficient, just note that L-min homogeneity (resp. L-max homogeneity) implies $\{0\}$-idempotency (resp. $\{1\}$-idempotency).

(iii) Marichal [13, §2.2.3] showed that, when L is a chain, a nondecreasing and idempotent function $f\colon L^n \to L$ is Boolean min homogeneous (resp. Boolean max homogeneous) if and only if we have $f(\mathbf{e} \wedge c) \in \{f(\mathbf{e}), c\}$ (resp. $f(\mathbf{e} \vee c) \in \{f(\mathbf{e}), c\}$) for every $\mathbf{e} \in \{0,1\}^n$ and every $c \in L$.

Quasi-polynomial functions on bounded chains

Miguel Couceiro Jean-Luc Marichal

Mathematics Research Unit, University of Luxembourg
162A, avenue de la Faïencerie, L-1511 Luxembourg, Luxembourg
Email: {miguel.couceiro, jean-luc.marichal}@uni.lu

Abstract— *Two emergent properties in aggregation theory are investigated, namely horizontal maxitivity and comonotonic maxitivity (as well as their dual counterparts) which are commonly defined by means of certain functional equations. We present complete descriptions of the function classes axiomatized by each of these properties, up to weak versions of monotonicity, in the cases of horizontal maxitivity and minitivity. While studying the classes axiomatized by combinations of these properties, we introduce the concept of quasi-polynomial function which appears as a natural extension of the well-established notion of polynomial function. We present further axiomatizations for this class both in terms of functional equations and natural relaxations of homogeneity and median decomposability. As noteworthy particular cases, we investigate those subclasses of quasi-term functions and quasi-weighted maximum and minimum functions, and present characterizations accordingly.*

Keywords— Discrete Sugeno integral, quasi-polynomial function, horizontal maxitivity and minitivity, comonotonic maxitivity and minitivity, functional equation.

1 Introduction

Aggregation functions arise wherever aggregating information is important: applied and pure mathematics (probability, statistics, decision theory, functional equations), operations research, computer science, and many applied fields (economics and finance, pattern recognition and image processing, data fusion, etc.). For recent references, see Beliakov et al. [1] and Grabisch et al. [10].

A noteworthy aggregation function is the so-called discrete Sugeno integral, which was introduced by Sugeno [15, 16] and which has been widely investigated in aggregation theory, due to its many applications for instance in fuzzy set theory, decision making, and image analysis. For general background, see also the edited book [11].

A convenient way to introduce the discrete Sugeno integral is via the concept of (lattice) polynomial functions, i.e., functions which can be expressed as combinations of variables and constants using the lattice operations $\wedge$ and $\vee$. As shown by Marichal [13], the discrete Sugeno integrals are exactly those polynomial functions $f : L^n \to L$ which are idempotent, that is, satisfying $f(x, \ldots, x) = x$. Several axiomatizations of the class of discrete Sugeno integrals (as idempotent polynomial functions) have been recently given; see [4].

Of particular interest in aggregation theory, are the so-called horizontal maxitivity and comonotonic maxitivity (as well as their dual counterparts), usually expressed in terms of certain functional equations, and which we now informally describe.

Let L be a bounded chain. For every $\mathbf{x} \in L^n$ and every $c \in L$, consider the horizontal maxitive decomposition of $\mathbf{x}$ obtained by "cutting" it with c, namely $\mathbf{x} = (\mathbf{x} \wedge c) \vee [\mathbf{x}]_c$, where $[\mathbf{x}]_c$ is the n-tuple whose ith component is 0, if $x_i \leqslant c$, and x_i, otherwise. A function $f\colon L^n \to L$ is said to be *horizontally maxitive* if

$$f(\mathbf{x}) = f(\mathbf{x} \wedge c) \vee f([\mathbf{x}]_c)$$

for every $\mathbf{x} \in L^n$ and every $c \in L$.

A function $f\colon L^n \to L$ is said to be *comonotonic maxitive* if, for any two vectors $\mathbf{x}$ and $\mathbf{x}'$ in the same standard simplex of L^n, we have

$$f(\mathbf{x} \vee \mathbf{x}') = f(\mathbf{x}) \vee f(\mathbf{x}').$$

As we are going to see (Lemma 6 below), these (as well as their duals) are closely related and constitute properties shared by discrete Sugeno integrals. Still, and as it will become evident, no combination of these with their dual forms suffices to fully describe the class of Sugeno integrals. Thus, and given their emergence in aggregation theory, it is natural to ask which classes of functions are axiomatized by combinations of these properties or, in fact, by each of these properties.

In this paper, we answer this question for both the maxitive and minitive comonotonic properties, and for horizontal maxitivity and minitivity properties, up to certain weak variants of monotonicity. While looking at combinations of the latter properties, we reach a natural generalization of polynomial functions, which we call *quasi-polynomial functions* and which are best described by the following equation

$$f(x_1, \ldots, x_n) = p(\varphi(x_1), \ldots, \varphi(x_n)),$$

where p is a polynomial function and φ a nondecreasing function (see Theorem 10 below). Searching for alternative descriptions, we introduce weaker versions of well-established properties, such as homogeneity and median decomposability, to provide further axiomatizations of the class of quasi-polynomial functions, accordingly.

This paper is organized as follows. We start by recalling basic notions and terminology in lattice function theory, as well as present some known results, needed throughout this paper (Section 2). In Section 3, we study the properties of horizontal maxitivity and comonotonic maxitivity, as well as their dual forms, and determine those function classes axiomatized by each of this properties. Combinations of the latter are then considered in Section 4.1, where the notion of quasi-polynomial function is introduced. In Section 4.2, we propose weaker versions of homogeneity and median decomposability, and provide further characterizations of quasi-polynomial functions, accordingly. In Section 5, we introduce and axiomatize few noteworthy subclasses of quasi-polynomial functions, namely, those of quasi-term functions and those quasi-weighted maximum and minimum functions.

2 Basic notions and preliminary results

In this section we recall basic terminology as well as some results needed in the current paper. For general background we refer the reader to, e.g., Burris and Sankappanavar [3] and Rudeanu [14].

2.1 General background

Throughout this paper, let L be a bounded chain with operations $\wedge$ and $\vee$, and with least and greatest elements 0 and 1, respectively. A subset S of a chain L is said to be *convex* if for every $a, b \in S$ and every $c \in L$ such that $a \leqslant c \leqslant b$, we have $c \in S$. For any subset $S \subseteq L$, we denote by $\overline{S}$ the convex hull of S, that is, the smallest convex subset of L containing S. For every $a, b \in S$ such that $a \leqslant b$, the *interval* $[a, b]$ is the set $[a, b] = \{c \in L : a \leqslant c \leqslant b\}$. For any integer $n \geqslant 1$, let $[n] = \{1, \ldots, n\}$.

For any bounded chain L, we regard the Cartesian product L^n, $n \geqslant 1$, as a distributive lattice endowed with the operations $\wedge$ and $\vee$ given by

$$\begin{aligned}(a_1, \ldots, a_n) \wedge (b_1, \ldots, b_n) &= (a_1 \wedge b_1, \ldots, a_n \wedge b_n),\\ (a_1, \ldots, a_n) \vee (b_1, \ldots, b_n) &= (a_1 \vee b_1, \ldots, a_n \vee b_n).\end{aligned}$$

The elements of L are denoted by lower case letters $a, b, c, \ldots$, and the elements of L^n, $n > 1$, by bold face letters $\mathbf{a}, \mathbf{b}, \mathbf{c}, \ldots$. We also use $\mathbf{0}$ and $\mathbf{1}$ to denote the least element and greatest element, respectively, of L^n. For $c \in L$ and $\mathbf{x} = (x_1, \ldots, x_n) \in L^n$, set

$$\mathbf{x} \wedge c = (x_1 \wedge c, \ldots, x_n \wedge c) \quad \text{and} \quad \mathbf{x} \vee c = (x_1 \vee c, \ldots, x_n \vee c).$$

The *range* of a function $f\colon L^n \to L$ is defined by $\mathcal{R}_f = \{f(\mathbf{x}) : \mathbf{x} \in L^n\}$. A function $f\colon L^n \to L$ is said to be *nondecreasing* (*in each variable*) if, for every $\mathbf{a}, \mathbf{b} \in L^n$ such that $\mathbf{a} \leqslant \mathbf{b}$, we have $f(\mathbf{a}) \leqslant f(\mathbf{b})$. The *diagonal section* of f, denoted δ_f, is defined as the unary function given by $\delta_f(x) = f(x, \ldots, x)$. Note that if f is nondecreasing, then δ_f is nondecreasing and $\overline{\mathcal{R}}_{\delta_f} = \overline{\mathcal{R}}_f = [f(\mathbf{0}), f(\mathbf{1})]$.

2.2 Polynomial functions and their representations

In this paper the so-called polynomial functions will play a fundamental role. Formally, an *n-ary polynomial function* on L is any function $f : L^n \to L$ which can be obtained by finitely many applications of the following rules:

(i) For each $i \in [n]$ and each $c \in L$, the projection $\mathbf{x} \mapsto x_i$ and the constant function $\mathbf{x} \mapsto c$ are polynomial functions from L^n to L.

(ii) If f and g are polynomial functions from L^n to L, then $f \vee g$ and $f \wedge g$ are polynomial functions from L^n to L.

Polynomial functions are also called lattice functions (Goodstein [9]), algebraic functions (Burris and Sankappanavar [3]) or weighted lattice polynomial functions (Marichal [13]). Idempotent polynomial functions (i.e., satisfying $f(c, \ldots, c) = c$ for every $c \in L$) are referred to by aggregation theorists as (*discrete*) *Sugeno integrals*, and those obtained from projections by finitely many applications of (ii) are usually referred to as (*lattice*) *term functions*. A noteworthy term function that we shall make use in the sequel is the median function, defined by

$$\operatorname{median}(x, y, z) = (x \wedge y) \vee (y \wedge z) \vee (z \wedge x).$$

As observed by Goodstein [9] (see also Rudeanu [14]), polynomial functions are exactly those functions which can be represented by formulas in disjunctive and conjunctive normal forms. In fact, each polynomial function $f\colon L^n \to L$ is uniquely determined by its restriction to $\{0, 1\}^n$. Due to their relevance in the sequel, we recall some known results concerning normal form representations of polynomial functions in the special case where L is a chain. The following result is due to Goodstein [9].

Proposition 1. *(a) Every polynomial function is completely determined by its restriction to $\{0, 1\}^n$.*

(b) A function $g\colon \{0, 1\}^n \to L$ can be extended to a polynomial function $f\colon L^n \to L$ if and only if it is nondecreasing. In this case, the extension is unique.

(c) For any $f\colon L^n \to L$, the following are equivalent:

(i) f is a polynomial function.

(ii) There exists $\alpha\colon 2^{[n]} \to L$ such that

$$f(\mathbf{x}) = \bigvee_{I \subseteq [n]} \big(\alpha(I) \wedge \bigwedge_{i \in I} x_i\big). \tag{1}$$

(iii) There exists $\beta\colon 2^{[n]} \to L$ such that

$$f(\mathbf{x}) = \bigwedge_{I \subseteq [n]} \big(\beta(I) \vee \bigvee_{i \in I} x_i\big). \tag{2}$$

The expressions given in (1) and (2) are usually referred to as the *disjunctive normal form* (DNF) representation and the *conjunctive normal form* (CNF) representation, respectively, of the polynomial function f.

Remark 1. By requiring α and β to be nonconstant functions from $2^{[n]}$ to $\{0, 1\}$ and satisfying $\alpha(\varnothing) = 0$ and $\beta(\varnothing) = 1$, respectively, we obtain the analogue of (c) of Proposition 1 for term functions.

As observed by Marichal [13], the DNF and CNF representations of polynomial functions $f\colon L^n \to L$ are not necessarily unique. For instance, we have

$$x_1 \vee (x_1 \wedge x_2) = x_1 = x_1 \wedge (x_1 \vee x_2).$$

However, from among all the possible set functions α (resp. β) defining the DNF (resp. CNF) representation of f, only one is isotone (resp. antitone), namely the function $\alpha_f\colon 2^{[n]} \to L$ (resp. $\beta_f\colon 2^{[n]} \to L$) defined by

$$\alpha_f(I) = f(\mathbf{e}_I) \qquad (\text{resp. } \beta_f(I) = f(\mathbf{e}_{[n] \setminus I})), \tag{3}$$

where $\mathbf{e}_I$ denotes the element of $\{0, 1\}^n$ whose ith component is 1 if and only if $i \in I$.

In the case when L is a chain, it was shown in [4] that the DNF and CNF representations of polynomial functions $f\colon L^n \to L$ can be refined and given in terms of standard simplices of L^n. Let σ be a permutation on $[n]$. The *standard simplex* of L^n associated with σ is the subset $L^n_\sigma \subset L^n$ defined by

$$L^n_\sigma = \{(x_1, \ldots, x_n) \in L^n : x_{\sigma(1)} \leqslant x_{\sigma(2)} \leqslant \cdots \leqslant x_{\sigma(n)}\}.$$

For each $i \in [n]$, define $S^{\uparrow}_\sigma(i) = \{\sigma(i), \ldots, \sigma(n)\}$ and $S^{\downarrow}_\sigma(i) = \{\sigma(1), \ldots, \sigma(i)\}$. As a matter of convenience, set $S^{\uparrow}_\sigma(n+1) = S^{\downarrow}_\sigma(0) = \varnothing$.

ISBN: 978-989-95079-6-8

Proposition 2. *For any function $f\colon L^n \to L$, the following conditions are equivalent:*

(i) *f is a polynomial function.*

(ii) *For any permutation σ on $[n]$ and every $\mathbf{x} \in L^n_\sigma$, we have*

$$f(\mathbf{x}) = \bigvee_{i=1}^{n+1} \big(\alpha_f(S^{\uparrow}_{\sigma}(i)) \wedge x_{\sigma(i)}\big),$$

where $x_{\sigma(n+1)} = 1$.

(iii) *For any permutation σ on $[n]$ and every $\mathbf{x} \in L^n_\sigma$, we have*

$$f(\mathbf{x}) = \bigwedge_{i=0}^{n} \big(\beta_f(S^{\downarrow}_{\sigma}(i)) \vee x_{\sigma(i)}\big),$$

where $x_{\sigma(0)} = 0$.

3 Motivating characterizations

Even though horizontal maxitivity and comonotonic maxitivity, as well as their dual counterparts, play an important role in aggregation theory (as properties shared by noteworthy classes of aggregation functions), they have not yet been described independently. In this section we investigate each of these properties and determine their corresponding function classes (up to weak versions of monotonicity, in the cases of horizontal maxitivity and minitivity).

3.1 Horizontal maxitivity and minitivity

Recall that a function $f\colon L^n \to L$ is said to be

- *horizontally maxitive* if, for every $\mathbf{x} \in L^n$ and every $c \in L$, we have

$$f(\mathbf{x}) = f(\mathbf{x} \wedge c) \vee f([\mathbf{x}]_c),$$

where $[\mathbf{x}]_c$ is the n-tuple whose ith component is 0, if $x_i \leqslant c$, and x_i, otherwise.

- *horizontally minitive* if, for every $\mathbf{x} \in L^n$ and every $c \in L$, we have

$$f(\mathbf{x}) = f(\mathbf{x} \vee c) \wedge f([\mathbf{x}]^c),$$

where $[\mathbf{x}]^c$ is the n-tuple whose ith component is 1, if $x_i \geqslant c$, and x_i, otherwise.

Let us consider the following weak forms of nondecreasing monotonicity:

$(\mathbf{P_1})$ $f(\mathbf{e} \wedge c) \leqslant f(\mathbf{e}' \wedge c)$ for every $\mathbf{e}, \mathbf{e}' \in \{0,1\}^n$ such that $\mathbf{e} \leqslant \mathbf{e}'$ and every $c \in L$.

$(\mathbf{D_1})$ $f(\mathbf{e} \vee c) \leqslant f(\mathbf{e}' \vee c)$ for every $\mathbf{e}, \mathbf{e}' \in \{0,1\}^n$ such that $\mathbf{e} \leqslant \mathbf{e}'$ and every $c \in L$.

$(\mathbf{P_2})$ $f(\mathbf{e} \wedge c) \leqslant f(\mathbf{e} \wedge c')$ for every $\mathbf{e} \in \{0,1\}^n$ and every $c, c' \in L$ such that $c \leqslant c'$.

$(\mathbf{D_2})$ $f(\mathbf{e} \vee c) \leqslant f(\mathbf{e} \vee c')$ for every $\mathbf{e} \in \{0,1\}^n$ and every $c, c' \in L$ such that $c \leqslant c'$.

Theorem 3. *A function $f\colon L^n \to L$ is horizontally maxitive and satisfies $\mathbf{P_1}$ if and only if there exists $g\colon L^n \to L$ satisfying $\mathbf{P_2}$ such that*

$$f(\mathbf{x}) = \bigvee_{I \subseteq [n]} g\Big(\mathbf{e}_I \wedge \bigwedge_{i \in I} x_i\Big).$$

In this case, we can choose $g = f$.

Similarly, we obtain the following dual characterization:

Theorem 4. *A function $f\colon L^n \to L$ is horizontally minitive and satisfies $\mathbf{D_1}$ if and only if there exists $g\colon L^n \to L$ satisfying $\mathbf{D_2}$ such that*

$$f(\mathbf{x}) = \bigwedge_{I \subseteq [n]} g\Big(\mathbf{e}_{[n]\setminus I} \vee \bigvee_{i \in I} x_i\Big).$$

In this case, we can choose $g = f$.

From Theorems 3 and 4 we have the following corollary.

Corollary 5. *A function $f\colon L^n \to L$ is horizontally maxitive (resp. horizontally minitive) and satisfies $\mathbf{P_1}$ (resp. $\mathbf{D_1}$) if and only if there are unary nondecreasing functions $\varphi_I\colon L \to L$, for $I \subseteq [n]$, such that*

$$\begin{aligned} f(\mathbf{x}) &= \bigvee_{I \subseteq [n]} \big(\alpha_f(I) \wedge \bigwedge_{i \in I} \varphi_I(x_i)\big) \\ \text{(resp. } f(\mathbf{x}) &= \bigwedge_{I \subseteq [n]} \big(\beta_f(I) \vee \bigvee_{i \in I} \varphi_I(x_i)\big)\text{)}, \end{aligned}$$

where the set function α_f (resp. β_f) is defined in (3). In this case, we can choose $\varphi_I(x) = f(\mathbf{e}_I \wedge x)$ (resp. $\varphi_I(x) = f(\mathbf{e}_{[n]\setminus I} \vee x)$) for every $I \subseteq [n]$.

Remark 2. (i) Theorem 3 (resp. Theorem 4) provides the description of those horizontally maxitive (resp. horizontally minitive) functions which are nondecreasing.

(ii) Every Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ satisfying $f(\mathbf{0}) \leqslant f(\mathbf{x})$ (resp. $f(\mathbf{x}) \leqslant f(\mathbf{1})$) is horizontally maxitive (resp. horizontally minitive). Moreover, not all such functions are nondecreasing, thus showing that condition $\mathbf{P_1}$ (resp. $\mathbf{D_1}$) is necessary in Theorem 3 (resp. Theorem 4).

(iii) As shown in [4], polynomial functions $f\colon L^n \to L$ are exactly those $\overline{\mathcal{R}}_f$-idempotent (i.e., satisfying $f(c, \ldots, c) = c$ for every $c \in \overline{\mathcal{R}}_f$) which are nondecreasing, horizontally maxitive, and horizontally minitive.

(iv) The concept of horizontal maxitivity was introduced, in the case when L is the real interval $[0,1]$, by Benvenuti et al. [2] as a general property of the Sugeno integral.

3.2 Comonotonic maxitivity and minitivity

Two vectors $\mathbf{x}, \mathbf{x}' \in L^n$ are said to be *comonotonic* if there exists a permutation σ on $[n]$ such that $\mathbf{x}, \mathbf{x}' \in L^n_\sigma$. A function $f\colon L^n \to L$ is said to be

- *comonotonic maxitive* if, for any two comonotonic vectors $\mathbf{x}, \mathbf{x}' \in L^n$, we have

$$f(\mathbf{x} \vee \mathbf{x}') = f(\mathbf{x}) \vee f(\mathbf{x}').$$

ISBN: 978-989-95079-6-8

- *comonotonic minitive* if, for any two comonotonic vectors $\mathbf{x}, \mathbf{x}' \in L^n$, we have

$$f(\mathbf{x} \wedge \mathbf{x}') = f(\mathbf{x}) \wedge f(\mathbf{x}').$$

Note that for any $\mathbf{x} \in L^n$ and any $c \in L$, the vectors $\mathbf{x} \vee c$ and $[\mathbf{x}]^c$ are comonotonic. As a consequence, if a function $f\colon L^n \to L$ is comonotonic maxitive (resp. comonotonic minitive), then it is horizontally maxitive (resp. horizontally minitive). It was also observed in [4] that if f is comonotonic maxitive or comonotonic minitive, then it is nondecreasing. Moreover, we obtain the following result.

Lemma 6. *A function $f\colon L^n \to L$ is comonotonic maxitive (resp. comonotonic minitive) if and only if it is horizontally maxitive (resp. horizontally minitive) and satisfies $\mathbf{P_1}$ (resp. $\mathbf{D_1}$).*

Combining Theorems 3 and 4 with Lemma 6, we immediately obtain the descriptions of the classes of comonotonic maxitive and comonotonic minitive functions.

Theorem 7. *A function $f\colon L^n \to L$ is comonotonic maxitive if and only if there exists $g\colon L^n \to L$ satisfying $\mathbf{P_2}$ such that*

$$f(\mathbf{x}) = \bigvee_{I \subseteq [n]} g\Big(\mathbf{e}_I \wedge \bigwedge_{i \in I} x_i\Big).$$

In this case, we can choose $g = f$.

Theorem 8. *A function $f\colon L^n \to L$ is comonotonic minitive if and only if there exists $g\colon L^n \to L$ satisfying $\mathbf{D_2}$ such that*

$$f(\mathbf{x}) = \bigwedge_{I \subseteq [n]} g\Big(\mathbf{e}_{[n]\setminus I} \vee \bigvee_{i \in I} x_i\Big).$$

In this case, we can choose $g = f$.

As before, we have the following corollary.

Corollary 9. *A function $f\colon L^n \to L$ is comonotonic maxitive (resp. comonotonic minitive) if and only if there are unary nondecreasing functions $\varphi_I\colon L \to L$, for $I \subseteq [n]$, such that*

$$\begin{aligned} f(\mathbf{x}) &= \bigvee_{I \subseteq [n]} \big(\alpha_f(I) \wedge \bigwedge_{i \in I} \varphi_I(x_i)\big) \\ \text{(resp. } f(\mathbf{x}) &= \bigwedge_{I \subseteq [n]} \big(\beta_f(I) \vee \bigvee_{i \in I} \varphi_I(x_i)\big)\text{)}, \end{aligned}$$

where the set function α_f (resp. β_f) is defined in (3). In this case, we can choose $\varphi_I(x) = f(\mathbf{e}_I \wedge x)$ (resp. $\varphi_I(x) = f(\mathbf{e}_{[n]\setminus I} \vee x)$) for every $I \subseteq [n]$.

Remark 3. (i) An alternative description of comonotonic maxitive (resp. comonotonic minitive) functions was obtained in Grabisch et al. [10, §2.5] in the case when L is a real interval.

(ii) It was shown in [4] that polynomial functions $f\colon L^n \to L$ are exactly those $\overline{\mathcal{R}}_f$-idempotent functions which are comonotonic maxitive and comonotonic minitive.

(ii) Comonotonic minitivity and maxitivity were introduced in the context of Sugeno integrals in de Campos et al. [5].

4 Quasi-polynomial functions

Motivated by the results of Section 3 concerning horizontal maxitivity and comonotonic maxitivity, as well as their dual counterparts, we now study combinations of these properties. This will lead to a relaxation of the notion of polynomial function, which we will refer to as *quasi-polynomial function*. Accordingly, we introduce weaker variants of well-established properties, such as homogeneity and median decomposability, which are then used to provide further axiomatizations of the class of quasi-polynomial functions.

4.1 Motivation and definition

We start by looking at combinations of those properties studied in Section 3. These are considered in the following result.

Theorem 10. *Let $f\colon L^n \to L$ be a function. The following assertions are equivalent:*

(i) f is horizontally maxitive, horizontally minitive, and satisfies $\mathbf{P_1}$ or $\mathbf{D_1}$.

(ii) f is comonotonic maxitive and comonotonic minitive.

(iii) f is horizontally maxitive and comonotonic minitive.

(iv) f is comonotonic maxitive and horizontally minitive.

(v) There exist a polynomial function $p\colon L^n \to L$ and a nondecreasing function $\varphi\colon L \to L$ such that

$$f(x_1, \ldots, x_n) = p(\varphi(x_1), \ldots, \varphi(x_n)).$$

If these conditions hold then we can choose for p the unique polynomial function p_f extending $f|_{\{0,1\}^n}$ and for φ the diagonal section δ_f of f.

Theorem 10 motivates the following definition.

Definition 11. We say that a function $f\colon L^n \to L$ is a *quasi-polynomial function* (resp. a *discrete quasi-Sugeno integral*, a *quasi-term function*) if there exist a polynomial function (resp. a discrete Sugeno integral, a term function) $p\colon L^n \to L$ and a nondecreasing function $\varphi\colon L \to L$ such that $f = p \circ \varphi$, that is,

$$f(x_1, \ldots, x_n) = p(\varphi(x_1), \ldots, \varphi(x_n)). \tag{4}$$

Remark 4. (i) Note that each quasi-polynomial function $f\colon L^n \to L$ can be represented as a combination of constants and a nondecreasing unary function φ (applied to the projections $\mathbf{x} \mapsto x_i$) using the lattice operations $\vee$ and $\wedge$.

(ii) In the setting of decision-making under uncertainty, the nondecreasing function φ in (4) can be thought of as a *utility function* and the corresponding quasi-polynomial function as a (qualitative) *global preference functional*; see for instance Dubois et al. [6].

Note that the functions p and φ in (4) are not necessarily unique. For instance, if f is a constant $c \in L$, then we could choose $p \equiv c$ and φ arbitrarily, or p idempotent and $\varphi \equiv c$. We now describe all possible choices for p and φ. For any integers $m, n \geqslant 1$, any vector $\mathbf{x} \in L^m$, and any function $f\colon L^n \to L$, we define $\langle \mathbf{x} \rangle_f \in L^m$ as the m-tuple

$$\langle \mathbf{x} \rangle_f = \operatorname{median}(f(\mathbf{0}), \mathbf{x}, f(\mathbf{1})),$$

where the right-hand side median is taken componentwise.

ISBN: 978-989-95079-6-8

Proposition 12. *Let $f\colon L^n \to L$ be a quasi-polynomial function and let $p_f : L^n \to L$ be the unique polynomial function extending $f|_{\{0,1\}^n}$. We have*

$$\{(p,\varphi)\colon f = p \circ \varphi\} = \{(p,\varphi)\colon p_f = \langle p\rangle_f \text{ and } \delta_f = \langle\varphi\rangle_p\},$$

where p and φ stand for polynomial and unary nondecreasing functions, respectively. In particular, we have $f = p_f \circ \delta_f$.

It was shown in Marichal [13] that every polynomial function $p\colon L^n \to L$ can be represented as $\langle q\rangle_p$ for some discrete Sugeno integral $q\colon L^n \to L$. Combining this with Proposition 12, we obtain the next result.

Corollary 13. *The class of quasi-polynomial functions is exactly the class of discrete quasi-Sugeno integrals.*

4.2 Further axiomatizations

We now recall some properties of polynomial functions, namely homogeneity and median decomposability, and we propose weaker variants of these to provide alternative axiomatizations of the class of quasi-polynomial functions.

4.2.1 Quasi-homogeneity

Let S be a subset of L. A function $f\colon L^n \to L$ is said to be *S-max homogeneous* (resp. *S-min homogeneous*) if for every $\mathbf{x} \in L^n$ and every $c \in S$, we have

$$f(\mathbf{x} \vee c) = f(\mathbf{x}) \vee c \qquad (\text{resp. } f(\mathbf{x} \wedge c) = f(\mathbf{x}) \wedge c).$$

Although polynomial functions $p\colon L^n \to L$ share both of these properties for any $S \subseteq \overline{\mathcal{R}}_p$, this is not the case for quasi-polynomial functions. For instance, let $f_1, f_2\colon [0,1] \to [0,1]$ be respectively given by $f_1(x) = x^2$ and $f_2(x) = \sqrt{x}$. Clearly, f_1 and f_2 are quasi-polynomial functions but, e.g., for $x = c$, we have

$$f_1(x \vee c) < f_1(x) \vee c \quad \text{and} \quad f_2(x \wedge c) > f_2(x) \wedge c.$$

This example motivates the following relaxations. We say that a function $f\colon L^n \to L$ is *quasi-max homogeneous* (resp. *quasi-min homogeneous*) if for every $\mathbf{x} \in L^n$ and $c \in L$, we have

$$f(\mathbf{x} \vee c) = f(\mathbf{x}) \vee \delta_f(c) \qquad (\text{resp. } f(\mathbf{x} \wedge c) = f(\mathbf{x}) \wedge \delta_f(c)).$$

Observe that if f is $\overline{\mathcal{R}}_f$-idempotent (i.e., satisfying $f(c,\ldots,c) = c$ for every $c \in \overline{\mathcal{R}}_f$), then $\overline{\mathcal{R}}_f$-min homogeneity (resp. $\overline{\mathcal{R}}_f$-max homogeneity) is equivalent to quasi-min homogeneity (resp. quasi-max homogeneity).

Lemma 14. *Let $f\colon L^n \to L$ be nondecreasing and quasi-min homogeneous (resp. quasi-max homogeneous). Then f is quasi-max homogeneous (resp. quasi-min homogeneous) if and only if it is horizontally maxitive (resp. horizontally minitive).*

Combining Theorem 10 and Lemma 14, we obtain a characterization of quasi-polynomial functions in terms of quasi-min homogeneity and quasi-max homogeneity.

Theorem 15. *A function $f\colon L^n \to L$ is a quasi-polynomial function if and only if it is nondecreasing, quasi-max homogeneous, and quasi-min homogeneous.*

4.2.2 Quasi-median decomposability

A function $f\colon L^n \to L$ is said to be *median decomposable* [13] if, for every $\mathbf{x} \in L^n$ and every $k \in [n]$, we have

$$f(\mathbf{x}) = \operatorname{median}\big(f(\mathbf{x}_k^0), x_k, f(\mathbf{x}_k^1)\big),$$

where $\mathbf{x}_k^c = (x_1,\ldots,x_{k-1},c,x_{k+1},\ldots,x_n)$ for any $c \in L$. As Marichal [13] showed, the class of polynomial functions are exactly those functions which are median decomposable.

In complete analogy with the previous subsection we propose the following weaker variant of median decomposability. We say that a function $f\colon L^n \to L$ is *quasi-median decomposable* if, for every $\mathbf{x} \in L^n$ and every $k \in [n]$, we have

$$f(\mathbf{x}) = \operatorname{median}\big(f(\mathbf{x}_k^0), \delta_f(x_k), f(\mathbf{x}_k^1)\big).$$

Note that every nondecreasing unary function is quasi-median decomposable.

Observe that $\vee$ and $\wedge$, as well as any nondecreasing function $\varphi\colon L \to L$, are quasi-median decomposable. Also, it is easy to see that any combination of constants and a nondecreasing unary function φ using $\vee$ and $\wedge$ is quasi-median decomposable and hence, by Remark 4 (i), every quasi-polynomial function is quasi-median decomposable. Our following result asserts that quasi-median decomposable functions $f\colon L^n \to L$ with a nondecreasing diagonal section δ_f are exactly the quasi-polynomial functions.

Theorem 16. *A function $f\colon L^n \to L$ is a quasi-polynomial function if and only if δ_f is nondecreasing and f is quasi-median decomposable.*

5 Some special classes of quasi-polynomial functions

In this final section we consider few noteworthy subclasses of quasi-polynomial functions, namely those of quasi-term functions and quasi-weighted maximum and minimum functions, and provide characterizations accordingly.

5.1 Quasi-term functions

We say that a function $f\colon L^n \to L$ is

- *conservative* if, for every $\mathbf{x} \in L^n$, we have $f(\mathbf{x}) \in \{x_1,\ldots,x_n\}$.
- *quasi-conservative* if, for every $\mathbf{x} \in L^n$, we have $f(\mathbf{x}) \in \{\delta_f(x_1),\ldots,\delta_f(x_n)\}$.

Note that, if f is idempotent, then it is quasi-conservative if and only if it is conservative.

Theorem 17. *A quasi-polynomial function $f\colon L^n \to L$ is a quasi-term function if and only if it is quasi-conservative.*

5.2 Quasi-weighted maximum and minimum functions

A function $f\colon L^n \to L$ is said to be a *weighted maximum function* if there are $v_0, v_1, \ldots, v_n \in L$ such that

$$f(\mathbf{x}) = v_0 \vee \bigvee_{i\in[n]} (v_i \wedge x_i). \tag{5}$$

Similarly, $f\colon L^n \to L$ is said to be a *weighted minimum function* if there are $w_0, w_1, \ldots, w_n \in L$ such that

$$f(\mathbf{x}) = w_0 \wedge \bigwedge_{i\in[n]} (w_i \vee x_i). \tag{6}$$

ISBN: 978-989-95079-6-8

We say that a function $f\colon L^n \to L$ is a *quasi-weighted maximum function* (resp. a *quasi-weighted minimum function*) if there exist a weighted maximum function (resp. a weighted minimum function) $p\colon L^n \to L$ and a nondecreasing function $\varphi\colon L \to L$ such that $f = p \circ \varphi$.

To present a axiomatization of each of these classes, we need to recall some terminology. We say that a function $f\colon L^n \to L$ is

- *maxitive* if, for every $\mathbf{x}, \mathbf{x}' \in L^n$, we have $f(\mathbf{x} \vee \mathbf{x}') = f(\mathbf{x}) \vee f(\mathbf{x}')$.
- *minitive* if, for every $\mathbf{x}, \mathbf{x}' \in L^n$, we have $f(\mathbf{x} \wedge \mathbf{x}') = f(\mathbf{x}) \wedge f(\mathbf{x}')$.

We first recall the descriptions of maxitive and minitive functions; see Dubois and Prade [8] and Marichal [12].

Proposition 18. *A function $f\colon L^n \to L$ is maxitive (resp. minitive) if and only if there are nondecreasing unary functions $f_i\colon L \to L$ ($i \in [n]$) such that, for every $\mathbf{x} \in L^n$,*

$$f(\mathbf{x}) = \bigvee_{i\in[n]} f_i(x_i) \qquad (\textit{resp. } f(\mathbf{x}) = \bigwedge_{i\in[n]} f_i(x_i)).$$

Theorem 19. *Let $f\colon L^n \to L$ be a quasi-polynomial function. Then f is a quasi-weighted maximum function (resp. quasi-weighted minimum function) if and only if it is maxitive (resp. minitive).*

Remark 5. (i) Idempotent weighted maximum functions $f\colon L^n \to L$ are those functions (5) for which $v_0 = 0$ and $\vee_{i\in[n]} v_i = 1$. Dually, idempotent weighted minimum functions $f\colon L^n \to L$ are those functions (6) for which $w_0 = 1$ and $\wedge_{i\in[n]} w_i = 0$. These functions were introduced on real intervals by Dubois and Prade [7] in fuzzy set theory.

(ii) As observed in Proposition 12, the underlying weighted maximum function (resp. weighted minimum function) defining a given quasi-weighted maximum function (resp. quasi-weighted minimum function) can be chosen to be idempotent.

Novel Methods for the Design of General Type-2 fuzzy Sets based on Device Characteristics and Linguistic Labels Surveys

Christian Wagner Hani Hagras

The Computational Intelligence Centre, School of Computer Science and Electronic Engineering, University of Essex
Colchester, United Kingdom
Email: chwagn@essex.ac.uk, hani@essex.ac.uk

Abstract—*Fuzzy Logic Systems are widely recognized to be successful at modelling uncertainty in a large variety of applications. While recently interval type-2 fuzzy logic has been credited for the ability to better deal with large amounts of uncertainty, general type-2 fuzzy logic has been a steadily growing research area. All fuzzy logic systems require the accurate specification of the membership functions' (MFs) parameters. While some work for automatic or manual design of these parameters has been proposed for type-1 and interval type-2 fuzzy logic, the problem has not yet been widely addressed for general type-2 fuzzy logic. In this paper we propose two methods which allow the automatic design of general type-2 MFs using either data gathered through a survey on the linguistic variables required or, in the case of physical devices (e.g. sensors, actuators), using data directly gathered from the specific devices. As such, the proposed methods allow for the creation of general type-2 MFs which directly model the uncertainty incorporated in the respective applications. Additionally, we demonstrate how interval type-2, type-1 and the recently introduced zSlices based general type-2 MFs can be extracted from the automatically designed general type-2 MFs. We also present a recursive algorithm that computes the convex approximation of generated fuzzy sets.*

Keywords— Type-2 fuzzy systems, general type-2 fuzzy sets, specification of fuzzy sets.

1 Introduction

Fuzzy Logic is widely applied because of its ability to model the uncertainties which are inherent to most real world applications and environments. The high levels of uncertainty encountered by such fuzzy logic systems can generally be attributed to one or more of the categories below:

- Uncertainties in inputs to FLCs which translate to uncertainties in the antecedent Membership Functions (MFs) as for example sensor measurements are typically noisy and affected by the conditions of observation (i.e. their characteristics are changed by the environmental conditions such as wind, sunshine, humidity, rain, etc.).
- Uncertainties in control outputs which translate to uncertainties in the consequent MFs of FLCs. Such uncertainties can result from the change of the actuators characteristics which can be due to wear, tear, environmental changes, etc.
- Linguistic uncertainties associated with the meaning of words (that are used as antecedents or consequents in FLCs or used as part of Computing With Words (CWW) applications) which can be uncertain as "words mean different things to different people" [1]. For example the perception of the linguistic label "warm" varies for different people while also being heavily subject to context, e.g. "warm" in the Caribbean will usually be associated with a different temperature than "warm" at the North Pole etc.

While the capability of modelling uncertainty provided by type-1 fuzzy sets has been intensively researched and shown to provide good results, in recent years interval type-2 fuzzy sets have been found to provide an even higher potential at modelling large amounts of uncertainty [1],[2],[3],[4]. Additionally, a variety of significant advances has been made in the area of general type-2 fuzzy logic which is hoped to provide the framework for an accurate model of uncertainty.

One of the main challenges during the design of any fuzzy based system (general type-2, interval type-2 or type-1) is the specification of the fuzzy Membership Functions (MFs). The choice of type of membership function (such as gaussian, triangular, etc.) as well as the choice of their specific parameters strongly affects the performance of the fuzzy system. A variety of methods to alleviate this problem have been researched for mainly type-1 and interval type-2 FLCs. Such methods are generally based on the use of expert knowledge, evolutionary techniques (such as genetic algorithms) and neural networks [5], [6]. However, there is still much work needed to standardize and simplify the selection of appropriate MFs.

Recent developments in general type-2 fuzzy theory [7], [8], [9], [10], [11] have made general type-2 applications a realistic option for the future. Hence, we have developed novel techniques to determine the appropriate parameters for general type-2 MFs which due to their complex nature are highly difficult to specify. The proposed techniques are based on directly using existing knowledge about the uncertainty contained within the variables represented by the MFs. Additionally, the proposed techniques have the advantage that they can be used for the generation of all currently common types of fuzzy sets: type-1, interval type-2 and general type-2.

Section 2 describes the design of fuzzy MFs modelling linguistic concepts using surveys while Section 3 details the design of fuzzy MFs based on physical device or variable characteristics. Both sections present real world examples to demonstrate the techniques. Section 4 describes how to extract zSlice based general type-2, interval type-2 and type-1 MFs from the general type-2 MFs generated in Section 2 and 3. In Section 5 we present the recursive convexity algorithm employed throughout the paper and give a detailed example of its application. Finally, in Section 6 we present

ISBN: 978-989-95079-6-8

the conclusions and address the work planned for the near future.

2 Design of general type-2 fuzzy sets based on the perception of linguistic labels determined through surveys.

2.1 The Human Perception of Linguistic Labels.

Fuzzy sets are frequently used to specify linguistic variables such as *temperature* or *height* used by people on an everyday basis. As such, the variable *temperature* can for example be modelled using three linguistic labels, *cold*, *moderate* and *warm* which in turn are represented using fuzzy MFs. While type-1 sets can be used to model such labels, it is clear that as type-1 MFs associate each input with a crisp membership value, hence a given type-1 MF will need to be constantly re-tuned for different perceptions of the same linguistic label. For example, the perception of the linguistic label *warm* can easily be seen to depend on factors such as the country of origin of a person (someone from Alaska will consider warm a different temperature than someone from the Caribbean), the age, sex, current season, etc.

Interval type-2 fuzzy sets can alleviate the above need for the continuous re-tuning of individual MFs as the incorporated Footprint of Uncertainty (FOU) allows for the model to include the full range of values associated with a specific linguistic label by different people in different contexts. Interval type-2 fuzzy sets nevertheless have the significant shortcoming that the uncertainty is spread evenly across the FOU which does not allow for variations of the uncertainty within this FOU to be modelled. For example, considering the example of *warm* temperature, if two people associate warm with 25°C and one person associates it with 28°C, a FOU incorporating 25°C and 28°C will not reflect that the majority of the people (here two) associate 25°C with the linguistic label *warm* - we have effectively lost this information.

This additional information can be modelled using general type-2 fuzzy sets by employing the third dimension associated with the FOU to encode the amount of uncertainty associated with each point within the FOU. In terms of our example, the FOU would be associated in its third dimension with more uncertainty towards 28°C and less uncertainty towards 25°C.

In the next few subsections we will describe how a survey on linguistic labels can be used to gather information on a specific linguistic variable using the example of *Indoor Temperature*. While this example is chosen to illustrate and simplify the process, the mechanism can be applied for any linguistic variable which is modelled by a series of consecutive linguistic labels. We will show how the information can be used to generate fuzzy MFs which model the linguistic labels and their associated uncertainty accurately using general type-2 fuzzy sets. In addition, we will present the mechanisms used to extract appropriate interval type-2 and type-1 MFs as well as zSlices based general type-2 MFs which were introduced in [11].

2.2 The survey on the linguistic variable "Indoor Temperature".

As part of our work on the generation of MFs from surveys we have conducted a survey investigating the perception of the linguistic variable *Indoor Temperature*. We have presented the participants with a questionnaire asking them to identify the position of the three linguistic labels *Cold*, *Moderate* and *Warm* in the context of an indoor environment on a temperature scale ranging from 0°C to 40°C. Further details on the survey and its results are given in Table 1. It should be noted that participants could supply additional information during the survey, specifically their age, sex and country of origin. While maintaining anonymity, we consider this information highly useful as it can be expected that factors such as the country of origin significantly affect people's perception for example of temperature.

Table 1: Details on the linguistic survey on the perception of *Indoor Temperature*. (* based on information supplied)

Number of participants:	62
Age range of participants:	18-58 years*
Mean age of participants:	30.145 years*
Number of different countries of origin:	22 countries*
Location of survey:	Colchester, UK
Date of survey:	January 2009
Minimum values with *cold, moderate, warm*:	0°C, 10°C, 16°C
Maximum values with *cold, moderate, warm*:	24°C, 27°C, 35°C
Mean values for *cold, medium, warm*:	12.062°C, 19.664°C, 25.664°C
Standard deviations for *cold, medium, warm*:	4.637, 3.552, 3.926

2.3 From a Survey to a General Type-2 Fuzzy Set model of the Linguistic Variable

In order to utilise the data provided through the survey to generate a general type-2 fuzzy set model of the linguistic variable which includes all the uncertainty information gathered in the data, we follow the following steps:

(1) Map all the values associated with a specific linguistic label to the frequency with which the values occur in the data. This step can be likened to creating a continuous histogram for the data where the xAxis represents the values (in our case, the temperature) and the yAxis represents the number of occurrences. Fig. 1 shows this mapping for our data using interpolation between the data points.

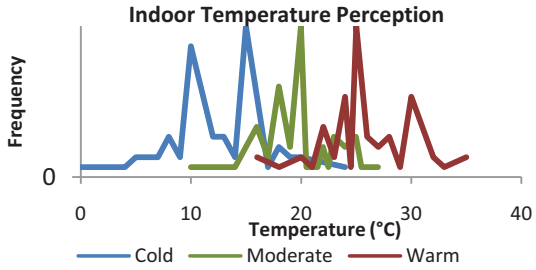

Figure 1: Mapping of survey data for the three linguistic labels *cold, moderate and warm*, showing the large amounts of uncertainty contained within the perceptions of the linguistic labels (e.g. large overlap).

(2) The data mapped in Step (1) and illustrated in Fig. 2 illustrates the significant variation in the perception of the individual linguistic labels as well as their strongly differing interrelation for different people. In order to

ISBN: 978-989-95079-6-8

utilize the information to define the third dimension of general type-2 fuzzy sets we normalise the frequency so it correlates with the uncertainty modelled in the third dimension of a fuzzy set, ie. the more frequent a specific sample was identified in the survey, the less uncertainty is associated with it.

(3) As convexity is a general requirement in several general type-2 fuzzy logic operations such as the join and meet computed on the membership grade presented in [12], we convert the normalised plots created in Step 2 to their convex approximation using a recursive algorithm which we describe in Section 5 in more detail. The original, normalised data as well as its convex approximations using our recursive algorithm and basic triangular approximation are shown for all three linguistic labels in Figs. 2a, 2b and 2c.

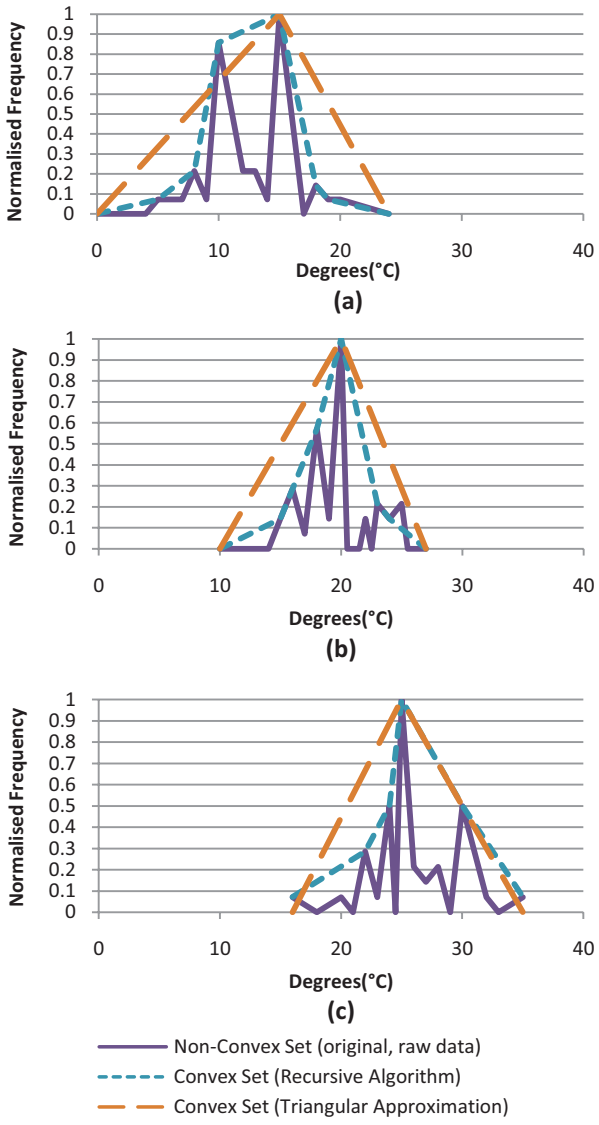

Figure 2: Representations of the linguistic labels, (a) H(cold), (b) H(moderate), (c) H(warm).

Fig. 2a, Fig. 2b and Fig. 2c clearly show that a more accurate convex approximation of the original sets is achieved when employing the proposed recursive algorithm (explained in Section 5) when compared to a simple triangular approximation. We refer to the "histogram based" representations of the linguistic labels cold, moderate and warm as H(cold), H(moderate) and H(warm).

(4) In order to create a fuzzy model of the linguistic variable *Indoor Temperature* we proceed one linguistic label at a time:

a. For *cold*, we associate H(cold) with the level 1 on the yAxis and H(moderate) with level 0 on the yAxis. We e*mploy* interpolation to recreate the general type-2 set for *cold* as shown in Fig. 3a, Fig. 3b and Fig 3c. It s*houl*d be noted that the positioning of H(cold) and H(modera*te)* at *thi*s step is not arbitrary but follows logically from the linguistic labels, i.e. H(cold) represe*nts* the temperature values associated with *cold*, hence they should be related to a yLevel of 1. H(moderate) on the other hand represents the *temp*erature values which are associated with *moderate* and as such not anymore related with *cold*, thus, in terms of the fuzzy set **cold**, it should be ass*ociated* with yLevel 0 at H(moderate).

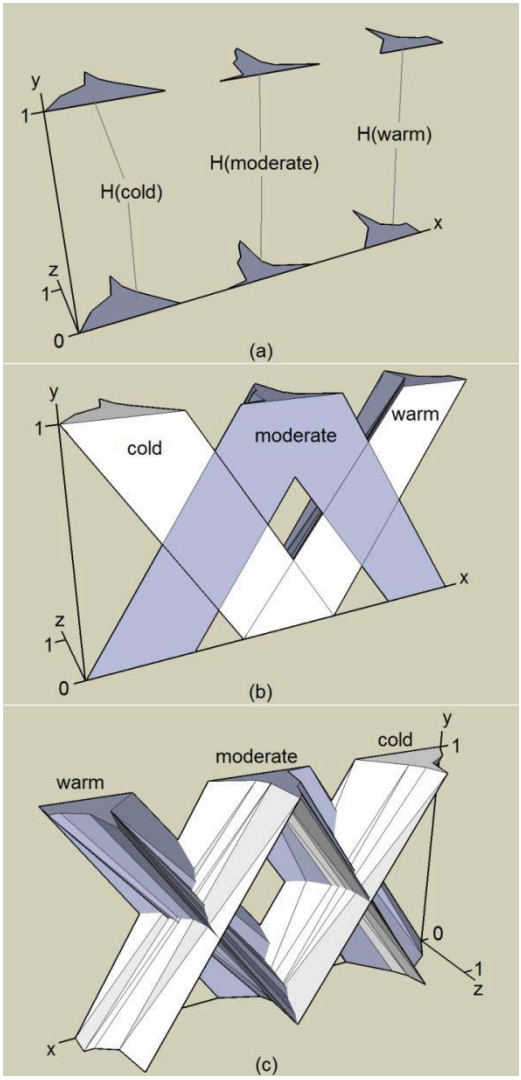

Figure 3: Schematic representation of the steps involved in creating the fuzzy set representation of linguistic labels. (a) "Histogram representations" of the linguistic labels associated with the respective levels on the yAxis before interpolation. (b) Fuzzy sets after interpolation from the front. (c) Fuzzy sets after interpolation from the rear.

ISBN: 978-989-95079-6-8

b. For *moderate*, we associate H(cold) with the level 0 on the yAxis, H(moderate) with level 1 on the yAxis and H(warm) with yLevel 0 on the yAxis. We employ interpolation to recreate the general type-2 set for *moderate* as shown in Fig. 3a, Fig. 3b and Fig. 3c.The reasoning of the positioning on the yAxis of H(cold), H(mod*erate) a*nd H(warm) is analogous to Step a.

c. Fo*r warm,* we associate H(moderate) with level 0 on the yAxis and H(warm) with yLevel 1 on the yAxis. We employ interpolation to recreate the general type-2 set for *warm* as shown in Fig 3(a)-(c).
The reasoning of the positioning on the yAxis of H(moderate) and H(war*m) i*s analogous to Step a.

We have shown in a series of steps how the data on a linguistic variable such as temperature can be used to generate a general type-2 representation of the given variable. It is straightforward to extract zSlices based general type-2 fuzzy sets as introduced in [11], interval type-2 and type-1 sets. The individual steps are shown for the general case in Section 4.

3 Design of fuzzy sets based on device or variable characteristics

In the context of Fuzzy Logic Controllers (FLCs), fuzzy logic sets are generally employed to model the uncertainty associated with the inputs and outputs of the FLC. In real world applications these inputs and outputs are commonly physical devices such as sensors and actuators which are susceptible to a wide range of sources for uncertainty, from wear and tear, to environmental conditions, signal noise etc. General type-2 fuzzy sets are well suited to model this uncertainty and in this section we are describing how information about the device or variable to be modelled can be directly incorporated into the fuzzy sets modelling. We will be using the illustrative example of generating the MFs for a sonar sensor from information which is directly retrieved from the device. While the example is referring to a sonar sensor, the overall method is applicable to every device or artefact that is to be modelled.

Generation of two MFs *Near* and *Far* which model the distance value measured using a Sonar sensor.

1. As a first step, we discretize the maximum sensor range into X steps. A finer level of discretization will result in a more accurate model of the uncertainty contained within the sensor outputs. The process of discretizing the sensor range of a Pioneer robot side sonar is shown in Fig. 4.
2. At every step, the device, in our case the sonar sensor is sampled (for example by presenting the sonar with an obstacle at the specified distance in our case) Y times. A larger number Y of samples will result in a more accurate model of the uncertainty contained within the sensor outputs. The series of Y readings are analysed to create a mapping detailing the normalized frequency of each specific sample. As such, in our case, the reading (or close group of readings) which was measured the largest number of times out of Y samples is mapped to 1, readings that have never been measured are mapped to 0 etc. This approach can be likened to a continuous (high discretization level) histogram. An example of this can be seen in Fig. 4. At each sampling step x, Y samples are taken which are translated to the respective histograms H(x).

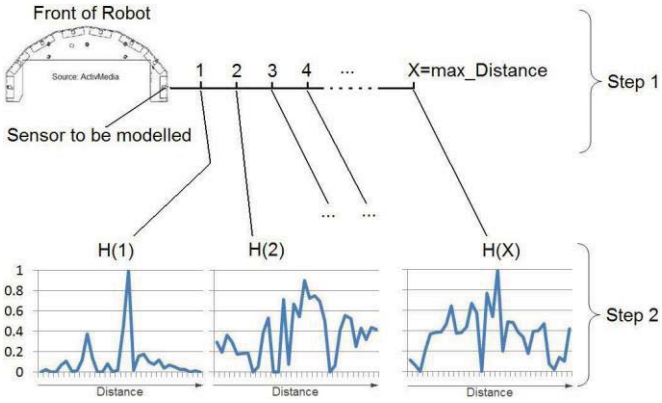

Fig. 4 Step 1 and 2 for the automatic generation of MFs for the sonar sensor mounted on a Pioneer robot.

3. The histograms generated in Step 2 are representative of the uncertainty encountered while sampling the specific distance x, i.e. while usually the majority of samples return the accurate reading, some will return a different reading because of sensor noise, environmental impact, etc. The information contained in the histograms can thus be employed to define the third dimension of general type-2 fuzzy sets which models the uncertainty within the sensor. In order to use the histograms to define the third dimension of general type-2 fuzzy sets, the histograms need to be strictly convex. The convexity of the third dimension of fuzzy sets is a general requirement in several general type-2 fuzzy logic operations such as the join and meet computed on the membership grade presented in [12]. While we are planning to address the direct handling of non-convex sets in the future, at this stage we are converting the existing histogram into a convex function. While this can be done through simple triangular approximation, this results in a very poor representation of the information contained in the initial histogram. We have devised a recursive algorithm which converts the histograms H(x) to their convex counterparts C(x) while preserving as much information as possible. An example comparing an initial histogram to its convex approximations using the triangular approach and our algorithm can be seen in Fig. 5 and an in depth

ISBN: 978-989-95079-6-8

description of the algorithm and further comparisons can be found in Section 5.

It should be noted that the algorithm can be applied to any type-1 fuzzy set and as such to the histograms as presented here as well as any vertical slices of the general type-2 fuzzy set if required.

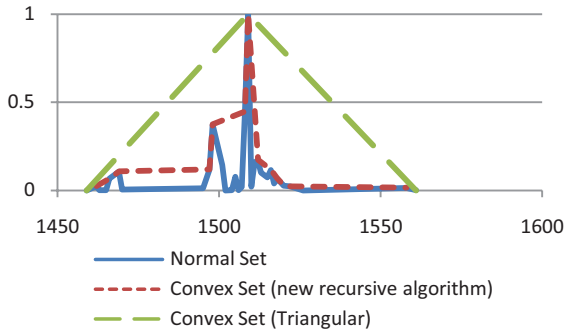

Figure 5: Comparison between an initial non-convex histogram (set) and its convex approximation using the triangular and our recursive algorithm approach.

4. For each linguistic label, we will need to determine the position of the linguistic labels within the device input/output range. In our example we are using triangular MFs and as such would define three points for every linguistic variable: its start, its maximum and its end. Fig.6 shows the Near MF for which in our example we defined the start as Ns, the maximum as Nm and the end as Ne. All previously generated convex H(x) where $x \in [start, end]$ are mapped to the triangle formed by {start, maximum, end}, "raising" them to the respective level on the yAxis. This process is illustrated in Fig. 6 for 5 histograms. In case there is uncertainty (for example due to linguistic uncertainties) about the positions of points Ns, Nm and Ne, we will have various triangles, each one is associated with the relevant histograms as shown in Fig.6. These triangles are then interpolated (as explained in the following step) in the x-y and the y-z domain to generate the FOU and third dimension of the general type-2 fuzzy set.

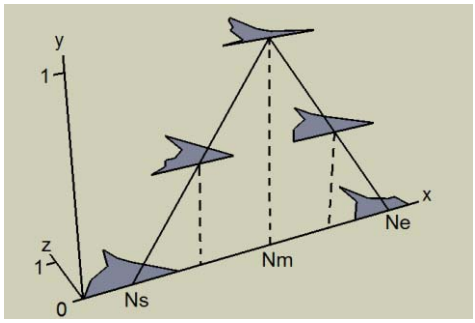

Fig. 6 The fuzzy MF *Near* is composed of the endpoints defined by the linguistic variable combined with the histograms of any sampling po*ints* which lie within the range of the linguistic variable. Here, five histograms are shown which have been "raised" to their respective level on the yAxis which is defined by the intersection of their sampling point x with the triangular {Ns,Nm,Ne}.

5. In the final step towards the generation of a general type-2 MF, the different histograms are linked through interpolation. It should be noted that the choice of interpolation method and the number of histograms directly affect the quality of the uncertainty model of the MF. Fig. 7 illustrates the front and side view of our exemplary MF *Near*. If it is requirement for the vertical slices of the resulting set to be strictly convex, the same convexity algorithm as described above can be applied to the vertical slice.

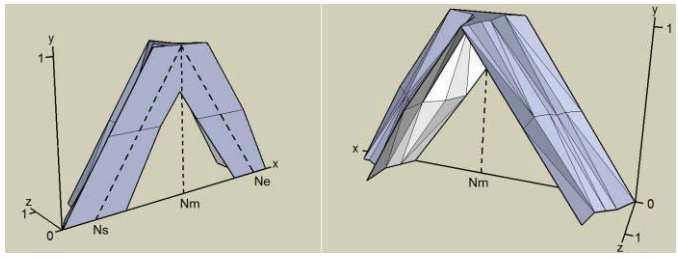

Figure 7: (a) Front view of the generated membership function for *Near*; (b) rear view of the same set.

The procedure *for* the automatic generation of general type-2 MFs presented in this section allows the generation of MFs which reflect and model the uncertainty encountered by or inherent to a specific device. The generated general type-2 MFs can easily be used to extract type-1, interval type-2 and zSlices based general type-2 fuzzy sets as we will be shown in Section 4.

4 Extraction of zSlice based general, interval type-2 and type-1 fuzzy sets.

It is straightforward to extract type-1 MFs and interval type-2 MFs from the general type-2 MFs generated in Sections 2 and 3 by restricting the zLevel (i.e. the value on the zAxis) to 1 or 0 respectively (in the case of interval type-2 MFs, they are subsequently "raised" to a zLevel of 1). This allows the process to generate type-1 and interval type-2 MFs from data without altering the procedure, which should facilitate the performance comparison between different levels of complexity in FLCs. An example of the MFs extracted from the general type-2 fuzzy sets shown in Fig. 7 is shown in Fig. 8.

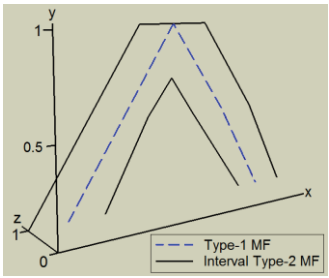

Figure 8: The type-1 and interval type-2 MFs extracted from the general type-2 MF shown in Fig. 7

ISBN: 978-989-95079-6-8

Finally, it is worth noting that the fuzzy sets generated in Sections 2 and 3 can easily be transformed to zSlices based MFs which were introduced in [11]. Fig. 9 shows an example of the generated zSlice based MF from the general type-2 MF shown in Fig. 7.

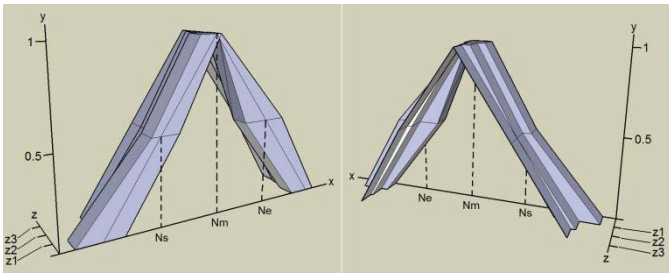

Figure 9: zSlice based general type-2 version (3 zSlices) of the general type-2 set shown in Fig. 15. It should be noted that only the zSlices 1-3 are shown, zSlice 0 has been omitted to improve visibility.

5 Approximation of a convex set from a non-convex set.

5.1 Description of the algorithm.

In order to generate a convex function from a non-convex function (more specifically, the discretized points from this function) while maintaining a high level of similarity to the original function, we have devised a recursive algorithm which is described in detail in this section.

The algorithm takes a discretized non-convex function (such as a type-1 fuzzy set) F as input. The discretization level along the xAxis is referred to as D. The function F matches each point on the xAxis x_d to a point y_d on the yAxis (where $d \in [1, D]$). As such, the function is represented as a series of points P_D in two-dimensional space where the x and y coordinates of a point P_d are referred to as P_{d_x} and P_{d_y}.

In our application of the convex approximation of "continuous histograms" (as discussed in Sections 2 & 3), the x-Axis represents the input axis, for example the distance, if we are considering a distance sensor, while the yAxis represents the number of samples. We denote the convex output set as O.

The recursive algorithm performs the following steps:

0.
   a. Traverse set from left to right (arbitrary- or from right to left) and find the coordinates of the discretized point P_{Max} (P_{Max} is defined in two-dimensional space by its coordinates P_{Max_x} and P_{Max_y}), where
      $P_{Max} \in P_D$ and
      $P_{Max_y} = \max\left(P_{d_y}\right), d \in [1, D]$.
      If more than one point with the same maximum is found, the middle point (according to its x coordinates P_{d_x}) is chosen. If the number of points with the same maximum is even, one of the middle points is chosen arbitrarily.
   b. Add point P_{Max} to the output set O.
   c. Split the series of points into two series: $\{P_1, \dots, P_{Max}\}$ and $\{P_{Max}, \dots, P_D\}$.
   d. Pass the series $\{P_1, \dots, P_{Max}\}$ to Step 1 and the series $P_{Max}, \dots, P_D\}$ to Step 2.

1.
   a. Refer to the given series of points as $[P_{start}, P_{end}]$.
   b. $IF\ (P_{start} == P_{end})$ THEN STOP.
   c. Find the new maximum point $P_{Max'}$ of the given series such that:
      $P_{Max'_y} > P_{start_y}\ AND\ P_{Max'_y} < P_{end_y}$
      $P_{Max'_y} = \max\left(P_{d_y}\right), d \in]start, end[$.
   d. Add point $P_{Max'}$ to the output set O.
   e. Split the given series into two series: $\{P_{start}, \dots, P_{Max'}\}$ and $\{P_{Max'}, \dots, P_{end}\}$ and pass both series separately to Step 1 (recursion).

2.
   a. Refer to the given series of points as $[P_{start}, P_{end}]$.
   b. $IF\ (P_{start} == P_{end})$ THEN STOP.
   c. Find the maximum point $P_{Max'}$ of the given series with endpoints such that
      $P_{Max'_y} < P_{start_y}\ AND\ P_{Max'_y} > P_{end_y}$
      $P_{Max'_y} = \max\left(P_{d_y}\right), d \in]start, end[$.
   d. Add point $P_{Max'}$ to the output set O.
   e. Split the given series into two series: $\{P_{start}, \dots, P_{Max'}\}$ and $\{P_{Max'}, \dots, P_{end}\}$ and pass both series separately to Step 2 (recursion).

Below we give an example of the application of the recursive algorithm.

5.2 Example application of the recursive algorithm.

In Table 2 we indicate the coordinates of a non convex set shown in Fig.10 taken from real world experiments and compare it to the coordinates computed by our algorithm and the triangular approximation.

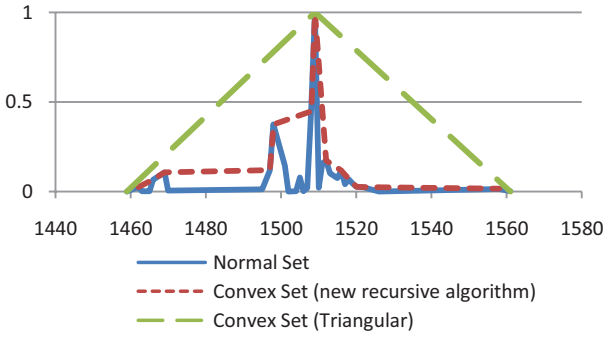

Fig. 10 A plot of the non convex input function as well as both the recursive and triangular approximated

From Table 2 it can be seen that both the recursive and the triangular algorithms omit a significant amount of detail in order to generate a convex approximation of the input set. Nevertheless the number of preserved samples and thus detail and information is much larger in the recursive approximation. This is also visible in Fig. 10 which shows that the recursive algorithm provides a vastly superior fit to

ISBN: 978-989-95079-6-8

the original function in comparison to the triangular approximation.

Table 2 Comparison of z and y tuples preserved by our recursive algorithm and a triangular algorithm while converting the non-convex set shown in Fig. 10.

6 Conclusions

In this paper we have addressed the reoccurring problem in fuzzy systems of specifying the parameters for fuzzy membership functions (MFs). The correct selection of parameter of fuzzy MFs is crucial in order for the fuzzy systems to model the uncertainty contained within the system correctly and thus to allow the generated fuzzy system to provide good performance. While the problem has been previously addressed to some extent for interval type-2 and type-1 fuzzy systems, the use of general type-2 fuzzy sets requires the specification of an even larger number of parameters for each MF and as such is set to exasperate the problem of choosing those parameters.

We have presented two novel methods which allow the design of general type-2 fuzzy MFs directly from data and as such eliminate the need for a manual design of the MFs or the use of artificial intelligence techniques in order to tune the MFs.

The first method allows the design of general type-2 fuzzy MFs using data on linguistic labels which is collected through a survey. The technique allows for an accurate representation of the perception of linguistic variables gathered through the survey without any loss of information.

The second method specifies the general type-2 MFs based on data which is directly sampled from the device (such as a sensor) which is to be modelled and as such creates an accurate representation of the uncertainty associated with the specific device.

Both methods further allow the extraction of type-1, interval type-2 and the recently introduced zSlices based general type-2 fuzzy sets.

Additionally, we have presented a recursive algorithm that computes a convex approximation of fuzzy sets while preserving significantly more detail than simple triangular approximation which in turn enables a more accurate modelling of the uncertainty within the fuzzy MFs.

In the future, we are planning to further refine the algorithms for the automatic definition of fuzzy sets while investigating their performance in real world applications. Particularly, we are looking to extend the theoretical frameworks to non-convex fuzzy sets and to investigate non-singleton fuzzification in conjunction with the automatically created sets.

***Abstract*—** *This paper proposes to analyze two flow line systems in which we include possibilistic data -the priority-discipline is possibilistic instead of probabilistic- and measure the performances of the systems with the effectiveness measure "waiting time in queue". In a previous work we have analyzed and developed a queuing model with uncertain priority-discipline, using Zadeh's extension principle. Because of it in this paper the analysis of the model takes the work realized by Prade as a starting point to incorporate an uncertain priority-discipline in a flow line system by means of a possibilistic distribution. To verify the validity of the proposed method, we calculate the possibility distribution of the priority-discipline and the possibility distribution of the performance measure "waiting time in queue", in two flow line systems with different waiting lines: the determinist flow line system $D/D/1$ and the classic flow line system $M/M/1/N$ with finite capacity. Since the performance measure is expressed by membership function rather than by crisp value, the fuzziness of input information is conserved completely, and more information is provided for capacity planning in flow line systems.*

Keywords— Flow Line Systems, Fuzzy Numbers, Possibility Theory, Priority-Discipline

1 Introduction

In this work we present two flow line systems to which we add a possibilistic priority-discipline instead of a probabilistic priority-discipline. For the development of the models we will follow the methodology exposed by *Prade* [1] about possibilistic models of queuing systems. In the literature regarding the queuing models with uncertain data we have not found any article that uses and develops his method in order to incorporate uncertainty in the queuing models with priority-discipline (except for *Prade*'s work). For example, the works of Li and Lee [2], Negi and Lee [3], or more recently Chen [4] or Pardo and de la Fuente [5,6] among others, study the flow line systems with uncertain data according to the Zadeh's extension principle [7], and in the work of Pardo and de la Fuente [8] the optimization of the fuzzy queuing model with priority-discipline is also studied according to the Zadeh's extension principle.

2 Calculation of the membership function of possibilistic priority-discipline

The possibilistic priority-discipline indicates the possibility that has the unit that arrives to the system in the position *n* to be overtaken, displaced or served in a different position that *n* in the waiting line. To develop the proposed models in this work, we need to define a possibility distribution of the priority-discipline but the possibility distribution can be calculated from the different existing methods to construct possibility distributions from real data or from the opinion of the experts (for example in Dubois et al. [9]).

In this way, we define the following possibility distribution (we denote by μ_i^n) and it provides us with the possibility that has the unit that has arrived in the position *n* to be served in the position $n+i$. Logically, this is valid when there is a queue length of one or more units at the arrival of one unit to the system, depending on the case. Besides and because of simplicity, the possibility distribution of the priority-discipline will be considered independent of the unit *n*. For this reason, the possibility of the unit *n* to advance one or more positions in the queue is:

1. The possibility of being served in the position *n* is: $\mu_0^n = 1$.
2. The possibility of being served in the position $n-1$ is: $\mu_{-1}^n = \sigma_1 \left(\sigma_1 \le 1\right)$.
3. The possibility of being served in the position $n-2$ is: $\mu_{-2}^n = \sigma_2 \left(\sigma_2 \le 1\right)$. In this case we consider that the unit $n-1$ and the unit $n-2$ move back one position in the waiting line.
4. The possibility of being served in the position $n+i$ with $i = -3,-4,...$ is: $\mu_i^n = 0$. In this way one unit can not advance more than two positions in the waiting line.

From the following hypotheses, we calculate the possibility that has the waiting unit to be moved back one position in the waiting line because of the arrival of one unit with higher priority. Then:

1. There are two reasons for the unit *n* to move back one position in the waiting line:
   i) Because the unit $n+1$ overtakes the unit *n*. That happens because it has priority to advance one position in the queue or because it has priority to advance two positions in the queue. The

ISBN: 978-989-95079-6-8

possibility of the event "the unit $n+1$ overtakes the unit n" is the association of the two previous events and it is know that it has a certain rate according to the fuzzy logic (Zimmermann [10]):

$$\max\{\sigma_1, \sigma_2\} \tag{1}$$

ii) If the unit $n+1$ does not have higher priority to the unit n, but the unit $n+2$ has higher priority to the units n and $n+1$ and advances two positions, the units n and $n+1$ move back one position and that happens with a possibility grade of σ_2.

Then, the possibility grade of the unit n to move one position back once it has arrived to the system is the association of the previous events, and according to the fuzzy logic (Zimmermann [10]):

$$\mu_1^n = \max\{\max\{\sigma_1, \sigma_2\}, \sigma_2\} = \max\{\sigma_1, \sigma_2\} \tag{2}$$

2. The unit n can move back two positions in the queue if it moves back twice consecutively, that means if the event "the unit n moves back one position" happens twice, what in fuzzy logic has a certain rate (Zimmermann [10]):

$$\mu_2^n = \min\{\mu_1^n, \mu_1^n\} = \mu_1^n = \max\{\sigma_1, \sigma_2\} \tag{3}$$

3. Likewise, the possibility grade of the unit to be moved back three or more positions in the waiting line can be calculated and in all of them we have:

$$\mu_i^n = \max\{\sigma_1, \sigma_2\} \quad \text{with} \quad i = 3, 4, \ldots \tag{4}$$

Then, the possibility grade of the unit n to move back in the waiting line, regardless of the number of positions is:

$$\mu_i^n = \max\{\sigma_1, \sigma_2\} \quad \text{with} \quad i = 1, 2, \ldots \tag{5}$$

The possibility distribution of the priority-discipline in the waiting line is:

$$\mu_i^n = \begin{cases} 0 & \text{if} \quad i = -3, -4, \ldots \\ \sigma_2 & \text{if} \quad i = -2 \\ \sigma_1 & \text{if} \quad i = -1 \\ 1 & \text{if} \quad i = 0 \\ \max\{\sigma_1, \sigma_2\} & \text{if} \quad i = 1, 2, \ldots \end{cases} \tag{6}$$

Once we know μ_i^n we obtain the "possibility distribution of the permanence time in line of the unit n" (denoted $\tilde{W}_q^n$), taking into account that if the unit n advances two positions, it does not have to wait in the waiting line to the service of the units $n-2$ and $n-1$. I it advances one position, we have to take away the service of the unit $n-1$. If it maintains its arrival position, its permanence time in queue does not change. And if it moves back in the queue it has to wait its permanence time and also so many service times as units that had overtaken it. Using Zadeh's notation to denote a fuzzy number (Zadeh [7]) (the possibility grade is previous to the symbol "/", the possible value is posterior, and the symbol "+" represents the association), if it is denoted by b the service time of one unit, the possibility distribution of the permanence time in queue of the unit n is:

$$\begin{aligned} \tilde{W}_q^n = {} & \mu_{-2}^n / \left(W_q^n - 2b\right) + \mu_{-1}^n / \left(W_q^n - b\right) + \\ & + \mu_0^n / W_q^n + \mu_1^n / \left(W_q^n + b\right) + \mu_2^n / \left(W_q^n + 2b\right) + \ldots \end{aligned} \tag{7}$$

Depending on the particular features of the flow line system to which is added this possibilistic priority-discipline, we obtain some results that differ among the different models. In the following sections we show the obtained theoretical results with two flow line systems with possibilistic priority-discipline.

3 Determinist flow line system $D/D/1$ with times among arrivals longer than the service time and possibilistic priority-discipline

In the determinist flow line system, the units arrive to the system with time among arrivals constant and are also served in constant times. It is supposed that the system is organised in a way that the arrivals happen in regular intervals and they are also regularly served in an only channel. The arrival source is considered unlimited and there is no limitation in the capacity of the system.

Saaty [11] analyses the determinist queuing system D/D/1 in transitory state. That means that the initial conditions (the number of units that there are in the system at the initial moment) affect the obtained results in the model. In addition to this, Saaty studies the system with times among arrivals longer than the service times. This condition supposes that the units take in arriving to the system more time that the system needs to serve them, that is why there will never be a waiting line when starting the system there are no units in it (initial condition $I = 0$ when $t = 0$, with I the number of initial units in the system). Each unit that arrives to the system is served before the arrival of the next unit. Due to this, Saaty studies the determinist model supposing that it is able to empty (the units in the system are not accumulated) under the initial existence conditions of I units in the system at the initial moment.

To know the evolution of this system and to calculate its performance measure, we have to analyse the behaviour of this flow line. The I units are found in the facilities when the system start to work and since the system is able to absorb the next arrivals (they are served very fast) then there will be an moment (denoted T) in which there will be no units in the system and each one arriving to the system will be served before the arrival of the next one. In T, the system reaches the steady state: the server stays idle until a new arrival, there are no units in the waiting line and the permanence time in queue is zero. In order to define the system completely, we need to calculate the number of units that arrive to the system before T (denoted A). They are the units that have to stay in the waiting line together with the initials.

ISBN: 978-989-95079-6-8

Regarding the performance measure "waiting time in queue of the unit *n*", W_q^n Saaty does not calculate it for the different values of *n*. That is why before incorporating a possibilistic priority-discipline, we will first calculate the variable *A* and the performance measure W_q^n. It will be so denoted:

a: Time among consecutive arrivals.

b: Service time.

I: Number of units in the system at the initial moment (including the unit that arrives to the system at the initial moment and the units that were already in it). The case $I=1$ means that at the arrival of the first unit, the system was empty.

The system reaches the steady state in *T* once the server has attended the initial units *I* and the new arrivals *A*. The arrival $A+1$ is the first one that finds the server free and goes directly to be attended. This arrival happens in $(A+1)a$. From here, the moment in that the first unit $A+1$ arrives to the system has to be longer than the time of service of the $I+A$ units, otherwise it is no possible that such arrival finds the system free. Then:

$$(A+1)a > (I+A)b \Leftrightarrow A > \frac{Ib-a}{a-b} \tag{8}$$

The variable *A* has to be the first entire number that fulfils the previous expression, then:

$$A = \left[\frac{Ib-a}{a-b}\right] + 1 = \left[\frac{b(I-1)}{a-b}\right] \tag{9}$$

where $[x]$ represents the whole part of the number *x*, that is to say, the largest integer less than or equal to a number *x* (floor function).

The performance measure of the permanence time in queue of the unit *n*, W_q^n is:

$$W_q^n = \begin{cases} (n-1)b & \text{if} \quad n \le I \\ (n-1)b-(n-I)a & \text{if} \quad I < n \le I+A \\ 0 & \text{if} \quad n > I+A \end{cases} \tag{10}$$

We obtain the result (10) from the following reasoning: If the arrival time to the system of the unit *n* is:

$$T_{ll}^n = \begin{cases} 0 & \text{if} \quad n \le I \\ (n-I)a & \text{if} \quad n > I \end{cases} \tag{11}$$

and the time when the unit *n* is served is:

$$T_s^n = \begin{cases} (n-1)b & \text{if} \quad n \le I+A \\ (n-I)a & \text{if} \quad n > I+A \end{cases} \tag{12}$$

then $W_q^n = T_s^n - T_{ll}^n$.

3.1 Example

Once we know the behaviour of the determinist flow line systems, following we show the incorporation of a possibilistic priority-discipline in the system $D/D/1$ with practice application, calculating the possibility distribution of the permanence time in queue for each unit that when arrive to the system have to stay in the waiting line for a flow line system with time among arrivals of 30 min., service time 20 min., 8 initial units and with the possibility distribution of the priority-discipline: $\mu_{-2}^n = 0.2$; $\mu_{-1}^n = 0.4$ and $\mu_0^n = 1$, from where we have that:

$$\mu_i^n = \max\{\sigma_1, \sigma_2\} = \max\{0.4, 0.2\} = 0.4\,,\ i = 1,2,...$$

First of all with the data of the example it will be $I=8$, $A=14$, and:

$$T_{ll}^n = \begin{cases} 0 & \text{if} \quad n \le 8 \\ (n-8)30 & \text{if} \quad n > 8 \end{cases} \qquad T_s^n = \begin{cases} (n-1)20 & \text{if} \quad n \le 22 \\ (n-8)30 & \text{if} \quad n > 22 \end{cases}$$

$$W_q^n = \begin{cases} (n-1)20 & \text{if} \quad n \le 8 \\ (n-1)20-(n-8)30 & \text{if} \quad 8 < n \le 22 \\ 0 & \text{if} \quad n > 22 \end{cases}$$

Before calculating the possibility distribution of the permanence time in queue of the client *n* and given the features of the system, we have to make the following remarks:

- Because of the evolution of this system there is a unit *N*, such that $I < N \le I+A$ $(8 < N \le 22)$, which fulfils that every unit $n > N$ is served before the arrival of the next unit and it is not possible for the unit $n+1$ to overtake the unit *n*. That means, if it is denoted by T_s^N at the same moment that the unit *N* is served and by T_{ll}^{N+1} the arrival time of the unit $N+1$, then *N* is the first unit that fulfils: $T_s^N < T_{ll}^{N+1}$, so there is no possibility for the position *n* to be moved back in the waiting line, then $\mu_j^n = 0$, $j = 1,2,...$ and $n > N$, with:

  $$T_s^N = (N-1)20 < (N+1-8)30 = T_{ll}^{N+1}$$

  From here, we obtain $N > 19$, then in the example it is $N = 20$. In this way we obtain:

  1. If $n < 20$ is $\mu_j^n = 0.4$ with $j = 1,2,...,20-n$ and $\mu_j^n = 0$ with $j = 20-n+1,....$
  2. If $n \ge 20$ is $\mu_j^n = 0$ with $j = 1,2,...$
  3. And if from the unit 20 it is not possible to move back in the waiting line, then it is not possible to overtake in the line from the unit 21 and the following ones. Then, if $n \ge 21$ is $\mu_{-2}^n = \mu_{-1}^n = 0$.

- The possibilities μ_{-2}^n and μ_{-1}^n when $n \le 20$ depend on the unit *n*:

ISBN: 978-989-95079-6-8

1. If $n=1$, that is, the first unit in the system, then: $\mu_{-2}^{1}=\mu_{-1}^{1}=0$.
2. If $n=2$, then: $\mu_{-2}^{2}=0$ and $\mu_{-1}^{2}=0.4$, given that the second unit arrives at the same time that the first one and there is a possibility that it advances in the waiting line.
3. If $3\le n\le I=8$, they are units that arrive to the system in the moment zero and there is a possibility that all of them change their position advancing one or two positions in the waiting line, then: $\mu_{-2}^{n}=0.2$ and $\mu_{-1}^{n}=0.4$
4. If $9\le n\le 20$, because of the features of that system we know that the waiting line diminishes for any unit that enters, that means that it is possible for the last arrivals that the level of the queue is lower than 2 or 1 unit and they can not advance one or two positions respectively. To determine what units can make its priority effective, we follow the next reasoning: We denote N_1 the unit with priority to advance two positions in the waiting line, in order to make this priority effective, the arrival time of the unit N_1 must be lower or the same that the service time of the unit N_1-2 (the unit previous to N_1 in two positions) so it can occupy its position, then $T_{ll}^{N_1}\le T_s^{N_1-2}$, and from here we get $N_1\le 18$. And we denote N_2 the unit with priority to advance one position in the waiting line, this priority can be likewise effective if the arrival time of the unit N_2 is lower or the same that the service time of the unit N_2-1 (the unit previous to N_2 one position), then $T_{ll}^{N_2}\le T_s^{N_2-1}$, from where it is $N_2\le 20$. Then:

   i) If $9\le n\le 18$, then $\mu_{-2}^{n}=0.2$ and $\mu_{-1}^{n}=0.4$

   ii) If $n=19$ or $n=20$, then $\mu_{-2}^{n}=0$ and $\mu_{-1}^{n}=0.4$

With all this we calculate the possibility distribution of the permanence time in queue of the unit *n*:

$$\begin{aligned}\tilde{W}_q^n=\ &\mu_{-2}^{n}/\left(W_q^n-40\right)+\mu_{-1}^{n}/\left(W_q^n-20\right)+\\ &+1/W_q^n+\mu_1^n/\left(W_q^n+20\right)+\mu_2^n/\left(W_q^n+40\right)+\\ &+\ldots+\mu_{20-n}^{n}/\left(W_q^n+(20-n)20\right)\end{aligned}$$

Following is detailed this possibility distribution for some values of *n*:

$$\begin{aligned}\tilde{W}_q^1&=1/0+0.4/20+\ldots+0.4/380\\ \tilde{W}_q^2&=0.4/0+1/20+0.4/40+\ldots+0.4/380\\ \tilde{W}_q^8&=0.2/100+0.4/120+1/140+0.4/160+\ldots+0.4/380\\ \tilde{W}_q^{15}&=0.2/30+0.4/50+1/70+0.4/90+\ldots+0.4/170\\ \tilde{W}_q^{20}&=0.4/0+1/20\\ \tilde{W}_q^{21}&=1/10\\ \tilde{W}_q^n&=1/0\quad\text{if}\quad n\ge 22\end{aligned}$$

Just as the possibilistic priority-discipline has been adapted to the determinist flow line system $D/D/1$, with time among arrivals longer than the service time, it can be incorporated to other determinist queuing systems only taking into account the features of the system and the evolution of the waiting line.

4 Flow line systems $M/M/1/N$ with possibilistic priority-discipline

The classic flow line system $M/M/1/N$ with finite capacity is considered, with times among arrivals and service time distributed according to an exponential of parameters λ and μ respectively, equals to all the units and regardless the kind of priority. The system has an unlimited enter source and the capacity is *N* units in the system.

The system is analysed in steady state so we know the probabilities of the system to be empty [12]:

$$P_0=\left(\sum_{n=0}^{N}\left(\frac{\lambda}{\mu}\right)^n\right)^{-1} \tag{13}$$

and that the units *n* are found in the system:

$$P_n=P_0\left(\frac{\lambda}{\mu}\right)^n \text{ with } n=1,2,\ldots,N \tag{14}$$

and we also know that the average permanence time in queue of each unit is:

$$W_q=\frac{L_q}{\lambda\left(1-P_N\right)} \tag{15}$$

where:

$$L_q=P_0\frac{\lambda}{\mu}\left(\sum_{n=2}^{N}(n-1)\left(\frac{\lambda}{\mu}\right)^{n-1}\right) \tag{16}$$

is average length of the units in queue.

To incorporate the possibilistic priority-discipline before indicated we have to take into account that in the stochastic flow line systems we do not know for sure the moment when the unit arrives to the system, which the length of the queue is when the unit arrives and if, after that, one ore more units can arrive and make that the previous unit move back in the queue from its arrival position. Then, we should calculate the average possibility to advance one or two

ISBN: 978-989-95079-6-8

positions in line, the average possibility to remain in the arrival position or the average possibility of moving back in the queue:

1. When the unit *n* arrives to the system, if it has priority to overtake 2 units and besides there is a waiting line with 2 or more units in the queue (3 units or more in the system), the priority-discipline will be made effective. The possibility of overtaken two units is μ_{-2}^{n} and the probability that 3 or more units are found in the system is $P_{n\geq 3} = 1 - P_0 - P_1 - P_2$. For this reason the average possibility of one unit advancing two positions in the queue (denoted p_{-2}) happens when both happen at the same time, and using the definition of Zadeh [13] of the probability of a fuzzy event is:

$$p_{-2} = \mu_{-2}^{n} \cdot P_{n\geq 3} \tag{17}$$

2. With a similar reasoning to the previous one, we conclude that the average possibility of one unit advancing one position is:

$$p_{-1} = \mu_{-1}^{n} \cdot P_{n\geq 2} \tag{18}$$

with $P_{n\geq 2} = 1 - P_0 - P_1$

3. The possibility of remaining in its position in the waiting line always happens, regardless the number of units that there are in the system at the moment that the unit *n* arrives, then:

$$p_0 = \mu_0^{n} = 1 \tag{19}$$

4. The average possibility of moving back in the queue, p_i with $i = 1, 2, ..., N-1$ happens when the unit has to wait to be attended since another unit can arrive meanwhile with higher priority. One unit has to wait if the system is busy when it arrives to it and this happens with probability $P_{n>0} = 1 - P_0$, then:

$$p_i = \mu_i^{n} \cdot P_{n>0} \tag{20}$$

Once we know the average possibility of advancing or moving back in the waiting line, the possibility distribution of the average permanence time in queue is:

$$\begin{aligned} \tilde{W}_q = {} & p_{-2} / \left(W_q - 2/\mu\right) + p_{-1} / \left(W_q - 1/\mu\right) + \\ & + p_0 / W_q + p_1 / \left(W_q + 1/\mu\right) + p_2 / \left(W_q + 2/\mu\right) + ... \end{aligned} \tag{21}$$

4.1 Example

To conclude, we illustrate with an example the incorporation of a possibilistic priority-discipline calculating the possibility distribution of the average permanence time in queue for a flow line system $M/M/1/10$ of parameters $\lambda = 6$ and $\mu = 8$ units per hour, and $N = 10$ units. The possibility distribution of the waiting discipline is: $\mu_{-2}^{n} = 0.4$, $\mu_{-1}^{n} = 0.6$ and $\mu_0^{n} = 1$. From here: $\mu_i^{n} = \max\{0.4, 0.6\} = 0.6$, with $i = 1, 2, ..., 9$.

With this data we have: $P_0 = 0.261$, $P_1 = 0.1958$ and $P_2 = 0.1468$, then $P_{n\geq 3} = 0.3964$, $P_{n\geq 2} = 0.5432$ and $P_{n>0} = 0.739$. The average possibility of advancing or moving back in the waiting line is: $p_{-2} = 0.1586$, $p_{-1} = 0.3259$, $p_0 = 1$ and $p_i = 0.4434$ with $i = 1, 2, ..., 9$ The average permanence time in the waiting line of one unit is: $W_q = 0.3004$. And the possibility distribution of the average permanence time in the queue is:

$$\begin{aligned} \tilde{W}_q = {} & 0.1586/0.0504 + 0.3259/0.1754 + \\ & + 1/0.3004 + 0.4434/0.4254 + \\ & + 0.4434/0.5504 + ... \end{aligned}$$

The possibility distribution $\tilde{W}_q$ is represented in the Fig. 1.

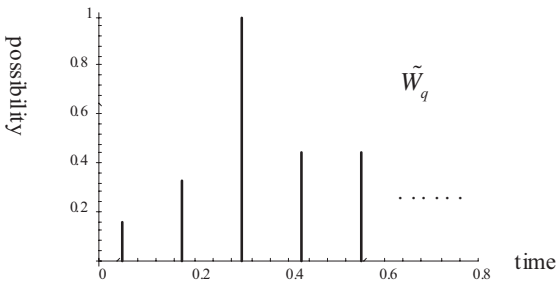

Figure 1: Possibility distribution $\tilde{W}_q$

The possibilistic priority-discipline can be adapted to other stochastic flow line system only by following a similar procedure to the one carried out in the last example.

5 Conclusions

In this work, taking the work started by *Prade* [1] as a starting point and incorporating it a possibilistic priority-discipline, we have given a more realistic representation of the flow line systems. For this we have defined a possibility distribution for the waiting-discipline but it can be calculated from real data or from the opinion of the experts. To illustrate the proposed method and the obtained theoretical results we have carried out two applications: one, to incorporate the possibilistic priority-discipline in a pure determinist flow line system and the other one to incorporate the uncertain priority-discipline in a classic flow line model. In both applications we have developed the technique to incorporate the priority-discipline given the particular features of the system and on the other hand, we have exposed an example that explains the proposed methodology.

Even so, the flow line systems with uncertain waiting line presented and developed in this work provide the decision maker with more complete and informative results and also with a better knowledge about the behaviour of the system due to the results that are possibility distributions that

ISBN: 978-989-95079-6-8

include all the uncertainty contained in the system. It is also a simple methodology that can be adapted to the different flow line systems with uncertain priority-discipline. For this reason we think that the proposed flow line system with uncertain data can have more applications than the classic one.

Abstract— *Interval-valued fuzzy sets are based on the algebra of subintervals of the unit interval* $[0,1]$. *We study valuations as a special type of measures on this algebra. We present a description of all valuations which preserve the standard fuzzy negation and extend the identity on the elements of the form* (x,x). *Consequences for sublattices are formulated.*

Keywords— Girard algebra, interval-valued fuzzy set, intuitionistic fuzzy set, measure, valuation

1 Introduction

In order to work with vague quantities, fuzzy sets were suggested [13]; their membership degrees are in the unit interval $I = [0,1]$. Sometimes this approach appeared too restrictive; instead of one value, the membership degree of a point was restricted to an interval in I. This led to the notion of *interval-valued fuzzy sets*. The original term was *intuitionistic fuzzy sets* [1, 2], but it causes misunderstandings because there is no relevance to the intuitionistic logic. Other synonyms found in the literature are *IFS events* [8], etc. The idea of using more general membership degrees is rather old, cf. [4].

Another motivation of interval-valued fuzzy sets is the following: If we determine the membership degree of a point p by an interval $(x,y) \in I^2$, $x \le y$, we say that p *belongs* to the fuzzy set with the degree at least x and *does not belong* to it with the degree at least $z = 1-y$; the remainder $1-(x+z) = y-x \ge 0$ represents missing knowledge. This approach works with pairs $(x,z) \in I^2$, $x+z \le 1$, representing *bipolar* information. It is distinguished for philosophical, psychological, and methodological reasons; from the mathematical point of view, the descriptions by the pair (x,y) or (x,z) lead to isomorphic models and results can be easily translated from one context to the other.

We refer to [3, 5, 6, 7, 8] for recent investigation of properties of interval-valued fuzzy sets, operations and measures on them.

2 Standard interval algebra

Here we define the standard algebra of all intervals in I. In the sequel, we shall also consider its subalgebras.

We shall work with the set

$$I_2 = \left\{(x,y) \in I^2 \mid x \le y\right\} . \tag{1}$$

Equipped with the usual pointwise ordering,

$$(x_1,y_1) \le (x_2,y_2) \iff (x_1 \le x_2 \text{ and } y_1 \le y_2) , \tag{2}$$

I_2 becomes a lattice with the least element $\mathbf{0} = (0,0)$ and the greatest element $\mathbf{1} = (1,1)$ and the lattice operations

$$(x_1,y_1) \wedge (x_2,y_2) = (\min(x_1,y_1), \min(x_2,y_2)) , \tag{3}$$
$$(x_1,y_1) \vee (x_2,y_2) = (\max(x_1,y_1), \max(x_2,y_2)) . \tag{4}$$

The sublattice

$$D = \{(x,x) \mid x \in I\} \subset I_2 \tag{5}$$

consists of the elements $(x,x) \in I_2$ which represent real membership degrees corresponding to $x \in I$ in standard fuzzy sets. Thus I_2 represents an extension of $D \cong I$ by elements $(x,y) \in I^2$, $x < y$.

The standard fuzzy negation $'\colon I \to I$, $x' = 1-x$, has a natural extension to the negation $'\colon I_2 \to I_2$,

$$(x,y)' = (y',x') . \tag{6}$$

Thus we have a bounded lattice with an antitone involutive operation $'$. We call this structure the *standard interval algebra* and—with some abuse of notation—we denote it again by I_2.

The standard interval algebra is often considered with additional operations. These are often derived from the *standard MV-algebra* $([0,1],0,\oplus,')$, where $'$ is the standard fuzzy negation and $\oplus$ is the Łukasiewicz t-conorm $a \oplus b = \min(1, a+b)$. Its dual operation is the Łukasiewicz t-norm $a \odot b = (a' \oplus b')' = \max(0, a+b-1)$. These operations are applied to elements of I_2 coordinatewise,

$$(x_1,y_1) \odot (x_2,y_2) = (x_1 \odot x_2, y_1 \odot y_2) , \tag{7}$$
$$(x_1,y_1) \oplus (x_2,y_2) = (x_1 \oplus x_2, y_1 \oplus y_2) . \tag{8}$$

Then $D \subset I_2$ becomes isomorphic to the standard MV-algebra.

Remark 1. *Other t-norms and t-conorms on* I_2, *not originated this way, are studied, e.g., in [3]. We do not deal with them here.*

Another line of research is due to S. Weber [10, 11]. He extends the MV-algebra D to a Girard algebra with operations

$$(x_1,y_1) \sqcap (x_2,y_2) = (x_1 \odot x_2, \max((x_1 \odot y_2), (y_1 \odot x_2))) , \tag{9}$$
$$(x_1,y_1) \sqcup (x_2,y_2) = (\min((x_1 \oplus y_2), (y_1 \oplus x_2)), y_1 \oplus y_2) . \tag{10}$$

Although rather strange, these operations arise as a unique solution of well-motivated algebraic conditions [11]. On D, they

ISBN: 978-989-95079-6-8

coincide with the Łukasiewicz operations and with (7), (8). The lattice reduct $(I_2, \vee, \wedge)$ of the Girard algebra is the same as in the former approach.

As we shall deal only with the lattice operations, the (standard) negation, and with the Łukasiewicz operations on D, we need not deal with the differences between the above two approaches; we study features which are common to both of them.

3 Measures on the interval algebra

In order to study probability of fuzzy events, we need to introduce (probability) measures on fuzzy sets. First of all, we need measures on the algebras of membership degrees; in our case, on the standard interval algebra I_2. Different conditions are imposed in order to extend the notion of probability from classical sets to fuzzy sets and interval-valued fuzzy sets. Here we follow one of the approaches suggested by S. Weber in [11], but analogous conditions are studied in many other papers. We refer to [12] for a comparison of many approaches to measures on collections of fuzzy sets.

Without referring to a specific definition, let us accept that the standard MV-algebra admits one very natural candidate for a measure—the identity. It commutes with the standard negation and satisfies all forms of additivity conditions (see [9] for details). Thus here we assume that the only measure on the standard MV-algebra is the identity. Also S. Weber in [11] studies measures m which are extensions of this measure on D, i.e.,

$$\forall x \in I : m(x,x) = x\,. \tag{M1+}$$

(For simplicity, we write $m(x,x)$ instead of $m((x,x))$.) For all elements $(x,y) \in I_2$, he imposes the following conditions as minimal requirements on so-called *uncertainty measures*:

$$m(\mathbf{0}) = 0\,, \qquad m(\mathbf{1}) = 1\,, \tag{M1}$$

$$A \le B \implies m(A) \le m(B)\,, \tag{M2}$$

$$m\,(A') = 1 - m(A)\,. \tag{M3}$$

(Condition (M1) follows from (M1+).) One of the additional conditions studied in [11] is the *valuation property*:

$$m(A \wedge B) + m(A \vee B) = m(A) + m(B)\,. \tag{V}$$

In this paper, we study mappings $m\colon I_2 \to [0,1]$ satisfying (M1+), (M2), (M3), and (V); we call them *valuation measures*.

3.1 Characterization of valuation measures on the standard interval algebra

Our principal contribution is the following (μ is a $\frac{1}{2}$-*Lipschitz* function if $|\mu(u) - \mu(v)| \le \frac{1}{2}\ |u - v|$ for all u, v):

Theorem 2. *A mapping $m\colon I_2 \to [0,1]$ is a valuation measure if and only if there is a $\frac{1}{2}$-Lipschitz function μ on $\left[0, \frac{1}{2}\right]$ such that m is of the form*

$$m(x,y) = \frac{x+y}{2} + \mu\left(\left|x - \tfrac{1}{2}\right|\right) - \mu\left(\left|y - \tfrac{1}{2}\right|\right)\,. \tag{12}$$

Proof: First, let us suppose that μ is a $\frac{1}{2}$-Lipschitz function and m is given by (12). If $x = y$, we obtain (M1+). Condition (M3) is verified as follows:

$$\begin{aligned} &m(1-y, 1-x)\\ &= \frac{1-y+1-x}{2} + \mu\left(\left|(1-y) - \tfrac{1}{2}\right|\right) - \mu\left(\left|(1-x) - \tfrac{1}{2}\right|\right)\\ &= 1 - \frac{x+y}{2} - \mu\left(\left|x - \tfrac{1}{2}\right|\right) + \mu\left(\left|y - \tfrac{1}{2}\right|\right)\\ &= 1 - m(x,y)\,. \end{aligned} \tag{13}$$

Monotonicity (M2) can be verified in each coordinate separately and follows from the $\frac{1}{2}$-Lipschitz condition. For $x_1 < x_2$, we obtain

$$\begin{aligned} &m(x_2,y) - m(x_1,y)\\ &= \frac{x_2 - x_1}{2} + \mu\left(\left|x_2 - \tfrac{1}{2}\right|\right) - \mu\left(\left|x_1 - \tfrac{1}{2}\right|\right)\\ &\ge \frac{x_2 - x_1}{2} - \frac{1}{2}\left|\left|x_2 - \tfrac{1}{2}\right| - \left|x_1 - \tfrac{1}{2}\right|\right|\\ &\ge \frac{x_2 - x_1}{2} - \frac{|x_2 - x_1|}{2} = 0\,. \end{aligned} \tag{14}$$

For $y_1 < y_2$, we obtain

$$\begin{aligned} &m(x,y_2) - m(x,y_1)\\ &= \frac{y_2 - y_1}{2} + \mu\left(\left|y_2 - \tfrac{1}{2}\right|\right) - \mu\left(\left|y_1 - \tfrac{1}{2}\right|\right)\\ &\ge \frac{y_2 - y_1}{2} - \frac{1}{2}\left|\left|y_2 - \tfrac{1}{2}\right| - \left|y_1 - \tfrac{1}{2}\right|\right|\\ &\ge \frac{y_2 - y_1}{2} - \frac{|y_2 - y_1|}{2} = 0\,. \end{aligned} \tag{15}$$

To check the valuation property (V), take $A = (x_1, y_1)$, $B = (x_2, y_2)$. Notice that, independently of all possible orderings of x_1, x_2 (resp. y_1, y_2), $m(A \wedge B) + m(A \vee B)$ expressed by (12) contains the same summands as $m(A) + m(B)$:

$$\begin{aligned} &m(A \wedge B) + m(A \vee B)\\ &= \frac{x_1 + x_2 + y_1 + y_2}{2}\\ &+ \mu\left(\left|x_1 - \tfrac{1}{2}\right|\right) + \mu\left(\left|x_2 - \tfrac{1}{2}\right|\right)\\ &- \mu\left(\left|y_1 - \tfrac{1}{2}\right|\right) - \mu\left(\left|y_2 - \tfrac{1}{2}\right|\right)\\ &= m(A) + m(B)\,. \end{aligned} \tag{16}$$

Thus m is a valuation measure.

To prove the reverse implication, let us assume that m is a valuation measure. Whenever $x + y = 1$, the element (x,y) is invariant to the negation and, due to (M3), $m(x,y) = \frac{1}{2}$.

We may define

$$\mu(z) = \tfrac{z}{2} + m\left(\tfrac{1}{2} - z, \tfrac{1}{2}\right)\,, \tag{17}$$

in particular,

$$\mu(0) = m\left(\tfrac{1}{2}, \tfrac{1}{2}\right) = \tfrac{1}{2}\,. \tag{18}$$

For $x \le y = \frac{1}{2}$, the right-hand side of (12) is

$$\begin{aligned} \tfrac{x}{2} + \tfrac{1}{4} + \mu\left(\tfrac{1}{2} - x\right) - \mu\left(0\right) &= \tfrac{x}{2} - \tfrac{1}{4} + \mu\left(\tfrac{1}{2} - x\right)\\ &= m\left(x, \tfrac{1}{2}\right) \end{aligned} \tag{19}$$

as desired.

ISBN: 978-989-95079-6-8

For $x \le y < \frac{1}{2}$, we take $A = \left(x, \frac{1}{2}\right)$, $B = (y, y)$. Then $A \wedge B = (x, y)$, $A \vee B = \left(y, \frac{1}{2}\right)$. Using the valuation property, (19), and (M1+), we obtain

$$\begin{aligned} m(x,y) &= m(A \wedge B) = m(A) + m(B) - m(A \vee B) \\ &= m\left(x, \tfrac{1}{2}\right) + m(y,y) - m\left(y, \tfrac{1}{2}\right) \\ &= \tfrac{x}{2} + \mu\left(\tfrac{1}{2} - x\right) + y - \tfrac{y}{2} - \mu\left(\tfrac{1}{2} - y\right) \\ &= \tfrac{x}{2} + \mu\left(\tfrac{1}{2} - x\right) + \tfrac{y}{2} - \mu\left(\tfrac{1}{2} - y\right) \end{aligned} \tag{20}$$

in accordance with (12).

The case $\frac{1}{2} < x \le y$ is obtained by duality.

In the remaining case $x \le \frac{1}{2} < y$, without loss of generality we may suppose that $x + y \le 1$ (the other case is dual). We take $A = (x, y)$, $B = \left(1 - y, \frac{1}{2}\right)$. Then $A \wedge B = \left(x, \frac{1}{2}\right)$, $A \vee B = (1 - y, y)$. Using the valuation property and (19), we obtain

$$\begin{aligned} m(x,y) = m(A) &= m(A \wedge B) + m(A \vee B) - m(B) \\ &= m\left(x, \tfrac{1}{2}\right) + m(1-y, y) - m\left(1-y, \tfrac{1}{2}\right) \\ &= \tfrac{x}{2} + \mu\left(\tfrac{1}{2} - x\right) + \tfrac{1}{2} - \tfrac{1-y}{2} + \mu\left(\tfrac{1}{2} - (1-y)\right) \\ &= \tfrac{x}{2} + \mu\left(\tfrac{1}{2} - x\right) + \tfrac{y}{2} - \mu\left(y - \tfrac{1}{2}\right) . \end{aligned} \tag{21}$$

It remains to prove that μ is $\frac{1}{2}$-Lipschitz. Suppose that $0 \le x_1 \le x_2 \le \frac{1}{2}$. One inequality follows from the monotonicity of m:

$$\begin{aligned} \mu(x_2) - \mu(x_1) &= \tfrac{x_2}{2} + m\left(\tfrac{1}{2} - x_2, \tfrac{1}{2}\right) - \tfrac{x_1}{2} - m\left(\tfrac{1}{2} - x_1, \tfrac{1}{2}\right) \\ &\le \tfrac{x_2 - x_1}{2} . \end{aligned} \tag{22}$$

To prove the second inequality, we take $A = \left(\frac{1}{2} - x_2, \frac{1}{2}\right)$, $B = \left(\frac{1}{2} - x_1, \frac{1}{2} - x_1\right)$. Then $A \wedge B = \left(\frac{1}{2} - x_2, \frac{1}{2} - x_1\right)$, $A \vee B = \left(\frac{1}{2} - x_1, \frac{1}{2}\right)$. We obtain

$$m(A \vee B) - m(A) = m(B) - m(A \wedge B) , \tag{23}$$

$$\begin{aligned} & m\left(\tfrac{1}{2} - x_1, \tfrac{1}{2}\right) - m\left(\tfrac{1}{2} - x_2, \tfrac{1}{2}\right) \\ &= m\left(\tfrac{1}{2} - x_1, \tfrac{1}{2} - x_1\right) - m\left(\tfrac{1}{2} - x_2, \tfrac{1}{2} - x_1\right) \\ &\le m\left(\tfrac{1}{2} - x_1, \tfrac{1}{2} - x_1\right) - m\left(\tfrac{1}{2} - x_2, \tfrac{1}{2} - x_2\right) = x_2 - x_1 , \end{aligned} \tag{24}$$

$$\begin{aligned} & \mu(x_1) - \mu(x_2) \\ &= \tfrac{x_1}{2} + m\left(\tfrac{1}{2} - x_1, \tfrac{1}{2}\right) - \tfrac{x_2}{2} - m\left(\tfrac{1}{2} - x_2, \tfrac{1}{2}\right) \\ &\le \tfrac{x_1 - x_2}{2} + x_2 - x_1 = \tfrac{x_2 - x_1}{2} . \end{aligned} \tag{25}$$

Corollary 3. *Every valuation measure on I_2 is continuous, even 1-Lipschitz.*

Function μ in (12) is determined by m uniquely up to an additive constant. Thus we may choose, e.g., $\mu(0) = 0$, then μ attains values from $\left[-\frac{1}{4}, \frac{1}{4}\right]$.

Example 4. *For $\mu_0 = 0$, we obtain the valuation measure*

$$m_0(x,y) = \frac{x+y}{2} \tag{26}$$

which is additive with respect to $\oplus, \odot$.

The extreme cases are $\mu_1(z) = \frac{z}{2}$, $\mu_{-1}(z) = -\frac{z}{2}$, which lead to

$$m_1(x,y) = \begin{cases} y & \text{if } x \le y \le \frac{1}{2} , \\ \frac{1}{2} & \text{if } x \le \frac{1}{2} < y , \\ x & \text{if } \frac{1}{2} < x \le y , \end{cases} \tag{27}$$

$$m_{-1}(x,y) = \begin{cases} x & \text{if } x \le y \le \frac{1}{2} , \\ x + y - \frac{1}{2} & \text{if } x \le \frac{1}{2} < y , \\ y & \text{if } \frac{1}{2} < x \le y . \end{cases} \tag{28}$$

The choice of function μ is not limited to linear functions in (12).

3.2 Convex structure of the space of valuation measures

In this section, we consider the set $\mathcal{M}$ of all valuation measures on I_2. We consider $\mathcal{M}$ equipped with the product topology inherited from $[0,1]^{I_2} \supseteq \mathcal{M}$. As the defining conditions of valuation measures can be written in the form of equations using only continuous operations, the set $\mathcal{M}$ is closed. It can be easily checked that a convex combination of valuation measures is a valuation measure; thus $\mathcal{M}$ is also convex. Valuation measures μ_1, μ_{-1} of Example 4 are (some of) its extreme points.

Moreover, convex combinations are preserved by (12) in the following sense:

Proposition 5. *Let m_a, resp. m_b, be a valuation measure on I_2 and μ_a, resp. μ_b, the corresponding $\frac{1}{2}$-Lipschitz function satisfying (12). Let $\lambda \in [0,1]$. Then the convex combination $\lambda\, m_a + (1-\lambda)\, m_b$ is a valuation measure which satisfies (12) for $\mu = \lambda\, \mu_a + (1-\lambda)\, \mu_b$.*

4 Generalizations

Theorem 2 described valuation measures on the standard interval algebra. This case is important, but very special. It describes all interval-valued fuzzy subsets of a singleton. Here we extend Theorem 2 to more general cases.

4.1 Valuation measures on the set of all interval-valued fuzzy sets

Now we shall extend Theorem 2 to finite products of algebras isomorphic to the standard interval algebra. These products are isomorphic to the collections of all interval-valued fuzzy subset of a finite set.

Let $n \in \mathbb{N}$. We denote by I_2^n the product of n standard interval algebras, i.e., the cartesian product $\prod_{i=1}^n I_2$ with the lattice operations and negation applied to each coordinate separately.

Theorem 6. *Let $n \in \mathbb{N}$. A mapping $m\colon I_2^n \to [0,1]$ is a valuation measure if and only if there are valuation measures $m_1, \ldots, m_n$ on I_2 and real coefficients $c_1, \ldots, c_n \in [0,1]$ such that $\sum_{i=1}^n c_i = 1$ and m is of the form*

$$m(A_1, \ldots, A_n) = \sum_{i=1}^n c_i\, m_i(A_i) . \tag{29}$$

Proof: Suppose first that m is of the form (29), i.e., a convex combination of valuation measures $m_1, \ldots, m_n$ on I_2. For each $i = 1, \ldots, n$, we denote by π_i the projection on the ith coordinate,

$$\pi_i(A_1, \ldots, A_n) = A_i . \tag{30}$$

ISBN: 978-989-95079-6-8

It is a lattice homomorphism of I_2^n onto I_2. Thus the composition $m_i \circ \pi_i \colon I_2^n \to [0,1]$,

$$(m_i \circ \pi_i)(A_1, \ldots, A_n) = m_i(\pi_i(A_1, \ldots, A_n)) = m_i(A_i)\,, \tag{31}$$

is a valuation measure on I_2^n. As a convex combination of valuation measures, m is also a valuation measure.

Second, suppose that m is a valuation measure on I_2^n. Let $\mathcal{B}$ be the collection of all sharp (=crisp) elements of I_2^n, i.e., all n-tuplets $(A_1, \ldots, A_n)$ such that $A_i \in \{\mathbf{0}, \mathbf{1}\}$ for all $i = 1, \ldots, n$. Then $\mathcal{B}$ is a finite Boolean algebra with n atoms $(\delta_{i1}, \ldots, \delta_{in})$, $i = 1, \ldots, n$, where

$$\delta_{ik} = \begin{cases} \mathbf{1} & \text{if } i = k\,, \\ \mathbf{0} & \text{if } i \neq k\,. \end{cases} \tag{32}$$

This means that $(\delta_{i1}, \ldots, \delta_{in}) = (\mathbf{0}, \ldots, \mathbf{0}, \mathbf{1}, \mathbf{0}, \ldots, \mathbf{0}) \in I_2^n$, where the unit is in the ith coordinate. A valuation measure on a Boolean algebra is a classical probability measure. Thus m it is of the form

$$m(A_1, \ldots, A_n) = \sum_{i=1}^{n} c_i\, s_i(A_1, \ldots, A_n)\,, \tag{33}$$

where $c_i = m(\delta_{i1}, \ldots, \delta_{in})$, $i = 1, \ldots, n$, and $s_1, \ldots, s_n$ are valuation measures on I_2^n such that

$$s_i(\delta_{i1}, \ldots, \delta_{in}) = 1\,. \tag{34}$$

As

$$s_i((\delta_{i1}, \ldots, \delta_{in})') = s_i(\delta'_{i1}, \ldots, \delta'_{in}) = 0\,, \tag{35}$$

we obtain

$$s_i(B_1, \ldots, B_n) = 0 \tag{36}$$

whenever

$$(B_1, \ldots, B_n) \leq (\delta_{i1}, \ldots, \delta_{in})'\,. \tag{37}$$

Thus $s_i(A_1, \ldots, A_n)$ depends only on the ith coordinate, $A_i = \pi_i(A_1, \ldots, A_n)$. We may express s_i in the form $s_i = m_i \circ \pi_i$ for some mapping $m_i \colon I_2 \to [0,1]$. The image of I_2^n under π_i is isomorphic to I_2. As π_i is a homomorphism, m_i must be a valuation measure on I_2. The proof is finished.

The characterization can be extended also to infinite products of the standard interval algebra, thus to collections of interval-valued fuzzy subsets of an infinite universe. This requires valuation measures concentrated not only in coordinates, but also in the points of the underlying Stone space of the Boolean algebra in question. This way, we may also admit subalgebras of products, so that the underlying Boolean algebra is not the whole power set. We leave these extensions for future research.

Theorems 2 and 6 can be combined. We obtain a characterization of valuation measures on the product I_2^n using $\frac{1}{2}$-Lipschitz functions μ_i, $i = 1, \ldots, n$. These functions can be different in different coordinates.

4.2 Extension to subalgebras

S. Weber in [11] investigates valuation measures on finite Girard algebras, mainly on finite subalgebras of I_2 of the form

$$\tilde{\mathbb{C}}_n = \left\{ \left(\tfrac{j}{n}, \tfrac{k}{n}\right) \middle| j, k \in \mathbb{Z},\ 0 \leq j \leq k \leq n \right\}\,, \tag{38}$$

where $n \geq 1$ is a fixed integer. Valuation measures on I_2, when restricted to $\tilde{\mathbb{C}}_n$, become valuation measures on $\tilde{\mathbb{C}}_n$. Conversely, each valuation measure on $\tilde{\mathbb{C}}_n$ admits an extension to a valuation measure on I_2. This holds also for other sublattices of I_2:

Theorem 7. *Let L be a sublattice of I_2. Suppose that $(0,0), (1,1) \in L$ and $(x,y) \in L$ implies (x,x), (y,y), $(y',x') \in L$. A mapping $m \colon L \to [0,1]$ is a valuation measure if and only if it satisfies the condition of Theorem 2.*

The proof follows the pattern of Theorem 2. Analogously, we can also generalize Theorem 6 and obtain a characterization of valuation measures on subalgebras of I_2^n. These subalgebras are isomorphic to general collections of (not all possible) interval-valued fuzzy sets. For this, it is necessary to add assumptions on closedness of these collections under the lattice operations. We leave further details to future research.

5 Conclusions

We studied measures on finite products of the algebra of subintervals of $[0,1]$. We gave a characterization of measures which (besides the obvious properties of monotonicity and boundary conditions)

1. are compatible with the negation,
2. extend the identity on elements of the form (x,x), $x \in [0,1]$,
3. are valuations.

This is aimed as the first step towards the characterization of such measures on collections of interval-valued fuzzy sets.

Our conditions do not represent the only choice, rather a necessary minimum. Other conditions could be added, depending on the application domain. Our general characterization forms a basis for description of measures restricted by additional conditions, too.

Abstract— Multi-criteria group decision-making and evaluation (MCGDME) method typically aggregates information in evaluation tables. For various reasons, evaluation tables (decision matrix) often include missing data that highly affect correct decision-making and evaluation. Most existing imputation methods of missing data are based on statistical features which do not exist in an MCGDME setting. This paper proposes an imputation method of missing data (IMD) in evaluation tables. The IMD method measures the similarity betweent two evaluators' mental models. Evaluators are then classed into several groups based on their similarities by using fuzzy clustering methods. Finally, missing data are imputated under the assumption that the imputated value of missing data does not change the previous clustering results. The proposed IMD method is implemented and tested in two numerical experiments.

Keywords— decision making, missing data, multi-criteria evaluation, opinion clustering, aggregation

1 Introduction

Multi-criteria group decision-making (MCGDM) methods have been widely used in various fields such as new product development in industries [9], clinical diagnose, service strategies selection in business, as well as public economic policy evaluation [11]. In a typical MCGDM process, evaluating alternatives and aggregating assessments based on decision matrices are two crucial processes. Evaluators (or experts) assess alternatives in terms of a set of identified criteria. The assessments are recorded into several decision matrices, also known as decision tables, which are further analyzed and integrated. The aggregation process implements a specific aggregation model to achieve an overall assessment for each alternative and based on which the best alternative(s) is/are selected. Majority of existing research focuses particularly on the problem of how to efficiently integrate heterogeneous quantitative or qualitative information from multiple information sources. Most processes are conducted mainly on the assumption that those obtained decision matrices are intact, i.e., those tables do not include missing values. However, this assumption may not be completely satisfied in real situations.

Various reasons result in missing values in decision matrices. Values may be missed in the course of data collection by device faults or human errors. Evaluators who are lack of relevant background for some criteria or are not willing to provide opinions on some criteria may leave blanks in their decision tables. Security or privacy policies may also prevent evaluators from providing answers to some criteria. An evidently result of missing values reduce the reliability of decision making or evaluation and to produce extraordinary bias towards appropriate decisions. Moreover, missing values may result in invalid evaluation and decision making. Hence, necessary and efficient missing data imputation is required in real applications such as in nuclear material safeguards information management.

Literature indicates missing data processing has a long research history [4–6, 8, 12]. However, most research is mainly conducted on the theory and application of statistics sciences [5]. Existing techniques, such as the LOCF (last observation carried forward), best or worst case imputation, mean imputation, and case deletion [1], generally require the collected data has specific and identifiable features. Such features include, for examples, the data is time-related or follows a particular statistics distribution, as well as has sufficient volume. These features do not hold in a typical MCGDM settings in general. Assessments in a typical MCGDM problem have uniqueness in the sense that each assessment is uniquely linked to a unique alternative, a unique evaluator, and a unique criterion. Moreover, because evaluators are generally not asked or are not willing to repeat same evaluation procedures, the obtained assessment values are always onetime data which is irrelevant to observation time. Therefore, not enough volume of data exists with the same features of a missing value. Besides the uniqueness and small volume of assessments, assessment values are generated through information processing in evaluators' mental model of the given decision problem which cannot be strictly expressed through a formalized and quantified model. Moreover, the links among the selected criteria are generally weak and unclear, because evaluation criteria are always deliberately selected to represent different considerations for alternatives. These features make it very hard to use statistics-based missing data imputation methods to MCGDM problems.

This paper presents an imputation method for missing assessments (IMD) in decision tables for MCGDM. The presented method mainly includes two steps. A fuzzy clustering method is first used to classify evaluators into several groups based on their opinions reflected in their assessments. Then missing assessments are imputed according to those assessments of evaluators belonging to the same group. The rest of the paper is organized as follows. Section 2 reviews the main steps of the presented IMD method. Details of each step is introduced in Section 3. To further illustrate the IMD method,

ISBN: 978-989-95079-6-8

two case studies are conducted. Finally, main results and future works are discussed in Section 5.

2 Overview

2.1 Formalization of typical MCGDM problems

A typical MCGDM problem is composed of a set of alternatives (e.g., action choices, policies), a hierarchy of attributes (i.e., decision criteria), weights associated with criteria, a set of decision matrices (i.e., decision tables), as well as a set of evaluators who present those decision matrices. Three main steps are involved in selections of alternatives [13]: 1) determine the relevant criteria and alternatives; 2) evaluate the relative impacts of alternatives on those criteria; and 3) determine a ranking of each alternatives. Roughly, an MCGDM process can be expressed by a 4-tuple model:

$$\mathcal{M} = (\mathcal{C}, \mathcal{E}, \mathcal{A}, \mathcal{T}), \tag{1}$$

where $\mathcal{C} = \{(c_j, wc_j)|j = 1, 2, \ldots, n\}$ is a set of criteria and their corresponding weights (importance); $\mathcal{E} = \{(e_k, we_k)|k = 1, 2, \ldots, m\}$ is a set of evaluators (experts) and their corresponding weights (reliabilities); $\mathcal{A} = \{a_i|i = 1, 2, \ldots, p\}$ is a set of alternatives (action choices); and $\mathcal{T} = \{T_i = (v^i_{jk})_{n\times m}|i = 1, 2, \ldots, p\}$ is a set of decision matrices. For each a_i, the overall assessment y_i based on the model $\mathcal{M}$ is explicitly expressed as

$$\begin{aligned} y_i &= W_C \circ T_i \diamond W_E^{\mathrm{T}} \\ &= (wc_1, \cdots, wc_n) \circ \begin{pmatrix} v^i_{11} & v^i_{12} & \cdots & v^i_{1m} \\ v^i_{21} & v^i_{22} & \cdots & v^i_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ v^i_{n1} & v^i_{n2} & \cdots & v^i_{nm} \end{pmatrix} \diamond \begin{pmatrix} we_1 \\ we_2 \\ \vdots \\ we_m \end{pmatrix} \end{aligned}$$

where $\circ$ and $\diamond$ are operations in $\mathcal{M}$, W_C is the weight vector for criteria, and W_E the weight vector for evaluators. Once $\circ$ and $\diamond$ are given in explicit forms, the model $\mathcal{M}$ is then determined. For example, let $\circ$ and $\diamond$ be a weighted sum. For any vectors $\boldsymbol{w}$ and $\boldsymbol{v}$

$$\boldsymbol{w} \circ \boldsymbol{v}^{\mathrm{T}} = (w_1, \cdots, w_n) \circ (v_1, \cdots, v_n)^{\mathrm{T}} = \sum_{i=1}^{n} w_i v_i, \tag{2}$$

then y_i can be written as

$$y_i = \sum_{j=1}^{n} \left(wc_i \cdot \sum_{k=1}^{m} v_{jk} we_k \right) = \sum_{k=1}^{m} \left(\sum_{j=1}^{n} wc_j v_{jk} \right) \cdot we_k. \tag{3}$$

Note that most research works on MCGDM focus on how to define these two operations which are mostly studied in the framework of aggregation operators.

In the following, let $T_i = (\boldsymbol{v}^i_1, \boldsymbol{v}^i_2, \cdots, \boldsymbol{v}^i_k)$, where $\boldsymbol{v}^i_k = (v^i_{1k}, v^i_{2k}, \cdots, v^i_{nk})^{\mathrm{T}}$ is called the evaluation vector of evaluator e_k on alternative a_i. T_i is called complete if no missing values in T_i. T_i is called incomplete if at least one evaluation vector includes missing values. For convenience, the following analysis will omit the alternative index i.

2.2 Distance and similarity of evaluator opinions

For each $\boldsymbol{v}_k$ in T, $\boldsymbol{v}_k$ can be seen as an output of evaluator e_k's mental model with the physical nature of alternative as input and denoted by x, i.e., this can be formally described as

$$\boldsymbol{v}_k = f_k(x), \quad k = 1, 2, \ldots, m. \tag{4}$$

Figure 1 illustrates a generalized procedure of obtaining an evaluation table. Notice that the input of each evaluator's mental model is the same, the difference among the obtained evaluation vectors can only be introduced by the difference among evaluators' mental models. Assume that the relationship between evaluators' mental models exists and can be found through their outputs, i.e., the evaluation vectors, then missing values can be approximately imputed with the aid of those relationships. In the light of this idea, the following strategy is adopted to impute missing values. First, a distance measure d between two evaluation vectors is defined, which is then taken as the distance between two evaluators' opinions. Next, the similarity of two evaluators' mental models is induced from the distance. Based on the similarities between each pair of evaluators, a fuzzy clustering method is used to segment evaluators to several clusters. For each of missing values, a predicted value is obtained according to the evaluation vectors provided by evaluators belonging to the same group. This value is the imputed value.

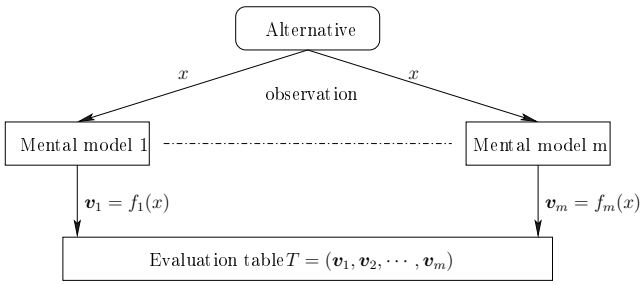

Figure 1: Producing of an evaluation table.

To implement the above-mentioned strategy, we consider some relevant issues. First, the difference of criteria weights is considered when defining a distance measurement. The weight of a criterion indicates the importance degree or relevance degree of that criterion to the decision goal. Some criteria are more important than others. Hence, criteria with bigger weights should contribute more distance to the overall distance between two evaluation vectors. For this reason, we use an aggregation operator to define the overall distance between two evaluation vectors. Another issue is concerned about criteria to that not all missing values must be imputed. For criteria with very small weights, the imputation of missing data is not essential because the bias from appropriate decision induced by discrepancy in those criteria is insignificant. Thus, a parameter α is defined to filter criteria with small weights. Missing data with respect to those filtered criteria are not imputed. Moreover, a second parameter β is used in the segmentation of evaluators, which indicates the at least similarity required when two evaluators are treated with the similar opinion. It can be proved that the bigger the β is, the more obtained clusters and the reduced number of evaluators belong to a certain cluster.

Because the presented strategy adopts two extra parameters α and β, the presented method is thus called an α-β imputation. Next section will give details of the α-β imputation method.

ISBN: 978-989-95079-6-8

3 An α-β imputation method

This section illustrates the details of the α-β imputation method for missing data (assessments, evaluations). For convenience, let all weights for criteria and evaluators be real numbers in the real unit interval [0, 1] and all assessment values be real numbers in [0, 1], too. Without loss of generality, the following discussion will consider the decision matrix for only one alternative.

3.1 Distance between evaluation vectors

An evaluation vector refers to a column in a decision matrix T^i which records the assessments presented by a certain evaluator. As each evaluation vector reflects the opinion of an evaluator, distance of evaluation vectors could be used to reflect the difference between two evaluators' opinions. Based on this idea, we first measure the distance between evaluation vectors. Suppose $\boldsymbol{u}$ and $\boldsymbol{v}$ are two evaluation vectors.

For each criterion c_j ($j = 1, 2, \ldots, n$), let u and v be two assessments from different evaluators about c_j. Then the distance between u and v can be calculated. Suppose the distance is calculated through a distance function d_j which is with respect to c_j and $d_j(u, v)$ is a real number in $[0, 1]$, then d_j can be treated as a function from $[0, 1] \times [0, 1]$ to $[0, 1]$. In the following, let $d_1, d_2, \ldots, d_n$ be the selected distance functions with respect to criteria $c_1, c_2, \ldots, c_n$, respectively without other specifications. Here, we do not require that all d_j be of the same form.

Based on the selected d_j, $j = 1, 2, \ldots, n$, the overall distance between two evaluation vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ can be calculated as follows. Let Agg be an aggregation operator [10] defined from $[0, 1]^n$ to $[0, 1]$ and $\beta_1, \beta_2, \ldots, \beta_n$ be the normalized weights of those criteria, i.e.,

$$\beta_j = \frac{wc_j}{\sum_{j=1}^{n} wc_j}, \quad j = 1, 2, \ldots, n. \tag{5}$$

The distance function $\hat{d}$ between the two evaluation vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ is a function from $[0, 1]^n$ to $[0, 1]$ such that

$$\hat{d}(\boldsymbol{u}, \boldsymbol{v}) = \mathrm{Agg}\left\{(\beta_j, d_j(u_j, v_j))|j = 1, 2, \ldots, n\right\}. \tag{6}$$

Example 3.1 *Suppose Table 1 gives an example setting. Let* Agg *be the weighted-mean. Then the distance between evaluation vectors* $\boldsymbol{u}$ *and* $\boldsymbol{v}$ *is:*

$$\frac{0.12}{1.52} \times 0.75 + \frac{0.47}{1.52} \times 0.11 + \frac{0.93}{1.52} \times 0.57 = 0.44.$$

If Agg *is the OWA operator, then the distance becomes*

$$\frac{0.12}{1.52} \times 0.75 + \frac{0.47}{1.52} \times 0.57 + \frac{0.93}{1.52} \times 0.11 = 0.30.$$

Table 1: An example settings

	d_j	wc_j	$\boldsymbol{u}$	$\boldsymbol{v}$
c_1	$\lvert u - v\rvert$	0.12	0.07	0.82
c_2	$\lvert u - v\rvert^2$	0.47	0.64	0.97
c_3	$\lvert u - v\rvert^3$	0.93	0.93	0.1

Equation (6) indicates the distance between two evaluation vectors that are determined by the selected aggregation operator and the distance functions for each of criteria. It is possible to choose different operators and measures according to the real problem.

3.2 Similarity between two evaluation vectors

Similar to the definition of distance, similarity for individual criterion is first given and then an overall similarity is calculated by a selected aggregation operator.

Let g_j ($j = 1, 2, \ldots, n$) be the selected similarity function with respect to criterion c_j. g_j should satisfy the following two conditions: for any u and v,

$$g_{j_1}(u, v) \geqslant g_{j_2}(u, v) \text{ if } wc_{j_1} \leqslant wc_{j_2}, \quad j_1, j_2 \in \{1, \cdots, n\}; \tag{7}$$

and g_j is a non-increasing function with respect to d_j. Then function g_j is also called a similarity measure with respect to criterion c_j, $j = 1, 2, \ldots, n$. (7) indicates that a more important criterion has less similarity with respect to the same distance between two assessments.

For example, the following functions can be treated as a set of similarity measures.

$$g_j(u, v) = 1 - d_j(u, v)^{\sigma/wc_j}, \quad j = 1, 2, \ldots, n, \tag{8}$$

where $\sigma \in \{wc_j | j = 1, 2, \ldots, n\}$.

In the light of individual similarity measures $\{g_j\}$, an overall similarity $\hat{g}$ between two evaluation vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ is defined, which is a non-increasing function from $[0, 1]^n$ to $[0, 1]$ such that

$$\hat{g}(\boldsymbol{u}, \boldsymbol{v}) = \mathrm{Agg}\{(\beta_j, g_j(u_j, v_j)), j = 1, 2, \ldots, n\}, \tag{9}$$

where Agg is a selected aggregation operators, β_j is the normalized weights of those criteria, $j = 1, 2, \ldots, n$.

In Example 3.1, suppose $g_j(u, v) = 1 - d_j(u, v)$, then the similarities for the weighted-sum aggregation and OWA aggregation are 0.56 and 0.70, respectively. Obviously $\hat{g}(\boldsymbol{u}, \boldsymbol{v}) = 1 - \hat{d}(\boldsymbol{u}, \boldsymbol{v})$. However, this does not hold if we change the relationship between g_j and d_j for any j. This indicates that in real problems we can select the appropriate operators to define the similarity. Moreover, we should notice that $\hat{g}(\boldsymbol{u}, \boldsymbol{v})$ is given through individual distance d_j and individual similarity g_j, $j = 1, 2, \ldots, n$, rather than the overall distance $\hat{d}(\boldsymbol{u}, \boldsymbol{v})$. The reason for separately defining them is to provide more flexibilities to consider the individual influence of criteria.

3.3 Evaluator segmentation

The similarity between two evaluation vectors reflects to what extend two evaluators' opinions are similar, which is used to define the similarity between two evaluators' mental models. Evaluators, thus, can be clustered into several groups based on the similarity of their mental models.

Suppose the similarities between any two pair of evaluators are calculated and recorded in a similarity matrix $M = (s_{jk})_{m \times m}$ where s_{jk} is the similarity between evaluators e_j and e_k. To segment evaluators based on M, we use the fuzzy clustering technique here. Let $\bar{M}$ be the transitive closure of M obtained by

$$\bar{M} = \bigcup_{i=1} M^i, \tag{10}$$

where M^i is the i-th power of M by the max-min composition [11]. Therefore, a clustering result can be obtained from the

ISBN: 978-989-95079-6-8

matrix $\bar{M}$. For example, suppose the matrix $\bar{M}$ is

$$\bar{M} = \begin{pmatrix} 1.0 & 0.6 & 0.8 & 0.6 \\ 0.6 & 1.0 & 0.6 & 0.7 \\ 0.8 & 0.6 & 1.0 & 0.6 \\ 0.6 & 0.7 & 0.6 & 1.0 \end{pmatrix}. \tag{11}$$

Then the clustering result is shown in the following figure.

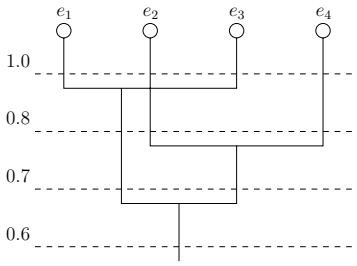

Figure 2: An evaluator clustering results.

From Figure 2, the segmentation results may change with different levels of similarity. For instance, the segmentation result at $\hat{g} = 0.8$ is $\{e_1, e_3\}$, $\{e_2\}$, and $\{e_4\}$; while all evaluators belong to the unique group at $\hat{g} = 0.6$. Hence, a parameter β is used here to indicate at which level the segmentation result is concerned about. In the following let the segmentation result with respect to the given β be $\Gamma(\beta)$.

3.4 Imputation of missing data

To impute missing data, we consider relevant issues and illustrate corresponding solutions here.

First, some missing data need not to be imputed when the associated criteria have infinitesimal effects to the decision G. Therefore, a parameter α is introduced to filter criteria with smaller weights than α. For those criteria, missing data are not imputed.

Next, the evaluator segmentation in Section 3.3 is conducted under the assumption that the decision matrix is a complete one. When the decision matrix is incomplete, we make the following adjustment. Without loss of generality, set

$$T = \begin{pmatrix} A \\ B \end{pmatrix}, \tag{12}$$

where A is a sub-matrix of T which is complete and B is the remainder of T in which each row contains at least one missing data. The evaluator segmentation is obtained based on A, i.e., taking A as the basis to calculate distance and similarity between evaluation vectors. Values in B are used to generate imputations of missing values. Let $\boldsymbol{u}$ and $\boldsymbol{v}$ be two evaluation vectors and divide them into two parts according to A, B,

$$\boldsymbol{u} = \begin{pmatrix} u_A \\ u_B \end{pmatrix}, \qquad \boldsymbol{v} = \begin{pmatrix} v_A \\ v_B \end{pmatrix}.$$

Suppose $u_j \in u_B$ is a missing value and $v_j \in v_B$ exists. To estimate u_j from v_j, we follow the principle that adding missing value does not change the established similarity between the two evaluation vectors. That means if the established similarity between u_A and v_A is g, then the similarity between $u_{A\cup\{u_j\}}$ and $v_{A\cup\{v_j\}}$ is still g after imputation the missing value u_j. Formally, this can be expressed as the following equation

$$\begin{aligned} &\mathrm{Agg}\Big\{(\beta'_l, g_l(u_l, v_l)), l \in \delta(A)\cup\{j\}\Big\} \\ &\quad = \mathrm{Agg}\Big\{(\beta_l, g_l(u_l, v_l)), l \in \delta(A)\Big\}, \end{aligned} \tag{13}$$

where $\delta(A) = \{l | u_l \in A\}$, β' is the normalized weight after adding the criterion c_j and is calculated by

$$\beta'_l = \frac{wc_l}{\sum_{r\in\delta(A)\cup\{j\}} wc_r} = \frac{wc_l}{wc_j + \sum_{r\in\delta(A)} wc_r}. \tag{14}$$

Notice in (13) only u_j is unknown, therefore, the solution(s) of the equation is/are possible estimation(s) of the missing value u_j in $\boldsymbol{u}$ in terms of $\boldsymbol{v}$.

For example, suppose the Agg is the weighted mean and $g_j(\boldsymbol{u}, \boldsymbol{v}) = 1 - d_j(\boldsymbol{u}, \boldsymbol{v})$, $j = 1, 2, \ldots, n$. Then by (13), we have

$$\begin{aligned} &\mathrm{Agg}\Big\{(\beta'_l, g_l(u_l, v_l)), l \in \delta(A)\cup\{j\}\Big\} \\ &\quad = \mathrm{Agg}\Big\{(\beta_l, g_l(u_l, v_l)), l \in \delta(A)\Big\}, \end{aligned}$$

Hence,

$$\sum_{l\in\delta A\cup\{j\}} \beta'_l g_l(u_l, v_l) = \sum_{l\in\delta(A)} \beta_l g_l(u_l, v_l),$$

$$\sum_{l\in\delta(A)\cup\{j\}} \frac{wc_l \cdot g_l(u_l, v_l)}{wc_j + \sum_{r\in\delta(A)} wc_r} = \sum_{l\in\delta(A)} \frac{wc_l \cdot g_l(u_l, v_l)}{\sum_{r\in\delta(A)} wc_r},$$

$$1 - \sum_{l\in\delta(A)\cup\{j\}} \frac{wc_l \cdot d_l(u_l, v_l)}{wc_j + \sum_{r\in\delta(A)} wc_r} = 1 - \sum_{l\in\delta(A)} \frac{wc_l \cdot d_l(u_l, v_l)}{\sum_{r\in\delta(A)} wc_r}$$

So,

$$d_j(u_j, v_j) = \frac{\sum_{l\in\delta(A)} wc_l \cdot d_l(u_l, v_l)}{\sum_{r\in\delta(A)} wc_r} = \hat{d}(u_A, v_A). \tag{15}$$

Equation (15) indicates that u_j can be obtained simply by the d_j and $\hat{d}$ under the above assumptions. Notice that (15) is obtained from g_j and $\hat{g}$, this equation also indicates that the estimation of u_j is determined by the selection of g_j and $\hat{g}$. Hence given different definitions of them, the relationship in (15) may vary.

3.5 Discussions

To find solution of (15), we notice that the equation may produce more than one estimation of the missing value. The question, then, raises naturally that how to determine a unique one. This paper partly resolves this problem through calculating the change $\tilde{d}$ of overall distance induced by an obtained estimation. The estimation that produces the least $\tilde{d}$ will be taken as the imputation of missing data. The overall distance change $\tilde{d}$ is defined as

$$\tilde{d}(u_j) = \sum_{v\in\Gamma(u)\setminus\{u\}} d_j(u_j, v_j), \tag{16}$$

where $\Gamma(u)$ is the cluster of evaluation vectors in which u belongs to. By (16), the best estimation is the one which produces the least distance sum between itself to other evaluation

ISBN: 978-989-95079-6-8

vectors belonging to the same cluster. Examples in the following section have shown that this method can reduce some estimations although they cannot grantee the uniqueness of estimation. Hence, more work is being done to provide other strategy to resolve this problem.

Another question raising from the above imputation procedure is the obtained evaluator segmentation may not be correct because the segmentation is conducted based on A only. Accounting for this problem, we extend the above procedure as follows. For any $\boldsymbol{u}$ and $\boldsymbol{v}$, the distance $\hat{d}(\boldsymbol{u}, \boldsymbol{v})$ and the similarity $\hat{g}(\boldsymbol{u}, \boldsymbol{v})$ are calculated in terms of criteria on which both $\boldsymbol{u}$ and $\boldsymbol{v}$ are not missed rather than limited to criteria corresponding to A. That means the obtained distance and similarity between $\boldsymbol{u}$ and $\boldsymbol{v}$ are the most possible values from the current incomplete decision table. An experiment of the extended process is given in the next section.

4 Experiments and observations

The presented α-β imputation method of missing data is programmed in the Java^{TM} programming language running on a Linux system.

4.1 Experiment 1

Experiment 1 is conducted on a complete decision table with 16 criteria and 5 evaluators. Missing data are randomly selected from the decision table.

To impute the missing data, we set the distance measure for each criteria as $d_j(u_j, v_j) = |u_j - v_j|$ $(j = 1, 2, \ldots, 16)$ and the similarity measure for each criterion as $g_j(u_j, v_j) = 1 - d_j(u_j, v_j)$, the aggregation operators used in calculating overall distance and similarity are the same, say the weighted mean; and set the two parameters $\alpha = 0.2$ and $\beta = 0.6$.

Table 2: The original evaluation table in which missing data are marked by bold font.

wc_j	e_1	e_2	e_3	e_4	e_5
0.262	0.877	0.035	0.88	0.772	0.941
0.334	0.977	0.458	0.903	0.898	0.227
0.823	0.845	0.065	0.894	0.122	0.555
0.216	0.532	0.630	**0.676**	0.353	0.858
0.803	0.862	0.073	0.183	0.618	0.784
0.227	0.797	0.046	**0.721**	0.551	0.950
0.794	0.159	0.995	0.621	0.808	0.307
0.811	0.227	0.936	0.994	0.973	0.134
0.945	0.304	0.901	0.636	0.225	**0.927**
0.892	0.967	0.717	0.851	0.835	**0.035**
0.344	0.641	**0.336**	0.666	0.281	0.598
0.016	**0.475**	0.915	0.743	0.876	0.651
0.235	0.026	0.999	0.501	0.431	0.586
0.905	0.307	0.371	0.757	0.832	0.66
0.316	0.541	0.003	0.438	0.113	0.275
0.068	0.042	0.27	0.929	0.675	0.206

By the given distance and similarity measure, we get the distance matrix $\mathcal{D}$ and the similarity matrix $\mathcal{M}$ as follows:

$$\mathcal{D} = \begin{pmatrix} 0 & 0.571 & 0.35 & 0.392 & 0.233 \\ 0.571 & 0 & 0.348 & 0.332 & 0.55 \\ 0.35 & 0.348 & 0 & 0.255 & 0.382 \\ 0.392 & 0.332 & 0.255 & 0 & 0.394 \\ 0.233 & 0.55 & 0.382 & 0.394 & 0 \end{pmatrix} \tag{17}$$

and

$$\mathcal{M} = \begin{pmatrix} 1 & 0.429 & 0.65 & 0.608 & 0.767 \\ 0.429 & 1 & 0.652 & 0.668 & 0.45 \\ 0.65 & 0.652 & 1 & 0.745 & 0.618 \\ 0.608 & 0.668 & 0.745 & 1 & 0.606 \\ 0.767 & 0.45 & 0.618 & 0.606 & 1 \end{pmatrix}. \tag{18}$$

By the fuzzy clustering method, we get the following clustering result.

$$\bar{\mathcal{M}} = \begin{pmatrix} 1 & 0.65 & 0.65 & 0.65 & 0.767 \\ 0.65 & 1 & 0.668 & 0.668 & 0.65 \\ 0.65 & 0.668 & 1 & 0.745 & 0.65 \\ 0.65 & 0.668 & 0.745 & 1 & 0.65 \\ 0.767 & 0.65 & 0.65 & 0.65 & 1 \end{pmatrix} \tag{19}$$

i.e., we have only one class $\{e_1, e_2, e_3, e_4, e_5\}$. By the imputation method in Section 3.4, the following result is obtained (shown in Table 3).

Table 3: Decision table after imputation of missing data (bold number for estimations and # for still missing data).

4.2 Experiment 2

In the presented imputation method of missing data, aggregation operators are used for calculation of overall distance and overall similarity of two evaluation vectors. Different aggregation operators may lead to different clustering results and, in turn, may result in different imputations. Experiment 2 compares three widely-used aggregation operators, i.e., the weighted mean (Agg_w); the arithmetic mean (Agg_a)

$$\mathrm{Agg}_a(x_1, x_2, \cdots, x_n) = \frac{1}{n}\sum_{i=1}^{n} x_i; \tag{20}$$

and the OWA operator (Agg_o)

$$\mathrm{Agg}_o(x_1, x_2, \cdots, x_n) = \sum_{i=1}^{n} w_i x_{\sigma(j)}, \tag{21}$$

where σ is a permutation such that $x_{\sigma(1)} \geqslant x_{\sigma(2)} \geqslant \cdots \geqslant x_{\sigma n}$. To conduct this experiment, we change the distance measure and the similarity measure for each individual criterion,

ISBN: 978-989-95079-6-8

i.e.,

$$d_j(u_j, v_j) = |u_j - v_j|, \quad g_j(u_j, v_j) = 1 - d_j(u_j, v_j).$$

The original evaluation table is still the one shown in Table 2. The comparison results are shown in Table 4.

Table 4: Comparison results.

missing data		original value	imputations		
row	col		Agg_w	Agg_o	Agg_a
3	2	0.676	0.608	0.527	0.581
5	2	0.721	0.296	0.756	0.323

From the comparison, we can observe that different aggregation operators may produce different imputations. Even more, some aggregation operators may not produce estimation of missing data. Moreover, the bias between an imputation and an original value is bigger for some criteria. The independence nature of the data and the unsupervised nature of the presented method are two possible reasons for these results.

5 Conclusions and Future Works

Imputation of missing data is a vital step in decision making and evaluation problems. Due to various reasons, decision tables are often including missing data. Therefore, how to efficient impute the missed data will affect correct decision making and evaluation. However, few work is reported on imputation of missing data for decision tables. In this paper, an α-β imputation method of missing data (IMD) in a decision table is proposed. The IMD method estimates missing data based on the similarity between evaluators' mental models. First, the IMD method uses an overall distance to measure the similarity of two evaluators mental models through their evaluation vectors. Then a fuzzy clustering method is used to segment evaluators based on the similarity of their mental models. Finally, missing data are imputed by the clustering results under the assumption that an imputed data should not change the clustering results. Two numerical experiments are conducted to test the proposed IMD method. Experiments indicate the IMD method can efficiently estimate some missing data. Moreover, those experiments also show that selecting different aggregation operators, distance measure, and similarity measure may change the imputed values. However, from these experiments, we notice that some estimations of missing data have bigger bias from the originals due to the independence nature of the data and lack of backgrounds as well as other possible reasons. Hence, more work still need to be done such as how to improve the accuracy of an estimation of missing data and how to combine relevant background to the imputation. Now, some related work is undertaking.

Currently, we notice that another missing value processing problem in fuzzy preference relations for group decision-making problem has been discussed in [2, 3]. Method based on additive consistency has been discussed [7]. Although the missing value in that method is different from the one discussed in the presented work, ideas in those work can be introduced into the presented work to improve the efficiency and accuracy. Some work is conducting.

Application of Zadeh's Impossibility Principle to Approximate Explanation

Vesa A. Niskanen

Dept. of Economics & Management, University of Helsinki, PO Box 28, 00014 Helsinki, Finland
Email : vesa.a.niskanen@helsinki.fi

Abstract: *We consider application of Zadeh's impossibility principle and extended logic FLe to approximate scientific explanation from the standpoint of the philosophy of science. First, traditional explanation models are sketched. Second, Zadeh's principle is considered in the broader context which includes reasoning and theory formation. Third, application ideas for using the impossibility principle to approximate explanation are provided. We focus on the role of approximate reasoning, approximate hypothesis assessment and approximate probability in explanation. It seems that approximate explanation can be usable when imprecise entities are involved in the conduct of inquiry.*

Keywords: *approximate explanation, approximate reasoning, impossibility principle.*

1 Introduction

Scientific explanations make our objects of research intelligible for us [28]. In practice this means that we aim to find the causes, functions or purposes of the phenomena under study. An explanation constitutes of two parts, the phenomenon or problem to be explained (explanandum) and our explanation for it (explanans). Explanations play an important role in theory formation and hypothesis assessment [12,17,18,28,29].

The study on the causes of the phenomena is a central issue in explanation. If we study the causes, Aristotle already suggested four types of causes, viz. material, formal, effective and final causes. Today, only two of these are usually applied in the conduct of inquiry. The natural sciences focus on the effective causes, whereas in the human sciences final causes are also considered [18].

Today, the mainstream seems to aim at precise explanation models, but thanks for the fuzzy systems and Zadeh's impossibility principle, it seems that we can also construct corresponding approximate models in the future.

Below we consider the prospects for applying the impossibility principle and other Zadeh's recent ideas to scientific explanation from the standpoint of the philosophy of science. Due to our philosophical approach, we mainly provide some general ideas for applying these methods. Lack of space puts also restrictions on our examination. Section 2 briefly presents the prevailing explanation models. In section 3 we integrate the impossibility principle with reasoning, theory formation, hypothesis testing and explanation. Section 4 considers aspects of approximate explanation, and section 5 concludes our examination.

2 Traditional explanation models

The pragmatic approach to explanation, which seems widely-used today, considers such phenomena as facts, regularities and occurrences. Our task is to provide the cause, origin, history, function or goal of a given phenomenon. In practice we provide such questions as "why?", "how?", "what is the purpose for?", "what is the reason for?" and "what is the function of?" [18,27,29].

The positivistic tradition, in turn, has emphasized syntactical and semantical aspects of explanation in which case concept analysis and logical structures are essential [18,27].

Another categorization of explanation stems from the causes. If we attempt to find effective causes of a phenomenon, we consider which agents, factors or events have initiated the phenomena under study. The well-known example of this idea is the subsumption model in the natural sciences [12,13,17].

The final causes, in turn, are those goals, purposes, intentions or motives of agents, in particular those of the human beings, which guide their behavior. Aristotle's and von Wright's practical syllogism models [29] apply this idea. The subsumption approach mainly provides why?- and how?-questions, and the latter tradition usually asks what is the purpose for or what is the reason for something.

We usually search for effective causes in the inanimated world, but in the animated world the problem arises whether we should also search for final causes. From the philosophical standpoint, the former approach mainly stems from the positivistic tradition and Marxism and the latter, which studies both of these causes, is known as the Geisteswissenschaft approach (hermeneutics, phenomenology etc.). In [29] these competitive approaches are referred to as the Galilean and Aristotelian traditions, respectively, and we use these terms below.

The explanation of the behavior of the human being has been a long-lasting controversy between these two traditions. The Galilean tradition assumes that our behavior is based on our stimulus-response functions and such feedback systems which are analogous to homeostats. In this framework we can even deal with *goal-directed* behavior of beings.

The Aristotelian tradition presupposes that the human beings are *goal-oriented* agents and thus we must also study their aims, intentions, motives and other underlying causes of behavior. Our goals can be both conscious and subconscious, and intentionality is usually related to the former category. A classical example within this tradition is that we should explain (inanimate) nature but understand history, i.e., historical research also takes into account the intentional factors of beings [2,7,15,26].

If we consider the nature of causes on the time axis, the distinction between the Galilean and Aristotelian explanations essentially means that in the former case the cause precedes and in the latter case it follows the effect. Another way to state this is that we use causal and teleological explanations, respectively.

ISBN: 978-989-95079-6-8

For example, if we state in the first day of the IFSA '09 Congress that Lotfi Zadeh is present because he was requested to deliver the keynote speech, we use the Galilean explanation. If, in turn, we state that Lotfi Zadeh is present in order to deliver the keynote speech, the Aristotelian approach is adopted. Naturally, we can often use these explanations simultaneously.

Hence, in this sense we can establish that

1. Requested for speech (causal explanans) → **Zadeh is present in the IFSA '09 (explanandum).**
2. **Zadeh is present in the IFSA '09 (explanandum)** ← In order to deliver speech (teleological explanans):

Other models for explanation are also available. For example, the genetic explanations aim to discover causes by examining the history or chronological order of events of a phenomenon. In the historical research and forensic sciences, inter alia, abduction is usually applied in this context.

The statistical and probabilistic explanations, in turn, are based on statistical results and probabilistic models, respectively. An example of the former type would be the reasoning that most of the participants in the IFSA '07 Congress were males because about 90 % of the researchers in the fuzzy community are males. In the latter case we could provide an explanation that if we are tossing a coin, about 50 % of the outcomes are heads because the frequency probability for this event is .5. In particular in the human sciences these explanation models are relevant because the human behavior is usually indeterministic by nature.

The traditional explanation models aim to operate with precise entities and traditional deduction, and thus certain problems can arise. First, they usually apply bivalent logic and this approach can yield overly rough models. Second, if mathematical expressions are used, they can be oversimplified or too idealized for modeling the corresponding real-world phenomena. Finally, this approach lacks an appropriate uniform language which can be used in the context of imprecise entities. Fuzzy systems, in turn, can provide some resolutions to these problems.

3 Impossibility principle and FLe

Recently, Zadeh has established the principles of the extended fuzzy logic, *FLe* (a.k.a. FL+), which is a combination of "traditional" provable and precisiated fuzzy logic, *FLp*, as well as a novel meta-level unprecisiated fuzzy logic, *Flu* [31,38]. He maintains that in the *FLp* the objects of discourse and analysis can be imprecise, uncertain, unreliable, incomplete or partially true, whereas the results of reasoning, deduction and computation are expected to be provably valid. In the *Flu*, in turn, membership functions and generalized constraints are not specified, and they are a matter of perception rather than measurement.

In our framework below this means that we can apply both traditional bivalent-based and novel approximate validity, definitions, axioms, theories and explanations, inter alia. In the former case we thus operate with precise theorems, classical deducibility, syllogisms and formal logic, whereas the latter is related to "f-entities" within informal and approximate reasoning and incomplete information (Fig. 1).

For example [31, p. 2],

"A simple example of a f-theorem in f-geometry is: f-medians of f-triangle are f-concurrent. This f-theorem can be f-proved by fuzzification of the familiar proof of the crisp version of the theorem."

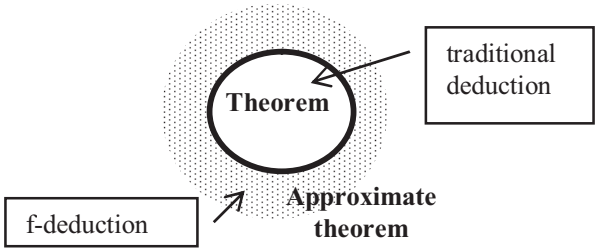

Figure 1. Precise and approximate theorem by applying the *FLe*.

F-validity and f-theoremhood in the *Flu* are examples of Zadeh's Impossibility Principle [31]. This principle informally states that in an environment of imprecision, uncertainty, incompleteness of information, conflicting goals and partiality of truth, p-validity is not, in general, an achievable objective.

The fuzzy modus ponens is the well-known application of this principle in semantic validity, i.e., we can replace the traditional syllogism [8,11,14,19]

A
If A, then B
Thus, B

with its approximate counterpart

A'
If A, then B
Thus B'

in which A≈A' and B≈B'. In the latter case we can thus draw approximate conclusions, i.e., if A' resembles the antecedent A, the conclusion B' resembles the consequent B. In other words, the approximate conclusion is in the proximity to its true counterpart. F-validity is the corner stone in the *FLe* and it is also essential in approximate theory formation and explanation.

In [21,22,23], Zadeh's *FLe* is considered from the standpoint of reasoning and theory formation and it was assumed that the approximation stems essentially from the former. We assume below that if our statements are true, it means that they are identical with their true counterparts. The non-true statements, in turn, are more or less distinct from their true counterparts, or in other words, their distances between their true counterparts are non-zero.

For example, given that John is young (true counterpart), we can reason that the statement

"John is young"

is true. On the other hand, "John is fairly young" is non-true because the predicates "is young" and "is fairly young" are dissimilar.

In fact, we can thus operate with a f-similarity relation of the *Flu,* and then the truth values are specified according

ISBN: 978-989-95079-6-8

to this operation. The higher this similarity, the more true the statement in consideration [23].

Then it seems plausible that, for example, the truth value of the statement

"John is fairly young", provided that he is young

is fairly true [23].

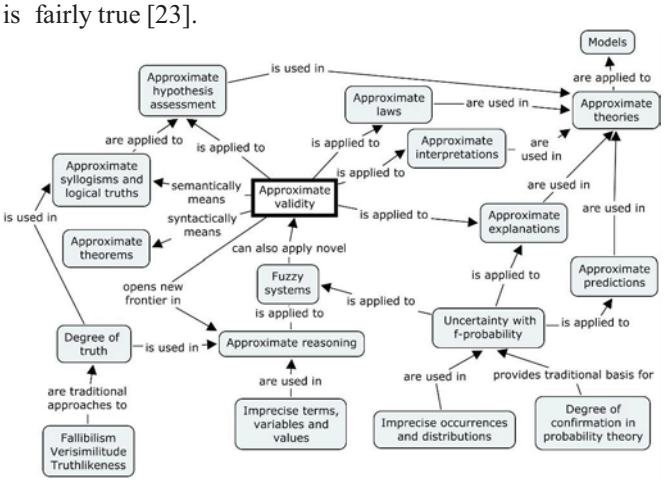

Figure 2. The role of Zadeh's *FLe* in the conduct of inquiry.

We thus assume that approximate theorems are in the neighborhood of their true counterparts. We can also assume that in theory formation approximate laws and theories are in the proximity to their true counterparts and approximate explanations are close to the corresponding true explanations. Figure 2 depicts these ideas at a general level when we establish that our examination on the *FLe* is mainly based approximate validity.

In the case of theory formation, for example, the constituent or "law" of one physical theory states that the boiling point of water is 100 ºC at sea level, but we can also apply it as an approximate law in the low altitudes in general, i.e., we can state that the boiling point of water is *approximately 100 ºC close to* sea level [19,22].

In addition, within the traditional approach to the theory formation and model construction we only use their approximations and idealizations on some occasions. In the former case the degree of truth of a theory or model often increases when we replace the approximate theory, law or model with its less approximate counterpart [18,19]. Hence, in this respect the law

the boiling point of water is 100 ºC at sea level

is a more true than

the boiling point of water is 100 ºC.

Idealizations, in turn, are typical when mathematical or statistical models are used. For example, in statistics such ideal curves as the Gaussian curve are used when the empirical data sets, the distributions of which are only more or less similar to their mathematical counterparts, are examined. Thus, we actually draw statistical conclusions on approximate grounds (c.f. also section 4).

Popper has already considered the foregoing aspects in his theory of verisimilitude from the bivalent standpoint [24,25]. He presupposes that we aim to formulate true theories (cognitivism) but in practice our theories can be non-true. If we perform successful research, our theories will approach their true counterparts and thus they are always corrigible by nature. The similar idea is applied in Peirce's fallibilism [17,18], and in general, in scientific realism (Peirce, Lenin, Popper, Hempel). Niiniluoto [20] has considered approximate theories and explanations within his theory of truthlikeness, but he has also applied bivalent logic in this context. In fact, if we replace bivalent logic with *FLe*, our approach is fairly close to his ideas [23].

4 Approximate explanation

As was stated above, our examination is based on the idea of approximate reasoning in the *FLe*. Thus, in an approximate explanation model the explanans is in the neighborhood of its true counterpart. In practice we now assess the degree of similarity between our explanans and its true counterpart. The higher the degree of similarity, the higher the degree of truth for our explanans (Fig. 3).

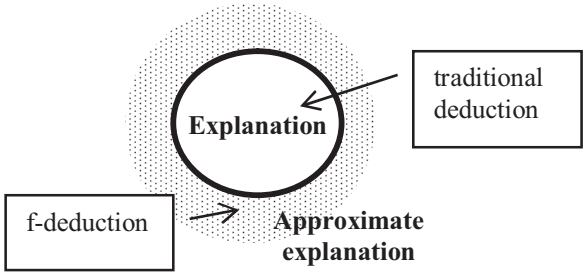

Figure 3. Precise and approximate explanation by applying the *FLe*.

Hence, we have to consider again which logical tools are appropriate to us. As above, within simple statements we assess the similarity between the predicates, i.e.,

truth(John is fairly young), provided that he is young,

is based on the similarity between "young" and "fairly young".

The more complex statements can also be examined within the *FLe* because we can apply the fuzzy similarity measure to compound and quantified statements [31-38]. Then, for example, we should be able to assess such truth values as

truth(John is fairly young and very decent),

provided that he is young and decent.

Another example is the assessment of such quantified expressions as

truth(all Swedes are fairly tall),

provided that most Swedes are tall.

In the former case some concrete resolutions are already available in the *FLe*, whereas fuzzy quantification still awaits usable truth evaluation results. Approximate quantification is problematic because then we operate at two levels, with approximate quantifiers and (compound) statements. Application of the extension principle and Zadeh's idea on

ISBN: 978-989-95079-6-8

f-transformation [38] can be a possible resolution for these, and one method is suggested in [23]. Naturally, these approaches are context-dependent by nature. Hence, more concrete results are expected for assessing the truth values and validity within the *FLe*.

In the probability and statistical explanation models mentioned above we can apply corresponding approximate theories. For example, if in the former case we are tossing the coin in the real world, only approximately 50 % will be heads. Hence, if we ask why about 50 % of these outcomes are heads, we can provide an approximate explanation that it is due to this approximate frequency probability. In other words, our approximate probability statements are close to their true counterparts.

The same goes with the statistical explanations. If we explain why most of the attendants in the IFSA '07 Congress were males, we rely on the approximate statistical result that about 90 % of persons in the fuzzy community are males.

We have to bear in mind that both probabilistic and statistical explanation models above are distinct from the forecasting models. In the former case we know the conclusion and we derive it from the relevant premises, whereas in forecasting the conclusion is unknown for us. Naturally, the systematic power of a theory presupposes both of these features.

In the foregoing models fuzzy probability approach usually means approximate probability variables and values of these variables, i.e., statements of the type

the probability that John is young is very high,

and this area has already been studied quite much in the literature [4,5,6,9,31,37]. In Zadeh's *FLe* we can also apply such approximate probability distributions as approximate normal distributions by using the f-transformation. In this case even such precise variable values as

probability(John's age is 20 years)

yield approximate probabilities. With imprecise values (e.g., John is fairly old) we obtain even more imprecise outputs (Fig. 4).

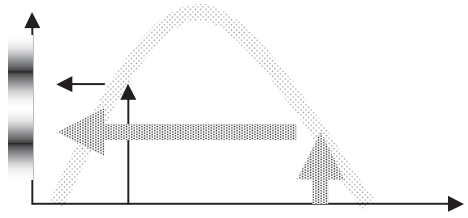

Figure 4. Approximate probability distributions yield approximate outputs even from precise inputs.

The foregoing examples of probability are mainly based on the physicalistic cases, i.e., on the facts and data of the real world. However, Zadeh's theories seem also applicable to epistemic probability in which case these outcomes base on our inference and beliefs [1,30]. In practice we consider the relationship between the hypotheses and their evidence, and we thus assess the degrees of truth, confirmation or belief of hypotheses according to the available relevant evidence.

The gradation of truth was already studied above. As regards the hypothesis testing in general, due to the lack of space we only focus on the degree of confirmation in the context of the explanatory hypotheses and the hypothetico-deductive method [12,13,17,18].

In this hypothesis assessment we usually apply three methods. First, Mill's method of difference [17,18], i.e.,

> *"If an instance in which the phenomenon under investigation occurs, and an instance in which it does not occur, have every circumstance in common save one, that one occurring only in the former; the circumstance in which alone the two instances differ, is the effect, or the cause, or an indispensable part of the cause, of the phenomenon."*

Second, the disjunctive syllogism

A or B
not A
thus, B.

Third, the modus tollens syllogism

if A, then B
not B
thus, not A.

Mill's principle and the disjunctive syllogism provide us with the general roadmap for excluding the false hypotheses and within the hypothetico-deductive method this task is carried out in practice by applying the modus tollens syllogism.

Hence, given the hypothesis A and its observable or testable logical consequence B, the justifiability of B is assessed according to our knowledge, experiments and observations. If these facts are inconsistent with B, the modus tollens leads us to the conclusion that our hypothesis is false. According to the disjunctive syllogism, in turn, this hypothesis can be rejected or excluded.

If, on the other hand, our experiments and observations correspond with B, the traditional modus tollens will not provide us with any resolution. Hence, in the latter case we have to replace deduction with induction, and we can use such expressions as "our hypothesis is confirmed" in this context [17,18,24,25]. Sufficient degree of confirmation, in turn, will lead to the truth or acceptance of the hypothesis (c.f. below).

In the traditional conduct of inquiry this method thus uses the hypotheses, which stem from the researcher's context of discovery and inventions, deduces tests and experiments from these hypotheses and finally either rejects or confirms the hypotheses according to the known facts and empirical evidence. However, this approach does not provide any resolution to the problem how we can invent or discover novel hypotheses.

Statistical tests also apply the disjunctive method and physicalistic probability when we consider the acceptance of the null and alternative hypotheses according to the tests of significance. We accept the null hypothesis if the value of our test variable does not deviate too much from the "usual" case. Hence, in fact we consider the so-called type 1 error, i.e., we attempt to find justified reasons to reject the null hypotheses. In practice this error is estimated with the p-

ISBN: 978-989-95079-6-8

value in which case we consider the rejection of the null hypotheses if the p-value is sufficiently small (e.g., $p < .05$), i.e., the p-value is our risk to make an erroneous decision if we reject the null hypothesis.

In practice, we have three alternatives in this case [10,16], viz.

1. the null hypothesis is true but our data set is exceptional
2. the null hypothesis is false and our data set is typical
3. the null hypothesis is false and our data set is exceptional

In the conventional case the statistical hypotheses are mutually exclusive, and thus the rejection of one means the acceptance of the other. Hence, according to the disjunctive method, our reasoning boils down to the metarules

1. if the p-value is not small, accept the null hypothesis
2. if the p-value is small, reject the null hypothesis (and accept the alternative hypothesis)

The statistical decision making is thus in this respect based on approximate reasoning and probability. Zadeh's *FLe* can make this reasoning more formal and informative if we operated with the degrees of acceptance and rejection in this context. Then, we could apply such metarule as

> the smaller the p-value, the lower the risk to reject the null hypothesis (the higher the degree of rejection for the null hypothesis)

With the *FLe* we could also take into account better the borderline of these two, viz. the area in which we hesitate over these alternatives. This would mean the fuzzy rules which we have already stated above, i.e.,

1. If the p-value is not small, then accept the null hypothesis.
2. If the p-value is small, then reject the null hypothesis.

With these rules the corresponding fuzzy system could also operate fluently with the borderline cases of p. However, more concrete tools for considering this problem are still expected within the *FLe*.

As regards the modus tollens syllogism in hypothesis assessment, we already considered its bivalent version above. If we apply its approximate version, we can also use linguistic and approximate constituents. Thus, given that $A \approx A'$ and $B \approx B'$, these syllogisms are such as [23]

> if A, then B
> B'
> thus, A'

In this case the truth values of the premises may also be between true and false. This syllogism is analogous to the bivalent case when A' and B' are the antonyms of A and B, respectively, because given that the implication and B' are true, B is false, and thus A must be false (and A' is thus true).

Within the *FLe* the other extreme could be that B' is false in which case B is true and A is thus anything from false to true (and A' is also anything from false to true). In practice this could mean that our hypothesis, A, may be true at least to some extent.

For example,

> If John is young, then he is still a schoolboy.
> John is retired.
> Thus, John is old and reject the hypothesis "John is young".

> If John is young, then he is still a schoolboy.
> John is still a schoolboy.
> Thus, the degree of truth for John being young can be non-zero.

It seems that the approximate version of the modus tollens is more versatile because it is also usable when the second premise is non-false. Then we can at least approximately apply the metarule that the more convincing the evidence for the hypothesis, the higher the degree of truth of our hypothesis. In addition, the more various experiments and observations support our hypotheses, the more true hypothesis is obtained. We can also use the concepts "degree of confirmation" or "degree of acceptance / rejection" in this context if necessary.

Within the *FLe* we can also assume that the implication in the approximate modus tollens syllogism is non-true. For example, if this implication is only fairly true, we can establish that even the false B does not necessarily lead to mere false hypotheses. Equally the truth value of B close to true may already lead to conclusion that the truth value of our hypothesis is anything between false and true. In general, we may thus assume that the non-true implications cause more "dispersion", granulation or imprecision to our conclusions, and loose reasoning links of this type are typical in the human sciences in which we usually operate with noisy data and the complex interrelationships between the variables.

We may also apply the foregoing hypothesis testing to interpretation, which is a widely-used technique in the qualitative research. In this context we attempt to provide a "true" interpretation according to our preliminary interpretation hypothesis (*foreknowledge* in hermeneutics). This procedure of assessing hypotheses is often more subjective by nature than in the quantitative research. However, the *FLe* also seems appropriate to qualitative hypotheses assessment because this inquiry is usually linguistic and approximate by nature [2,3,23].

Zadeh has also considered the idea of the second-order probability under the *FLe* [31,37]. In this context we examine such statements as

> The probability that "the probability of John being very young is fairly high" is high.

This subject matter would also extend a new frontier within both the fuzzy systems and the probability theory, but it also awaits much further studies.

Approximate scientific explanation is related to reasoning, theory formation and hypothesis testing. These, in turn, base much on approximate and probabilistic reasoning. Hence, this object of research is very wide. Zadeh's *FLe* seems to provide promising tools for resolving many of the foregoing problems, but much further studies are still expected in this area.

ISBN: 978-989-95079-6-8

5 Conclusions

We have provided some guidelines how Zadeh's impossibility principle and the extended logic *FLe* could be applied to scientific explanation. We have also examined reasoning, hypothesis assessment and theory formation because these are closely related to explanation.

First traditional reasoning, theory formation and explanation, which use precise entities and bivalent logic in particular in the quantitative research, were considered.

Second, we dealt with Zadeh's *FLe* and his other recent theories, and we examined how we could design usable approximate theories and explanations which essentially base on approximate reasoning and probability.

In particular, we provided examples on our approximation approach to scientific laws, theory formation, statistical and probabilistic reasoning, hypothesis assessment and two well-known syllogisms. These ideas, in turn, were relevant when approximate explanation was considered.

It seems that the foregoing methods are usable in approximate explanation and in this context we could apply the general principle that approximate explanations are in the neighborhood of their true counterparts. This aim is essentially achieved by using approximate reasoning.

Zadeh's novel ideas seem promising in particular in the qualitative research because then we operate with imperfect information, and in this context we still lack a uniform and usable logico-linguistic system. It also seems possible to apply his ideas to the quantitative research, in particular if we attempt to mimic human reasoning in a computer environment.

We must bear in mind that several of the foregoing issues are still controversial even in the philosophy of science, and the same problem will likely concern Zadeh's and Author's ideas above.

However, due to the lack of space, this paper only provides at metalevel some general guidelines for approximate scientific explanation and related topics from the standpoint of philosophy of science, and hence this relevant subject matter still awaits much further studies in the future.

Acknowledgements

The author expresses his deep gratitude to Prof. Lotfi Zadeh at the UC Berkeley for the original ideas, articles, several discussions and encouragement which made it possible to write this article. I also express my thanks to the anonymous referees for their valuable comments.

Abstract— Preference modeling consists in constructing a preference relation from initial preferences given by a decision maker. We are interested in the preference relation obtained from the use of the Choquet integral. The necessity preference is constructed as the intersection of all preference relations corresponding to a Choquet integral which are compatible with the initial preferences of the decision maker. We study some properties of this necessity relation on some classes of initial preferences. This gives some properties on the completion or extension ability of the Choquet integral.

Keywords— Choquet integral, capacity, initial preferences.

1 Introduction

Multi-Criteria Decision Aid aims at representing the preferences of a Decision Maker (DM) over some options described by several points of view or attributes. We are interested in this paper in the case where the preference relation can be described by an overall utility in which the aggregation of the attributes is obtained with the Choquet integral. The preference model is then thoroughly constructed once the parameters of the Choquet integral - namely the fuzzy measure - are determined.

To this end, the facilitator asks the DM to provide some preferential information. The most broadly used type of preferential information is when the DM says that an option is preferred to another one. The major difficulty the facilitator faces is that there usually does not exist one single fuzzy measure that fulfils this preferential information. Most of the elicitation methods based on the Choquet integral consist in selecting a fuzzy measure (fulfilling the preferential information) that maximizes some functional, which may be an entropy for instance [1, 2, 3]. This is not quite satisfactory for the DM since he does not usually understand what maximizing the functional really means. The use of a maximization problem introduces some additional information that does not come from the DM.

The facilitator shall rather stick strictly to what the DM says and add no further information. One then looks for a robust way to recommend some comparisons among the options from the preferential information [4]. The concept of *necessity preference relation* has been recently introduced for robust quantitative multi-criteria decision models [5, 6]. It has been applied to the Choquet integral in [7]. An option is *necessarily* preferred to another option according to the necessity preference relation, if the first option is preferred to the second one according to all models that fulfill the preferential information provided by the DM. This necessity preference relation is usually incomplete, unless the model is completely specified from the preferential information of the DM. The necessity preference relation is cautious in the sense that its outcomes cannot be contradicted.

The goal of this paper is to study the necessity preference relation for several examples of typical preferential information, in the case where the underlying model is the Choquet integral. In particular, we want to analyze the strength of the completion mechanism obtained from the Choquet integral. This will give complementary insights (compare to the axiomatic characterizations) on the ability of the Choquet integral to represent DM preferences. For each preferential information, the layout is the following:

- Statement of the preferential information and precise description in terms of binary relations.
- Equivalence conditions on the model. We determine the necessary and sufficient conditions on the parameters of the model for this latter to satisfy the preferential information.
- Description of the necessity preference relation derived from the preferential information.

Section 2 presents a more formal description of the problem. The Choquet integral is defined in Section 3. Section 4 describes the process elicitation of the preferential information. Three decision strategies are then studied: the case of empty preference information (see Section 5), the relative importance (see Section 6) and the veto (see Section 7).

2 Description of the problem

Multi-Criteria Decision Aid aims at modeling the preferences of a Decision Maker (DM) over alternatives described by several points of view $N = \{1, \ldots, n\}$. The points of view to be taken into account in the decision making process are denoted by $X_1, \ldots, X_n$. An alternative is characterized by a value w.r.t. each point of view

ISBN: 978-989-95079-6-8

and is thus identified to a point in the Cartesian product X of the points of view: $X = X_1 \times \cdots \times X_n$.

Preference modeling aims at helping a DM to compare the options of a set $\Xi \subseteq X$ containing the alternatives of interest for him. We denote by $\succsim$ the preference relation over X that we wish to define. We are interested in the case where $\succsim$ results from an algebraic utility model. According to this model, the preference relation $\succsim$ can be represented by an overall utility $U : X \to \mathbb{R}$. Hence for all $x, y \in X$, we have

$$x \succsim y \iff U(x) \geq U(y).$$

A standard representation of U is the so-called transitive decomposable model $U(x) = F(u(x))$, where $u_i : X_i \to \mathbb{R}$ is the utility function on attribute $i \in N$, $u(x) = (u_1(x_1), \ldots, u_n(x_n))$, and $F : \mathbb{R}^N \to \mathbb{R}$ is the aggregation function. We assume here that u is known so that the options can be described by a vector in $\mathbb{R}^n$. Hence $X = \mathbb{R}^n$ and the utility functions are the identity function. The aggregation function is characterized by some parameter vector w that need to be determined. Let $\mathcal{W}$ the set of values of the parameters. The preference relation obtained from the parameter vector w is denoted by $\succsim_w$. We denote by $\succ_w$ and $\sim_w$ the asymmetric and symmetric parts of $\succsim_w$.

Any binary relation on $\mathbb{R}^n$ can be identified to a subset of $(\mathbb{R}^n)^2$ composed of the pairs (a, b) such that a is in relation with b.

The fact that the DM needs some help to compare the options in Ξ, means that the comparison of at least some of the options in Ξ is complex. Some preferential information, containing the preferences of the DM over several options in $X \backslash \Xi$, is asked to the DM. This preferential information is encoded by three partial orders $\trianglerighteq, \triangleright, \equiv$ over X. For $x, y \in X$, relation $x \trianglerighteq y$ means that the DM finds x at least as good as y, $x \triangleright y$ means that the DM finds x strictly better than y, and $x \equiv y$ means that the DM finds x similar to y. We set $\square = (\trianglerighteq, \triangleright, \equiv)$. In order to deduce a comparison of the elements of Ξ from $\square$, one necessarily needs some completion mechanism. We want to construct three binary relations $\succsim$, $\succ$ and $\sim$ on X that extend $\square$. The strength of the completion is measured through the differences $\succsim \backslash \trianglerighteq$, $\succ \backslash \triangleright$ and $\sim \backslash \equiv$ compare to $\trianglerighteq, \triangleright, \equiv$ respectively. For a very weak completion, we have $\succsim \backslash \trianglerighteq = \emptyset$, $\succ \backslash \triangleright = \emptyset$ and $\sim \backslash \equiv = \emptyset$.

Let $\mathcal{W}(\square)$ be the set of parameter vectors w for which $x \succsim_w y$ whenever $x \trianglerighteq y$, $x \succ_w y$ whenever $x \triangleright y$, and $x \sim_w y$ whenever $x \equiv y$. The completion is necessarily based on the family $\{\succsim_w\}_{w \in \mathcal{W}(\square)}$. A classical completion is the preference relation $\succsim_w$ corresponding to a particular $w \in \mathcal{W}(\square)$ solution to an optimization problem [1, 2, 3]

$$w = \text{argmax}_{w \in \mathcal{W}(\square)} G_\square(w) \tag{1}$$

where $G_\square$ is the function depending on $\square$ to be maximized. As said in the introduction, we are interested in the *necessity* preference relation $\succsim^{\mathcal{W}}_{\text{N},\square}$ that is constructed from $\square$ as follows [7, 5, 6]:

$$x \succsim^{\mathcal{W}}_{\text{N},\square} y \iff [\forall w \in \mathcal{W}(\square) \;\; x \succsim_w y]\,. \tag{2}$$

One may also define $\succ^{\mathcal{W}}_{\text{N},\square}$ and $\sim^{\mathcal{W}}_{\text{N},\square}$ by

$$x \succ^{\mathcal{W}}_{\text{N},\square} y \iff [\forall w \in \mathcal{W}(\square) \;\; x \succ_w y]$$
$$x \sim^{\mathcal{W}}_{\text{N},\square} y \iff [\forall w \in \mathcal{W}(\square) \;\; x \sim_w y]\,.$$

Note that one may have $\succsim^{\mathcal{W}}_{\text{N},\square} \neq \succ^{\mathcal{W}}_{\text{N},\trianglerighteq} \cup \sim^{\mathcal{W}}_{\text{N},\square}$.

Another interesting order relation derived from $\square$ is the so-called *possibility preference relation* defined as follows [7, 5, 6]:

$$x \succsim^{\mathcal{W}}_{\Pi,\square} y \iff [\exists w \in \mathcal{W}(\square) \;\; x \succsim_w y]\,.$$

Let us mention that these concepts of necessary and possible preference representation are originated from earlier works on preference modelling. In the context of decision rules, the necessary and possibility preference relations are the lower and upper approximations of a rough set [8]. Moreover, in qualitative decision models, these concepts correspond to the dominance and ordering queries for the Ceterus Paribus nets [9].

The choice of the representation of $\succsim_w$ (and thus of the family of aggregation functions F) is very important since it characterizes directly the completion mechanism. The choice of the family F results from a compromise: if the completion is too strong, we deduce much more than what the DM expresses and the DM may not agree with the outcome. If the completion is too weak, we basically do not deduce really more than what the DM says. Moreover, the stronger the completion mechanism, the less information $\square$ needs to be given.

As an example, the completion resulting from a simple model such a weighted sum is stronger than that obtained from a more general model such as the Choquet integral. We will illustrate this in the main part of the paper. Consider the case where F is the usual weighted sum: $F(x) = \sum_{i \in N} w_i\, x_i$ where w_i is the weight of criterion i. Thanks to the additivity properties of this model, one can deduce that $(1, \frac{1}{2}, 0) \succsim^{\mathcal{W}}_{\text{N},\square} (0, 1, \frac{1}{2})$, from the simplier comparisons $(\frac{1}{2}, \frac{1}{2}, 0) \trianglerighteq (0, \frac{1}{2}, \frac{1}{2})$, $(\frac{1}{2}, 0, 0) \trianglerighteq (0, \frac{1}{2}, 0)$ provided by the DM. The previous deduction is wrong for the Choquet integral. The weighted sum, which is a very simple aggregation model, implies a very strong completion mechanism.

The necessity preference relation $\succsim^{\mathcal{W}}_{\text{N},\square}$ corresponds to the comparisons among the options in X that can be made for sure. If the initial preferences $\square$ of the DM are fixed, the recommendation given by the facilitator shall be based only on $\succsim^{\mathcal{W}}_{\text{N},\square}$.

Now, if $\succsim^{\mathcal{W}}_{\text{N},\square}$ is not enough complete, the facilitator will probably try to enrich $\square$ with new comparisons provided by the DM. The candidate comparisons must be picked up from the possibility preference relation. Assume indeed that $\square$ is enriched with a new information "x is at least as good as y" such that $x \not\succsim^{\mathcal{W}}_{\Pi,\square} y$. The enriched preferential information is $\square' = (\trianglerighteq', \triangleright', \equiv')$ with $\trianglerighteq' = \trianglerighteq \cup \{(x, y)\}$, $\triangleright' = \triangleright$ and $\equiv' = \equiv$. Since $x \not\succsim^{\mathcal{W}}_{\Pi,\square} y$, we obtain $\mathcal{W}(\square') = \emptyset$. Hence the new preferential information to add to $\square$ must belong to $\succsim^{\mathcal{W}}_{\Pi,\square}$, $\succ^{\mathcal{W}}_{\Pi,\square}$ or $\sim^{\mathcal{W}}_{\Pi,\square}$. One clearly has [5, Proposition 4.1]

$$\succsim^{\mathcal{W}}_{\text{N},\square} \subseteq \succsim^{\mathcal{W}}_{\Pi,\square}\,.$$

ISBN: 978-989-95079-6-8

The comparisons contained in the necessity preference relation are automatically deduced from $\Box$, and do not therefore enrich $\Box$. In other words, if $(x,y) \in \succsim^{\mathcal{W}}_{\mathrm{N},\Box}$, then $\mathcal{W}(\Box') = \mathcal{W}(\Box)$, where $\Box' = (\trianglerighteq', \rhd', \equiv')$ with $\trianglerighteq' = \trianglerighteq \cup \{(x,y)\}$, $\rhd' = \rhd$ and $\equiv' = \equiv$. This proves that the new relevant preferential information to add to $\Box$ actually belongs to

$$\succsim^{\mathcal{W}}_{\Pi,\Box} \setminus \succsim^{\mathcal{W}}_{\mathrm{N},\Box}\ ,\ \succ^{\mathcal{W}}_{\Pi,\Box} \setminus \succ^{\mathcal{W}}_{\mathrm{N},\Box} \quad \text{or} \quad \sim^{\mathcal{W}}_{\Pi,\Box} \setminus \sim^{\mathcal{W}}_{\mathrm{N},\Box}\ .$$

In this paper, we will not study specifically the possibility preference relation. We will focus only on the necessity preference relation. The reason is that $\succsim^{\mathcal{W}}_{\mathrm{N},\Box}$ and $\succsim^{\mathcal{W}}_{\Pi,\Box}$ are strongly linked together. More precisely, since $\succsim_w$ is a complete preorder, we have

$$x \succsim^{\mathcal{W}}_{\Pi,\Box} y \iff y \not\succ^{\mathcal{W}}_{\mathrm{N},\Box} x.$$

In other words, $\succsim^{\mathcal{W}}_{\Pi,\Box} = X^2 \setminus (\succ^{\mathcal{W}}_{\mathrm{N},\Box})^{-1}$.

3 Notation and the Choquet integral

We hereafter restrict to the case where F is a Choquet integral.

3.1 Choquet integral

A fuzzy measure (also called *capacity*) on a set N of criteria is a set function $\mu : 2^N \to [0,1]$ such that [10]

- $\mu(\emptyset) = 0$, $\mu(N) = 1$,
- $\forall A \subseteq B \subseteq N\ ,\ \mu(A) \leq \mu(B)$

Let $\mathcal{M}$ be the set of all fuzzy measures. A fuzzy measure is said to be additive if $\mu(A \cap B) = \mu(A) + \mu(B)$ for every pair (A,B) of disjoint coalitions.

The Choquet integral of $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$ defined w.r.t. a capacity μ has the following expression [11] :

$$C_\mu(x_1, \ldots, x_n) = \sum_{i=1}^{n} \left(x_{\tau(i)} - x_{\tau(i-1)}\right) \times \mu\left(\{\tau(i), \cdots, \tau(n)\}\right), \qquad (3)$$

where τ is a permutation on N such that $x_{\tau(1)} \leq x_{\tau(2)} \leq \cdots \leq x_{\tau(n)}$, and $x_{\tau(0)} := 0$. The Choquet integral has been proved to be able to model both the importance of criteria and the interaction between criteria. One fundamental property of the Choquet integral is that

$$C_\mu(1_A, 0_{N \setminus A}) = \mu(A). \qquad (4)$$

3.2 k-additive capacities

We introduce a useful linear transformation of fuzzy measures. The *Möbius transform* m of a fuzzy measure μ is the unique solution of the equation

$$\forall A \subseteq N \quad \mu(A) = \sum_{B \subseteq A} m(B), \qquad (5)$$

and is given by:

$$m^\mu(A) := \sum_{B \subseteq A} (-1)^{|A|-|B|} \mu(B). \qquad (6)$$

A fuzzy measure is defined by 2^n coefficients, which is much more than a weighted sum. The concept of k-additive fuzzy measure has a complexity in-between a fuzzy measure and a weighted sum. More precisely, a fuzzy measure μ is said to be k-additive [12] if $m^\mu(A) = 0$ whenever $|A| > k$ and there exists A with $|A| = k$ such that $m^\mu(A) \neq 0$. We denote by $\mathcal{M}^k$ the set of fuzzy measures that are at most k-additive (i.e. 1, or 2, or ..., or k additive). Note that $\mathcal{M} = \mathcal{M}^n$ and that $\mathcal{M}^1$ are the additive fuzzy measures and corresponds to the usual weighted sum. An interesting particular case is when $k = 2$.

3.3 Interpretation

A capacity contains 2^n terms, which makes its interpretation complex for a DM. In order to ease its interpretation, several global indices have been defined. The first index called *importance index* aims at measuring the degree to which a criterion is important for the decision. The importance index of criterion $i \in N$ is defined by [13]:

$$v_i := \sum_{A \subset N \setminus \{i\}} \frac{(n - |A| - 1)!|A|!}{n!} [\mu(A \cup \{i\}) - \mu(A)].$$

Note that the definition is originated from Cooperative Game Theory in which it corresponds to a fair share of a common wealth among several players.

The interaction index I_{ij} of the couple of criteria $\{i,j\}$ is defined by [14]

$$I_{ij} := \sum_{A \subset N \setminus \{i,j\}} \frac{(n - |A| - 2)!|A|!}{(n-1)!} [\mu(A \cup \{i,j\}) - \mu(A \cup \{i\}) - \mu(A \cup \{j\}) + \mu(A)].$$

The Shapley index v_i can be interpreted as a kind of average value of the contribution of criterion i alone in all coalitions. The interaction index I_{ij} can be interpreted as a kind of average value of the *added value* obtained by putting criterion i and j together. When I_{ij} is positive (resp. negative), the interaction is said to be positive (resp. negative). These two concepts correspond to a mean behavior and are anyhow not so easy to understand for a DM.

3.4 Initial preferential information

We denote by $\mathcal{M}^k(\Box)$ the set of capacities in $\mathcal{M}^k$ that satisfy the preferential information $\Box = (\trianglerighteq, \rhd, \equiv)$:

$$\mathcal{M}^k(\Box) = \Big\{ \mu \in \mathcal{M}^k\ , \forall a, b \in \mathbb{R}^n \quad a \trianglerighteq b \ \Rightarrow\ C_\mu(a) \geq C_\mu(b) \quad a \rhd b \ \Rightarrow\ C_\mu(a) > C_\mu(b) \quad a \equiv b \ \Rightarrow\ C_\mu(a) = C_\mu(b) \Big\}$$

The necessity preference relation on $\mathbb{R}^n$ is a cautious way to take into account the fact that the aggregation model is not uniquely determined from a knowledge of $\Box$, and

ISBN: 978-989-95079-6-8

is defined by:

$$\forall a, b \in \mathbb{R}^n \quad , \quad a \succsim_{\mathrm{N},\Box}^{\mathcal{M}^k} b \iff [\forall \mu \in \mathcal{M}^k(\Box) \quad C_\mu(a) \geq C_\mu(a)] \, .$$

It is easy to see that $\succsim_{\mathrm{N},\Box}^{\mathcal{M}^k}$ is usually incomplete, but is transitive and reflexive. One can define $\succ_{\mathrm{N},\Box}^{\mathcal{M}^k}$ and $\sim_{\mathrm{N},\Box}^{\mathcal{M}^k}$ as in Section 2. One has

$$\sim_{\mathrm{N},\Box}^{\mathcal{M}^k} = \succsim_{\mathrm{N},\Box}^{\mathcal{M}^k} \cap (\succsim_{\mathrm{N},\Box}^{\mathcal{M}^k})^{-1} \quad \text{and} \quad \succ_{\mathrm{N},\Box}^{\mathcal{M}^k} \subseteq \succsim_{\mathrm{N},\Box}^{\mathcal{M}^k} \setminus \sim_{\mathrm{N},\Box}^{\mathcal{M}^k} .$$

Let us define finally the incomparability as $I_{\mathrm{N},\Box}^{\mathcal{M}^k} = (\mathbb{R}^n)^2 \setminus (\succsim_{\mathrm{N},\Box}^{\mathcal{M}^k} \cup (\succsim_{\mathrm{N},\Box}^{\mathcal{M}^k})^{-1})$.

4 Elicitation process

The preference model is usually constructed iteratively through a decision aiding process [15]. This process is centered around the interaction between the DM and the decision aiding system. The information that the DM expresses regarding his preferences can be of two types:

- The first type of information can be easily produced and interpreted by the DM. It is usually admitted that the DM can naturally compare some options. In this paper, the only information of this type corresponds to the three binary relations $\Box = (\trianglerighteq, \rhd, \equiv)$. It is called the *Preferential information*.

- The second type of information (called *Decision strategies*) corresponds to abstract information concerning the preference model. It can typically concern concepts such as the mean importance, veto, relative importance,... The DM can understand them but only to some extend, but it is unexpected that he will naturally provide information of this type. If the decision analyst guesses that the DM fulfills to a decision strategy, he needs to convert it to preferential information in order to check the validity of his guess.

At the end, the only learning data that is considered from the DM corresponds to some preferential information $\Box$. It is transformed in the *internal representation* of the model. This is the set of parameter vectors fulfilling the preferential information, that is $\mathcal{M}^k(\Box)$. It is not understood by the DM. Consistency and completeness is checked in this representation. The necessity preference relation can then be constructed. This relation can be presented to the DM in different ways. It can be directly applied to the set Ξ of options of interest for the DM. It is also possible to interpret the necessity preference relation in terms of decision strategies. The interpretation may concern some indices regarding the mean importance, veto, relative importance, if all the admissible capacities $\mathcal{M}^k(\Box)$ share some common properties on one of these concepts.

The elicitation process can thus be seen as a flow diagram between the three concepts and is organized on the steps *a* to *f* in Figure 1:

- *a*: The DM can express some abstract information regarding his decision strategies. He may express for instance that a criterion is more important than another one.

- *b*: The DM can express information in the format of the order relations $\Box$. He may say for instance that an option is preferred to another one. If the DM has already given some preferential information (denoted by $\Box'$) in a previous step of the elicitation process and he wishes to enrich $\Box'$, the new preferential information shall lie in the sets $\succsim_{\Pi,\Box'}^{\mathcal{M}^k} \setminus \succsim_{\mathrm{N},\Box'}^{\mathcal{M}^k}$, $\succ_{\Pi,\Box'}^{\mathcal{M}^k} \setminus \succ_{\mathrm{N},\Box'}^{\mathcal{M}^k}$ or $\sim_{\Pi,\Box'}^{\mathcal{M}^k} \setminus \sim_{\mathrm{N},\Box'}^{\mathcal{M}^k}$.

- *c*: When the DM expresses abstract information (decision strategies), they shall be converted into preferential information through $\Box$ in order to be precisely set and taken into account by the elicitation method.

- *d*: The preferential information is transformed into constraints in the parameter set. This corresponds to the set $\mathcal{M}^k(\Box)$. This step is sometimes called disaggregation step.

- *e*: An interpretation of the set $\mathcal{M}^k(\Box)$ is presented in terms of, for instance, veto, importance, interaction indices. It can also provide the necessity and possibility preference relations. This step is sometimes called aggregation step.

- *f*: An interpretation of the results of the elicitation is displayed to the DM in some understandable way.

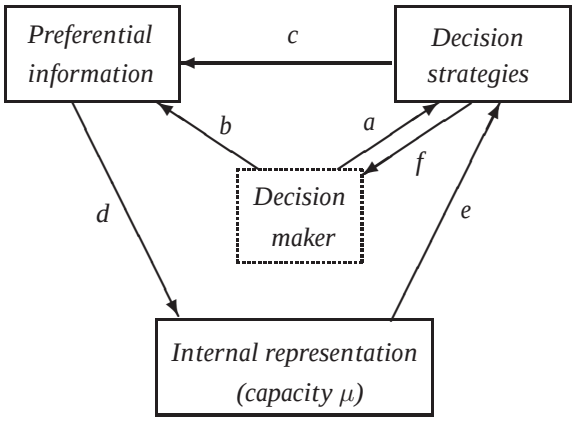

Figure 1: Eliciation process.

In the remaining of this paper, we are interested in some abstract decision strategies that the DM often wishes to express in practice. For each type of preferential information, we determine how it is converted into order relations $\Box$ (step *c*). Then, we construct the necessity preference relation corresponding to this preferential information (steps *d* and *e*).

5 Case of empty preference information

We denote by $\Box_\emptyset$ the empty preference information. When the DM says nothing, there is of course no new

ISBN: 978-989-95079-6-8

constraint on the fuzzy measure:

$$\mathcal{M}^k(\Box_\emptyset) = \mathcal{M}^k.$$

Moreover, it is easy to check that for all $k \in \{1, \ldots, n\}$

$$\succsim^{\mathcal{M}^k}_{\mathrm{N},\Box_\emptyset} = \mathcal{P}_{\mathrm{a}} := \{(a,b) \in \mathbb{R}^n \ , \ \forall i \in N \ \ a_i \geq b_i\} \ .$$

This relation extends [5, Remark 4.1] to the case of the Choquet integral. This is the standard Pareto dominance order. When no preferential information is given, the necessary preferential information is similar to the Pareto dominance order, which is what one expects.

6 Relative importance between criteria

6.1 Statement of the preferential information

We want to express a preferential information regarding the relative importance between two criteria – namely that criterion p is more important than criterion q. The first idea is to interpret this as the relation $v_p > v_q$ based on the Shapley value. This relation is considered in [1, 7]. However, as explained in Section 3.3, the Shapley value is not a simple concept for a DM. It is not clear at all whether the statement *"criterion p is more important than criterion q"* expressed by a DM can be represented by the relation $v_p > v_q$. We wish only to express the previous statement only as binary relations denoted by $\Box^{p,q}_{\mathrm{RelImp}} = (\trianglerighteq^{p,q}_{\mathrm{RelImp}}, \triangleright^{p,q}_{\mathrm{RelImp}}, \equiv^{p,q}_{\mathrm{RelImp}})$. The following definition seems to express quite accurately the previous statement.

Definition 1 ([16]) *A criterion $p \in N$ is said to be* more important *than criterion $q \in N \setminus \{p\}$ iff*

$$\left(\gamma_p, \beta_q, a_{N\setminus\{p,q\}}\right) \triangleright^{p,q}_{\mathrm{RelImp}} \left(\beta_p, \gamma_q, a_{N\setminus\{p,q\}}\right) \qquad (7)$$

for all $\gamma, \beta \in \mathbb{R}$ with $\gamma > \beta$, and all $a_{N\setminus\{p,q\}} \in \mathbb{R}^{n-2}$, where $\left(\alpha_p, \beta_q, a_{N\setminus\{p,q\}}\right)$ denotes the alternative having value α on criterion p, value β on criterion q, and value $a_{N\setminus\{p,q\}}$ on the remaining criteria.

Note that (7) makes sense only if the scales of the criteria are commensurate.

6.2 Conditions on the fuzzy measure

Let $\delta_{p,q}\mu(A) := \mu(A \cup \{p\}) - \mu(A \cup \{q\})$.

Lemma 1 *For all $k \in \{2, \ldots, n\}$, criterion p is more important than criterion q with the Choquet integral with a capacity in $\mathcal{M}^k$ iff*

$$\forall A \subseteq N \setminus \{p,q\} \quad \delta_{p,q}\mu(A) > 0. \qquad (8)$$

6.3 Completion

We have the following result.

Proposition 1 *Let $p, q \in N$ with $p \neq q$. Then for all $k \in \{2, \ldots, n\}$*

$$\begin{aligned}
&\succsim^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \\
&= \Big\{ \Big((\gamma_p, \beta_q, a_{N\setminus\{p,q\}}), (\beta'_p, \gamma'_q, a'_{N\setminus\{p,q\}}) \Big) \in (\mathbb{R}^n)^2 \ , \\
&\quad \gamma > \beta \ , \ \gamma' > \beta' \ , \gamma' \leq \gamma \ , \ \beta' \leq \beta \text{ and} \\
&\quad \text{for all } i \in N \setminus \{p,q\} \ \ a'_i \leq a_i \Big\} \bigcup \mathcal{P}_{\mathrm{a}} \\
&\succ^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \\
&= \Big\{ \Big((\gamma_p, \beta_q, a_{N\setminus\{p,q\}}), (\beta'_p, \gamma'_q, a'_{N\setminus\{p,q\}}) \Big) \in (\mathbb{R}^n)^2 \ , \\
&\quad \gamma > \beta \ , \ \gamma' > \beta' \ , \gamma' \leq \gamma \ , \ \beta' \leq \beta \ \text{and} \\
&\quad \text{for all } i \in N \setminus \{p,q\} \ \ a'_i \leq a_i \Big\} \bigcup \mathcal{P}^p_{\mathrm{a}>} \\
&\sim^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} = \Big\{ (a,a) \ , \ \ a \in \mathbb{R}^n \Big\}
\end{aligned}$$

where $\mathcal{P}^p_{\mathrm{a}>} = \{(a,b) \in \mathcal{P}_{\mathrm{a}} \ , \ a_p > b_p\}$.

When $\gamma > \beta$, $(\gamma_p, \beta_q, a_{N\setminus\{p,q\}})$ is at least as good as $(\beta_p, \gamma_q, a_{N\setminus\{p,q\}})$ from $\Box^{p,q}_{\mathrm{RelImp}}$. From the Pareto relation $\mathcal{P}_{\mathrm{a}}$, $(\beta_p, \gamma_q, a_{N\setminus\{p,q\}})$ is at least as good as $(\beta'_p, \gamma'_q, a'_{N\setminus\{p,q\}})$ whenever $\gamma' \leq \gamma$, $\beta' \leq \beta$ and $a'_k \leq a_k$ for all $k \in N \setminus \{p,q\}$. The completion of $\Box^{p,q}_{\mathrm{RelImp}}$ by a k-additive Choquet integral (with $k \geq 2$) is just the combination of the definition of $\Box^{p,q}_{\mathrm{RelImp}}$ and the Pareto dominance order. Therefore, there is no side effect coming from the Choquet model.

Lemma 2 *Let $p, q \in N$ with $p \neq q$. Then*

$$\begin{aligned}
&\succsim^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \\
&= \Big\{ \Big((\gamma_p, \beta_q, a_{N\setminus\{p,q\}}), (\beta'_p, \gamma'_q, a'_{N\setminus\{p,q\}}) \Big) \in (\mathbb{R}^n)^2 \\
&\quad \gamma \geq \beta' \ , \ \gamma - \beta + \beta' - \gamma' \geq 0 \\
&\quad \text{and for all } i \in N \setminus \{p,q\} \ \ a'_i \leq a_i \Big\} \bigcup \mathcal{P}_{\mathrm{a}} \\
&\succ^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \\
&= \Big\{ \Big((\gamma_p, \beta_q, a_{N\setminus\{p,q\}}), (\beta'_p, \gamma'_q, a'_{N\setminus\{p,q\}}) \Big) \in (\mathbb{R}^n)^2 \\
&\quad \gamma > \beta' \ , \ \gamma - \beta + \beta' - \gamma' \geq 0 \ , \ \gamma' \leq \gamma \ , \ \beta' \leq \beta \\
&\quad \text{and for all } i \in N \setminus \{p,q\} \ \ a'_i \leq a_i \Big\} \cup \mathcal{P}^p_{\mathrm{a}>} \\
&\sim^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} = \Big\{ (a,a) \ , \ \ a \in \mathbb{R}^n \Big\}
\end{aligned}$$

There is a strange condition $\gamma - \beta + \beta' - \gamma' \geq 0$ in the necessity preference relation of the model $\mathcal{M}^1$.

One has for all $k \in \{2, \ldots, n\}$

$$\begin{aligned}
\succsim^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} &\subset \succsim^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \\
\succ^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} &\subset \succ^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \\
\sim^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} &\subset \sim^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}}
\end{aligned}$$

The information $\succsim^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \setminus \succsim^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}}$ and $\succ^{\mathcal{M}^1}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}} \setminus \succ^{\mathcal{M}^k}_{\mathrm{N},\Box^{p,q}_{\mathrm{RelImp}}}$ is contained neither in Definition

ISBN: 978-989-95079-6-8

1 nor in the Pareto set $\mathcal{P}_{\rm a}$. This proves that the completion resulting from the Choquet integral fits exactly with the preferential information provided by the DM, whereas the completion resulting from the weighted sum is strong. The Choquet is thus able to represent the relative importance without adding new information not provided by the DM.

7 Veto criteria

7.1 Statement of the preferential information

As in group decision, one can define a veto criterion. The preferential information corresponding to a veto criterion p is denoted by $\Box^p_{\rm Veto} = (\trianglerighteq^p_{\rm Veto}, \triangleright^p_{\rm Veto}, \equiv^p_{\rm Veto})$.

Definition 2 *Criterion p is a* veto *criterion if for all $x, y \in \mathbb{R}^n$*

$$(x_{N\setminus\{p\}}, 0_p) \equiv^p_{\rm Veto} (y_{N\setminus\{p\}}, 0_p).$$

It is straightforward to see that the evaluation of the option $(x_{N\setminus\{p\}}, 0_p)$ is zero. This means that a bad score on a veto criterion cannot be saved by good scores on the remaining criteria.

7.2 Conditions on the fuzzy measure

Lemma 3 *Criterion $p \in N$ is a veto iff*

$$\forall S \subset N \setminus \{p\}\ , \quad \mu(S) = 0\ . \tag{9}$$

7.3 Completion

There is a unique additive fuzzy measure for which p is a veto. It is defined by $\mu(A) = 1$ if $p \in A$ and $= 0$ otherwise. Criterion p is then interpreted as a dictator. All the other criteria are merely discarded. Hence $\succsim^{\mathcal{M}^1}_{{\rm N},\Box^p_{\rm Veto}}$ is a complete order.

The following result shows that the necessity preference relation does not depend on k for $k \geq 2$.

Proposition 2 *Let P be the preferential information stating that criterion p is a veto. Then for all $k \in \{2, \ldots, n\}$*

$$\begin{aligned}
\succsim^{\mathcal{M}^k}_{{\rm N},\Box^p_{\rm Veto}} &= \Big\{(a,b) \in (\mathbb{R}^n)^2\ ,\ a_p \geq b_p \textit{ and} \\
&\quad \forall i \in N \setminus \{p\} \textit{ either } a_i \geq b_i \textit{ or } [a_i < b_i \textit{ and } a_i \geq b_p]\Big\} \\
\succ^{\mathcal{M}^k}_{{\rm N},\Box^p_{\rm Veto}} &= \Big\{(a,b) \in (\mathbb{R}^n)^2\ ,\ a_p > b_p \textit{ and} \\
&\quad \forall i \in N \setminus \{p\} \textit{ either } a_i > b_i \textit{ or } [a_i \leq b_i \textit{ and } a_i > b_p]\Big\} \\
\sim^{\mathcal{M}^k}_{{\rm N},\Box^p_{\rm Veto}} &= \Big\{(a,b) \in (\mathbb{R}^n)^2\ ,\ a_p = b_p \textit{ and} \\
&\quad \forall i \in N \setminus \{p\} \textit{ either } a_i = b_i \textit{ or } [a_i \geq a_p \textit{ and } b_i \geq a_p]\Big\}
\end{aligned}$$

The condition $a_i < b_i$ and $a_i \geq b_p$ means that the relatively bad score of a on criterion i is hidden by the score of b on the veto criterion p. Hence the necessity preference relation is completely natural. The completion mechanism of the Choquet integral is once more easily interpretable.

8 Conclusion

We have studied the completion mechanism produced by the Choquet integral on three types of preferential information: empty prior information, relative importance and veto. The result is trivial on the empty prior information since one recovers the Pareto ordering. Concerning the two other types of preferential information, we have shown that the Choquet integral does not introduce weird phenomena in the robust completion corresponding to the necessity preference relation. Moreover, the completion does not depend on order k for k-additive fuzzy measures, provided that $k \geq 2$. On the contrary, the weighted sum produced a strong completion.

Fuzzy Implications and the Weak Law of Importation

Sebastià Massanet Joan Torrens

Departament de Ciències Matemàtiques i Informàtica
Universitat de les Illes Balears
07122 Palma de Mallorca, Spain
Email: sebasmassanet@gmail.com, dmijts0@uib.es

Abstract— *Some open problems on fuzzy implications dealing with the so-called importation law are studied and totally or partially solved in this work. In particular, it is proved that such property (in fact a weaker version than the law of importation) is stronger than the exchange principle. Along this study, new characterizations of (S, N)-implications and R-implications involving the law of importation are showed.*

Keywords— Implication function, exchange principle, law of importation, (S, N)-implication, R-implication.

1 Introduction

Fuzzy implications are an essential tool in fuzzy control and approximate reasoning, as well as in many fields where these theories apply. This is because they are used not only to model fuzzy conditionals, but also to make inferences in any fuzzy rule based system (see for instance [1] or [2]) through the modus ponens and modus tollens. Moreover, fuzzy implications are also useful in many other fields like fuzzy relational equations and fuzzy mathematical morphology ([3]), fuzzy DI-subsethood measures and image processing ([4] and [5]), and data mining ([6]). Due to this great quantity of applications many authors have focused their interest in the theoretical study of fuzzy implications. See for instance the recent book [7], exclusively devoted to fuzzy implications, and the references therein.

From this theoretical study some open problems on fuzzy implications have been recently posed in some works about this topic. In this paper we want to deal with some of them involving the so-called law of importation, that is derived from the tautology in classical logic

$$(p \wedge q) \to r \equiv p \to (q \to r) \tag{1}$$

which, translated to fuzzy logic, becomes the functional equation:

$$I(T(x, y), z) = I(x, I(y, z)) \quad \text{for all } x, y, z \in [0, 1] \tag{2}$$

where T is a t-norm and I is a fuzzy implication. This property has been extensively studied in [8] and [9] for many kinds of implications derived from t-norms and t-conorms. Moreover, an extension of (2) involving uninorms instead of t-norms has been also studied in [10]. From this study some open problems for fuzzy implications involving the law of importation have been posed (see [11]) that we will try to solve in next sections. During the process, new characterizations of (S, N)-implications and R-implications involving the law of importation are showed.

2 Preliminaries

We will suppose the reader to be familiar with the theory of t-norms, t-conorms and fuzzy negations (all necessary results and notations can be found in [12]). We recall here only some facts on implications.

Definition 1 *A binary operator $I : [0, 1]^2 \to [0, 1]$ is said to be an* implication function*, or an* implication*, if it satisfies:*

(I1) $I(x, z) \geq I(y, z)$ *when* $x \leq y$*, for all* $z \in [0, 1]$.

(I2) $I(x, y) \leq I(x, z)$ *when* $y \leq z$*, for all* $x \in [0, 1]$.

(I3) $I(0, 0) = I(1, 1) = 1$ *and* $I(1, 0) = 0$.

Note that, from the definition, it follows that $I(0, x) = 1$ and $I(x, 1) = 1$ for all $x \in [0, 1]$ whereas the symmetrical values $I(x, 0)$ and $I(1, x)$ are not derived from the definition.

Special interesting properties for implication functions are:

- The *law of importation* with a t-norm T,

$$I(T(x, y), z) = I(x, I(y, z)), \quad \text{for all} \quad x, y, z \in [0, 1]. \tag{LI}$$

- The *exchange principle*,

$$I(x, I(y, z)) = I(y, I(x, z)), \quad \text{for all} \quad x, y, z \in [0, 1]. \tag{EP}$$

- The *ordering property*,

$$x \leq y \iff I(x, y) = 1, \quad \text{for all} \quad x, y \in [0, 1]. \tag{OP}$$

Among other models (see [3] and [7]), the most used fuzzy implications are derived from t-norms and t-conorms and they are:

- R-implications derived from a left-continuous t-norm T,

$$I_T(x, y) = \sup\{z \in [0, 1] \mid T(x, z) \leq y\} \tag{3}$$

  for all $x, y \in [0, 1]$.

- (S, N)-implications derived from a t-conorm S and a strong negation[1] N,

$$I_{S,N}(x, y) = S(N(x), y) \qquad \text{for all} \quad x, y \in [0, 1]. \tag{4}$$

[1] This kind of implications has been characterized also when N is strict or continuous, see [13]. However, (LI) has been studied only in the cases when N is strict or strong, but not when N is only continuous.

ISBN: 978-989-95079-6-8

But also QL-implications and D-implications respectively given by

$$I_{QL}(x,y) = S(N(x), T(x,y)) \tag{5}$$

for all $x, y \in [0,1]$, and

$$I_D(x,y) = S(T(N(x), N(y)), y) \tag{6}$$

for all $x, y \in [0,1]$, where T is a t-norm, S a t-conorm and N a strong negation. For all these kinds of implications the (LI) is equivalent to the (EP) and moreover, there is one and only one t-norm for which the (LI) holds (see [8] and [9]).

Finally let us recall the characterizations of (S,N) and R-implications. Several of these characterizations can be found in the literature:

Theorem 1 *([13]) For a function $I : [0,1]^2 \to [0,1]$ the following statements are equivalent:*

(i). I is an (S,N)-implication generated from some t-conorm S and some continuous (strict, strong) fuzzy negation N

(ii). I satisfies (I1), (EP) and $I(x,0) = N(x)$ is a continuous (strict, strong) fuzzy negation.

Theorem 2 *([14], [15] or [7]) Let $I : [0,1]^2 \to [0,1]$ be a function. Then I is an R-implication derived from a left-continuous t-norm, if and only if, I satisfies (I2), (OP), (EP) and I is right-continuous with respect to the second variable.*

With the assumption of continuity we have a characterization of the following subclass of R-implications, that are also (S,N)-implications, known as the Smets-Magrez Theorem, see [16] and see also [17] for the current version.

Theorem 3 *Let $I : [0,1]^2 \to [0,1]$ be a function. Then I is a continuous function satisfying (OP), (EP), if and only if, I is conjugate with the Łukasiewicz implication, that is, there exists a unique increasing bijection $\varphi : [0,1] \to [0,1]$ such that*

$$I(x,y) = \varphi^{-1}(\min\{1, 1 - \varphi(x) + \varphi(y)\}) \tag{7}$$

for all $x, y \in [0,1]$.

3 Main results

Due to the commutativity of the t-norm T (or the uninorm), it is clear that the law of importation implies the exchange principle, but in all known cases the converse also holds and the t-norm for which (LI) holds is uniquely determined. The first two open problems (posed in [11], Problem 8.1) that we want to study are just the following:

1. **(OP1)** Does the exchange principle imply that there exists a t-norm such that the law of importation holds? If not, give an example and characterize all fuzzy implications for which the answer is positive.

2. **(OP2)** Is the t-norm in the law of importation uniquely determined?

Note that for R, (S,N), QL and D-implications derived from t-norms and t-conorms the answer of both problems is positive (see [8] and [9]). With respect to (OP1) a negative answer has been done in [10] (see also [7], Section 7.3) by using implications derived from uninorms. The examples given in these works are implications satisfying (EP) such that they do not satisfy (LI) for any t-norm. However, in all these cases there exists a conjunctive uninorm for which the (LI) holds and thus, the problems above are just translated to the following more general versions:

1. **(OP1')** Does the exchange principle imply that there exists a uninorm (or a more general binary operation) such that the law of importation holds? If not, give an example and characterize all fuzzy implications for which the answer is positive.

2. **(OP2')** Is the uninorm in the law of importation uniquely determined?

Moreover, the answer of both problems is again positive for R, S, QL and D-implications derived from uninorms (see [10]).

Along the paper, we will prove that (OP1') has a negative answer in general and we will characterize some particular cases for which the answer is positive. On the other hand, with respect to (OP2) some counterexamples have been proved in [7] for implications I for which $I(x,0)$ equals the greatest or the least fuzzy negation (the same examples work for (OP2')). We will discuss however the case when $I(x,0)$ is at least a continuous fuzzy negation.

3.1 The Weak Law of Importation (WLI)

To deal with these problems let us introduce a weaker law of importation than (LI), by reducing the requirements on the function T. To maintain its relation with the exchange principle we need to take T commutative, and due to the monotonicity of implication functions it seems also adequate to take T nondecreasing, but no more conditions are necessary. Thus we introduce the following

Definition 2 *Let $I : [0,1]^2 \to [0,1]$ be a function. We say that I satisfies the* weak law of importation *if there exists a commutative and nondecreasing function $F : [0,1]^2 \to [0,1]$ such that*

$$I(F(x,y),z) = I(x, I(y,z)) \quad \textit{for all } x,y,z \in [0,1] \tag{WLI}$$

and then we say that I satisfies (WLI) with the function F.

First of all, note that (WLI) clearly implies (EP).

On the other hand, when I is an (S,N), a QL or a D-implication it satisfies the following boundary property

$$I(x,0) = N(x), \quad \text{for all} \quad x \in [0,1] \tag{BP}$$

where N is a (continuous, strict, strong) fuzzy negation.

We want to study the properties of those functions $I : [0,1]^2 \to [0,1]$ that satisfy (WLI) and (BP). These properties will be useful in order to find a counterexample to the equivalence of (EP) and (LI).

Proposition 1 *Let $I : [0,1]^2 \to [0,1]$ be a function which satisfies (WLI) with a commutative and nondecreasing function F and (BP) with a fuzzy negation N. Then*

ISBN: 978-989-95079-6-8

- *I satisfies (I3).*
- *I satisfies right contrapositive symmetry, that is,*

$$I(x, N(y)) = I(y, N(x)) \text{ for all } x, y \in [0,1]. \quad (8)$$

Moreover, if N is continuous, then

- *I satisfies (I1) and (I2), and consequently I is a fuzzy implication.*
- *I satisfies left neutrality principle, that is,*

$$I(1, y) = y \text{ for all } y \in [0,1]. \quad (9)$$

Finally, if N is strong then

- *I satisfies contrapositive symmetry, that is,*

$$I(N(y), N(x)) = I(x, y) \text{ for all } x, y \in [0,1]. \quad (10)$$

Proof: I satisfies (EP) due to the commutativity of F and (WLI). Furthermore, I satisfies also (I3) because

$$\begin{array}{ll} I(0,0) & = N(0) = 1 \\ I(1,0) & = N(1) = 0 \\ I(1,1) & = I(1, I(0,0)) = I(0, I(1,0)) = I(0,0) = 1. \end{array}$$

In addition, I satisfies right contrapositive symmetry because

$$I(x, N(y)) = I(x, I(y,0)) = I(y, I(x,0)) = I(y, N(x)).$$

From now on, N will be a continuous negation. Let us prove (I1). If $x \leq y$, using the continuity of N, we only need to show that $I(x, N(z)) \geq I(y, N(z))$ for all $z \in [0,1]$.

$$\begin{array}{ll} I(x, N(z)) & = I(x, I(z,0)) = I(F(x,z), 0) = N(F(x,z)) \\ & \geq N(F(y,z)) = I(F(y,z), 0) = I(y, I(z,0)) \\ & = I(y, N(z)) \end{array}$$

A similar argument shows (I2). If $y \leq z$, using the continuity of N, we will show that $I(x, N(y)) \geq I(x, N(z))$ for all $x, y, z \in [0,1]$.

$$\begin{array}{ll} I(x, N(y)) & = I(x, I(y,0)) = I(F(x,y), 0) = N(F(x,y)) \\ & \geq N(F(x,z)) = I(F(x,z), 0) = I(x, I(z,0)) \\ & = I(x, N(z)) \end{array}$$

Furthermore, I satisfies the left neutrality principle

$$\begin{array}{ll} I(1, N(y)) & = I(1, I(y,0)) = I(y, I(1,0)) \\ & = I(y,0) = N(y) \end{array}$$

Finally, if N is strong, we have

$$\begin{array}{ll} I(N(y), N(x)) & = I(N(y), I(x,0)) = I(x, I(N(y),0)) \\ & = I(x, N(N(y))) = I(x,y). \end{array}$$

■

It is known that in general, (EP) and (BP) with a continuous (even strong) fuzzy negation N do not imply (I1). For example, the function

$$I(x,y) = \begin{cases} 1-x & \text{if } y = 0 \\ y & \text{if } x = 1 \\ 0.5 & \text{otherwise} \end{cases} \quad (11)$$

satisfies (EP) and (BP) with $N(x) = 1 - x$ the classical strong negation, but it does not satisfy the nonincreasingness in the first variable, (I1) (see [13]). Consequently, I can not satisfy (WLI), by the previous proposition. So, we have just found a counterexample proving that, for functions $I : [0,1]^2 \to [0,1]$ in general, (EP) does not imply (WLI). In section 3.3 we will prove that a counterexample for fuzzy implications is also available.

3.2 (WLI) and (S,N)-implications

The main target of this section is the study of (WLI) on (S,N)-implications. We will show a new characterization of (S,N)-implications based on (WLI) and we will partially solve (OP2).

Proposition 2 *Let $I : [0,1]^2 \to [0,1]$ be a binary operator satisfying (WLI) with a commutative and nondecreasing function F and (BP) with a continuous (strict, strong) fuzzy negation N. Then I is an (S,N)-implication generated from a t-conorm S and the negation N.*

Proof: Due to proposition 1, it follows that I satisfies (I1) and (EP). So, by using theorem 1, I is an (S,N)-implication generated from some t-conorm S and some continuous (strict, strong) fuzzy negation N. ■

After that let us take a look to the verification of (WLI) on (S,N)-implications.

Proposition 3 *An (S,N)-implication I generated from a t-conorm S and a strict (strong) negation N satisfies (WLI) with a function $F : [0,1]^2 \to [0,1]$ if and only if F is the N-dual t-norm of S, that is*

$$F(x,y) = N^{-1}(S(N(x), N(y))) \text{ for all } x, y \in [0,1]. \quad (12)$$

Proof: Let I be an (S,N)-implication generated from a t-conorm S and a strict negation N. If I satisfies (WLI) with a function F, then for all $x, y, z \in [0,1]$ we have

$$\begin{array}{ll} I(F(x,y), z) & = S(N(F(x,y)), z) \\ I(x, I(y,z)) & = S(N(x), I(y,z)) = S(N(x), S(N(y), z)) \end{array}$$

Taking $z = 0$ in both expressions and using (WLI), we obtain $N(F(x,y)) = S(N(x), N(y))$, and consequently, $F(x,y) = N^{-1}(S(N(x), N(y)))$ for all $x, y \in [0,1]$. Conversely, if F is the N-dual t-norm of S, a straightforward computation proves that I satisfies (WLI) with F. ■

Remark 1 *Proposition 3 is the counterpart for (WLI) of an analogous result for (LI) in [8] and [13]. Note that none property of F is used in the proof. Thus, for (S,N)-implications with N strict or strong (LI) and (WLI) are equivalent and in fact, the N-dual t-norm of S is the only function $F : [0,1]^2 \to [0,1]$ (without any further assumption) for which (WLI) is satisfied.*

ISBN: 978-989-95079-6-8

We will see that the equivalence in the previous remark also holds for (S,N)-implications with N continuous (not necessarily strict), but something different occurs in this case. We will see that they also satisfy (WLI), but the function F for which they satisfy (WLI) needs not to be unique. However, among the functions F for which the (S,N)-implication satisfies (WLI), there is at least one of them that is a t-norm.

To do this, let us consider the following definition.

Definition 3 *(see [13]) Given any continuous fuzzy negation N, we consider the function $\mathfrak{R}_N : [0,1] \to [0,1]$ defined by*

$$\mathfrak{R}_N(x) = \begin{cases} N^{(-1)}(x) & \text{if } x \in (0,1] \\ 1 & \text{if } x = 0 \end{cases} \tag{13}$$

where $N^{(-1)}$ stands for the pseudo-inverse of N given by

$$N^{(-1)}(x) = \sup\{z \in [0,1] \mid N(z) > x\} \quad \text{for all } x \in [0,1]. \tag{14}$$

In [13], it is proved that $\mathfrak{R}_N$ is a strictly decreasing negation, $\mathfrak{R}_N^{(-1)} = N$, $N \circ \mathfrak{R}_N = id_{[0,1]}$ and

$$\mathfrak{R}_N \circ N|_{\text{Ran}(\mathfrak{R}_N)} = id|_{\text{Ran}(\mathfrak{R}_N)},$$

where $\text{Ran}(\mathfrak{R}_N)$ stands for the range of function $\mathfrak{R}_N$. This function $\mathfrak{R}_N$ plays the role of the "inverse" function of N and therefore, we have the following result:

Proposition 4 *An (S,N)-implication I generated from a t-conorm S and a continuous fuzzy negation N satisfies (WLI) with the function $F(x,y) = \mathfrak{R}_N(S(N(x),N(y)))$ for all $x,y \in [0,1]$.*

Proof: It is clear from its definition that F is commutative and nondecreasing. Now,

$$\begin{array}{ll} I(T(x,y),z) & = S(N(T(x,y)),z) \\ & = S(N(\mathfrak{R}_N(S(N(x),N(y)))),z) \\ (N \circ \mathfrak{R} = id_{[0,1]}) & = S(S(N(x),N(y)),z) \\ & = S(N(x),S(N(y),z)) \\ & = S(N(x),I(y,z)) = I(x,I(y,z)) \end{array}$$

■

Contrary to what happens in the case when N is strict (or strong), the function F in the proposition above is not the only one for which the (S,N)-implication satisfies (WLI). Note that the key fact in the proof of the previous proposition is that $N \circ \mathfrak{R}_N = id_{[0,1]}$ (in fact it is only necessary that $N(F(x,y)) = S(N(x),N(y))$ for all $x,y \in [0,1]$). When N is continuous but non-strict there are other functions than $\mathfrak{R}_N$ satisfying this condition, and consequently different functions F for which I satisfies the (WLI). See for instance the following example.

Example 1 *(see [13]) Consider the continuous fuzzy negation N given by*

$$N(x) = \begin{cases} -2x+1 & \text{if } x \in [0,0.25] \\ 0.5 & \text{if } x \in (0.25,0.75) \\ -2x+2 & \text{if } x \in [0.75,1]. \end{cases} \tag{15}$$

An easy calculation shows that

$$\mathfrak{R}_N(x) = \begin{cases} -0.5x+1 & \text{if } x \in [0,0.5) \\ -0.5x+0.5 & \text{if } x \in [0.5,1], \end{cases} \tag{16}$$

but taking N_1 given by

$$N_1(x) = \begin{cases} -0.5x+1 & \text{if } x \in [0,0.5] \\ -0.5x+0.5 & \text{if } x \in (0.5,1], \end{cases} \tag{17}$$

we also obtain $N \circ N_1 = id_{[0,1]}$. Consequently, given I any (S,N)-implication, derived from a t-conorm S and the negation N, defining $F_1(x,y) = N_1(S(N(x),N(y)))$ we have that I satisfies (WLI) with both functions, F (obtained from Proposition 4) and F_1.

Proposition 5 *Let S be a t-conorm and N a continuous fuzzy negation. Then the function $F(x,y) = \mathfrak{R}_N(S(N(x),N(y)))$ for all $x,y \in [0,1]$ is a t-subnorm, i.e., it is nondecreasing, commutative, associative and such that $F(x,y) \leq \min(x,y)$ for all $x,y \in [0,1]$.*

Proof: F is clearly nondecreasing and commutative. To see associativity, note that from the associativity of S we easily obtain

$$\begin{array}{ll} F(F(x,y),z) & = \mathfrak{R}_N(S(S(N(x),N(y)),N(z)) \\ & = F(x,F(y,z)). \end{array}$$

Finally, using the definition of $\mathfrak{R}_N$ we easily obtain

$$\mathfrak{R}_N(S(N(x),N(y))) \leq x \text{ for all } x \in [0,1]$$

and so $F(x,y) \leq \min(x,y)$ for all $x,y \in [0,1]$. ■

However, they are not t-norms in general because we have

$$F(1,y) = \mathfrak{R}_N(S(0,N(y))) = \mathfrak{R}_N(N(y))$$

and $\mathfrak{R}_N \circ N$ is the identity function only for values in $\text{Ran}(\mathfrak{R}_N)$. Nevertheless, one can always find a t-norm for which the (S,N)-implication satisfies (WLI) as follows.

Proposition 6 *Let I be a (S,N)-implication generated from a t-conorm S and a continuous fuzzy negation N. Then*

$$T(x,y) = \begin{cases} \mathfrak{R}_N(S(N(x),N(y))) & \text{if } \max\{x,y\} < 1 \\ \min\{x,y\} & \text{if } \max\{x,y\} = 1 \end{cases}$$

is a t-norm such that I satisfies (LI) with T.

Proof: T is clearly a t-norm since it is constructed in the usual way to obtain a t-norm from a given t-subnorm (see for instance, [12], Proposition 1.6). Thus, we only need to prove that I satisfies (LI) with T. From Proposition 4 it is sufficient to verify (LI) when $x = 1$ or $y = 1$. But, for $x = 1$ we have

$$I(T(1,y),z) = I(y,z) = I(1,I(y,z))$$

and similarly for $y = 1$. ■

Corollary 1 *Let I be an implication satisfying (BP) with a continuous fuzzy negation N. Then*

$$I \text{ satisfies (LI)} \quad \Leftrightarrow \quad I \text{ satisfies (WLI)}$$

Remark 2 *Note that the construction given in the Propositions 5 and 6 works only for the function $\mathfrak{R}_N$. For the other functions N_1 satisfying $N \circ N_1 = id_{[0,1]}$ the monotonicity of T is not guaranteed (it is enough to take $S = \max$, N and N_1 as in Example 1 and $x = 0.5 > y$, then $N_1(\max(N(0.5),N(y))) = 0.75 > 0.5$). Thus, for (S,N)-implications with N continuous we have found many functions F for which (WLI) holds, but only one t-norm for which (LI) holds. However, we are convinced that there can be found t-conorms S such that even the t-norm is not unique.*

ISBN: 978-989-95079-6-8

At this point, we propose a new characterization of (S,N)-implications based on (WLI).

Theorem 4 *For a function $I:[0,1]^2\to[0,1]$ the following statements are equivalent:*

(i). I is an (S,N)-implication generated from a t-conorm S and a continuous (strict, strong) fuzzy negation N

(ii). I satisfies (WLI) with a commutative and nondecreasing function F and (BP) with a continuous (strict, strong) fuzzy negation N.

In this case possible functions F are given by $F(x,y)=N_1(I(x,N(y)))$ for all $x,y\in[0,1]$, where N_1 is a fuzzy negation with $N\circ N_1=id_{[0,1]}$. Moreover, when N is strict (strong) then such F is unique with $N_1=N^{-1}$.

Proof: If I satisfies $i)$, then $I(x,0)=S(N(x),0)=N(x)$ and I satisfies (BP) with N. Moreover, it also satisfies (WLI) from Proposition 4. The converse is guaranteed by Proposition 2. ∎

Finally and returning to the question about the equivalence of (EP) and (LI), we have the following result.

Proposition 7 *Let I be an implication satisfying (BP) with a continuous fuzzy negation N. Then*

$$I \text{ satisfies (EP)} \Leftrightarrow I \text{ satisfies (LI)} \Leftrightarrow I \text{ satisfies (WLI)}$$

Proof: We already know that (LI) implies (EP). To see the converse, note that if I is an implication it satisfies in particular (I1) and then Theorem 1 implies that I is an (S,N)-implication generated from a t-conorm S and a continuous fuzzy negation N. Finally, Proposition 4 and Corollary 1 ensures that I satisfies (LI). The other equivalence has been already proved in Corollary 1. ∎

3.3 Counterexample for implications

To sum up, we have proved that (EP) and (LI) are equivalent for implications satisfying (BP) with a continuous fuzzy negation N. So, to find a counterexample we need to search among those implications I such that $I(x,0)=N(x)$ is non-continuous (it is always a fuzzy negation). In next proposition we give such a counterexample which proves not only that (EP) does not imply (LI), but also that it does not imply (WLI).

Proposition 8 *Let S be a nilpotent t-conorm and N a strict negation. Let $I:[0,1]^2\to[0,1]$ be the function given by*

$$I(x,y)=\begin{cases}0 & \text{if } y=0 \text{ and } x\neq 0\\ S(N(x),y) & \text{otherwise.}\end{cases} \tag{18}$$

Then I is a fuzzy implication that satisfies (EP), but there is no function F for which I satisfies (WLI).

Proof: We divide the proof in two steps.

- I satisfies (EP). When $z\neq 0$ we have $I(x,z)\neq 0$ for all $x\in[0,1]$ and then I satisfies (EP) because it is given as an (S,N)-implication.

  When $z=0$ and $x,y\neq 0$ then

  $$I(x,I(y,0))=I(y,I(x,0))=0.$$

  Finally, when $z=0$ and $\min\{x,y\}=0$ then

  $$I(x,I(y,0))=I(y,I(x,0))=1.$$

- I does not satisfy (WLI) with any F. Suppose on the contrary that I satisfies (WLI) with a function F. Then for all $x,y\in[0,1]$ and $z\neq 0$ (WLI) derives into

  $$S(N(F(x,y)),z)=S(S(N(x),N(y)),z). \tag{19}$$

  If we denote by N_S the strong negation associated to S (i.e., $N_S(x)=\varphi^{-1}(1-\varphi(x))$ where φ is the normalized additive generator of S), the left hand side of the previous equation equal 1 if and only if $N(F(x,y))\geq N_S(z)$, whereas the right hand side equals 1 if and only if $S(N(x),N(y))\geq N_S(z)$. Consequently for all $x,y\in[0,1]$ and $z\neq 0$

  $$N(F(x,y))\geq N_S(z)\Longleftrightarrow S(N(x),N(y))\geq N_S(z).$$

  Let us now prove from this equivalence that

  $$F(x,y)=N^{-1}(S(N(x),N(y)) \quad \text{for all } x,y\in[0,1]. \tag{20}$$

  Note that when $F(x,y)=0$, $N(F(x,y))\geq N_S(z)$ for all $z\in[0,1]$ and, from the equivalence before we obtain $S(N(x),N(y))=1$ and equation (20) holds. On the other hand, when $F(x,y)>0$ there exists $z\in[0,1]$ such that $N_S(z)>N(F(x,y))$ and then equation (19) can be written as

  $$\begin{aligned}&\varphi^{-1}(\varphi(N(F(x,y)))+\varphi(z))\\ &=\varphi^{-1}(\varphi(S(N(x),N(y)))+\varphi(z))\end{aligned}$$

  and consequently equation (20) also holds.

  Thus, F should be given by equation (20). However, I does not satisfy (WLI) with this F when $z=0$. To see it just take $x,y\neq 0$ such that $S(N(x),N(y))=1$ since then $F(x,y)=0$ and we obtain

  $$\begin{aligned}I(x,I(y,0)) &= I(x,0)=0\\ I(F(x,y),0) &= I(0,0)=1\end{aligned}$$

  ∎

3.4 R-implications derived from left-continuous t-norms

A characterization of those functions $I:[0,1]^2\to[0,1]$ that are R-implications derived from a left-continuous t-norm is given in Theorem 2, and the case of continuous R-implications is characterized in Theorem 3. Note that in this last case condition (I2) is not necessary to derive the conclusion. It was claimed in [17] that the same happens in the general case. Specifically it was claimed that (EP) and (OP) imply (I2). This is not true and a counterexample was recently proved in [18].

In this section, we will prove that the situation is completely different if we change (EP) by (WLI). We begin by proving that (I2) can be derived from (WLI) and (OP).

Proposition 9 *Let $I:[0,1]^2\to[0,1]$ be a function satisfying (OP) and (WLI) with a commutative and nondecreasing function F. Then I satisfies (I2), i.e, it is nondecreasing in the second variable.*

ISBN: 978-989-95079-6-8

Proof: Consider $x, y, z \in [0,1]$ with $y \leq z$ and let us divide our argument in two cases.

- If $x \leq z$, then $I(x,y) \leq I(x,z) = 1$.
- If $y \leq z < x$, then by (OP) and (WLI),

  $$1 = I(I(x,y), I(x,y)) = I(F(I(x,y),x), y)$$

  and consequently $F(I(x,y),x) \leq y \leq z$. Thus

  $$1 = I(F(I(x,y),x), z) = I(I(x,y), I(x,z))$$

  and therefore, $I(x,y) \leq I(x,z)$. ∎

Moreover, we have also the following properties.

Proposition 10 *Let $I : [0,1]^2 \to [0,1]$ be a function satisfying (OP) and (WLI) with a commutative and nondecreasing function F. Then*

i) I satisfies (I1), i.e, it is nonincreasing in the first variable.

ii) $I(x,-)$ is right-continuous for all $x \in [0,1]$.

Proof: To prove i) consider $x, y, z \in [0,1]$ with $x \leq y$. We divide our argument in two cases.

- If $x \leq z$, then $I(y,z) \leq I(x,z) = 1$.
- If $x > z$, then by (OP) and (WLI),

  $$1 = I(I(y,z), I(y,z)) = I(F(I(y,z),y), z)$$

  and consequently $F(I(y,z),y) \leq z$. Since F is nondecreasing we also have $F(I(y,z),x) \leq z$. Thus

  $$1 = I(F(I(y,z),x), z) = I(I(y,z), I(x,z))$$

  and therefore, $I(y,z) \leq I(x,z)$.

To prove ii), since I is nondecreasing in the second variable, it is enough to show that $\inf\{I(x,y_n)\} = I(x, \inf\{y_n\})$ for all $x \in [0,1]$. Say $y = \inf\{y_n\}$, it is clear that $I(x,y) \leq I(x,y_n)$ for all n and consequently $I(x,y) \leq \inf\{I(x,y_n)\}$. Moreover, for all n we have

$$1 = I(I(x,y_n), I(x,y_n)) = I(F(I(x,y_n),x), y_n)$$

which implies $F(I(x,y_n),x) \leq y_n$ for all n and thus $F(I(x,y_n),x) \leq y$. Finally, we have

$$1 = I(F(I(x,y_n),x), y)) = I(I(x,y_n), I(x,y)),$$

that is, $I(x,y_n) \leq I(x,y)$ and thus $\inf\{I(x,y_n)\} \leq I(x,y)$.∎

Due to the previous results we can reformulate the characterization of R-implications given by theorem 2.

Theorem 5 *Let $I : [0,1]^2 \to [0,1]$ be a function. Then I is an R-implication derived from a left-continuous t-norm, if and only if, I satisfies (OP) and (WLI) with a commutative and nondecreasing function F.*

Moreover, in this case F must be the t-norm from which I is obtained by residuation.

Finally, it is well know that if a function $I : [0,1]^2 \to [0,1]$ satisfies (OP), (EP) and (BP) with a continuous fuzzy negation N, then N must be strong. However, note that from the previous results more properties are derived.

Corollary 2 *Let $I : [0,1]^2 \to [0,1]$ satisfy (OP), (EP) and (BP) with a continuous fuzzy negation N. Then I satisfies (I2), I is right-continuous in the second variable and so, I is an R-implication derived from a left-continuous t-norm.*

Abstract— *We describe parametric fuzzy partitions based on parametric shape functions and we show that the Perfilieva's Fuzzy Transform defined on parametric fuzzy partitions has the properties of a smoother. We also illustrate some examples.*

Keywords— Parametric Fuzzy Partition, Fuzzy Transform, Smoothing Functions, Fuzzy Numbers

1 Introduction

The fuzzy transform has been recently introduced by I. Perfilieva and the theoretical investigations and several connections between theory and applications are covered e.g. in [3], [4], [5] and [9].

In a recent paper (see [6]), we suggested the use of a parametrized class of fuzzy numbers (see [7], [8]) to define general parametric partitions for the fuzzy transform. The proposed flexible family of fuzzy partitions allows the possibility of estimating the shapes of the fuzzy partition to obtain better approximation properties.

In this paper we suggest an extension of the fuzzy partitions (section 3) and we describe the corresponding direct and inverse fuzzy transforms (section 4). Then, in section 5, we show that the inverse fuzzy transform based on extended partitions has an important smoothing property and we illustrate it by numerical examples.

2 Fuzzy Transform and Parametric Fuzzy Partitions

We briefly recall the basic definitions and properties

Definition: (Perfilieva[3]) A *fuzzy partition* of a given real compact interval $[a,b]$ is constructed by a decomposition $\mathbb{P} = \{a = x_1 < x_2 < ... < x_n = b\}$ of $[a,b]$ into $n-1$ subintervals $[x_{k-1}, x_k]$, $k = 2, ..., n$ and by a family $\mathbb{A} = \{A_1, A_2, ..., A_n\}$ of n fuzzy numbers (the *basic functions*), identified by their membership functions $A_1(x), A_2(x), ..., A_n(x)$ for $x \in [a,b]$ and with the properties (to complete this notation, we set $x_0 = a$ and $x_{n+1} = b$):

1. $A_k : [a,b] \longrightarrow [0,1]$ is continuous with $A_k(x_k) = 1$, $A_k(x) = 0$ for $x \notin [x_{k-1}, x_{k+1}]$;
2. for $k = 2, 3, ..., n$, A_k is increasing on $[x_{k-1}, x_k]$ and decreasing on $[x_k, x_{k+1}]$; A_1 is decreasing on $[a, x_2]$; A_n is increasing on $[x_{n-1}, b]$;
3. for all $x \in [a,b]$ the following partition of unity condition holds

$$\sum_{k=1}^{n} A_k(x) = 1.$$

We denote a fuzzy partition by the pair $(\mathbb{P}, \mathbb{A})$. The fuzzy numbers $A_1, A_2, ..., A_n$ giving the family of basic functions can be defined by $n-1$ increasing functions $L_2(x), ..., L_n(x)$ as follows

$$A_1(x) = 1 - L_2(x) \text{ if } x \in [a, x_2],$$

$$A_k(x) = \begin{cases} L_k(x) & \text{if} \quad x \in [x_{k-1}, x_k] \\ 1 - L_{k+1}(x) & \text{if} \quad x \in [x_k, x_{k+1}] \end{cases} \quad \text{for } k = 2, ..., n-1 \tag{1}$$

$$A_n(x) = L_n(x) \text{ if } x \in [x_{n-1}, b]$$

where $L_k(x_{k-1}) = 0$ and $L_k(x_k) = 1$.

In the standard case, the support of each basic function $A_k(x)$ is the compact interval $[x_{k-1}, x_{k+1}]$ so that, on each subinterval $[x_{k-1}, x_k]$ of the decomposition $\mathbb{P}$ only two basic functions $A_{k-1}(x)$ and $A_k(x)$ are non zero for $k = 2, ..., n$.

Definition 1: (Perfilieva[3]) Given a continuous function $f : [a,b] \longrightarrow R$ and a fuzzy partition (P, A), the direct fuzzy transform (F-transform) of f with respect to (P, A) is the n-tuple of real numbers $F = (F_1, F_2, ..., F_n)^T$ given by (notation $(\cdot)^T$ means transposition)

$$\text{For } k = 1, 2, ..., n \tag{2}$$

$$F_k = \frac{\int_a^b f(x)A_k(x)dx}{\int_a^b A_k(x)dx} = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x)A_k(x)dx}{\int_{x_{k-1}}^{x_{k+1}} A_k(x)dx}$$

Definition 2: (Perfilieva[3]) Given a continuous function $f : [a,b] \longrightarrow R$, a fuzzy partition (P, A) and the direct fuzzy transform $(F_1, F_2, ..., F_n)^T$ of f with respect to (P, A), the inverse F-transform is the continuous function $\widehat{f}_F : [a,b] \longrightarrow R$ given by

$$\widehat{f}_F(x) = \sum_{k=1}^{n} F_k A_k(x) \text{ for } x \in [a,b]. \tag{3}$$

The following property (Th. 2 in Perfilieva[3]) is one of the fundamentals of the F-transform setting.

Property 1: If $f : [a,b] \longrightarrow R$ is a continuous function then, for any positive real ε, there exists a fuzzy partition $(P_\varepsilon, A_\varepsilon)$ such that the corresponding F-transform $F_\varepsilon = (F_{1,\varepsilon}, F_{2,\varepsilon}, ..., F_{n_\varepsilon,\varepsilon})^T$ and inverse fuzzy transform $\widehat{f}_{F_\varepsilon} : [a,b] \longrightarrow R$ satisfy

$$\left| f(x) - \widehat{f}_{F_\varepsilon}(x) \right| < \varepsilon \text{ for all } x \in [a,b].$$

To define a fuzzy partition $(\mathbb{P}, \mathbb{A})$ we can use a general decomposition $\mathbb{P} = \{a = x_1 < x_2 < ... < x_n = b\}$ of $[a,b]$ into $n-1$ subintervals $[x_{k-1}, x_k]$, and a general set of basic functions $\mathbb{A} = \{A_1, A_2, ..., A_n\}$ of n fuzzy numbers

ISBN: 978-989-95079-6-8

$A_1, A_2, ..., A_n$ on $[a, b]$; denote, in general, $h_k = x_k - x_{k-1}$, $k = 2, ..., n$.

If the decomposition $\mathbb{P}$ is uniform, we have $x_k = a + (k-1)h$ where $h = \frac{b-a}{n-1}$.

We can have uniform $\mathbb{P}$ and general $\mathbb{A}$.

To obtain families of basic functions $A_1, A_2, ..., A_n$ in (1), defined by $n-1$ increasing functions $L_2, ..., L_n$, we suggested to use parametric monotonic functions $p(t; \beta_0, \beta_1)$, $t \in [0, 1]$ such that, for any parameters $\beta_0, \beta_1 \geq 0$, the following Hermite-type interpolation conditions are satisfied:

$$\begin{aligned} p(0; \beta_0, \beta_1) &= 0,\ p(1; \beta_0, \beta_1) = 1, \\ p'(0; \beta_0, \beta_1) &= \beta_0,\ p'(1; \beta_0, \beta_1) = \beta_1 \end{aligned}$$

and $p'(t; \beta_0, \beta_1) \geq 0\ \forall t \in [0, 1]$ (derivatives at $t = 0$ and $t = 1$ are, respectively, right and left derivatives).

Valid examples of function $p(t; \beta_0, \beta_1)$ are reported in see [7]; to exemplify, we will use here the (2,2)-rational spline:

$$p_{rat22}(t; \beta_0, \beta_1) = \frac{t^2 + \beta_0 t(1-t)}{1 + (\beta_0 + \beta_1 - 2)t(1-t)}. \quad (4)$$

By using parametric monotonic functions $p(t; \beta_0, \beta_1)$, $t \in [0, 1]$ we obtain increasing functions $L_2, ..., L_n$ that define the basic membership functions of the fuzzy partition $A_1, A_2, ..., A_n$:

$$\begin{aligned} L_k(x) &= p(\frac{x - x_{k-1}}{x_k - x_{k-1}}; \beta_{k,0}, \beta_{k,1}) \quad (5) \\ \text{for } x &\in [x_{k-1}, x_k] \text{ and } k = 2, ..., n \end{aligned}$$

and each fuzzy partition $(\mathbb{P}, \mathbb{A})$ contains $2(n-1)$ parameters $\beta_{k,0}, \beta_{k,1}$, $k = 2, ..., n$ giving the first derivatives $L'_k(x_{k-1}) = \beta_{k,0}/(x_k - x_{k-1})$ and $L'_k(x_k) = \beta_{k,1}/(x_k - x_{k-1})$ (to be intended as right and left derivatives, respectively).

We define a *uniform fuzzy partition* $(\mathbb{P}, \mathbb{A})$ if $\mathbb{P}$ is uniform and $\beta_{k,0} = \beta_{j,0}, \beta_{k,1} = \beta_{j,1}$ for all j, k.

We define a *balanced fuzzy partition* $(\mathbb{P}, \mathbb{A})$ if $\mathbb{P}$ is uniform and $\beta_{k,0} = \beta_{k+r,0}, \beta_{k,1} = \beta_{k+r,1}$ for all k..

We obtain a uniform and balanced partition $(\mathbb{P}, \mathbb{A})$ by requiring that $\beta_{k,0} = \beta_{k,1} = \beta_{j,0} = \beta_{j,1}$ for all j, k.

3 Extended Fuzzy Partitions

On the interval $[a, b]$ with a decomposition $\mathbb{P} = \{a = x_1 < x_2 < ... < x_n = b\}$ into $n-1$ subintervals $[x_{k-1}, x_k]$, $k = 2, ..., n$ the basic functions of the fuzzy partition can be defined such that the support of each A_k is more extended than two intervals, identified by three points x_{k-1}, x_k, x_{k+1}. Consider an integer $r \geq 1$ and $2r+1$ consecutive points of $\mathbb{P}$, $x_{k-r}, ..., x_k, ..., x_{k+r}$ for all $k = 1, 2, ..., n$ (to complete the notation, we extend the points to $x_{1-r} < ... < x_0 < a$ and $b < x_{n+1} < ... < x_{n+r}$).

Definition 3: we define a *fuzzy r-partition* of $[a, b]$ to be $(\mathbb{P}, \mathbb{A}^{(r)})$ with the family of $n + 2r - 2$ continuous, normal, convex fuzzy numbers

$$\begin{aligned} \mathbb{A}^{(r)} &= \{A_k^{(r)} : [a, b] \longrightarrow [0, 1] | \\ k &= -r+2, ..., 1, 2, ..., n, ..., n+r-1\} \end{aligned}$$

where $A_k^{(r)}$ has core $\{x_k\}$ and support $[x_{k-r}, x_{k+r}]$ i.e.

a. for $k = 1, 2, ..., n$, $A_k^{(r)}$ is a continuous fuzzy number with $A_k^{(r)}(x_k) = 1$ (i.e. the core is $\{x_k\}$) and $A_k^{(r)}(x) = 0$ for $x \notin [x_{k-r}, x_{k+r}]$ (i.e. the support is $[x_{k-r}, x_{k+r}]$);

b. for $k = 1, 2, ..., n$, $A_k^{(r)}$ is increasing on $[x_{k-r}, x_k]$ and decreasing on $[x_k, x_{k+r}]$;

c. for $k = -r+2, ..., 0$, $A_k^{(r)}$ is decreasing on $[x_k, x_{k+r}]$;

d. for $k = n+1, ...n+r-1$, $A_k^{(r)}$ is increasing on $[x_{k-r}, x_k]$;

e. for all $x \in [a, b]$ the following *$r-$partition of unity* condition holds

$$\frac{1}{r} \sum_{k=-r+2}^{n+r-1} A_k^{(r)}(x) = 1.$$

If $r = 1$ we have the standard partition of unity.

We can construct parametric *fuzzy r-partition* of $[a, b]$ by considering $n + r - 2$ shape functions $p(t; \beta_0, \beta_1)$ of types (4); then by defining

$$\begin{aligned} \text{for } k &= 2, ..., n+r-1 \\ L_k^{(r)}(x) &= p(\frac{x - x_{k-r}}{x_k - x_{k-r}}; \beta_{k,0}, \beta_{k,1}) \end{aligned}$$

the basic functions are

$$\begin{aligned} \text{for } k &= 2, ..., n-1 \\ A_k^{(r)}(x) &= \begin{cases} L_k^{(r)}(x) & \text{if } x \in [x_{k-r}, x_k] \\ 1 - L_{k+r}^{(r)}(x) & \text{if } x \in [x_k, x_{k+r}] \\ 0 & \text{otherwise} \end{cases} \quad (6) \end{aligned}$$

$$\begin{aligned} \text{for } k &= -r+2, ..., 1 \\ A_k^{(r)}(x) &= \begin{cases} 1 - L_{k+r}^{(r)}(x) & \text{if } x \in [x_k, x_{k+r}] \\ 0 & \text{otherwise} \end{cases} \quad (7) \end{aligned}$$

$$\begin{aligned} \text{for } k &= n, ..., n+r-1 \\ A_k^{(r)}(x) &= \begin{cases} L_{k-r}^{(r)}(x) & \text{if } x \in [x_{k-r}, x_k] \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

It is a matter of simple algebraic manipulations to show that for all $x \in [a, b]$ the *$r-$partition of unity* condition holds; in fact for $k = 1, 2, ..., n$ and $x \in [x_{k-1}, x_k]$, only $A_{k-r}^{(r)}, ..., A_k^{(r)}, ..., A_{k+r-1}^{(r)}$ are different from zero and

$$\begin{aligned} \sum_{j=k-r}^{k+r-1} A_j^{(r)}(x) &= \sum_{j=k-r}^{k-1} (1 - L_{j+r}^{(r)}(x)) + \sum_{j=k}^{k+r-1} L_j^{(r)}(x) \\ &= \sum_{j=k}^{k+r-1} (1 - L_j^{(r)}(x)) + \sum_{j=k}^{k+r-1} L_j^{(r)}(x) \\ &= r. \end{aligned}$$

Consider for example $r = 2$; we need $n + r - 2 = n$ shape functions and (we remove the superscript $^{(r)}$ for simplicity) define $L_k(x) = p(\frac{x - x_{k-2}}{x_k - x_{k-2}}; \beta_{k,0}, \beta_{k,1})$ for $k = 2, ..., n+1$. So (in the relevant subintervals, otherwise the functions are null)

$$\begin{aligned} \text{for } k &= 2, ..., n-1 \\ A_k(x) &= \begin{cases} L_k(x) & \text{if } x \in [x_{k-2}, x_k] \\ 1 - L_{k+2}(x) & \text{if } x \in [x_k, x_{k+2}] \end{cases} \end{aligned}$$

ISBN: 978-989-95079-6-8

$$\begin{aligned} \text{for } k &= 0, 1, n, n+1 \\ A_0(x) &= 1 - L_2(x) \text{ if } x \in [x_0, x_2] \\ A_1(x) &= 1 - L_3(x) \text{ if } x \in [x_1, x_3] \\ A_n(x) &= L_n(x) \text{ if } x \in [x_{n-2}, x_n] \\ A_{n+1}(x) &= L_{n+1}(x) \text{ if } x \in [x_{n-1}, x_{n+1}]. \end{aligned}$$

The figures below illustrate three *fuzzy r-partition* $(\mathbb{P}, \mathbb{A}^{(r)})$ for $r = 1$ (standard case), $r = 2$ (each $A_k(x)$ covers four intervals) and $r = 3$ (each $A_k(x)$ covers six intervals).

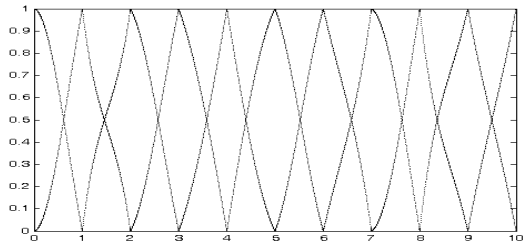

Figure 1a) *fuzzy r-partition* $(\mathbb{P},\mathbb{A}^{(r)})$ with $r = 1$

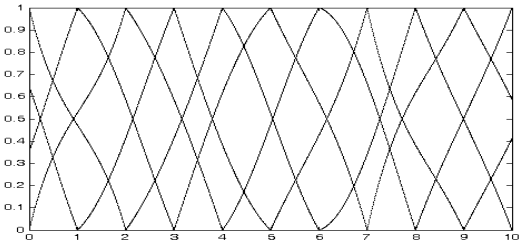

Figure 1b) *fuzzy r-partition* $(\mathbb{P},\mathbb{A}^{(r)})$ with $r = 2$

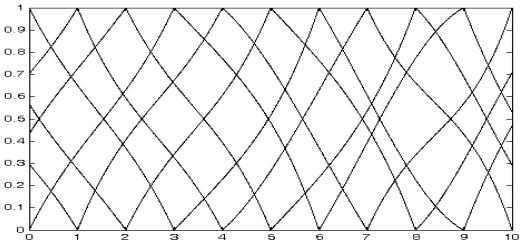

Figure 1c) *fuzzy r-partition* $(\mathbb{P},\mathbb{A}^{(r)})$ with $r = 3$

4 Fuzzy Transform with Extended Partitions

The direct F$^{(r)}$-transform (of degree r) based on the given *fuzzy r-partition* $(\mathbb{P}, \mathbb{A}^{(r)})$ can be defined by the vector $F^{(r)} = (F_1^{(r)}, F_2^{(r)}, ..., F_n^{(r)})^T$

$$F_k^{(r)} = \frac{\int_a^b f(x)A_k^{(r)}(x)dx}{\int_a^b A_k^{(r)}(x)dx}, k = 1, 2, ..., n \tag{8}$$

and the inverse F$^{(r)}$-transform by

$$\widehat{f}^{(r)}(x) = \frac{1}{r}\sum_{k=1}^{n} F_k^{(r)} A_k^{(r)}(x). \tag{9}$$

We see that each $\widehat{f}^{(r)}(x_k)$ has the structure of a moving average of the values $\{F_j^{(r)}, j = 1, ..., n\}$; in fact, at the points $x = x_k$ we have (assume $F_k^{(r)} = 0$ if $k < 1$ or $k > n$)

$$\widehat{f}^{(r)}(x_k) = \frac{1}{r}\sum_{j=k-r}^{k+r} F_j^{(r)} A_j^{(r)}(x_k) \tag{10}$$

i.e. a weighted average of $F_{k-r}^{(r)}, ..., F_k^{(r)}, ..., F_{k+r}^{(r)}$ with weights $\frac{A_{k-r}^{(r)}(x_k)}{r}, ..., \frac{1}{r}, ..., \frac{A_{k+r}^{(r)}(x_k)}{r}$, respectively.

It is possible to see that the F$^{(r)}$-transform has analogues properties to theorem 1 and theorem 2 of Perfilieva ([3]) i.e.

1. the local (for any $k = 1, 2, ..., n$) "error" function $\frac{1}{r}\int_a^b [f(x) - y]^2 A_k^{(r)}(x)dx$ is minimized by $y = F_k^{(r)}$;

2. the minimizer of $\frac{1}{r}\sum_{k=1}^{n}\int_a^b [f(x) - y_k]^2 A_k^{(r)}(x)dx$ is $y = F^{(r)} = (F_1^{(r)}, F_2^{(r)}, ..., F_n^{(r)})^T$ (notation $(\cdot)^T$ means transposition);

3. for fixed $r \geq 1$ and for any $\varepsilon > 0$ there exists a *fuzzy r-partition* $(\mathbb{P}_\varepsilon, \mathbb{A}_\varepsilon^{(r)})$ with the corresponding inverse F$^{(r)}$-transform $\widehat{f}_\varepsilon^{(r)}$ such that $\sup_x \left| f(x) - \widehat{f}_\varepsilon^{(r)}(x) \right| < \varepsilon$.

For a given family of parametric basic functions $A_k^{(r)}$ consider the linear combination (with $\theta = (\theta_1, \theta_2, ..., \theta_n)^T$)

$$C_{\mathbb{A}^{(r)}}(x; \theta, \beta) = \frac{1}{r}\sum_{j=1}^{n} \theta_j A_j^{(r)}(x; \beta) \text{ for } x \in [a, b] \tag{11}$$

where β is the vector of the non negative slope parameters $\beta_{j,0}$, $\beta_{j,1}$ giving $L_j(x; \beta_{j,0}, \beta_{j,1})$.

The following minimization defines $C_{\mathbb{A}^{(r)}}(x; \widehat{\theta}, \widehat{\beta})$ as the *least squares approximation* of $f(x)$ over interval $[a, b]$

$$\underset{\theta,\beta}{Minimize} \quad \int_a^b [f(x) - C_{\mathbb{A}^{(r)}}(x; \theta, \beta)]^2 dx \tag{12}$$

where $(\widehat{\theta}, \widehat{\beta})$ is the minimizing point.

For fixed β, the linear parameters $\widehat{\theta}$ are obtained by putting to zero the partial derivatives (for $i = 1, 2, ..., n$) and we obtain the equations

$$\int_a^b A_i^{(r)}(x; \beta) f(x)dx = \frac{1}{r}\sum_{j=1}^{n} \widehat{\theta}_j \int_a^b A_i^{(r)}(x; \beta) A_j^{(r)}(x; \beta)dx \tag{13}$$

From definition of the F$^{(r)}$-transform $F^{(r)}(\beta)$ as a function of β, we have

$$\int_a^b A_i^{(r)}(x; \beta) f(x)dx = F_i^{(r)}(\beta) \int_a^b A_i^{(r)}(x; \beta)dx \tag{14}$$

and we finally obtain the linear system of n equations

$$\begin{aligned} C^{(r)}(\beta)\widehat{\theta} &= rF^{(r)}(\beta) \quad i.e. \\ \sum_{j=1}^{n} c_{i,j}^{(r)}(\beta)\widehat{\theta}_j &= rF_i^{(r)}(\beta), \quad i = 1, 2, ..., n \end{aligned} \tag{15}$$

where the matrix $C^{(r)}(\beta)$ has elements

$$c_{i,j}^{(r)}(\beta) = \frac{1}{r}\int_a^b A_i^{(r)}(x; \beta) A_j^{(r)}(x; \beta)dx. \tag{16}$$

For fixed parameters β, we can obtain a matrix form for θ in the definition of function (11).

Given $f : [a, b] \longrightarrow \mathbb{R}$ and a fuzzy r-partition $(\mathbb{P}, \mathbb{A}^{(r)}(\beta))$ with the associated direct F$^{(r)}$-transform $F^{(r)}(\beta) = (F_1^{(r)}, F_2^{(r)}, ..., F_n^{(r)})^T$ and inverse F$^{(r)}$-transform

$$\widehat{f}_F^{(r)}(x; \beta) = \frac{1}{r}\sum_{j=1}^{n} F_j^{(r)}(\beta) A_j^{(r)}(x; \beta). \tag{17}$$

ISBN: 978-989-95079-6-8

Define the following vectors (we omit reference to β and r for simplicity of notation), obtained by evaluating $f(x)$ and $\widehat{f}_F(x)$ at points $x_1, x_2, ..., x_n$

$$f = \begin{bmatrix} f(x_1) \\ f(x_2) \\ \\ f(x_n) \end{bmatrix}, \quad \widehat{f} = \begin{bmatrix} \widehat{f}_F(x_1) \\ \widehat{f}_F(x_2) \\ \\ \widehat{f}_F(x_n) \end{bmatrix}, \quad F = \begin{bmatrix} F_1^{(r)} \\ F_2^{(r)} \\ \\ F_n^{(r)} \end{bmatrix} \tag{18}$$

and the following $n \times n$ matrix

$$\begin{aligned} A^{(r)} &= [a_{i,j}] \text{ with} \\ a_{i,j} &= A_j^{(r)}(x_i). \end{aligned} \tag{19}$$

Matrix $A^{(r)}$ is a $(2r-1)$-band matrix and its $i-th$ row has the form ($i = 1, 2, ..., n$)

$$a_{i,j} = \begin{cases} 0 & j = 1, ..., i-r \\ A_j^{(r)}(x_i) & j = i-r+1, ..., i-1 \\ 1 & j = i \\ A_j^{(r)}(x_i) & j = i+1, ..., i+r-1 \\ 0 & j = i+r, ..., n \end{cases} \tag{20}$$

It is immediate that

$$\widehat{f} = \frac{1}{r}(A^{(r)})^T F \tag{21}$$

and $\frac{1}{r}(A^{(r)})^T$ represents a *moving average operator* acting on F to produce $\widehat{f}$.

4.1 Discrete $F^{(r)}$-Transform

Matrix A in (19) can be defined also for the discrete direct and inverse F$^{(r)}$-transforms. For m points $(t_i, y_i), i = 1, 2, ..., m$, where $y_i = f(t_i)$ and defining $A^{(r)}(\beta) = [a_{i,j}(\beta) = A_j^{(r)}(t_i, \beta)]$ for the family $\{A_j^{(r)}(t; \beta) | j = 1, 2, ..., n\}$ of basic functions, the discrete F$^{(r)}$-transform is

$$\begin{aligned} \text{For } j &= 1, 2, ..., n \\ F_j^{(r)}(\beta) &= \frac{g_j(\beta)}{s_j(\beta)} \text{ where} \\ g_j(\beta) &= \sum_{i=1}^{m} y_i A_j^{(r)}(t_i; \beta) \text{ and } s_j = \sum_{i=1}^{m} A_j^{(r)}(t_i; \beta) > 0 \end{aligned}$$

If the elements s_j are organized into a diagonal $n-$matrix

$$S = diag(s_1, s_2, ..., s_n)$$

so that

$$S^{-1} = diag(\frac{1}{s_1}, \frac{1}{s_2}, ..., \frac{1}{s_n})$$

and denote

$$\begin{aligned} y &= (y_1, ..., y_m)^T, \\ F^{(r)}(\beta) &= (F_1^{(r)}(\beta), ..., F_n^{(r)}(\beta))^T, \\ g(\beta) &= (g_1(\beta), ..., g_n(\beta))^T, \end{aligned}$$

then we have $(A^{(r)}(\beta))^T y = g(\beta)$ so that

$$F^{(r)}(\beta) = S(\beta)^{-1}(A^{(r)}(\beta))^T y.$$

Denote also, for $i = 1, 2, ..., m$ (note that for $i = r, ..., n-r+1$ we have $d_i = r$),

$$\begin{aligned} d_i(\beta) &= \sum_{j=1}^{n} A_j(t_i; \beta) > 0 \\ D &= diag(d_1, d_2, ..., d_m). \end{aligned}$$

For the discrete inverse F$^{(r)}$-transform

$$f_{F,\beta}^{(r)}(x) = \frac{\sum_{j=1}^{n} F_j^{(r)} A_j^{(r)}(x; \beta)}{\sum_{j=1}^{n} A_j^{(r)}(x; \beta)}$$

and denoting $f_{F,\beta}^{(r)} = (f_{F,\beta}^{(r)}(t_1), f_{F,\beta}^{(r)}(t_2), ..., f_{F,\beta}^{(r)}(t_m))^T$, we get

$$\begin{aligned} f_{F,\beta}^{(r)} &= D(\beta)^{-1} A^{(r)}(\beta) F^{(r)} \\ &= D(\beta)^{-1} A^{(r)}(\beta) S(\beta)^{-1} (A^{(r)}(\beta))^T y. \end{aligned} \tag{22}$$

5 Smoothing functions from $F^{(r)}$-Transform

In this section we investigate the smoothing effect of the inverse $F^{(r)}$-Transform $f^{(r)}$ on a finite set of data points (t_i, y_i), $i = 1, 2, ..., m$; the discrete direct and inverse F$^{(r)}$-transform are obtained with a partition $(\mathbb{P}, \mathbb{A}^{(r)}(\beta))$, where

$$\begin{aligned} \mathbb{P} &= \{a = x_1 < x_2 < ... < x_n = b\} \text{ and} \\ a &= \min\{t_i\}, \ b = \max\{t_i\} \\ x_i &= a + (i-1)/(n-1), i = 1, 2, ..., n. \end{aligned}$$

We first consider the parameters β as fixed for the family of basic functions $\mathbb{A}^{(r)}(\beta)$.

For a given function $f : [a, b] \longrightarrow \mathbb{R}$ a measure of smoothness can be given by its total variation

$$V(f) = \sup\{\sum_{j=1}^{k-1} |f(\alpha_{j+1}) - f(\alpha_j)|; \forall k \geq 2, \forall \alpha_j \in [a, b]\}$$

or by the following *total* variation (see [1], [2] and the references therein)

$$\widetilde{V}(f) = \sum_{j=1}^{m-1} |f(t_{j+1}) - f(t_j)|. \tag{23}$$

By increasing the integer value of r, the total variation $\widetilde{V}(f^{(r)})$ of the inverse transform functions $f^{(r)}$ tend to decrease to zero, as illustrated by the graphical representation in Fig. 2. we can obtain inverse fuzzy transform functions $f^{(r)}$ with arbitrarily small $\widetilde{V}(f^{(r)})$. A graphical representation is in Fig. 2.

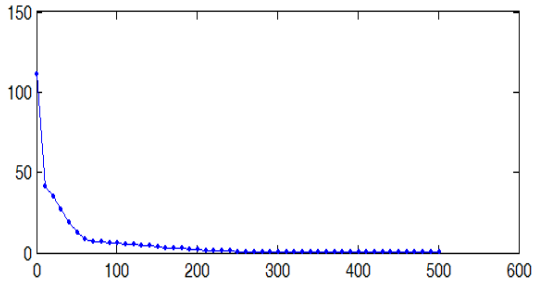

Figure 2. *Total variation $\widetilde{V}(f^{(r)})$ of inverse fuzzy transform function for increasing r.*

ISBN: 978-989-95079-6-8

It is interesting to see the combined effect of changing n and r; in figures 3a)-3c), $m = 101$ data points are generated from function $f(t) = 1+0.2t+sin(t).cos(t)$ by adding a Gaussian random noise with zero mean and standard deviation $\sigma = 2$, i.e. $y_i = f(t_i) + z_i$ and $z_i \in N(0, \sigma^2)$ (the t_i are uniform on $[-2\pi, 2\pi]$). In all the figures of this section, the continuos line is the original data, the dotted line is the inverse fuzzy transform $f^{(r)}$ and the circles are the direct $F^{(r)}$-transform.

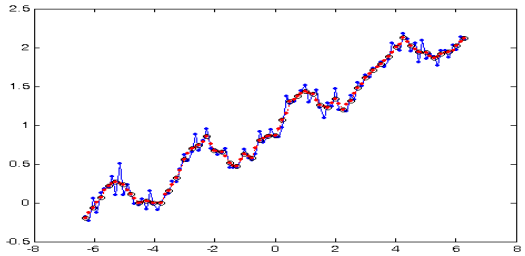

Figure 3a) Smoothing of m=101 data points, n=51, r=1.

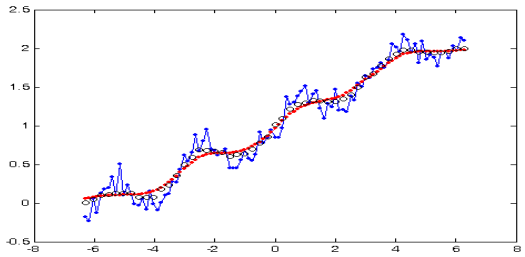

Figure 3b) Smoothing of m=101 data points, n=51, r=5.

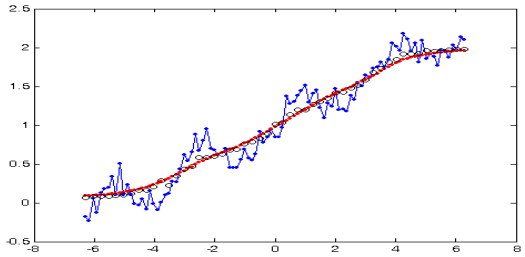

Figure 3c) Smoothing of m=101 data points, n=51, r=9.

In figures 4a)-4c) the data are generated from the same model but $n = 21$ is smaller then in previous case. When n is reduced, the smoothing effect is increased but it is more visible at a global scale: compare figures 3a) with 4a), 3b) with 4b) and 3c) with 4c).

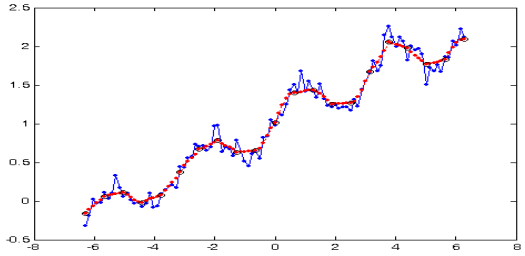

Figure 4a) Smoothing of m=101 data points, n=21, r=1.

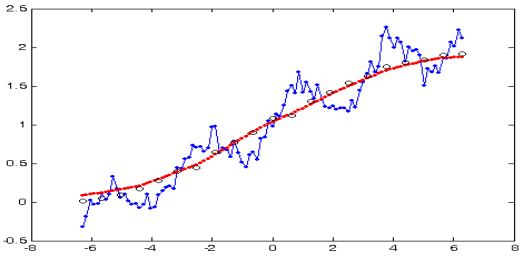

Figure 4b) Smoothing of m=101 data points, n=21, r=5.

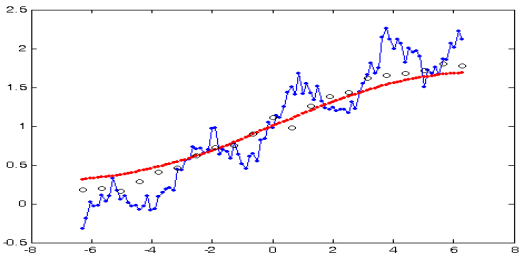

Figure 4c) Smoothing of m=101 data points, n=21, r=9.

If n is small with respect to m as in figures 5a) and 5b), the global smoothing is increased further.

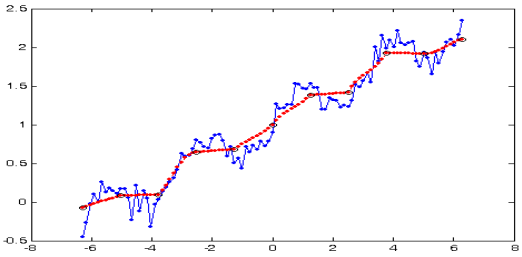

Figure 5a) Smoothing of m=101 data points, n=11, r=1.

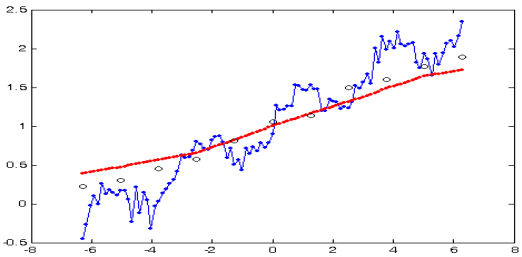

Figure 5b) Smoothing of m=101 data points, n=11, r=5.

So, according to the general properties of the $F^{(r)}$-transform, the discussion above illustrates that, in general, there are two possible sources for smoothness: for fixed m and r, reducing n will increase the smoothing effect; for fixed m and n, increasing r will increase the smoothness.

5.1 A Smoothing Procedure

Let (t_i, y_i), $i = 1, 2, ..., m$ be given observations and define $T_1 = \{i | x_1 \leq t_i \leq x_2\}$, $T_k = \{i | x_{k-1} < t_i \leq x_k\}$ for $k = 2, ..., n-1$.

The parameters β (if not fixed) can be estimated from the data by solving the following criterion, a penalized nonlinear least squares problem where the objective function is penalized by the total variation and a positive tuning parameter $\lambda > 0$ is introduced

$$\underset{\beta}{\text{Minimize}} \quad \left\| f^{(r)}_{F,\beta} - y \right\|^2 + \lambda \widetilde{V}(f^{(r)}_{F,\beta}). \qquad (24)$$

ISBN: 978-989-95079-6-8

Suppose that each T_k has a sufficient number of elements to allow the following approximation problem be well defined: determine $\beta = (\beta_{2,0}, ..., \beta_{n+r-1,0}\beta_{2,1}, ..., \beta_{n+r-1,1})$ to minimize the functional

$$\Phi^{(r)}(\beta) = \left\| L^{(r)}(\beta)F^{(r)}(\beta) - y \right\|^2 + \lambda \widetilde{V}(f^{(r)}_{F,\beta}) \quad (25)$$

where matrix $L^{(r)}(\beta)$ is

$$L^{(r)}(\beta) = D^{(r)}(\beta)^{-1}A^{(r)}(\beta) \text{ and}$$
$$F^{(r)}(\beta) = S^{(r)}(\beta)^{-1}(A^{(r)}(\beta))^T y$$

Alternatively, we can tune the total variation $\widetilde{V}(f^{(r)}_{F,\beta})$ by fixing a variation level $\overline{V} > 0$ and solving the following constrained problem

$$\Phi^{(r)}(\widehat{\beta}) = Minimize \left\| L^{(r)}(\beta)F^{(r)}(\beta) - y \right\|^2 \quad (26)$$
$$s.t. \quad \widetilde{V}(f^{(r)}_{F,\beta}) \leq \overline{V}$$

We show the procedure with the following example and with the value of $\overline{V} = \gamma \widetilde{V}(y)$ (a fraction γ of the total variation of the data); the generated data are $y_i = f(t_i) + 2z_i$ and $z_i \in N(0,1)$ (the $m = 101$ points t_i are uniform on $[0,2]$) with the function $f(t) = 5e^{-0.5t}sin^2(\pi t)$. For the generated data, $\widetilde{V}(y) = 210.25$. Figs 6a)-6c) illustrate the best smoothing obtained by solving (26) for different values of $\gamma \in \{0.5, 0.2, 0.1\}$ and $n = 21$; Figs 7a)-7b) show the best smoothing for $\gamma \in \{0.2, 0.1\}$ and $n = 51$.

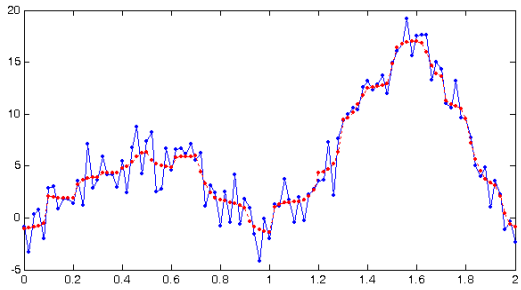

Figure 6a) Best smoothing fit with $n = 21, \gamma = 0.5$ ($r = 1$)

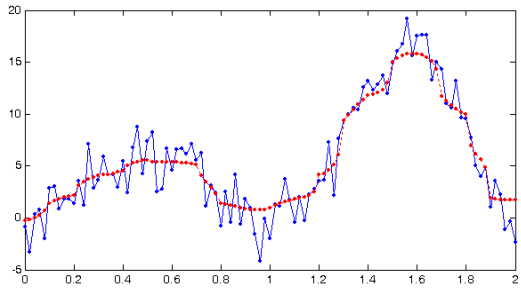

Figure 6b) Best smoothing fit with $n = 21, \gamma = 0.2$ ($r = 2$)

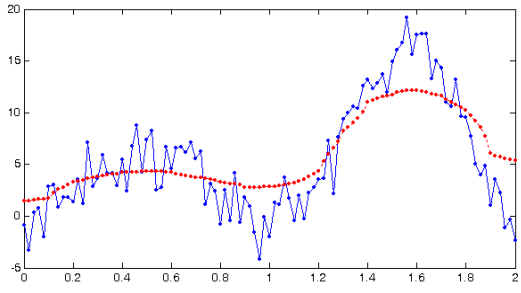

Figure 6c) Best smoothing fit with $n = 21, \gamma = 0.1$ ($r = 6$)

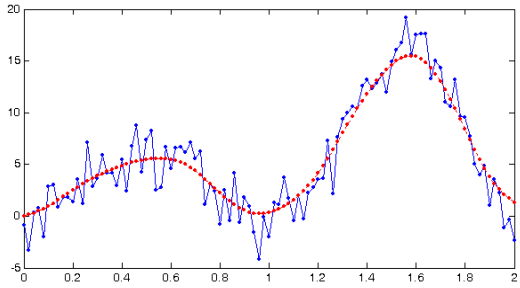

Figure 7a) Best smoothing fit with $n = 51, \gamma = 0.2$ ($r = 4$)

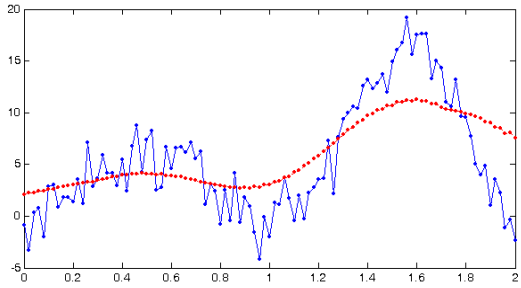

Figure 7b) Best smoothing fit with $n = 51, \gamma = 0.1$ ($r = 8$)

Email: Irina.Perfilieva, Martina.Dankova@osu.cz

Abstract— The aim of this contribution is to show how the F-transform technique can be generalized from the case of constant components to the case of polynomial components. For this purpose, we choose complete functional spaces with inner products. After a general presentation of F^m-transform where $m \geq 0$, a detailed characterization of the F^1-transform is given. We applied a technique of numeric integration in order to simplify computation of F^1-transform components. The inverse F^m-transform, $m \geq 0$, is defined in the same way as the ordinary F-transform.

Keywords— F-transform, F^m-transform, fuzzy partition, orthogonal basis, Gaussian quadrature

1 Introduction

The goal of this paper is to provide a deeper analysis of fuzzy modeling and its contribution to general mathematics. In [1], we introduced the notion of a fuzzy transform (F-transform, for short) which explains modeling with fuzzy IF-THEN rules as a specific transformation. This enabled us to compare the success of fuzzy modeling with the success of classical transforms (Fourier, Laplace, integral, wavelet etc.). From this point of view, fuzzy transforms contribute to the theory of linear and, in particular, integral transforms. Moreover, they initiated a theory of semi-linear spaces (see [2]).

In [1], the approximation property of fuzzy transform has been described and then, in [3], it has been shown how shapes of basic functions influence the approximation quality. The F-transform has many other useful properties and great potential for various applications, such as special numerical methods, solution of ordinary and partial differential equations with fuzzy initial condition [4, 5], mining dependencies from numerical data [6], applications to signal processing, compression and decompression of images [7, 8], and fusion of images [9].

We aim at showing how the F-transform technique can be generalized in the sense that constant components considered as polynomials of 0 degree are replaced by polynomials of degree $m \geq 1$. For this purpose, we choose complete functional spaces with inner products. After presentation of the generalized approach, a detailed characterization of the F^1-transform is given. We applied a technique of numeric integration in order to simplify computation of F^1-transform components. The inverse F^m-transform, $m \geq 1$, is defined in the same way as the inverse F-transform.

The paper is organized as follows: in Section 2, we introduce the concept of F^m-transform of finite degree $m \geq 0$, and show some of its properties and its relation to the ordinary F-transform. In Section 3, F^1-transform is introduced in details. Moreover, a simplification of F^1-transform components computation is discussed. The inverse F^m-transform is discussed in Section 4.

2 F-transform of an Arbitrary Finite Degree

Let us recall that the (direct) F-transform of an integrable function is a certain vector with real components. In [1], we proposed various formulas which represent components of the F-transform and showed a relationship between a given function and its F-transform. In this contribution, we propose to generalize our view on the F-transform and consider it as a vector of components that are orthogonal projections of an original function onto a linear subspace of certain functions that have polynomial representation. In the particular, if the degree of polynomials is zero, we obtain the originally proposed F-transform which will be referred to as F^0-transform in the sequel.

2.1 Fuzzy partition

Let $[a, b]$ be an interval on the real line $\mathbb{R}$. Fuzzy sets on $[a, b]$ will be identified with their membership functions, i.e. mappings from $[a, b]$ into $[0, 1]$. The notion of fuzzy partition is a principle one for our construction so that we will repeat it from [1] and slightly change below.

Definition 1
Let $[a, b]$ be an interval on $\mathbb{R}$, $n \geq 2$ and $x_1, \ldots, x_n$ nodes such that $a = x_1 < \ldots < x_n = b$. We say that fuzzy sets $A_1, \ldots, A_n$, identified with their membership functions, constitute a fuzzy partition *of $[a, b]$ if for $k = 1, \ldots, n$, they fulfill the following conditions :*

1. *$A_k : [a, b] \longrightarrow [0, 1]$, $A_k(x_k) = 1$;*
2. *for $k = 2, \ldots, n$, $A_k(x) = 0$ if $x \in [a, x_{k-1}]$ and for $k = 1, \ldots, n-1$, $A_k(x) = 0$ if $x \in [x_{k+1}, b]$,*
3. *$A_k(x)$ is continuous;*
4. *for $k = 2, \ldots, n$, $A_k(x)$ strictly increases on $[x_{k-1}, x_k]$ and for $k = 1, \ldots, n-1$, $A_k(x)$ strictly decreases on $[x_k, x_{k+1}]$;*
5. *for all $x \in [a, b]$*

$$\sum_{k=1}^{n} A_k(x) = 1. \tag{1}$$

The membership functions $A_1, \ldots, A_n$ are called basic functions.

ISBN: 978-989-95079-6-8

Let us extend $[a,b]$ by two extra nodes $x_0 = 2a - x_2$ and $x_{n+1} = 2b - x_{n-1}$ and for $x \in [x_0, a)$ define $A_1(x) = A_1(2a - x)$, and for $(b, x_{n+1}]$ define $A_n(x) = A_n(2b - x)$. Further on we will always assume that $[a,b]$ and membership functions A_1, A_n are extended.

We say that the fuzzy partition $A_1, \ldots, A_n$, $n \geq 3$, is *h-uniform* if nodes $x_0, \ldots, x_{n+1}$ are h-equidistant, i.e. for all $k = 1, \ldots, n$, $x_k = a + h(k-1)$ where $h = (b-a)/(n-1)$, and two additional properties are met:

6. $A_k(x_k - x) = A_k(x_k + x)$, for all $x \in [0, h]$, $k = 1, \ldots, n$,
7. $A_k(x) = A_{k-1}(x - h)$, for all $k = 2, \ldots, n$ and $x \in [x_{k-1}, x_{k+1}]$.

2.2 F-transform in a space of functions with scalar product

Let us fix $[a,b]$, $n \geq 3$, nodes $x_0 < \ldots < x_{n+1}$ and fuzzy partition $A_1, \ldots, A_n$ of $[a,b]$. For every $k = 1, \ldots, n$, let us denote $L_2(A_k)$ a set of functions $f : [x_{k-1}, x_{k+1}] \longrightarrow \mathbb{R}$ for which the following integral

$$\int_{x_{k-1}}^{x_{k+1}} f(x)^2 A_k(x) dx$$

exists. Let

$$(f,g)_k = \int_{x_{k-1}}^{x_{k+1}} f(x) g(x) A_k(x) dx, \tag{2}$$

be a weighted scalar product of functions f and g. Then $L_2(A_k)$ is a *linear space of functions with scalar product*.

For every integer $m \geq 0$, let $\varphi_0^k, \varphi_1^k, \ldots, \varphi_m^k \in L_2(A_k)$, be an orthogonal system of polynomials where $\varphi_0^k = 1$ and orthogonality is considered with respect to (2). Denote $L_2^m(A_k)$ a linear subspace of $L_2(A_k)$ with the basis $\varphi_0^k, \varphi_1^k, \ldots, \varphi_m^k$.

The following trick allows us to extend arbitrary function $f : [a,b] \longrightarrow \mathbb{R}$ to function $f^{ex} : [x_0, x_{n+1}] \longrightarrow \mathbb{R}$:

$$f^{ex}(x) = \begin{cases} f(a-x) = 2f(a) - f(a+x), \text{ if } x \in [0, x_2 - a], \\ f(x), \text{ if } x \in [a,b], \\ f(b+x) = 2f(b) - f(b-x), \text{ if } x \in [0, b - x_{n-1}] \end{cases}$$

Definition 2
Let $f : [a,b] \longrightarrow \mathbb{R}$ be a given function and f^{ex} its extension to $[x_0, x_{n+1}]$. Assume that for all $k = 1, \ldots, n$, $f^{ex}|_{[x_{k-1}, x_{k+1}]} \in L_2(A_k)$. Let F_k^m be the k-th orthogonal projection of f^{ex} on $L_2^m(A_k)$, $k = 1, \ldots, n$. Then the n-tuple $[F_1^m, \ldots, F_n^m]$ of functions is the F^m-transform of f with respect to $A_1, \ldots, A_n$. Every function F_k^m, $k = 1, \ldots, n$, is called the F^m-transform component.

Remark 1
Definition 2 does not provide us with a formal representation of components $F_1^m, \ldots, F_n^m$. Let us show how they can be obtained. According to the definition above, every component F_k^m minimizes the scalar product $(f^{ex} - g, f^{ex} - g)_k$ where g is an arbitrary function from $L_2^m(A_k)$. Taking into account that $\varphi_0^k, \varphi_1^k, \ldots, \varphi_m^k$ is the basis of $L_2^m(A_k)$, we can represent g by a linear combination $x_0\varphi_k^0 + x_1\varphi_k^1 + \ldots + x_m\varphi_k^m$ of basis functions. Assume that $c_0, c_1 \ldots, c_m$ are coefficients that minimize the following integral

$$\int_{x_{k-1}}^{x_{k+1}} (f^{ex}(x) - (x_0\varphi_k^0(x) + x_1\varphi_k^1(x) + \ldots + x_m\varphi_k^m(x)))^2 A_k(x) dx. \tag{3}$$

Hence, $F_k^m = c_0\varphi_k^0 + c_1\varphi_k^1 + \ldots + c_m\varphi_k^m$.

Below, we will prove the following fact: the original F-transform (see, e.g. [1]) is actually (up to the first and the last components) the F^0-transform. This requires to show that every F-transform component F_k, $k = 2, \ldots, n-1$, that has been originally introduced by

$$F_k = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x) A_k(x) dx}{\int_{x_{k-1}}^{x_{k+1}} A_k(x) dx}, \tag{4}$$

is the k-th orthogonal projection of f on $L_2^0(A_k)$. In order to prove this fact, we recall that the basis of $L_2^0(A_k)$ consists of the constant function φ_k^0 that has the value 1. Then the assertion above immediately follows from the proposition given below which has been proved in [1]:

Theorem 1
Let f be a continuous function on $[a,b]$ and $A_1, \ldots, A_n$ be basic functions which constitute a fuzzy partition of $[a,b]$. Then the k-th component F_k (4) of the F-transform gives minimum to the function

$$\Phi(y) = \int_a^b (f(x) - y)^2 A_k(x) dx$$

defined on $[f(a), f(b)]$.

3 F^1-transform

On the example of F^1-transform, we will show how an arbitrary component of F^m, $m \geq 1$, can be computed. Actually, one possibility of computation directly follows from minimization of integral (3) (see Remark 1). We will use another approach which corresponds to the definition of F^1-transform.

Throughout this section, we fix an h-uniform partition $A_1, \ldots, A_n$ of $[a,b]$ where $n \geq 3$, and assume that $f : [a,b] \longrightarrow \mathbb{R}$ is a function such that for all $k = 1, \ldots, n$, $f^{ex}|_{[x_{k-1}, x_{k+1}]} \in L_2(A_k)$. The explanation below will be given for an arbitrary k, $k = 1, \ldots, n$.

3.1 F^1-transform components

Since component F_k^1 of the F^1-transform is the k-th orthogonal projection of f^{ex} on $L_2^m(A_k)$, and $L_2^m(A_k)$ is a linear subspace of $L_2(A_k)$ with orthogonal basis φ_k^0, φ_k^1, we will begin this subsection with a characterization of orthogonal polynomials φ_k^0, φ_k^1 of degrees 0 and 1.

Lemma 1
Polynomials $\varphi_k^0, \varphi_k^1 : [x_{k-1}, x_{k+1}] \longrightarrow \mathbb{R}$ such that for all $x \in [x_{k-1}, x_{k+1}]$, $\varphi_k^0(x) = 1$, $\varphi_k^1(x) = x - x_k$ are orthogonal with weight A_k, $k = 1, \ldots, n$.

PROOF: The proof is technical and follows from the following assertions:

(i) $\int_{x_{k-1}}^{x_{k+1}} A_k(x) dx = h$,

ISBN: 978-989-95079-6-8

(ii) $\int_{x_{k-1}}^{x_{k+1}} xA_k(x)dx = hx_k$,

and properties of the uniform partition. □

Remark 2
Orthogonal polynomials of degrees 0 *and* 1, *described in Lemma 1, are invariant to shapes of* A_k.

Theorem 2
Under the assumptions above, the F^1*-transform of* f *with respect to* $A_1, \ldots, A_n$ *is the vector* $[F_1^1, \ldots, F_n^1]$ *of linear functions such that an arbitrary component* F_k^1, $k = 1, \ldots, n$, *is represented as follows:*

$$F_k^1(x) = c_k^0 + c_k^1(x - x_k), \quad x \in [x_{k-1}, x_{k+1}]$$

where

$$c_k^0 = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x)A_k(x)dx}{h}, \tag{5}$$

$$c_k^1 = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x)(x - x_k)A_k(x)dx}{\int_{x_{k-1}}^{x_{k+1}} (x - x_k)^2 A_k(x)dx}. \tag{6}$$

PROOF: The proof will be given for one fixed component F_k^1 where $k = 1, \ldots, n$. By Definition 2, F_k^1 is the k-th orthogonal projection of f^{ex} on $L_2^1(A_k)$ where the orthogonality is determined by (2). Therefore,

$$f^{ex}|_{[x_{k-1}, x_{k+1}]} = c_k^0 + c_k^1(x - x_k) + R_k(x)$$

where R_k is orthogonal to each basis functions φ_k^0 and φ_k^1. Therefore,

$$c_k^0 = \frac{(f^{ex}, \varphi_k^0)_k}{(\varphi_k^0, \varphi_k^0)_k},$$

$$c_k^1 = \frac{(f^{ex}, \varphi_k^1)_k}{(\varphi_k^1, \varphi_k^1)_k}$$

which after substitution gives the required expressions for c_k^0 and c_k^1. □

Corollary 1
Under the assumptions above, $c_k^0 = F_k$ *where* F_k *is the* k*-th component (4) of the ordinary* F*-transform.*

PROOF: The proof follows from expressions (4), (6) and equality $\int_{x_{k-1}}^{x_{k+1}} A_k(x)dx = h$. □

3.2 Simplification of F^1*-transform components computation*

In this subsection, we will show how Gaussian quadratures and the properties of orthogonal polynomials can be used for replacing integral $\int_{x_{k-1}}^{x_{k+1}} (x - x_k)^2 A_k(x)dx$ in the denominator of c_k^1 by its precise value.

At first, let us recall the notion of Gaussian quadratures (see e.g.[10]). The approximate equality

$$\int_{x_{k-1}}^{x_{k+1}} f(x)A_k(x)dx \approx \frac{h}{2} \sum_{i=1}^{N} d_i f(t_i) \tag{7}$$

which is precise for all polynomials of the highest possible degree is a Gaussian quadrature. We will put $N = 2$ and characterize arguments t_1, t_2 and the highest possible degree of polynomials which turn (7) into a precise equality. The following statement (see e.g.[10]) gives the required characterization: if

(i) t_1, t_2 are roots of polynomial φ_k^2 which is orthogonal to φ_k^0 and φ_k^1, and

(ii) equality

$$\int_{x_{k-1}}^{x_{k+1}} P_l(x)A_k(x)dx = h(d_1 P_l(t_1) + d_2 P_l(t_2)), \tag{8}$$

holds true for some coefficients d_1, d_2 and all polynomials P_l of degrees $l = 0, 1$,

then (8) holds true for all polynomials P_l of degrees $0 \leq l \leq 3$.

Thus, our next purpose is to find a polynomial of the degree 2, orthogonal to φ_k^0 and φ_k^1, as well as to find its roots. Due to positivity and symmetry of A_k, two lemmas below hold true.

Lemma 2
If t_1, t_2 *are symmetrical with respect to* x_k *then equalities*

$$\int_{x_{k-1}}^{x_{k+1}} A_k(x)dx = h(\frac{1}{2} + \frac{1}{2}) = h,$$

$$\int_{x_{k-1}}^{x_{k+1}} (x - x_k)A_k(x)dx = \frac{h}{2}((t_1 - x_k) + (t_2 - x_k)) = 0,$$

hold true for $l = 0, 1$.

Lemma 3
If we denote

$$I_2 = \int_{x_{k-1}}^{x_{k+1}} (x - x_k)^2 A_k(x)dx$$

then polynomial φ_k^2, *represented by*

$$\varphi_k^2(x) = (x - x_k)^2 - \frac{I_2}{h} \tag{9}$$

is orthogonal to φ_k^0 *and* φ_k^1 *on* $[x_{k-1}, x_{k+1}]$.

The roots t_1, t_2 *of* φ_k^2 *belong to* (x_{k-1}, x_{k+1}) *and are symmetrical with respect to* x_k, *i.e. for some* δ, $t_1 = x_k - \delta$ *and* $t_2 = x_k + \delta$.

The statement above together with Lemmas 2, 3 leads to the equality

$$\int_{x_{k-1}}^{x_{k+1}} (x - x_k)^2 A_k(x)dx = h\delta^2.$$

Thus, the desired simplified representation of c_k^1 is as follows:

$$c_k^1 = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x)(x - x_k)A_k(x)dx}{h\delta^2}.$$

ISBN: 978-989-95079-6-8

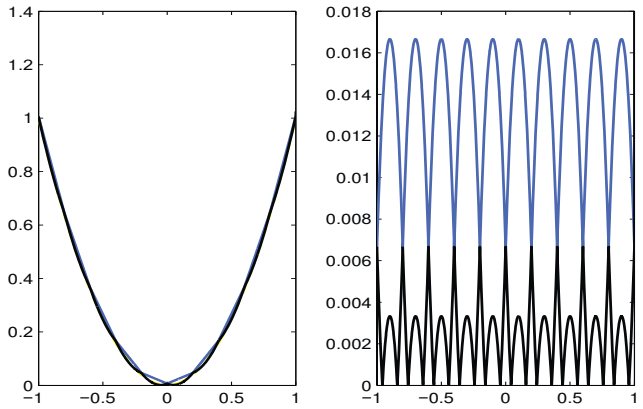

Figure 1: *Left.* The function x^2 and its inverse F^0 (gray line) and F^1 (black line) transforms. *Right.* Graphs of the error functions. Maximal errors of approximation are: 0.017 (the inverse F^0-transform) and 0.062 (the inverse F^1-transform).

4 Inverse F^m-transform

Similarly to the ordinary F-transform, the inverse F^m-transform is defined as a linear combination of the basic functions with "coefficients" given by the F^m-transform components.

Definition 3
Let $f : [a, b] \longrightarrow \mathbb{R}$ be a given function and f^{ex} its extension to $[x_0, x_{n+1}]$ such that for all $k = 1, \ldots, n$, $f^{ex}|_{[x_{k-1}, x_{k+1}]} \in L_2(A_k)$. For a certain $m \geq 0$, let $[F_1^m, \ldots, F_n^m]$ be the F^m-transform of f with respect to $A_1, \ldots, A_n$. Then the function

$$f_{F,m,n}(x) = \sum_{k=1}^{n} F_k^m A_k(x) \tag{10}$$

is called the inverse F^m-transform.

The following recurrent formula easily follows from Definition 3 and the whole structure of the F^m-transform, $m \geq 1$:

$$f_{F,m,n}(x) = f_{F,m-1,n}(x) + \sum_{k=1}^{n} c_m \varphi_k^m(x) A_k(x). \tag{11}$$

By Remark 1, the components F_k^m, $k = 1, \ldots, n$, $m \geq 0$, are the best approximation of f among all elements represented by linear combinations $a_0\varphi_k^0 + a_1\varphi_k^1 + \ldots + a_m\varphi_k^m$. Therefore, for each $k = 1, \ldots, n$, F_k^m is a better approximation of f than F_k^{m-1}. This observation together with (11) implicitly demonstrates that the quality of approximation of f by $f_{F,m,n}$ is better than that of approximation by $f_{F,m-1,n}$. The same conclusion follows also from our experiments (see Figure 1). The proof of this assertion is a matter of future investigation.

5 Conclusion

We have generalized the F-transform technique to the case where its components are polynomials. A detailed characterization of the F^1-transform with linear components was given. We have shown how a computation of F^1-transform components can be simplified if the technique of Gaussian quadratures is used. The inverse F^m-transform, $m \geq 1$, is defined in the same way as the inverse F-transform.

Some chaotic and mixing properties of Zadeh's extension

Jiří Kupka

Institute for Research and Applications of Fuzzy Modeling, University of Ostrava
30. dubna 22, 701 33 Ostrava, Czech Republic
Email: Jiri.Kupka@osu.cz

Abstract— *Let X be a compact metric space, let φ be a continuous self-map on X, and let $\mathbb{F}(X)$ denote the space of fuzzy sets on X equipped with the levelwise topology. In this paper we study relations between various dynamical properties of a given (crisp) dynamical system (X, φ) and its Zadeh's extension Φ on $\mathbb{F}(X)$. Among other things we study various (weak, strong, mild etc.) mixing properties and also several kinds of chaotic behaviors (Li-Yorke chaos, ω-chaos, distributional chaos, topological chaos etc.).*

Keywords— Zadeh's extension, fuzzification, chaos, mixing, transitivity, topological entropy.

1 Introduction

Throughout this paper, let (X, d_X) be a compact metric space and let $C(X)$ denote the space of continuous maps $\varphi : X \to X$. A discrete dynamical system is a pair (X, φ). For other notions and notations mentioned in this section, we refer to Section **??**. It is well known ([**?**]) that the discrete dynamical system (X, φ) naturally induces a dynamical system $(\mathbb{F}(X), \Phi)$ on the space $\mathbb{F}(X)$ of all fuzzy compact subsets of X. The map Φ is called the *fuzzification* (or *Zadeh's extension*) (see (**??**)).

It is natural to ask the following **question:** *how is the dynamical complexity of the fuzzified (resp. crisp) dynamical system related to the dynamical properties of the original (resp. fuzzy) one*. There are only a few papers devoted to this question so far – for example, [**?**], [**?**] and [**?**], where different chaotic properties of fuzzy discrete dynamical systems were considered.

In this paper, we consider the space $\mathbb{F}(X)$ of upper semi-continuous fuzzy sets with compact supports. This space is equipped with the topology induced by the levelwise metric d_∞ (see (**??**)), since this topology is stronger than the other topologies commonly used in fuzzy topological dynamics (e.g. see [**?**]). We especially deal with the subspace $\mathbb{F}^1(X) \subseteq \mathbb{F}(X)$ of all normal fuzzy sets on X (see (**??**)). The reason for this is the following: no fuzzification $\Phi : \mathbb{F}(X) \to \mathbb{F}(X)$ admits one of the simplest chaotic behaviors (namely the transitivity, see Proposition **??**) and, consequently, it does not admit more complex behavior.

This paper is a partial answer to the question mentioned above. Our results concerning the most commonly used chaotic and mixing properties can be summarized as follows:

• if P denotes either the distributional or Li-Yorke or topological or ω-chaos then

$$(\varphi \text{ has } P \Rightarrow \Phi \text{ has } P), \text{ but } (\Phi \text{ has } P \not\Rightarrow \varphi \text{ has } P), \quad (1)$$

• if P denotes either transitivity or total transitivity, then

$$(\Phi \text{ has } P \Rightarrow \varphi \text{ has } P), \text{ but } (\varphi \text{ has } P \not\Rightarrow \Phi \text{ has } P), \quad (2)$$

• if P denotes one of the following properties: exactness, sensitive dependence, weak mixing, mild mixing, or strong mixing, then

$$(\Phi \text{ has } P \Rightarrow \varphi \text{ has } P), \quad (3)$$

but the validity of the converse implication is unknown.

This paper is organized as follows: in Section **??**, we introduce notation and definitions used in this paper. Then, in Section **??**, some preliminary results are proven, showing also connections between the set-valued and fuzzified system induced by the same original system. Finally, the chaotic and mixing properties are studied in Section **??**.

2 Definitions and notation

Further we denote by $\mathbb{N}$ and $\mathbb{R}$ the set of integers and real numbers, respectively. Now we define some classic notions from topological dynamics. For a given dynamical system (X, φ) and a given point $x \in X$, we define the n-th *iteration* of the point x inductively by $\varphi^0(x) = x$, $\varphi^{n+1}(x) = \varphi(\varphi^n(x))$ for any $n \in \mathbb{N}$. Then, the sequence $\{\varphi^n(x)\}_{n\in\mathbb{N}}$ of all iterations of x is called the *trajectory* of the point x. Any limit point of the trajectory of the point x is called an *ω-limit point* of the point x, and the union $\omega_\varphi(x)$ of all ω-limit points of the point x is the *ω-limit set* of the point x. The iterations of a given set $A \subseteq X$ are defined analogously. The point $x \in X$ is called *fixed* if $\varphi(x) = x$ or *periodic* if $\varphi^k(x) = x$ for some $k \in \mathbb{N}$. We denote by $\omega(\varphi)$, $P(\varphi)$ and $Fix(\varphi)$ the set of ω-limit, periodic and fixed points, respectively.

A map $\varphi \in C(X)$ is called *transitive* if for any non-empty open subsets $U, V \subseteq X$, there exists some $k \in \mathbb{N}$ such that $\varphi^k(U) \cap V \neq \emptyset$. The map φ is *totally transitive* if the n-th iteration of φ is transitive for any $n \in \mathbb{N}$. The map φ is *weakly mixing* if the product map $\varphi \times \varphi$ is transitive. The map φ is *strongly mixing* if for any non-empty open subsets $U, V \subseteq X$ there exists some $m \in \mathbb{N}$ such that $\varphi^k(U) \cap V \neq \emptyset$ for any $k \geq m$. The map φ is *topologically exact* (or simply *exact*) if for any non-empty subset $U \subseteq X$, there exists some $k \in \mathbb{N}$, such that $\varphi^k(U) = X$.

2.1 Chaotic properties

When defining chaotic properties we follow the notation introduced in [**?**]. The notion of distributional chaos was introduced in [**?**]. For any $x, y \in X$, $t \in \mathbb{R}$ and $n \in \mathbb{N}$, set

$$\xi(x, y, t, n) = \#\{i,\ 0 \leq i < n \wedge d(\varphi^i(x), \varphi^i(y)) < t\}. \quad (4)$$

Set

$$F^\star_{xy}(t) = \limsup_{n\to\infty} \frac{1}{n}\xi(x, y, t, n) \quad (5)$$

ISBN: 978-989-95079-6-8

and

$$F_{xy}(t) = \liminf_{n\to\infty} \frac{1}{n}\xi(x,y,t,n). \quad (6)$$

Obviously, both maps $F^{\star}_{xy}$ and F_{xy} are nondecreasing, $0 \leq F_{xy}(t) \leq F^{\star}_{xy}(t) \leq 1$ for all $t \in \mathbb{R}$, $F^{\star}_{xy}(t) = 0$ if $t \leq 0$ and $F^{\star}_{xy}(t) = 1$ if $t \geq diam(X)$. The map $F^{\star}_{xy}$ ($F_{xy}(t)$) is an upper (a lower) distribution function for $x, y \in X$.

The map φ is *distributionally chaotic* of type 1 (d_1C) if $F^{\star}_{xy} \equiv 1$ and $F_{xy}(t) = 0$ for some $t > 0$. The map φ is *distributionally chaotic* of type 2 (d_2C) if $F^{\star}_{xy} \equiv 1$ and $F^{\star}_{xy}(t) > F_{xy}(t)$ for some $t > 0$. Finally, the map φ is *distributionally chaotic* of type 3 (d_3C) if $F^{\star}_{xy}(t) > F_{xy}(t)$ for all $t \in J$, where J is a nondegenerate interval.

It follows from the definition that

$$d_1C \Rightarrow d_2C \Rightarrow d_3C. \quad (7)$$

However, the converse implications are not valid (see, for instance, [**?**] and [**?**]).

Two points $x, y \in X$ form a *Li-Yorke pair* if

$$\limsup_{n\to\infty} d_X(\varphi^n(x), \varphi^n(y)) > 0 \quad (8)$$

and

$$\liminf_{n\to\infty} d_X(\varphi^n(x), \varphi^n(y)) = 0. \quad (9)$$

A set $S \subseteq X$ is a *LY-scrambled set* for the map φ if $\#S \geq 2$ and every pair from S is Li-Yorke. The map φ is *Li-Yorke chaotic* (shortly *LYC*) if there exists an uncountable LY-scrambled set.

A map $\varphi \in C(X)$ is *ω-chaotic* ([**?**]) (shortly ωC) if there exists an uncountable *ω-scrambled* set $S \subseteq X$, i.e. for any two points $x, y \in S$, the following conditions are satisfied: (i) $\omega_\varphi(x) \setminus \omega_\varphi(y)$ is uncountable, (ii) $\omega_\varphi(x) \setminus \omega_\varphi(y) \neq \emptyset$ and (iii) $\omega_\varphi(x) \cap P(\varphi) \neq \emptyset$.

If a map $\varphi : X \to X$ is transitive and $P(\varphi)$ is dense in X then φ is called *Devaney chaotic*. It should be mentioned that in the original definition of Devaney, φ *depends sensitively on initial conditions*,i.e. there exists $\delta > 0$ such that for any $x \in X$ and any open neighborhood U of x there is $y \in U$ satisfying $d_X(\varphi^k(x), \varphi^k(y)) > \delta$ for some $k \in \mathbb{N}$. But it was proved that this condition is implied by the transitivity and density of periodic points (see [**?**] and [**?**]).

The notion of positive topological entropy was firstly defined by Bowen ([**?**]). The topological entropy of a map φ is a number $h(\varphi) \in [0, \infty]$, defined by

$$h(\varphi) = \lim_{\varepsilon>0} \limsup_{n\to\infty} \#E(n, \varphi, \varepsilon), \quad (10)$$

where $E(n, \varphi, \varepsilon)$ is a $(n, \varphi, \varepsilon)$-*span* with a minimal possible number of points, i.e. a set such that for any $x \in X$ there exists a $y \in E(n, \varphi, \varepsilon)$ satisfying $d(\varphi^k(x), \varphi^k(y)) < \varepsilon$ for any j, $1 \leq j \leq n$. A map φ is *topologically chaotic* (shortly PTE) if $h(\varphi) > 0$. It is well-known that the topological entropy is monotone in the following way: for any $A, B \subseteq X$,

$$A \subseteq B \quad \Rightarrow \quad h(\varphi|_A) \leq h(\varphi|_B). \quad (11)$$

A map $\varphi \in C(X)$ has the *specification property* if for any $\varepsilon > 0$ there is a positive $M \in \mathbb{N}$ such that for any integer $k \geq 2$ and any k points $x_i \in X$, $i = 1, 2, \ldots, k$ and any $2k$ integers $a_1 \leq b_1 < a_2 \leq b_2 < \ldots < a_k \leq b_k$ with $a_i - b_{i-1} \geq M$, there exists $z \in X$ for which

$$d(\varphi^n(z), \varphi^n(x_i)) < \varepsilon \quad (12)$$

for any $n = a_i, \ldots, b_i$ and any $i = 1, 2, \ldots, k$.

The following implications are currently known among the chaotic and mixing properties mentioned above:

$$\begin{gathered}\text{specification property} \Rightarrow \text{strong mixing} \Rightarrow \\ \text{mild mixing} \Rightarrow \text{weak mixing} \Rightarrow \\ \text{total transitivity} \Rightarrow \text{transitivity}.\end{gathered} \quad (13)$$

For further details and relations among the chaotic properties, we refer to [**?**] and to the references therein.

2.2 Metric spaces of fuzzy sets

Let (X, d) denote a compact metric space, and let A, B be non-empty closed subsets of X. The *Hausdorff metric* D_X between A and B is defined, as usual, by

$$D_X(A, B) = \inf\{\varepsilon > 0 \,|\, A \subseteq U_\varepsilon(B) \wedge B \subseteq U_\varepsilon(A)\}, \quad (14)$$

where

$$U_\varepsilon(A) = \{x \in X \,|\, D(x, A) < \varepsilon\}, \quad (15)$$

and

$$D(x, A) = \inf_{a\in A} d(x, a). \quad (16)$$

By $\mathbb{K}(X)$ we denote the space of all nonempty compact subsets of X, equipped with the Hausdorff metric D_X. It is well known (c.f. [**?**]) that $(\mathbb{K}(X), D_X)$ is compact, complete and separable whenever X is compact, complete and separable.

A fuzzy set A on the space X is a function $A : X \to I$ where I denotes the closed unit interval $[0, 1]$. The *α-cuts* (or the *α-level sets*) $[A]_\alpha$ and the *support* $supp(A)$ of a given fuzzy set A are defined as usual by -

$$[A]_\alpha = \{x \in X \,|\, A(x) \geq \alpha\}, \ \alpha \in [0, 1], \quad (17)$$

and

$$supp(A) = \overline{\{x \in X \,|\, A(x) > 0\}}. \quad (18)$$

Further, we define $\mathbb{F}(X)$ as the system of all upper semi-continuous fuzzy sets $A : X \to I$ having compact supports. Moreover, let

$$\mathbb{F}^1(X) = \{A \in \mathbb{F}(X) \,|\, A(x) = 1 \text{ for some } x \in X\} \quad (19)$$

denote the system of all *normal* fuzzy sets on X. Finally, we define $\emptyset_X$ as the *empty fuzzy set* ($\emptyset_X(x) = 0$ for each $x \in X$) on the space X, and $\mathbb{F}_0(X)$ as the system of all nonempty fuzzy sets.

Let us define a *levelwise* metric d_∞ on $\mathbb{F}_0(X)$ by

$$d_\infty(A, B) = \sup_{\alpha\in(0,1]} D_X([A]_\alpha, [B]_\alpha). \quad (20)$$

This equality defines the levelwise metric correctly only for non-empty fuzzy sets $A, B \in \mathbb{F}_0(X)$ whose maximal values are identical, since the Hausdorff distance D_X is only measured between two non-empty closed subsets of the space X.

ISBN: 978-989-95079-6-8

Thus, we consider the following extension of the Hausdorff metric D_X:

$$D_X(\emptyset,\emptyset) = 0 \text{ and } D_X(\emptyset, A) = diam\,(X) \qquad (21)$$

for any $A \in \mathbb{K}(X)$. With this extension, **(??)** correctly defines the levelwise metric on $\mathbb{F}(X)$. It is obvious that

$$d_\infty(\emptyset_X,\emptyset_X) = 0 \text{ and } d_\infty(\emptyset_X, A) = diam\,(X) \qquad (22)$$

for any $A \in \mathbb{F}_0(X)$.

It should be noted that the metric d_∞ is one of the three most commonly used metrics in fuzzy topological dynamics. We also recall that the metric space $(\mathbb{F}(X), d_\infty)$ is complete but is not separable and not compact and that the levelwise topology induced by d_∞ is stronger than the remaining (*sendograph* and *endograph*) ones. For more details we refer to [**?**] and to the references therein.

2.3 Zadeh's extension

Let X be a compact metric space and $\varphi \in C(X)$. Then a *fuzzification* (or *Zadeh's extension*) of the (crisp) dynamical system (X, φ) is a map $\Phi : \mathbb{F}(X) \to \mathbb{F}(X)$ defined by

$$(\Phi(A))(x) = \sup_{y\in\varphi^{-1}(x)} \{A(y)\} \qquad (23)$$

for any $A \in \mathbb{F}(X)$ and $x \in X$.

It is shown recently by [**?**] that, if X is a compact metric space, then the fuzzification $\Phi : \mathbb{F}(X) \to \mathbb{F}(X)$ is continuous if and only if $\varphi : X \to X$ is continuous. The last statement was generalized about the case of locally compact metric spaces in [**?**] recently.

It is known that, for any $\alpha \in (0, 1]$ and any $A \in \mathbb{F}(X)$,

$$\varphi([A]_\alpha) = [\Phi(A)]_\alpha. \qquad (24)$$

Similarly, $\varphi(supp(A)) = supp(\Phi(A))$ holds.

3 Preliminary results

Inspired by the results mentioned, for instance, in [**?**], we define some basic properties of generalized extensions. For any $U \subseteq X$, we define

$$e(U) = \{B \in \mathbb{F}(X) \,|\, supp(B) \subseteq U\} \qquad (25)$$

It is obvious that $e(U) \neq \emptyset$ if and only if $U \neq \emptyset$. Moreover, we have the following assertion (Lemma **??**) that was partially proved in [**?**]:.

Lemma 1 *A subset U is a non-empty open subset of X if and only if $e(U)$ is a non-empty open subset of $\mathbb{F}(X)$.*

Proof. Since the implication "⇒" has been proven in [**?**], the converse remains to be proven. So let $e(U)$ be a non-empty open subset of $(\mathbb{F}(X), d_\infty)$. Assume by contradiction that U is not open. Take any $x \in U \setminus int(U)$ and consider a fuzzy set $\chi_{\{x\}}$. Then, for any $\varepsilon > 0$, an open ε-neighborhood $V \subseteq X$ of x intersects the exterior of U. Consequently, χ_V is ε-close to $\chi_{\{x\}}$ (by the definition of d_∞), but $\chi_V \notin e(U)$. Thus no ε-neighborhood V of $\chi_{\{x\}}$ is a subset of $e(U)$. This contradicts the fact that $e(U)$ is open in $(\mathbb{F}(X), d_\infty)$. □

Lemma 2 (Representation theorem of Negoita-Ralescu, e.g. [**?**]) *Consider a family $\{B_\alpha \,|\, \alpha \in [0, 1]\}$ of closed subsets of X satisfying the following two conditions:*
(a) $B_\beta \subseteq B_\alpha \subseteq B_0$ if $0 \leq \alpha \leq \beta$,
(b) if $\{\alpha_n\}$ is an increasing sequence in I converging to α_0 then $B_{\alpha_0} = \bigcap_{n\in\mathbb{N}} B_{\alpha_n}$.
Then there exists $B \in \mathbb{F}(X)$ such that $[B]_\alpha = B_\alpha$.

Conversely, if B is a fuzzy set on X then the system $\{B_\beta\}_{\beta\in I}$ defined by $B_\beta = [B]_\beta$ for any $\beta \in (0, 1]$ and $B_0 = supp(B)$ satisfies conditions (a) and (b).

Lemma 3 *Let U, V be two subsets of X and $\varphi \in C(X)$. Then*
(i) $e(U \cap V) = e(U) \cap e(V)$,
(ii) $\Phi(e(U)) \subseteq e(\varphi(U))$,
(iii) $\Phi(e(U)) = e(\varphi(U))$ whenever U is closed.

Proof. The statements (i) and (ii) were already proved in [**?**].

The statement (iii) still remains to be proven. The inclusion $\Phi(e(U)) \subseteq e(\varphi(U))$ in (iii) follows from (ii). Let us prove $e(\varphi(U)) \subseteq \Phi(e(U))$ if U is closed. Take any $A \in e(\varphi(U))$. We want to show that there exists $B \in e(U)$ such that $\Phi(B) = A$. Since $A \neq \emptyset_X$ and upper semi-continuous, there exists $\alpha_0 = \max_{x\in X}\{A(x) \,|\, A(x) > 0\}$. Moreover, for any $\alpha \in (0, \alpha_0]$, $[A]_\alpha$ is nonempty, closed and, consequently by the continuity of φ, $\varphi^{-1}([A]_\alpha) \cap U$ is also nonempty and closed.

By the definition of the fuzzification Φ, $\max(A) = \max(B)$ whenever $B \in \mathbb{F}(X)$ is any preimage of A. So a fuzzy set $B \in e(U)$ can be defined as follows. For any $\beta \in (0, \alpha_0]$ we put

$$[B]_\beta = \varphi^{-1}([A]_\beta) \cap U. \qquad (26)$$

We also put $[B]_0 = U$ and $[B]_\beta = \emptyset$ for any $\beta \in (\alpha_0, 1]$. Obviously the system $\{[B]_\beta\}_{\beta\in I}$ satisfies the condition (a) of Lemma **??**. We shall now show that the condition (b) of Lemma **??** is satisfied, i.e. $B \in \mathbb{F}(X)$. Then, by the definition of B, we obtain that $B \in e(U)$.

Assume that $\{\beta_n\} \subseteq I$ is an increasing sequence that converges to $\beta_0 \leq \alpha_0$. Suppose by contradiction that $[B]_{\beta_0} \neq \bigcap_{n\in\mathbb{N}}[B]_{\beta_n}$. By the monotonicity of $\{\beta_n\}$ and Lemma **??** (a), the only possibility is that $[B]_{\beta_0}$ is a proper subset of $\bigcap_{n\in\mathbb{N}}[B]_{\beta_n}$, i.e.

$$\Big(\bigcap_{n\in\mathbb{N}} [B]_{\beta_n}\Big) \setminus [B]_{\beta_0} \neq \emptyset. \qquad (27)$$

Take any $x_0 \in \bigcap[B]_{\beta_n} \setminus [B]_{\beta_0}$ and then take $x_n \in [B]_{\beta_n} \setminus [B]_{\alpha_0}$ such that $\{x_n\}$ converges to x_0. Obviously, since $x_0 \notin [B]_{\beta_0}$ we obtain from **(??)** that

$$\varphi(x_0) \notin [A]_{\beta_0}. \qquad (28)$$

On the other hand, $x_n \in [B]_{\beta_n}$ for any $n \in \mathbb{N}$, i.e.,

$$\varphi(x_n) \in [A]_{\beta_n}, \text{ for any } n \in \mathbb{N}. \qquad (29)$$

Now the continuity of φ implies that $\{\varphi(x_n)\}$ converges to $\varphi(x_0)$. Hence **(??)** and **(??)** imply that $[A]_{\beta_0}$ is a proper subset of $\bigcap_{n\in\mathbb{N}}[A]_{\beta_n}$, i.e. $A \notin \mathbb{F}(X)$ by Lemma **??** – a contradiction. Thus, we have shown that $B \in \mathbb{F}(X)$.

ISBN: 978-989-95079-6-8

Finally, by the construction of B, we have $\Phi(B) = A$. □

We will need some further notation. For any $\alpha \in (0,1]$ and $U \subseteq X$, set

$$e_\alpha(U) = \{A \in \mathbb{F}(X) \mid [A]_\alpha \neq \emptyset \text{ and } [A]_\alpha \subseteq U\} \tag{30}$$

and

$$\vartheta(U) = e_1(U) \cap e(U). \tag{31}$$

Lemma 4 *For any $\alpha \in (0,1]$, $e_\alpha(U)$ is open in $(\mathbb{F}(X), \tau_\infty)$ if and only if $U \subseteq X$ is open in X.*

Proof. Let $\alpha \in (0,1]$ be fixed. We shall show that $e_\alpha(U)$ is open in $(\mathbb{F}(X), \tau_\infty)$ if U is open. Take any $A \in e_\alpha(U)$. Since $[A]_\alpha \subseteq U$ is closed and U is open, there exists an open ε-neighborhood V of $[A]_\alpha$ lying in U for any $\varepsilon > 0$. Consequently, by the definition of d_∞, if we consider an open ε-neighborhood $V' \subseteq (\mathbb{F}(X), d_\infty)$ of A with $\varepsilon < diam(X)$, then for any $B \in V'$,

$$[B]_\alpha \subseteq V \subseteq U. \tag{32}$$

Thus, there exists an open neighborhood V' of A in $e_\alpha(U)$, i.e., $e_\alpha(U)$ is open in $(\mathbb{F}(X), \tau_\infty)$.

Let us prove the converse implication. Assume by contradiction that U is not open and take any $x \in U \setminus int(U)$. Then, by the definition of $e_\alpha(U)$, $\chi_{\{x\}}$ belongs to $e_\alpha(U)$ but no ε-neighborhood of $\chi_{\{x\}}$ is a subset of $e_\alpha(U)$, i.e. $e_\alpha(U)$ is not open - a contradiction. □

Corollary 1 *A subset $U \subseteq X$ is open in X if and only if $\vartheta(U)$ is open in $(\mathbb{F}(X), \tau_\infty)$ (and therefore also in $(\mathbb{F}^1(X), d_\infty)$).*

Lemma 5 *Let X be a compact metric space and $\varphi \in C(X)$ Then, for any $\alpha \in (0,1]$ and $U, V \subseteq X$,*
(i) $e_\alpha(U \cap V) = e_\alpha(U) \cap e_\alpha(V)$,
(ii) $\Phi(e_\alpha(U)) \subseteq e_\alpha(\varphi(U))$.

Proof. Clearly, for any $\alpha \in (0,1]$, $A \in e_\alpha(U \cap V)$ if and only if $[A]_\alpha \subseteq U \cap V$, if and only if $[A]_\alpha \subseteq U$ and $[A]_\alpha \subseteq V$, if and only if $A \in e_\alpha(U)$ and $A \in e_\alpha(V)$, if and only if $A \in e_\alpha(U) \cap e_\alpha(V)$. Thus, (i) holds.

Let us prove (ii). Consider any $A \in \Phi(e_\alpha(U))$. Then there exists $B \in e_\alpha(U)$ for which $\Phi(B) = A$. Since $[B]_\alpha \subseteq U$ it follows from **(??)** and from the continuity of φ that

$$\varphi([B]_\alpha) = [\Phi(B)]_\alpha = [A]_\alpha \subseteq \varphi(U), \tag{33}$$

i.e. $A \in e_\alpha(\varphi(U))$, and the inclusion is valid for any $\alpha \in (0,1]$. □

We are ready to modify Lemma **??** and to prove the next lemma, which is used for the further study of dynamics in the space of normal fuzzy sets on X. For completeness, we note the obvious fact that $\vartheta(U) \neq \emptyset$ if and only if $U \neq \emptyset$.

Lemma 6 *Let U, V be two subsets of X and $\varphi \in C(X)$. Then*
(i) $\vartheta(U \cap V) = \vartheta(U) \cap \vartheta(V)$,
(ii) $\Phi(\vartheta(U)) \subseteq \vartheta(\varphi(U))$,
(iii) $\Phi(\vartheta(U)) = \vartheta(\varphi(U))$ whenever U is closed.

Proof. The statements (i) and (ii) are easy consequences of Lemmas **??** and **??**. Moreover, the proof of the statement (iii) is a slight modification of the proof of Lemma **??** ($\max_{x \in X} A(x) = \alpha_0 = 1$). □

At the end of this section we mention two simple properties of the usual fuzzification. By χ_A we denote the characteristic function of a given set $A \subseteq X$.

Lemma 7 *Let X be a compact metric space, $\varphi \in C(X)$ let Φ be a fuzzification of φ. Then*

$$\Phi(\alpha\chi_A) = \alpha\chi_{\varphi(A)} \tag{34}$$

for any $\alpha \in (0,1]$.

Proof. Obvious. □

Lemma 8 *Let X be a compact metric space. Then the map $i : (\mathbb{K}(X), D_X) \to (\mathbb{F}(X), d_\infty)$ defined by $i(A) = \chi_A$ for any $A \in \mathbb{K}(X)$ is an isometrical embedding.*

Proof. It is obvious that the map i is correctly defined. It follows directly from the definition of the metric d_∞ on the space of fuzzy sets that

$$d_X(x,y) = d_\infty(\chi_{\{x\}}, \chi_{\{y\}}) \tag{35}$$

for any $x, y \in X$, and also

$$D_X(U,V) = d_\infty(\chi_U, \chi_V) \tag{36}$$

for any $U, V \in \mathbb{K}(X)$. Thus, by Lemma **??**, i is injective, continuous and isometric. □

Remark 1 *The same assertion is true when we consider either the sendograph or endograph topology instead of the levelwise one, since the equalities used in the proof are valid also in those topologies. Consequently, some results (Propositions **??** and **??**) presented in the next section are valid also in all mentioned topologies. The property mentioned in Lemma **??** was firstly mentioned in Kloeden's pioneering paper [**?**] in a little bit different setting.*

4 Chaotic and mixing properties.

Firstly we study some chaotic properties. It follows from Lemma **??** that any fuzzified system is an extension of the set-valued dynamical system $(\mathbb{K}(X), \tilde{\varphi})$ induced by the original dynamical system (X, φ). Consequently, we can use results published in [**?**] to easily provide some answers (Propositions **??** and **??**) to the question mentioned at the beginning of this paper.

Lemma 9 [**?**] *Let X be a compact metric space and $\varphi \in C(X)$.*

(i) If there is a set $S \subseteq X$ that is d_jC-scrambled ($j = 1,2,3$) (ω-scrambled, LY-scrambled, resp.) for the map φ then there exists d_jC-scrambled ($j = 1,2,3$) (ω-scrambled, LY-scrambled, resp.) set for $\tilde{\varphi}$ with the same cardinality as S.

(ii) If φ is d_jC (LYC, ωC, resp.) then the same holds for $\tilde{\varphi}$.

ISBN: 978-989-95079-6-8

Lemma 10 [**?**] *There exists a compact metric space X with a zero topological entropy map φ for which there exist no LY pairs, d_3C-scrambled sets, or ω-scrambled sets, such that $\tilde{\varphi}$ is PTE, d_1C, ωC and LYC.*

Proposition 1 *Let X be a compact metric space, $\varphi \in C(X)$ and let Φ be a fuzzification of φ. Then*

(i) If there is a set $S \subseteq X$ that is d_jC-scrambled ($j = 1, 2, 3$) (ω-scrambled, LY-scrambled, resp.) for the map φ, then there exists a d_jC-scrambled ($j = 1, 2, 3$) (resp. ω-scrambled, LY-scrambled) set S' for Φ, with the same cardinality as S.

(ii) If φ is d_jC (resp. LYC, ωC), then the same holds for Φ.

Proof. Let $S' = \{A \in \mathbb{F}(X) \mid A = \chi_{\{x\}} \text{ and } x \in S\}$. Then this proposition is a corollary of Lemmas **??**, **??** and **??**. □

Proposition 2 *Let Φ denote a fuzzification of φ. There exists a compact metric space X with a zero topological entropy map φ for which there exists no LY pairs, neither d_3C-scrambled set, nor ω-scrambled set such that Φ is PTE, d_1C, ωC and LYC.*

Proof. This proposition is an easy consequence of Lemmas **??**, **??** and **??**, and of the fact that the three versions of distributional chaos are comparable (**??**). □

The following proposition justifies why we study dynamical properties of fuzzified dynamical systems on the space of normal fuzzy sets in the rest of this paper.

Proposition 3 *Let X be a compact metric space and $\varphi \in C(X)$. Then no fuzzification $\Phi : (\mathbb{F}(X), d_\infty) \to (\mathbb{F}(X), d_\infty)$ of φ is transitive.*

Proof. Take any $A, B \in \mathbb{F}(X)$ such that $\max(A) \neq \max(B)$. By the definition of d_∞, there is an open ε-neighborhood U_ε of A (resp., an open ϑ-neighborhood V_ϑ of B) for some $\varepsilon, \vartheta > 0$ such that $\max(A') = \max(A)$ for any $A' \in U_\varepsilon$ (resp., $\max(B') = \max(B)$ for any $B' \in V_\vartheta$). Moreover, Φ preserves the maxima of fuzzy sets from U_ε and V_ϑ. Thus, by the choice of A and B, $\Phi^n(U_\varepsilon) \cap V_\vartheta = \emptyset$ (resp., $U_\varepsilon \cap \Phi^n(V_\vartheta) = \emptyset$) for any $n \in \mathbb{N}$, i.e., Φ is not transitive. □

Corollary 2 *Let X be a compact metric space and $\varphi \in C(X)$. Then a fuzzification $\Phi : (\mathbb{F}(X), d_\infty) \to (\mathbb{F}(X), d_\infty)$ of φ has none of the properties listed in (**??**) (specification property, strong mixing, mild mixing, weak mixing and total transitivity).*

Proof. The proof is an obvious consequence of Proposition **??** and (**??**). □

For completeness, it follows directly from Lemmas **??** and (**??**) that if the original dynamical system (X, φ) is topologically chaotic then also the fuzzified system $(\mathbb{F}^1(X), \Phi)$ (and hence $(\mathbb{F}(X), \Phi)$) is topologically chaotic. Now we would like to mention a recent paper [**?**] where the conditions defining Devaney chaos ([**?**]) were studied on the space of all fuzzy sets on X. We recall that we extended their results since no such fuzzification can be Devaney chaotic by Lemma **??**.

Moreover, dynamical properties of fuzzifications on the space of normal fuzzy sets on X have been never studied before. So we study them in the rest of this section.

Proposition 4 *Let X be a compact metric space, $\varphi \in C(X)$ and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is transitive then φ is transitive, but the converse implication does not hold.*

Proof. Let the assumptions be fulfilled. Consider any open subsets $U, V \subseteq X$. We want to show that φ is transitive, i.e. there exists $n \in \mathbb{N}$ such that

$$\varphi^n(U) \cap V \neq \emptyset. \tag{37}$$

First we take open subsets $U', V' \subseteq X$ such that $U' \subseteq \overline{U'} \subseteq U$ and $V' \subseteq \overline{V'} \subseteq V$. Then, by Corollary **??**, $\vartheta(U')$ and $\vartheta(V')$ are open subsets of $(\mathbb{F}^1(X), \tau_\infty)$. Since Φ is transitive, there exists $n \in \mathbb{N}$ for which $\Phi^n(\vartheta(U')) \cap \vartheta(V') \neq \emptyset$. Then $\Phi^n(\vartheta(\overline{U'})) \cap \vartheta(\overline{V'}) \neq \emptyset$, and by using results (i) and (iii) of Lemma **??**, we obtain

$$\vartheta(\varphi^n(\overline{U'})) \cap \vartheta(\overline{V'}) \neq \emptyset \quad \Rightarrow \quad \vartheta(\varphi^n(\overline{U'}) \cap \overline{V'}) \neq \emptyset. \tag{38}$$

Therefore $\varphi^n(\overline{U'}) \cap \overline{V'} \neq \emptyset$, and consequently, (**??**) is proved.

A counterexample (an irrational rotation on the unit circle) showing that the converse implication does not hold was presented in [**?**] for the fuzzification Φ defined on $\mathbb{F}(X)$, but it can be applied also to $\Phi|_{\mathbb{F}^1(X)}$. □

Proposition 5 *Let X be a compact metric space, $\varphi \in C(X)$, and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is totally transitive, then φ is totally transitive, but the converse implication does not hold.*

Proof. This proposition is an easy corollary of Proposition **??**, since the transitivity of any iteration Φ^n of Φ on $\mathbb{F}^1(X)$ implies the transitivity of φ^n on X for any $n \in \mathbb{N}$.

As a counterexample to the converse, we again can use the example mentioned in [**?**]. Their example was used as the counterexample to

$$\varphi \text{ transitive } \not\Rightarrow \ \Phi \text{ transitive}, \tag{39}$$

but the map φ used in [**?**] is an irrational rotation on the unit circle, and it is obvious that any irrational rotation on the unit circle is totally transitive. □

Proposition 6 *Let X be a compact metric space, $\varphi \in C(X)$ and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is sensitively dependent, then φ is sensitively dependent.*

Proof. Let the assumptions be fulfilled. We shall show that φ is sensitively dependent for the same sensitivity constant δ as Φ. Take any $x \in X$ and any open neighborhood U of x. Then $\vartheta(U)$ is an open neighborhood of $\chi_{\{x\}}$ by Corollary **??**. Since Φ is sensitively dependent, there exist $A \in \vartheta(U)$ and $n \in \mathbb{N}$ such that

$$d_\infty(\Phi^n(\chi_{\{x\}}), \Phi^n(A)) > \delta. \tag{40}$$

ISBN: 978-989-95079-6-8

By Lemma **??**

$$d_\infty(\Phi^n(\chi_{\{x\}}), \Phi^n(A)) = d_\infty(\chi_{\{\varphi^n(x)\}}, \Phi^n(A)) > \delta. \quad (41)$$

Thus, by the definition of the metric d_∞, there exists $y_0 \in supp(A)$ such that $d_X(\varphi^n(x), \varphi^n(y_0)) > \delta$. Obviously, y_0 lies in U and this shows that φ is sensitively dependent. □

Proposition 7 *Let X be a compact metric space, $\varphi \in C(X)$, and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is exact, then φ is exact.*

Proof. Let the assumptions be fulfilled, and let $U \subseteq X$ be an open set. Then there exists a closed $U' \subseteq U$ with nonempty interior $int(U')$. By Corollary **??**, $\vartheta(int(U'))$ is an open subset of $\mathbb{F}^1(X)$. Since Φ is exact, there exists some $k \in \mathbb{N}$ for which $\Phi^k(\vartheta(int(U'))) = \mathbb{F}^1(X)$. Therefore, by the choice of U' and by Lemma **??**,

$$\mathbb{F}^1(X) = \Phi^k(\vartheta(int(U'))) \subseteq \Phi^k(\vartheta(U')) \quad (42)$$

and

$$\Phi^k(\vartheta(U')) = \vartheta(\varphi^k(U')) \subseteq \vartheta(\varphi^k(U)). \quad (43)$$

Thus, $\vartheta(\varphi^k(U))$ covers $\mathbb{F}^1(X)$ and hence, since $\mathbb{F}^1(X)$ also contains the characteristic functions of all singletons (see Lemma **??**), $\varphi^k(U) = X$. □

Remark 2 *The map Φ on $\mathbb{F}(X)$ cannot be exact since Φ cannot be transitive (see Lemma **??**). Moreover, the validity of the converse implication to Proposition **??** is still unknown.*

Proposition 8 *Let X be a compact metric space, $\varphi \in C(X)$ and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is strongly mixing then φ is strongly mixing.*

Proof. The proof of this proposition is a slight variation of the proof of Proposition **??**. □

Proposition 9 *Let X be a compact metric space, $\varphi \in C(X)$ and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is mildly mixing then φ is mildly mixing.*

Proof. Let the assumptions be fulfilled. Let Y be any compact metric space and (Y, ψ) be any transitive discrete dynamical system. According to the definition of the mild mixing property, we want to show that the product system $(X \times Y, \varphi \times \psi)$ is transitive, i.e. for any open sets $U, V \subseteq X \times Y$ there exists $k \in \mathbb{N}$ for which

$$(\varphi \times \psi)^k(U) \cap V \neq \emptyset. \quad (44)$$

So let $U, V \subseteq X \times Y$ be given. Then there are open subsets $U_1, V_1 \subseteq X$, $U_2, V_2 \subseteq Y$ for which $U_1 \times U_2 \subseteq U$ and $V_1 \times V_2 \subseteq V$. We also consider open subsets $U_1', V_1' \subseteq X$ such that $\overline{U_1'} \subseteq U_1$ and $\overline{V_1'} \subseteq V_1$. By Corollary **??**, $\vartheta(U_1')$ and $\vartheta(V_1')$ are open subsets of $\mathbb{F}^1(X)$. Thus, since Φ is mildly mixing, there exists $k \in \mathbb{N}$ for which

$$(\Phi \times \psi)^k(\vartheta(U_1') \times U_2) \cap (\vartheta(V_1') \times V_2) \neq \emptyset, \quad (45)$$

i.e.

$$\psi^k(U_2) \cap V_2 \neq \emptyset \quad (46)$$

and also

$$\Phi^k(\vartheta(U_1')) \cap \vartheta(V_1') \neq \emptyset. \quad (47)$$

As in the proof of Proposition **??** ($U_1' = U'$ and $V_1' = V'$), the last inequality implies that

$$\varphi^k(U_1) \cap V_1 \neq \emptyset. \quad (48)$$

Consequently, this together with (**??**) gives

$$(\varphi \times \psi)^k(U_1 \times U_2) \cap (V_1 \times V_2) \neq \emptyset. \quad (49)$$

Finally, by the choice of U_1, U_2, V_1, V_2, (**??**) is proven. □

Proposition 10 *Let X be a compact metric space, $\varphi \in C(X)$ and let Φ be the fuzzification of φ. If $\Phi : (\mathbb{F}^1(X), d_\infty) \to (\mathbb{F}^1(X), d_\infty)$ is weakly mixing, then φ is weakly mixing.*

Proof. The proof of this proposition is a slight variation of the proof of Proposition **??**. □

Abstract— The aim of this paper is to promote web geometry and, especially, the Reidemeister closure condition as a powerful and intuitive tool characterizing associativity of the Archimedean triangular norms. In order to demonstrate its possible applications, we provide the full solution to the problem of convex combinations of nilpotent triangular norms.

Keywords— Archimedean triangular norm, web geometry, Reidemeister closure condition.

1 Triangular norms

The notion of *triangular norm* was originally introduced within the framework of probabilistic metric spaces [12]. Since then, triangular norms have found diverse applications in the theory of fuzzy sets, fuzzy decision making, in models of certain many-valued logics or in multivariate statistical analysis; for a reference see the books by Alsina, Frank, and Schweizer [5] and by Klement, Mesiar, and Pap [8].

A conjunctor is a function $K\colon [0,1]^2 \to [0,1]$ which is nondecreasing in both arguments, commutative, and which satisfies the *boundary condition* $T(x,1) = x$ for all $x \in [0,1]$. A triangular norm (shortly a *t-norm*, usually denoted by T) is a conjunctor which satisfies the *associativity equation* $T(T(x,y),z) = T(x,T(y,z))$ for all $x,y,z \in [0,1]$. This paper deals mainly with *Archimedean t-norms*. Let us recall that for every t-norm T, a number $n \in \mathbb{N}\cup\{0\}$, and $x \in [0,1]$ a *natural power* of x, denoted $(x)_T^{(n)}$, is defined by:

$$(x)_T^{(n)} = \begin{cases} 1 & \text{if} \quad n = 0\,, \\ T\left(x,(x)_T^{(n-1)}\right) & \text{if} \quad n > 0\,. \end{cases} \tag{1}$$

A t-norm T is said to be *Archimedean* if and only if for every pair $x,y \in \,]0,1[$, $x < y$, there exists a natural number $n \in \mathbb{N}$ such that $(y)_T^{(n)} < x$. A t-norm which is continuous and strictly increasing on the half-open square $]0,1]^2$ is said to be *strict*. A continuous t-norm T is called *nilpotent* if and only if for every $x \in \,]0,1[$ there exists a natural number $n \in \mathbb{N}$ such that $(x)_T^{(n)} = 0$. A prototypical example of a strict and a nilpotent t-norm is the product t-norm, $T_{\mathbf{P}}(x,y) = x \cdot y$, and the Łukasiewicz t-norm $T_{\mathbf{L}}(x,y) = \max\{x+y-1,0\}$,

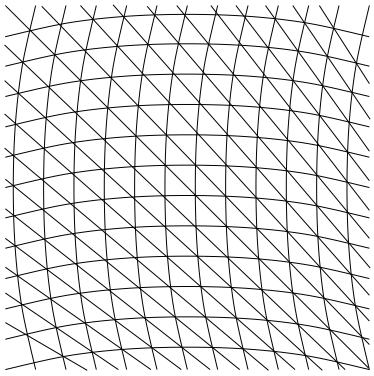

Figure 1: Example of a complete 3-web.

respectively. It is possible to show that a continuous Archimedean t-norm is either strict or nilpotent. A t-norm T is said to be *cancellative* if it satisfies $T(a,b) = T(a,c) \Rightarrow b = c$ for every $a,b,c \in [0,1]$, $a \neq 0$. A t-norm T is said to be *weakly cancellative* [9] if it satisfies $T(a,b) = T(a,c) \Rightarrow b = c$ for every $a,b,c \in [0,1]$ with $T(a,b) \neq 0$ and $T(a,c) \neq 0$. Every cancellative t-norm is weakly cancellative. Under the assumption of continuity, the set of cancelative t-norms and the set of strict t-norms coincide. Under the same assumption, the set of weakly cancelative t-norms coincides with the set of Archimedean t-norms.

2 Web geometry and local loops

In this section, *web geometry* is explained as a tool allowing to visualize algebraic identities. In particular, it is shown that it visualizes associativity of Archimedean t-norms. A detailed introduction to the subject is given in the monograph by Blashke and Bol [6]. Also the collection of papers by Aczél, Akivis, and Goldberg [1, 2, 3] can serve as an (English) introductory text.

Definition 2.1 *A* groupoid *(or a* magma*) is an algebraic structure $\mathcal{G} = (G,\circ)$ on a set G where $\circ\colon G\times G \to G$ is a binary operation. A* quasigroup *is a groupoid in which the*

ISBN: 978-989-95079-6-8

equations $a \circ x = b$ and $y \circ a = b$ have unique solutions for every a and b in G. Finally, a loop *is an algebraic structure $\mathcal{L} = (G, \circ, e)$ where $(G, \circ)$ is a quasigroup and e is an identity element, i.e. $x \circ e = x = e \circ x$ for every $x \in G$.*

The definition of a quasigroup, $\mathcal{G} = (G, \circ)$, allows to define the left and the right inverse. For this purpose we introduce a prefix notation $g(x, y) = x \circ y$.The left inverse is then defined for every $u \in G$ as ${}^{-1}g(u, y) = x$ such that $g(x, y) = u$. Similarly, the right inverse is, for every $v \in G$, $g^{-1}(x, v) = y$ such that $g(x, y) = v$. We say that g is *invertible* in x, resp. y. Defining a point $A = (a, b) \in G \times G$ we may introduce a new operation, $\bullet\colon G \times G \to G$, as

$$u \bullet v = g\left({}^{-1}g(u, b), g^{-1}(a, v)\right) . \qquad (2)$$

It is easy to show that $(G, \bullet)$ is a loop with a unit element $e = g(a, b)$; this loop is called a *local loop* of the quasigroup $(G, \circ)$ at the point $A = (a, b)$.

Definition 2.2 *Let M be a non-empty set and let $\lambda_1, \lambda_2, \lambda_3$ be three families of subsets of M. To elements of M we refer as to points and to elements of λ_α, $\alpha \in \{1, 2, 3\}$, as to lines. We say that the system $(M, \lambda_1, \lambda_2, \lambda_3)$ is a* complete 3-web *if and only if the following conditions hold:*

1. *Any point $p \in M$ is incident to just one line of each family λ_α, $\alpha \in \{1, 2, 3\}$.*
2. *Any two lines of different families are incident to exactly one point of M.*
3. *Two distinct lines from the same family λ_α are disjoint.*

Note that Item 3 of the definition is redundant and can be derived from Item 1. We kept the definition in this redundant form in order to keep some of the furher considerations simpler.

Usually M is equipped with a topology which turns the set into a manifold. In such a case the families λ_α are often required to be foliations. Figure 1 shows such an example of 3-web where M is a two dimmensional domain in plane and λ_α are foliations of co-dimension 1.

Notice that all the examples of 3-webs, shown in figures of this paper, are simplified. That means that only some particular lines from uncountable sets λ_α, $\alpha \in \{1, 2, 3\}$, are drawn.

Complete 3-webs are closely connected to quasigroups and, especially, loops. Every quasigroup defines a 3-web in the following way. Let $\mathcal{G} = (G, \circ)$ be a quasigroup defined on a manifold $M = G \times G$ and let $x, y \in G$. Let the lines of sets λ_1, λ_2, and λ_3 be given by the equations $x = a$, $y = b$, and $x \circ y = c$ respectively for fixed $a, b, c \in G$. The pair (M, λ_α), $\alpha \in \{1, 2, 3\}$, is then a 3-web.

Conversely, a 3-web (M, λ_α), $\alpha \in \{1, 2, 3\}$, on a manifold M, defines a binary operation which is invertible with respect to both operands; yet this time the result is not unique. Denote one set of the lines of the 3-web as λ_x, second as λ_y, and third as λ_z (the lines in the set λ_z are called *contour lines*), let $A \in M$ and let $g_x \in \lambda_x$ and $g_y \in \lambda_y$ be the lines passing through A; cf. Figure 2. Now we define an operation $*\colon \lambda_z \times \lambda_z \to \lambda_z$. Take $u, v \in \lambda_z$, define points $U, V \in M$ as $U = u \cap g_x$ and $V = v \cap g_y$, respectively. Let $g_u \in \lambda_y$ be the line passing through U and let $g_v \in \lambda_x$ be the line passing through V. Denote the intersection of these two lines as $W = g_u \cap g_v$; the line w passing through W is the result of the operation $u * v$.

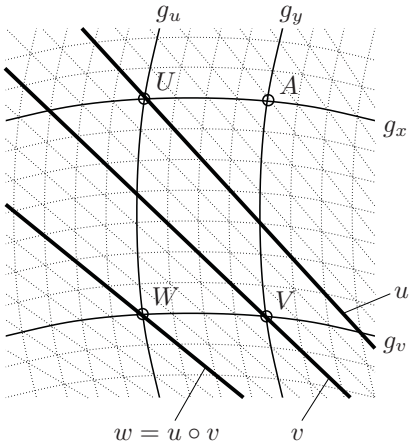

Figure 2: Operation defined on a complete 3-web.

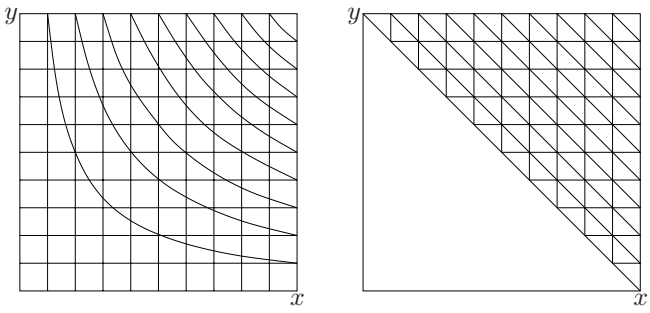

Figure 3: 3-webs given by the product t-norm, $T_{\mathbf{P}}$, and by the Łukasiewicz t-norm, $T_{\mathbf{L}}$.

It can be shown easily that the operation $*$ is invertible in both variables. Moreover, the line $e \in \lambda_z$, passing through the point A, behaves, with respect to the oparation $*$, as the unit element. Thus $(\lambda_z, *)$ is a loop. Moreover, this loop coincides, up to an isomorphism, with the local loop of $(G, \circ)$ at the point A.

T-norms, defined on the unit interval $[0, 1]$, form neither groupoids nor loops. Nevertheless, the 3-web given by a continuous Archimedean (i.e. strict or nilpotent) t-norm T satisfies all the requirements given by Definition 2.2 if the manifold M is defined as the subset of $[0, 1]^2$ where the t-norm attains non-zero values. A manifold, induced this way by a binary operation $T\colon [0, 1]^2 \to [0, 1]$, will be denoted as $\operatorname{Man} T$. Thus

$$M = \operatorname{Man} T = \left\{(x, y) \in [0, 1]^2 \mid T(x, y) > 0\right\} . \qquad (3)$$

Figure 3 shows 3-webs given by $T_{\mathbf{P}}$ and $T_{\mathbf{L}}$ as examples of a strict and a nilpotent t-norm respectively.

ISBN: 978-989-95079-6-8

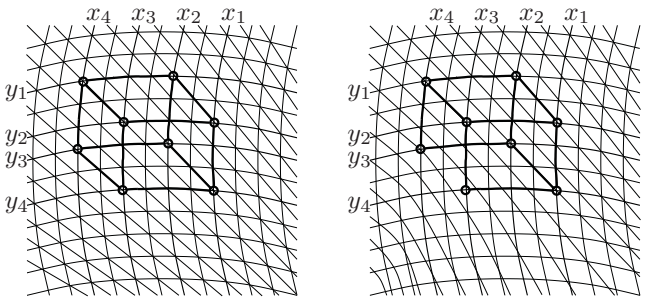

Figure 4: Example of a closed Reidemeister figure and a non-closed Reidemeister figure.

3 Reidemeister closure condition

Different types of 3-webs are characterized by closure conditions. These closure conditions have their counterparts in the related loops as algebraic properties of the loop operations. In this text we are interested in the associativity of t-norms since the associativity is the only property of a t-norm which cannot be intuitively interpreted from its graph. The 3-web counterpart of the associativity is the *Reidemeister closure condition*.

A 3-web satisfies the Reidemeister closure condition if and only if every Reidemeister figure in this web is closed; see Figure 4. Described in the terminology of contour lines, the Reidemeister closure condition is as follows. Let $x_1, x_2, x_3, x_4 \in \lambda_x$ and $y_1, y_2, y_3, y_4 \in \lambda_y$. If the points $(x_1 \cap y_2)$ and $(x_2 \cap y_1)$ lie on the same contour line (i.e. a line from the set λ_z), and if so do the pair of points $(x_1 \cap y_4)$ and $(x_2 \cap y_3)$, and the pair of points $(x_3 \cap y_2)$ and $(x_4 \cap y_1)$, then the points $(x_3 \cap y_4)$ and $(x_4 \cap y_3)$ also lie on the same contour line. The left part of Figure 4 shows a 3-web which satisfies the Reidemeister closure condition whereas the right part shows a 3-web where the condition is violated.

Let us now define a relation $\sim \subseteq M \times M$. We say that two points $A, B \in M$ are in the relation $\sim$, and we write $A \sim B$, if and only if they are both elements of the same line from the set λ_z. Using the language of $\sim$ the Reidemeister condition reads as:

$$\Big(\big((x_1 \cap y_2) \sim (x_2 \cap y_1)\big) \& \big((x_1 \cap y_4) \sim (x_2 \cap y_3)\big) \& \big((x_3 \cap y_2) \sim (x_4 \cap y_1)\big)\Big) \Rightarrow \big((x_3 \cap y_4) \sim (x_4 \cap y_3)\big). \quad (4)$$

4 Reidemeister closure condition and continuous Archimedean t-norms

We are going to show that the level set system of a continuous Archimedean t-norm always satisfies the Reidemeister closure condition. Moreover, the Reidemeister closure condition characterizes the associativity of a continuous Archimedean t-norm. For this purpose we recall that if we relax the requirement of the associativity in the definition of a t-norm, we obtain the definition of a conjunctor.

Let K be a continuous Archimedean conjunctor; for the sake of compactness we will use the infix notation: $K(x, y) = x \circ y$. Let (M, λ_α) be the corresponding 3-web defined on the manifold $M = \operatorname{Man} K = \{(x, y) \in [0, 1]^2 \mid x \circ y > 0\}$. Such a 3-web, as in the case of the continuous Archimedean t-norms, satisfies all the requirements given by Definition 2.2. In view of the previous section, the 3-web given by $\circ$ satisfies the Reidemeister closure condition if and only if the following condition holds for any $x_1, x_2, x_3, x_4, y_1, y_2, y_3, y_4 \in M$:

$$\Big(\big(x_1 \circ y_2 = x_2 \circ y_1\big) \& \big(x_1 \circ y_4 = x_2 \circ y_3\big) \& \big(x_3 \circ y_2 = x_4 \circ y_1\big)\Big) \Rightarrow \big(x_3 \circ y_4 = x_4 \circ y_3\big). \quad (5)$$

In the sequel, this condition will be denoted by $\mathbf{R}$.

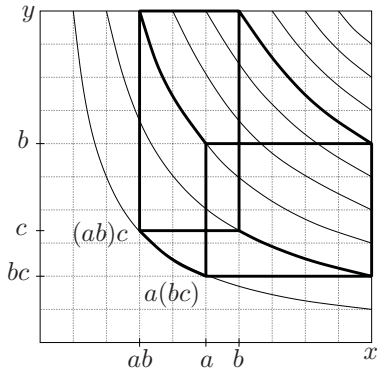

Figure 5: Reidemeister figure on the 3-web given by a continuous Archimedean t-norm.

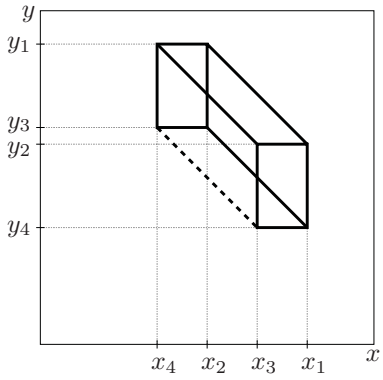

Figure 6: Illustration for the proof: an arbitrary Reidemeister figure.

Figure 5 shows that $\mathbf{R}$ implies the associativity of $\circ$ in a rather intuitive way. For any $a, b, c \in [0, 1]^2$, such that $(a \circ b) \circ c \in \operatorname{Man} \circ$ and $a \circ (b \circ c) \in \operatorname{Man} \circ$, there can be constructed a Reidemeister figure which, as can be seen in Figure 5, is closed if and only if $(a \circ b) \circ c = a \circ (b \circ c)$.

Figure 5 shows also that, in the other way round, if $\circ$ is associative then all the Reidemeister figures that "touch" the lines given by $x = 1$ and $y = 1$ are closed. In other words, $\mathbf{R}$ has to be satisfied for any $x_2, x_3, x_4, y_2, y_3, y_4 \in [0, 1]$ and, at least, for $x_1 = y_1 = 1$. Let us denote this weaker condition by $\mathbf{R_1}$. It is now clear that K is associative if and only if it

ISBN: 978-989-95079-6-8

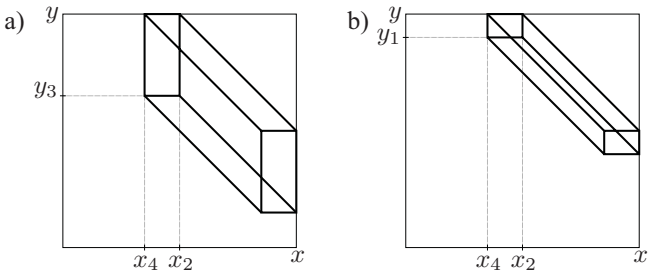

Figure 7: Illustration for the proof.

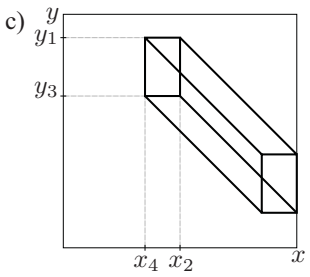

Figure 8: Illustration for the proof.

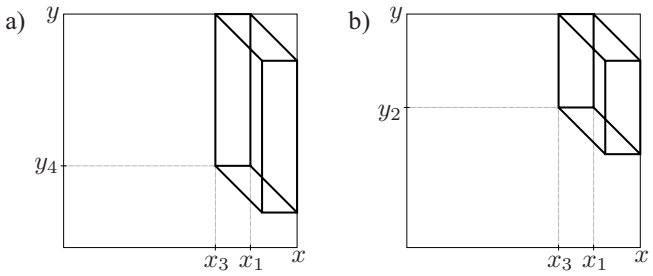

Figure 9: Illustration for the proof.

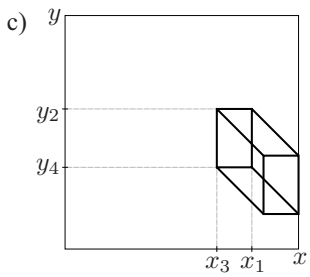

Figure 10: Illustration for the proof.

satisfies $\mathbf{R_1}$. In order to show that $\circ$ is associative if and only if it satisfies $\mathbf{R}$, we need to show that $\mathbf{R_1} \Leftrightarrow \mathbf{R}$. Obviously, $\mathbf{R} \Rightarrow \mathbf{R_1}$. The inverse implication, $\mathbf{R_1} \Rightarrow \mathbf{R}$, is given the following way.

Let us have a continuous Archimedean conjunctor K which satisfies $\mathbf{R_1}$. Let us have a Reidemeister figure drawn on its 3-web for arbitrary x_1, x_2, x_3, x_4, $y_1, y_2, y_3, y_4 \in [0, 1]$, see Figure 6. We are going to show that this figure shall be always closed. Thanks to $\mathbf{R_1}$, the Reidemeister figures, shown in Figure 7-a and Figure 7-b, are closed. Combining these two figures together it can be concluded that the Reidemeister figure in Figure 8-c is closed as well. By the same deduction, from the closedness of the Reidemeister figures in Figure 9-a and Figure 9-b it can be concluded that the Reidemeister figure in Figure 10-c is closed. Now, combining the closed Reidemeister figures in Figure 8-c and Figure 10-c, the closedness of the Reidemeister figure in Figure 6 is proven.

Corollary 4.1 *A continuous Archimedean conjunctor is associative (and, thus, a t-norm) if and only if it satisfies* $\mathbf{R}$.

5 Applications

5.1 Problem of convex combinations of t-norms

The question was introduced by Alsina, Frank, and Schweizer [4]. The approach of web geometry allows to give the following, recently published [11], answers:

Theorem 5.1 *Let T_1 and T_2 be two continuous Archimedean t-norms such that $\operatorname{Man} T_1 \neq \operatorname{Man} T_2$. Then no non-trivial convex combination F of T_1 and T_2 is a t-norm.*

Corollary 5.2 *Combining the result of Theorem 5.1 with the result given by Jenei [7], a non-trivial convex combination of two distinct nilpotent t-norms is never a t-norm.*

Corollary 5.3 *A non-trivial convex combination of a strict and a nilpotent t-norm is never a t-norm. This is an alternative proof of the result given earlier by Ouyang, Fang, and Li [10].*

Abstract— *In this paper we suggest and describe a new family of parametric representations for LR fuzzy numbers and use them for fuzzy calculations and arithmetic.*

Keywords— LR Fuzzy Numbers, LU-Fuzzy Parametrization, Fuzzy Arithmetic.

1 Introduction

The arithmetical structure of fuzzy numbers have been developed in the 1980's and Dubois and Prade introduced the well known LR model and the corresponding formulas for the fuzzy operations (see the recent publication [1] and the references therein).

In general, the arithmetic operations on fuzzy numbers can be approached either by the direct use of the membership function (by the Zadeh extension principle) or by the equivalent use of the $\alpha - cuts$ representation. A solid result in fuzzy theory and practice is that calculations cannot be performed by using the same rules as in arithmetic with real numbers and in fact fuzzy calculus will not always satisfy the same properties (e.g. distributivity, invertibility and others).

A parametric representation of LR fuzzy numbers and the derivation of the corresponding arithmetic operator have been first introduced by Giachetti and Young (see [2], [3]). In this paper, we will see that it is possible to define a more flexible parametric representation of fuzzy numbers that allow a large variety of possible shapes and is very simple to implement (see [5] and [6] for a parametric $\alpha - cuts$ representation).

We suggest a parametrization for the LR fuzzy numbers, similar to the work done for the LU parametrization in [5] and [6]. In terms of the parameters representing the LR fuzzy numbers, it is possible to define the operators for the fuzzy arithmetic and we show that the errors of the approximations can be reduced to any small tolerance (by increasing the number of parameters); in fact, within the space of differentiable fuzzy numbers, the approximations form a dense subspace.

2 Fuzzy Numbers in LR Parametric Form

We will consider fuzzy quantities, i.e. fuzzy sets defined over the field $\mathbb{R}$ of real numbers and we will focus on fuzzy numbers, having a particular form of the membership function.

A general *fuzzy set* over a given set (or space) $\mathbb{X}$ of elements (the universe) is usually defined by its membership function $\mu : \mathbb{X} \longrightarrow \mathbb{T} \subseteq [0,1]$ and a fuzzy (sub)set u of $\mathbb{X}$ is uniquely characterized by the pairs $(x, \mu_u(x))$ for each $x \in \mathbb{X}$; the value $\mu_u(x) \in [0,1]$ is the membership grade of x to the fuzzy set u. So, a fuzzy set is given by

$$\begin{aligned} u &= \{(x, \mu_u(x)) | x \in \mathbb{X}\} \\ \text{given } \mu_u &: \mathbb{X} \longrightarrow [0,1] \end{aligned}$$

Fundamental concepts in fuzzy theory are the *support*, the *level-sets* (or *level-cuts*) and the *core* of a fuzzy set (or of its membership function): let μ_u be the membership function of a fuzzy set u over $\mathbb{X}$. The support of u is the (crisp) subset of points of $\mathbb{X}$ at which the membership grade $\mu_u(x)$ is positive:

$$supp(u) = \{x | x \in \mathbb{X}, \mu_u(x) > 0\}; \tag{1}$$

we always assume that $supp(u) \neq \emptyset$. For $\alpha \in]0,1]$, the $\alpha-$level cut of u (or simply the $\alpha - cut$) is defined by

$$[u]_\alpha = \{x | x \in \mathbb{X},\ \mu_u(x) \geq \alpha\} \tag{2}$$

and for $\alpha = 0$ (or $\alpha \to +0$) by the closure of the support

$$[u]_0 = cl\{x | x \in \mathbb{X},\ \mu_u(x) > 0\}.$$

The core of u is the set of elements of $\mathbb{X}$ having membership grade 1

$$core(u) = \{x | x \in \mathbb{X}, \mu_u(x) = 1\} \tag{3}$$

and we say that u is normal if $core(u) \neq \emptyset$.

Of our interest are fuzzy sets when the space $\mathbb{X}$ is $\mathbb{R}$ (unidimensional real fuzzy sets).

Well-known properties of the $level - cuts$ are:

$$[u]_\alpha \subseteq [u]_\beta \text{ for } \alpha > \beta, \tag{4}$$

$$[u]_\alpha = \bigcap_{\beta < \alpha} [u]_\beta \text{ for } \alpha \in]0,1] \tag{5}$$

and (if $x \in supp(u)$, otherwise $\mu_u(x) = 0$)

$$\mu_u(x) = \sup\{\alpha |\ \alpha \in]0,1] \text{ for which } x \in [u]_\alpha\}. \tag{6}$$

A particular class of fuzzy sets is when the support is a convex set (C is said *convex* if $(1-t)x' + tx'' \in C$ for every $x', x'' \in C$ and all $t \in [0,1]$) and the membership function is quasi-concave: we say that the membership function μ_u is quasi-concave if $\mu_u((1-t)x' + tx'') \geq \min\{\mu_u(x'), \mu_u(x'')\}$ for every $x', x'' \in supp(u)$ and $t \in [0,1]$. Equivalently, μ_u is quasi-concave if the level-cuts $[u]_\alpha$ are convex sets for all $\alpha \in [0,1]$.

A third property of the fuzzy quantities is related to the semi-continuity of the membership function and to the closedness of the level-cuts: μ_u is said to be upper semicontinuous if $\lim_{x \longrightarrow \widehat{x}} \sup \mu_u(x) = \mu_u(\widehat{x})$ at every $\widehat{x} \in supp(u)$ or, equivalently, if the level-cuts $[u]_\alpha$ are closed sets for all $\alpha \in [0,1]$.

Definition (*fuzzy number):* u is a fuzzy number if

(i.) μ_u has nonempty bounded support and is normal,

(ii.) μ_u is quasi-concave,

(iii.) μ_u is upper semicontinuous

ISBN: 978-989-95079-6-8

or, equivalently:

(a.) $[u]_\alpha$ are nonempty convex sets for all $\alpha \in [0,1]$

(b.) $[u]_\alpha$ are closed and bounded (compact) sets for all $\alpha \in [0,1]$

(c.) $[u]_\alpha$ satisfy conditions (4) and (5).

We will denote by $\mathcal{F}$ the set of fuzzy numbers. It can be structured by an addition and a scalar multiplication, defined either by the level sets or, equivalently, by the Zadeh extension principle. Let $u, v \in \mathcal{F}$ have membership functions μ_u, μ_v and $\alpha - cuts$ $[u]_\alpha$, $[v]_\alpha$, $\alpha \in [0,1]$ respectively. The addition $u+v \in \mathcal{F}$ and the scalar multiplication $ku \in \mathcal{F}$ for $k \in \mathbb{R}\backslash\{0\}$ have membership functions (extension principle)

$$\mu_{u+v}(z) = \sup\{\min\{\mu_u(x), \mu_v(y)\} | z = x+y\} \quad (7)$$

$$\mu_{ku}(x) = \mu_u(\frac{x}{k}) \quad (8)$$

and level cuts

$$[u+v]_\alpha = [u]_\alpha + [v]_\alpha \quad (9)$$
$$= \{x+y | x \in [u]_\alpha,\ y \in [v]_\alpha\}$$
$$[ku]_\alpha = k[u]_\alpha = \{kx | x \in [u]_\alpha\}. \quad (10)$$

We denote by $[u_\alpha^-, u_\alpha^+], \forall \alpha \in [0,1]$ the level-cuts of $u \in \mathcal{F}$ and by $[\widehat{u}^-, \widehat{u}^+]$ its core (level set at $\alpha = 1$). If $u_\alpha^- = \widehat{u}^-$ and $u_\alpha^+ = \widehat{u}^+, \forall \alpha \in [0,1]$ we have a crisp interval or a crisp number. We say that u is positive if $u_\alpha^- > 0$, $\forall \alpha \in [0,1]$ and that u is negative if $u_\alpha^+ < 0, \forall \alpha \in [0,1]$.

Definition (*LR-fuzzy number*): An LR-fuzzy number (or interval) u has membership function of the form

$$\mu_u(x) = \begin{cases} L(\frac{x-a}{b-a}) & \text{if } x \in [a,b] \\ 1 & \text{if } x \in [b,c] \\ R(\frac{d-x}{d-c}) & \text{if } x \in [c,d] \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

where $L, R : [0,1] \longrightarrow [0,1]$ are two non-decreasing *shape functions* such that $R(0) = L(0) = 0$ and $R(1) = L(1) = 1$. If $b = c$ we obtain a fuzzy number. The support is the compact interval $[a,d]$ and the core is $[b,c]$.

If L and R are invertible functions, then the $\alpha - cuts$ are obtained by

$$[u]_\alpha = [u_\alpha^-, u_\alpha^+] \quad (12)$$
$$\text{with}$$
$$u_\alpha^- = a + (b-a)L^{-1}(\alpha)$$
$$u_\alpha^+ = d - (d-c)R^{-1}(\alpha)$$

The usual LR-fuzzy notation is $u = \langle a,b,c,d\rangle_{L,R}$ for an interval and $u = \langle a,b,c\rangle_{L,R}$ for a number. We refer to functions $L(.)$ and $R(.)$ as the left and right branches (shape functions) of u, respectively and to the functions $u_{(.)}^-$ and $u_{(.)}^+$ as the lower and upper branches on u, respectively. Note that, in the representation (12), we have $u_0^- = a$, $u_1^- = b$, $u_1^+ = c$ and $u_0^+ = d$.

2.1 Parametric LR-fuzzy numbers

In this section we present the basic elements of a parametric representation of the shape functions based on monotonic Hermite-type interpolation. We first introduce some models for differentiable monotonic shape functions $p : [0,1] \longrightarrow [0,1]$ such that $p(0) = 0$ and $p(1) = 1$ with $p(t)$ differentiable and increasing on $[0,1]$; for any given nonnegative parameters $\beta_i \geq 0$, $i = 0,1$ we consider functions $p : [0,1] \longrightarrow [0,1]$ satisfying the four Hermite interpolation conditions

$$p(0) = 0,\ p(1) = 1$$
$$p'(0) = \beta_0,\ p'(1) = \beta_1.$$

We obtain infinite many functions simply by fixing the two parameters β_i that give the slopes (first derivatives) of the function at $t = 0$ and $t = 1$. To explicit the slope parameters we denote the interpolating function p by

$$t \longrightarrow p(t; \beta_0, \beta_1) \text{ for } t \in [0,1].$$

We recall here two of the basic forms from [5]:

∘ (2,2)-rational spline:

$$p(t; \beta_0, \beta_1) = \frac{t^2 + \beta_0 t(1-t)}{1 + (\beta_0 + \beta_1 - 2)t(1-t)}; \quad (13)$$

∘ mixed exponential spline:

$$p(t; \beta_0, \beta_1) = \frac{1}{m}[t^2(3-2t) - \beta_0(1-t)^m + \beta_0 + \beta_1 t^m] \quad (14)$$
$$\text{where } m = 1 + \beta_0 + \beta_1.$$

Both functions p in (13) and (14) are strictly increasing on [0,1] and we obtain a linear $p(t) = t, \forall t \in [0,1]$ if $\beta_0 = \beta_1 = 1$ and a quadratic $p(t) = t^2 + \beta_0 t(1-t)$ if $\beta_0 + \beta_1 = 2$ with $\beta_0 \neq 1$.

The (parametric) monotonic functions like (13) and (14) can be used as models for the shape functions L and R; in fact, if $a \leq b \leq c \leq d$ and $\beta_{0,L}, \beta_{1,L} \geq 0$, $\beta_{0,R}, \beta_{1,R} \geq 0$ are given, we obtain an LR-fuzzy number with the membership function

$$\mu_u(x) = \begin{cases} p(\frac{x-a}{b-a}; \beta_{0,L}, \beta_{1,L}) & \text{if } x \in [a,b] \\ 1 & \text{if } x \in [b,c] \\ p(\frac{x-d}{c-d}; \beta_{0,R}, \beta_{1,R}) & \text{if } x \in [c,d] \\ 0 & \text{otherwise} \end{cases}. \quad (15)$$

To make a uniform notation,we denote a, b, c, d as $a = u_{0,L}$, $b = u_{1,L}$, $c = u_{1,R}$, $d = u_{0,R}$ and $\beta_{0,L}^* = \frac{\beta_{0,i}}{b-a}$, $\beta_{1,L}^* = \frac{\beta_{1,i}}{b-a}$, $\beta_{0,R}^* = \frac{\beta_{0,j}}{c-d}$, $\beta_{1,R}^* = \frac{\beta_{1,j}}{c-d}$; so, the eight parameters completely define u:

$$u = (u_{0,L}, \beta_{0,L}^*, u_{0,R}, \beta_{0,R}^*; u_{1,L}, \beta_{1,L}^*, u_{1,R}, \beta_{1,R}^*) \quad (16)$$

provided that $u_{0,L} \leq u_{1,L} \leq u_{1,R} \leq u_{0,R}$ and $\beta_{0,L}, \beta_{1,L} \geq 0$, $\beta_{0,R}, \beta_{1,R} \geq 0$.

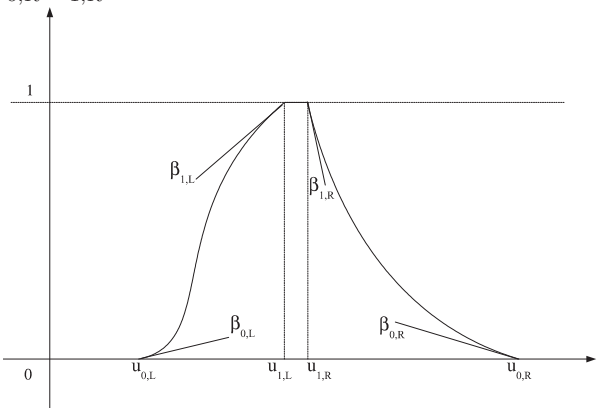

Figure 1: Typical LR parametric membership function

ISBN: 978-989-95079-6-8

Remark: As the nonnegative parameters $\beta_{i,L}$ and $\beta_{i,R}$ ($i = 1, 2$) are completely independent, each side of the membership function may have independent (monotonic) forms, e.g. concavity, convexity, inflextions etc. of left and right sides are independent, as illustrated in the figure. The shapes are simply "controlled" by the 4 parameters $\beta_{i,L}$ and $\beta_{i,R}$ ($i = 1, 2$).

Denote by $\mathbb{F}^{LR}$ the set of LR-fuzzy numbers defined by (16). The family of fuzzy numbers $\mathbb{F}^{LR}$, which include triangular and trapezoidal fuzzy numbers if all $\beta_{i,L} = \beta_{i,R} = 1$, are characterized by eight parameters and it appears that the inclusion of the slopes of left and right functions, even without generating piecewise monotonic approximations over subintervals is able to capture much more information than the linear approximation (see [5] and [6]).

The level sets included into the representation are the core and the support. Note that if we are interested to represent exactly the core, the support and the midpoint interval we require $N = 2$, $\alpha_0 = 0$, $\alpha_1 = 0.5$, $\alpha_2 = 1$, the support $[u_{0,L}, u_{0,R}]$ (corresponding to $\alpha = \alpha_0$), the midpoint interval $[u_{1,L}, u_{1,R}]$ (corresponding to $\alpha = \alpha_1$), the core $[u_{2,L}, u_{2,R}]$ (corresponding to $\alpha = \alpha_0$) and the six parameters $\beta_{i,L}, \beta_{i,R} \geq 0$ to model the first derivatives of $\mu_u(x)$ at the extremal point of the three intervals above.

More generally, we can design differentiable parametric shape functions $L()$ and $R()$ by fixing $N + 1$ distinct level sets $0 = \alpha_0 < \alpha_1 < ... < \alpha_N = 1$ and assigning, for each α_i ($i = 0, 1, ..., N$), the four parameters needed for each level.

In this general case, we need the values $u_{i,L}$, $u_{i,R}$ but, instead of the parameters $\beta_{i,L}, \beta_{i,R}$, it is convenient to give directly the first derivatives of $\mu_u(x)$ at $u_{i,L}$, $u_{i,R}$ and calculate the $\beta_{i,L}, \beta_{i,R} \geq 0$ to use in the monotonic functions like (13) and (14) and model the membership function like (15) piecewise on each subinterval $[u_{i-1,L}, u_{i,L}]$ and $[u_{i,R}, u_{i-1,R}]$.

For $i = 0, 1, ..., N$, denote directly by $\delta u_{i,L} \geq 0$ and by $\delta u_{i,R} \leq 0$ the first derivatives of $\mu_u(x)$ at the points $x = u_{i,L}$ and $x = u_{i,R}$, respectively and suppose they are given. The membership function $\mu_u(x)$ is obtained by the following simple procedure:

Assign first $\mu_u(x) = 0$ for all x;
for all $x \in [u_{N,L}, u_{N,R}]$ set $\mu_u(x) = 1$;
for $i = 1, 2, ..., N$
  for $x \in [u_{i-1,L}, u_{i,L}]$ set
    $\beta_0 = \frac{u_{ni} - u_{n-1,i}}{\alpha_n - \alpha_{n-1}} \delta u_{i-1,L}$
    $\beta_1 = \frac{u_{ni} - u_{n-1,i}}{\alpha_n - \alpha_{n-1}} \delta u_{i,L}$
    $\mu_u(x) = \alpha_{i-1} + (\alpha_i - \alpha_{i-1}) p(\frac{x - u_{n-1,i}}{u_{ni} - u_{n-1,i}}; \beta_0, \beta_1)$
  end
  for $x \in [u_{i,R}, u_{i-1,R}]$ set
    $\beta_0 = \frac{u_{nj} - u_{n-1,j}}{\alpha_n - \alpha_{n-1}} \delta u_{i-1,R}$
    $\beta_1 = \frac{u_{nj} - u_{n-1,j}}{\alpha_n - \alpha_{n-1}} \delta u_{i,R}$
    $\mu_u(x) = \alpha_{i-1} + (\alpha_i - \alpha_{i-1}) p(\frac{x - u_{n-1,j}}{u_{nj} - u_{n-1,j}}; \beta_0, \beta_1)$
  end
end

Denote by $\mathbb{F}_N^{LR}$ the fuzzy numbers obtained in the form above; as each shape function is monotonic, the left and right branches are monotonic increasing on $[u_{0,L}, u_{N,L}]$ (the left of μ_u) and decreasing on $[u_{N,R}, u_{0,R}]$ (the right of μ_u). The number of parameters is $4N + 4$ and they are simply constrained to be $u_{0,L} \leq ... \leq u_{N,L} \leq u_{N,R} \leq ... \leq u_{0,R}$ and $\delta u_{i,L} \geq 0$ and $\delta u_{i,R} \leq 0$ to ensure monotonicity. In general, we will have $u_{i-1,L} < u_{i,L}$ and $u_{i-1,R} > u_{i,R}$ but it is easy to consider case of equality so that the graph of μ_u is a vertical line (discontinuity) at $u_{i,.}$ if $u_{i-1,.} = u_{i,.}$.

In this general form, an LR fuzzy number is represented as follows:

$$u = (\alpha_i; u_{i,L}, \delta u_{i,L}, u_{i,R}, \delta u_{i,R})_{i=0,1,...,N}. \qquad (17)$$

Example:

Consider a quasi-Gaussian membership function ($m \in \mathbb{R}$, $k, \sigma \in \mathbb{R}^+$; if $k \to +\infty$ the support is unbounded)

$$\mu_{qG}(x) = \begin{cases} \exp(-\frac{(x-m)^2}{2\sigma^2}) & \text{if } m - k\sigma \leq x \leq m + k\sigma \\ 0 & \text{otherwise.} \end{cases} \qquad (18)$$

Its LR parametrization for $m = 0$, $\sigma = 2$, $k = 4$, approximated with $N = 4$ (five points), is

Table 1. LR parametrization of fuzzy number (18)

α_i	$u_{i,L}$	$\delta u_{i,L}$	$u_{i,R}$	$\delta u_{i,R}$
0.0	-8.0	0.00033	8.0	-0.00033
0.25	-3.33022	0.20814	3.33022	-0.20814
0.5	-2.35482	0.29435	2.35482	-0.29435
0.75	-1.51705	0.28445	1.51705	-0.28445
1.0	0.0	0.0	0.0	0.0

It is interesting to note that, in our parametric representation (17) of LR-fuzzy numbers, the membership function has differentiable left and right branches; if we require that $\mu_u(x)$ be differentiable in all the (internal) points of the support of u, in particular also at $x = u_{N,L}$ and $x = u_{N,R}$, we simply need to set $\delta u_{N,L} = 0$ and $\delta u_{N,R} = 0$ in the parametric representation (17). This seems to be an important advantage in all the applications (e.g. fuzzy intelligent systems, neuro-fuzzy learning models) where overall differentiability of μ_u is required.

The generated LR fuzzy numbers form a subspace of the space of fuzzy numbers. In the case of differentiable membership functions, it is immediate to understand that the union of all parametric fuzzy numbers having the form (17) for all integer $N \geq 1$, i.e.

$$\mathcal{F}^{LR} = \bigcup_{N \geq 1} \mathbb{F}_N^{LR},$$

is dense into the space of (differentiable) fuzzy numbers. In fact, each fuzzy number (17) has the property of interpolate (exactly) the values $u_{i,L}, u_{i,R}$ ($i = 0, 1, ..., N$) and it is sufficient to refine the points α_i to obtain any desired precision. In our experience, approximations with values of N from 5 to 20 have in general a very small error, of the order of $10^{-6} - 10^{-2}$.

Following [4], for $p \in [0, \infty]$, we can define a geometric distance $D_p(u, v)$ between fuzzy numbers $u, v \in \mathbb{F}_N^{LR}$, given by

$$D_p^{LR}(u, v) = \left(\sum_{i=0}^{N} |u_{i,L} - v_{i,L}|^p + |u_{i,R} - v_{i,R}|^p \right)^{1/p} + \\ + \left(\sum_{i=0}^{N} |\delta u_{i,L} - \delta v_{i,L}|^p + |\delta u_{i,R} - \delta v_{i,R}|^p \right)^{1/p}$$

and

ISBN: 978-989-95079-6-8

$$D_\infty^{LR}(u,v) = \max_{i=0,\dots,N}\{|u_{i,L}-v_{i,L}|, |u_{i,R}-v_{i,R}|\} + \\ + \max_{i=0,\dots,N}\{|\delta u_{i,L}-\delta v_{i,L}|, |\delta u_{i,R}-\delta v_{i,R}|\}.$$

If we model the LR-fuzzy numbers by a (2,2)-rational spline $p(\alpha;\beta_0,\beta_1)$ like (13) the inverse $p^{-1}(t;\beta_0,\beta_1)$ can be computed analytically as we have to solve the quadratic equation (with respect to α)

$$\alpha^2+\beta_0\alpha(1-\alpha) = t[1+(\beta_0+\beta_1-2)\alpha(1-\alpha)] \text{ i.e.}$$

$$\begin{aligned}(1+A(t))\alpha^2 - A(t)\alpha - t &= 0 \text{ where}\\ A(t) &= -\beta_0+\beta_0 t+\beta_1 t-2t.\end{aligned}$$

If $A(t)=-1$ then the equation is linear and the solution is $\alpha=t$. If $A(t)\neq -1$, then there exist two real solutions $\alpha_1 = \frac{2\sqrt{t}}{2+2A(t)}$, $\alpha_2 = \frac{2\sqrt{t}+2A(t)}{2+2A(t)}$ and we choose the one belonging to $[0,1]$.

3 Fuzzy arithmetic with LR parametrization

The fuzzy extension principle introduced by Zadeh is the basic tool for fuzzy calculus; it extends functions of real numbers to functions of fuzzy numbers and it allows the extension of arithmetic operations and calculus to fuzzy arguments. We have already defined the addition (7) and the scalar multiplication (8).

3.1 Basic arithmetic operators

Let $\circ \in \{+,-,\times,/\}$ one of the four arithmetic operations and let $u,v\in\mathbb{F}_{\mathbb{I}}$ be given fuzzy intervals (or numbers), having $\mu_u(.)$ and $\mu_v(.)$ as membership functions and level-cuts representations $u=(u^-,u^+)$, $v=(v^-,v^+)$; the extension principle for the extension of $\circ$ defines the membership function of $w=u\circ v$ by

$$\mu_{u\circ v}(z) = \sup\{\min\{\mu_u(x),\mu_v(y)\}|z=x\circ y\}. \qquad (19)$$

In terms of the $\alpha-cuts$, the four arithmetic operations and the scalar multiplication for $k\in\mathbb{R}$ are obtained by the well-known *interval arithmetic* (for all $\alpha\in[0,1]$)

Addition ($w=u+v$):
$[u+v]_\alpha = [u_\alpha^- + v_\alpha^-, u_\alpha^+ + v_\alpha^+]$,

Scalar multiplication ($w=ku$):
$[ku]_\alpha = [\min\{ku_\alpha^-, ku_\alpha^+\}, \max\{ku_\alpha^-, ku_\alpha^+\}]$,

Subtraction ($w=u-v$):
$[u-v]_\alpha = [u_\alpha^- - v_\alpha^+, u_\alpha^+ - v_\alpha^-]$,

Multiplication ($w=uv$):
$$\begin{cases}(uv)_\alpha^- = \min\{u_\alpha^-v_\alpha^-, u_\alpha^-v_\alpha^+, u_\alpha^+v_\alpha^-, u_\alpha^+v_\alpha^+\}\\ (uv)_\alpha^+ = \max\{u_\alpha^-v_\alpha^-, u_\alpha^-v_\alpha^+, u_\alpha^+v_\alpha^-, u_\alpha^+v_\alpha^+\}\end{cases},$$

Division ($w=u/v$): if $0\notin[v_0^-, v_0^+]$
$$\begin{cases}(u/v)_\alpha^- = \min\left\{\frac{u_I^-}{v_I^-}, \frac{u_I^-}{v_I^+}, \frac{u_I^+}{v_I^-}, \frac{u_I^+}{v_I^+}\right\}\\ (u/v)_\alpha^+ = \max\left\{\frac{u_I^-}{v_I^-}, \frac{u_I^-}{v_I^+}, \frac{u_I^+}{v_I^-}, \frac{u_I^+}{v_I^+}\right\}\end{cases}.$$

In recent work (see [7]) the following generalized subtraction has been defined and analyzed:

Definition: Let u,v be two fuzzy numbers; we define the generalized Hukuhara difference (gH-difference for short) of u and v as the fuzzy number w such that

$$u\ominus_g v = w \iff \begin{cases}(i) & u=v+w\\ \text{or} & (ii)\quad v=u-w\end{cases}. \qquad (20)$$

The α-cuts of both $u\ominus_g v$ can be expressed in terms of the α-cuts of u and v; but it is possible that $u\ominus_g v$ is not well defined; by the use of the parametrization (17) it is easy to test if the operation is well defined or not.

Consider two LR-fuzzy numbers u and v ($N=1$ for simplicity)

$$\begin{aligned}u &= (u_{0,L},\delta u_{0,L},u_{0,R},\delta u_{0,R}; \qquad (21)\\ &\quad u_{1,L},\delta u_{1,L},u_{1,R},\delta u_{1,R}),\\ v &= (v_{0,L},\delta v_{0,L},v_{0,R},\delta v_{0,R}; \qquad (22)\\ &\quad v_{1,L},\delta v_{1,L},v_{1,R},\delta v_{1,R}).\end{aligned}$$

Note that in the formulas below u and v are not restricted to have the same $L(.)$ and $R(.)$ shape functions and changing the slopes will change the form of the membership functions (in all the cases below, eventually assume $\frac{0}{0}=0$).

The values and the slopes at the considered α-cuts are computed exactly; in fact we use the exact standard formulae for the derivative of addition, multiplication, division and function composition. Corresponding to membership values $\alpha\neq\alpha_i$, $i=0,1,...,N$, the membership functions is approximated by using the rational (13) or the mixed (14) shape functions.

The approximate addition is the following

$$(u+v) = \left(\begin{array}{l} u_{0,L}+v_{0,L}, \frac{\delta u_{0,i}\,\delta v_{0,i}}{\delta u_{0,i}+\delta v_{0,i}},\\ u_{0,R}+v_{0,R}, \frac{\delta u_{0,j}\,\delta v_{0,j}}{\delta u_{0,j}+\delta v_{0,j}};\\ u_{1,L}+v_{1,L}, \frac{\delta u_{1,i}\,\delta v_{1,i}}{\delta u_{1,i}+\delta v_{1,i}},\\ u_{1,R}+v_{1,R}, \frac{\delta u_{1,j}\,\delta v_{1,j}}{\delta u_{1,j}+\delta v_{1,j}}\end{array}\right).$$

Nothe that if the left and right shapes of u and v are the same (e.g. linear, quadratic) then the addition is exact.

The general algorithm for approximate LR addition is
Algorithm (*LR addition*) $w=u+v$
for $i=0,1,...,N$
$w_{i,L}=u_{i,L}+v_{i,L}$, $w_{i,R}=u_{i,R}+v_{i,R}$
$\delta w_{i,L}=\frac{\delta u_{n_i}\,\delta v_{n_i}}{\delta u_{n_i}+\delta v_{n_i}}$, $\delta w_{i,R}=\frac{\delta u_{n_j}\,\delta v_{n_j}}{\delta u_{n_j}+\delta v_{n_j}}$
end

The difference $w=u-v$ is similar
Algorithm (*LR subtraction*) $w=u-v$
for $i=0,1,...,N$
$w_{i,L}=u_{i,L}-v_{i,R}$, $w_{i,R}=u_{i,R}-v_{i,L}$
$\delta w_{i,L}=\frac{\delta u_{n_i}\,\delta v_{n_j}}{\delta v_{n_j}-\delta u_{n_j}}$, $\delta w_{i,R}=\frac{\delta u_{n_j}\,\delta v_{n_i}}{\delta v_{n_i}-\delta u_{n_j}}$
end

Also the approximate multiplication $w=uv$ can be obtained easily; in the case of two positive LR-fuzzy numbers w is given by

$$w_{LR} = \left(\begin{array}{l} u_{0,L}v_{0,L}, \frac{\delta u_{0,i}\,\delta v_{0,i}}{v_{0,i}\,\delta v_{0,i}+u_{0,i}\,\delta u_{0,i}},\\ u_{0,R}v_{0,R}, \frac{\delta u_{0,j}\,\delta v_{0,j}}{v_{0,j}\,\delta v_{0,j}+u_{0,j}\,\delta u_{0,j}};\\ u_{1,L}v_{1,L}, \frac{\delta u_{1,i}\,\delta v_{1,i}}{v_{1,i}\,\delta v_{1,i}+u_{1,i}\,\delta u_{1,i}},\\ u_{1,R}v_{1,R}, \frac{\delta u_{1,j}\,\delta v_{1,j}}{v_{1,j}\,\delta v_{1,j}+u_{1,j}\,\delta u_{1,j}}\end{array}\right).$$

ISBN: 978-989-95079-6-8

The general algorithm for approximate LR multiplication is

Algorithm (*LR multiplication*) $w = uv$
(eventually, use $\frac{0}{0} = 0$)
for $i = 0, 1, ..., N$
$m_i = \min\{u_{i,L}v_{i,L}, u_{i,L}v_{i,R}, u_{i,R}v_{i,L}, u_{i,R}v_{i,R}\}$
$M_i = \max\{u_{i,L}v_{i,L}, u_{i,L}v_{i,R}, u_{i,R}v_{i,L}, u_{i,R}v_{i,R}\}$
$w_{i,L} = m_i \ , \ w_{i,R} = M_i$
if $u_{i,L}v_{i,L} = m_i$ **then** $\delta w_{i,L} = \frac{\delta u_{n_i}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} + u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,L}v_{i,R} = m_i$ **then** $\delta w_{i,L} = \frac{\delta u_{n_i}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} + u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,R}v_{i,L} = m_i$ **then** $\delta w_{i,L} = \frac{\delta u_{n_j}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} + u_{n_j}\, \delta u_{n_j}}$
elseif $u_{i,R}v_{i,R} = m_i$ **then** $\delta w_{i,L} = \frac{\delta u_{n_j}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} + u_{n_j}\, \delta u_{n_j}}$
endif
if $u_{i,L}v_{i,L} = M_i$ **then** $\delta w_{i,R} = \frac{\delta u_{n_i}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} + u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,L}v_{i,R} = M_i$ **then** $\delta w_{i,R} = \frac{\delta u_{n_i}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} + u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,R}v_{i,L} = M_i$ **then** $\delta w_{i,R} = \frac{\delta u_{n_j}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} + u_{n_j}\, \delta u_{n_j}}$
elseif $u_{i,R}v_{i,R} = M_i$ **then** $\delta w_{i,R} = \frac{\delta u_{n_j}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} + u_{n_j}\, \delta u_{n_j}}$
endif
end

The division is similar:

Algorithm (*LR division*) $w = u/v$, $0 \notin [v]_0$
(eventually, use $\frac{0}{0} = 0$)
for $i = 0, 1, ..., N$
$m_i = \min\{u_{i,L}/v_{i,L}, u_{i,L}/v_{i,R}, u_{i,R}/v_{i,L}, u_{i,R}/v_{i,R}\}$
$M_i = \max\{u_{i,L}/v_{i,L}, u_{i,L}/v_{i,R}, u_{i,R}/v_{i,L}, u_{i,R}/v_{i,R}\}$
$w_{i,L} = m_i \ , \ w_{i,R} = M_i$
if $u_{i,L}/v_{i,L} = m_i$ **then** $\delta w_{i,L} = \frac{v_{n_i}^2\, \delta u_{n_i}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} - u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,L}/v_{i,R} = m_i$ **then** $\delta w_{i,L} = \frac{v_{n_j}^2\, \delta u_{n_i}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} - u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,R}/v_{i,L} = m_i$ **then** $\delta w_{i,L} = \frac{v_{n_i}^2\, \delta u_{n_j}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} - u_{n_j}\, \delta u_{n_j}}$
elseif $u_{i,R}/v_{i,R} = m_i$ **then** $\delta w_{i,L} = \frac{v_{n_j}^2\, \delta u_{n_j}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} - u_{n_j}\, \delta u_{n_j}}$
endif
if $u_{i,L}/v_{i,L} = M_i$ **then** $\delta w_{i,R} = \frac{v_{n_i}^2\, \delta u_{n_i}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} - u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,L}/v_{i,R} = M_i$ **then** $\delta w_{i,R} = \frac{v_{n_j}^2\, \delta u_{n_i}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} - u_{n_i}\, \delta u_{n_i}}$
elseif $u_{i,R}/v_{i,L} = M_i$ **then** $\delta w_{i,R} = \frac{v_{n_i}^2\, \delta u_{n_j}\, \delta v_{n_i}}{v_{n_i}\, \delta v_{n_i} - u_{n_j}\, \delta u_{n_j}}$
elseif $u_{i,R}/v_{i,R} = M_i$ **then** $\delta w_{i,R} = \frac{v_{n_j}^2\, \delta u_{n_j}\, \delta v_{n_j}}{v_{n_j}\, \delta v_{n_j} - u_{n_j}\, \delta u_{n_j}}$
endif
end

The algorithm for the gH-difference $w = u \ominus_g v$ in LR form is also easy, if we recall that the α-cuts of w are the intervals (see [7]) $[\min\{u_\alpha^- - v_\alpha^-, u_\alpha^+ - v_\alpha^+\}, \max\{u_\alpha^- - v_\alpha^-, u_\alpha^+ - v_\alpha^+\}]$:

Algorithm (*LR gH-subtraction*) $w = u \ominus_g v$
(eventually, use $\frac{0}{0} = 0$)
for $i = 0, 1, ..., N$
define $d_{i,L} = u_{i,L} - v_{i,L}$ and $d_{i,R} = u_{i,R} - v_{i,R}$
if $d_{i,L} < d_{i,R}$ **then**
$w_{i,L} = d_{i,L}$, $w_{i,R} = d_{i,R}$
$\delta w_{i,L} = \frac{\delta u_{n_i}\, \delta v_{n_i}}{\delta v_{n_i} - \delta u_{n_i}}$, $\delta w_{i,R} = \frac{\delta u_{n_j}\, \delta v_{n_j}}{\delta v_{n_j} - \delta u_{n_j}}$
elseif $d_{i,L} > d_{i,R}$ **then**
$w_{i,R} = d_{i,L}$, $w_{i,L} = d_{i,R}$
$\delta w_{i,R} = \frac{\delta u_{n_i}\, \delta v_{n_i}}{\delta v_{n_i} - \delta u_{n_i}}$, $\delta w_{i,L} = \frac{\delta u_{n_j}\, \delta v_{n_j}}{\delta v_{n_j} - \delta u_{n_j}}$
else (here $d_{i,L} = d_{i,R} = d$)
$w_{i,L} = d$, $w_{i,R} = d$
$\delta w_{i,L} = 0$, $\delta w_{i,R} = 0$
endif
end
Test if the calculated $w_{i,L}, w_{i,R}$ are ordered correctly and $\delta w_{i,L} \geq 0, \delta w_{i,R} \leq 0$, then w is $u \ominus_g v$.

The operations above are exact at the nodes $\alpha = \alpha_i$, $i = 0, 1, ..., N$, and have very small global errors for all $\alpha \in [0, 1]$ (if N is sufficiently high, of the order of 5 to 20). Further, it is easy to control the error by using a sufficiently fine $\alpha-$decomposition and the results have shown that both the rational (13) and the mixed (14) models perform well.

Some parametric membership functions in the LR framework are present in many applications and the use of nonlinear shapes in increasing. Usually, one defines a given family, e.g. linear, quadratic, sigmoid, quasi gaussian, and the operations are performed within the same family.

Our proposed parametrization allows an extended set of flexible fuzzy numbers and is able to approximate all other forms with acceptable small errors and the additional advantage of producing good approximations to the results of the arithmetic operations even between LR fuzzy numbers having very different original shapes.

Furthermore, at the explicitly considered $\alpha-$cuts of the decomposition, all the values $w_{i,L}$, $w_{i,R}$ and the slopes $\delta w_{i,L}$, $\delta w_{i,R}$ $(i = 0, 1, ..., N)$ of the membership function are exact.

3.2 Computation of fuzzy-valued functions

For a continuous function $f : \mathbb{R}^n \to \mathbb{R}$, let $v = f(u_1, u_2, ..., u_n)$ denote its fuzzy extension, based on the application of the Zadeh's Extension Principle (EP for short). It is well known that the $\alpha - cuts$ $[v_\alpha^-, v_\alpha^+]$ of v are obtained by solving the following box-constrained global optimization problems ($\alpha \in [0, 1]$)

$$v_\alpha^- = \min\{f(x_1, ..., x_n) | x_k \in [u_k]_\alpha,\ k = 1, 2, ..., n\} \quad (23)$$

$$v_\alpha^+ = \max\{f(x_1, ..., x_n) | x_k \in [u_k]_\alpha,\ k = 1, 2, ..., n\} \quad (24)$$

where $[u_k]_\alpha = [u_{k,\alpha}^-, u_{k,\alpha}^+]$, $k = 1, 2, ..., n$, are the $\alpha - cuts$ of u_k.

The lower and upper values v_α^- and v_α^+ of v define equivalently (as f is assumed to be continuous) the image of the cartesian product $\underset{k=1}{\overset{n}{\times}} [u_k]_\alpha$ via f, i.e. $[v_\alpha^-, v_\alpha^+] = f([u_1]_\alpha, ..., [u_n]_\alpha)$.

Except for simple elementary cases for which the optimization problems above can be solved analytically, the direct application of (23) and (24) is difficult and computationally expensive (see [6]).

At least if f is differentiable, the advantages of the LR representation appear to be quite interesting, based on the fact that a small number of α points is in general sufficient to obtain good approximations (this is the essential gain in using the slopes to model fuzzy numbers), so reducing the number of constrained *min* (23) and *max* (24) problems to be solved directly. On the other hand, finding computationally efficient extension solvers is still an open research field in fuzzy calculations.

We now give the details of the fuzzy extension of general differentiable functions of only one variable, by the LR representation. The case of multidimensional differentiable functions can be approached in a similar way, by considering the

ISBN: 978-989-95079-6-8

partial derivatives of $f : \mathbb{R}^n \longrightarrow \mathbb{R}$ and the chain rules for the composition of multidimensional functions.

In all the computations we will adopt the EP method, but also if other approaches are adopted, the representation still remains valid.

Let $f : \mathbb{R} \to \mathbb{R}$; its *(EP)*-extension $v = f(u)$ to a fuzzy argument $u = (u^-, u^+)$ has $\alpha - cuts$

$$[v]_\alpha = [\min\{f(x) \mid x \in [u]_\alpha\}, \max\{f(x) \mid x \in [u]_\alpha\}]. \tag{25}$$

If f is monotonic increasing we obtain $[v]_\alpha = [f(u_\alpha^-), f(u_\alpha^+)]$ while, if f is monotonic decreasing, $[v]_\alpha = [f(u_\alpha^+), f(u_\alpha^-)]$; for simplicity, in the monotonic case we assume that the derivative of f is not null over the support of u, but it is possible to design the algorithm also in the case where, for some α, $f'(u_\alpha^+) = 0$ or $f'(u_\alpha^-) = 0$.

The LR representation of $v = (\alpha_i;\ v_{i,L}, \delta v_{i,L}, v_{i,R}, \delta v_{i,R})_{i=0,1,...,N}$ is obtained by the following algorithm:

Algorithm: (1-dim monotonic extension)

Let $u = (\alpha_i; u_{i,L}, \delta u_{i,L}, u_{i,R}, \delta u_{i,R})_{i=0,1,...,N}$ be given and $f : [u_{0,L}, u_{0,R}] \to \mathbb{R}$ be differentiable and monotonic; calculate $v = f(u)$.

for $i = 0, 1, ..., N$
  if (f is increasing) **then**
    $v_{i,L} = f(u_{i,L}),\ \delta v_{i,L} = \frac{\delta u_{n,i}}{f'(u_{n,i})}$
    $v_{i,R} = f(u_{i,R}),\ \delta v_{i,R} = \frac{\delta u_{n,j}}{f'(u_{n,j})}$
  elseif (f is decreasing) **then**
    $v_{i,L} = f(u_{i,R}),\ \delta v_{i,L} = \frac{\delta u_{n,j}}{f'(u_{n,j})}$
    $v_{i,R} = f(u_{i,R}),\ \delta v_{i,R} = \frac{\delta u_{n,j}}{f'(u_{n,j})}$
  endif
end

As an example, the monotonic exponential function $f(x) = \exp(x)$ has LR-fuzzy extension

$$\exp(u) = (\alpha_i; \exp(u_{i,L}), \exp(u_i^-)\,\delta u_{i,L}/\exp(u_{i,L}), \exp(u_{i,R}), \delta u_{i,R}/\exp(u_{i,R}))_{i=0,1,...N}$$

In the non monotonic (differentiable) case, we have to solve the optimization problems in (25) for each $\alpha = \alpha_i$, $i = 0, 1, ..., N$, i.e.

$$(EP_i): \begin{cases} v_{i,L} = \min\{f(x) | x \in [u_{i,L}, u_{i,R}]\} \\ v_{i,R} = \max\{f(x) | x \in [u_{i,L}, u_{i,R}]\}. \end{cases}$$

The $\min$ (or the $\max$) can occur either at a point which is coincident with one of the extremal values of $[u_{i,L}, u_{i,R}]$ or at a point which is internal; in the last case, the derivative of f is null and $\delta v_{i,L} = +\infty$ (or $\delta v_{i,R} = -\infty$).

In the calculations, we "approximate" $\pm\infty$ by $\pm BIG$ where BIG is a big positive number.

Algorithm: (1-dim non monotonic LR extension)

Let $u = (\alpha_i; u_{i,L}, \delta u_{i,L}, u_{i,R}, \delta u_{i,R})_{i=0,1,...,N}$ be given and $f : [u_{0,L}, u_{0,R}] \to \mathbb{R}$ be differentiable and monotonic; calculate $v = f(u)$.

for $i = 0, 1, ..., N$
  solve $\min\{f(x) | x \in [u_{i,L}, u_{i,R}]\}$
  let $\widehat{x}_i = \arg\min\{f(x) | x \in [u_{i,L}, u_{i,R}]\}$
  if $\widehat{x}_i = u_{i,L}$ **then** $v_{i,L} = f(u_{i,L}),\ \delta v_{i,L} = \frac{\delta u_{n,i}}{f'(u_{n,i})}$
  elseif $\widehat{x}_i = u_{i,R}$ **then** $v_{i,L} = f(u_{i,R}), \delta v_{i,L} = \frac{\delta u_{n,j}}{f'(u_{n,j})}$
  else $v_{i,L} = f(\widehat{x}_i),\ \delta v_{i,L} = BIG$
  endif
  solve $\max\{f(x) | x \in [u_{i,L}, u_{i,R}]\}$
  let $\widehat{x}_i = \arg\max\{f(x) | x \in [u_{i,L}, u_{i,R}]\}$
  if $\widehat{x}_i = u_{i,L}$ **then** $v_{i.R} = f(u_{i,L}), \delta v_{i,R} = \frac{\delta u_{n,i}}{f'(u_{n,i})}$
  elseif $\widehat{x}_i = u_{i,R}$ **then** $v_{i,R} = f(u_{i,R}), \delta v_{i,R} = \frac{\delta u_{n,j}}{f'(u_{n,j})}$
  else $v_{i,R} = f(\widehat{x}_i),\ \delta v_{i,R} = -BIG$
  endif
end

4 Conclusion and further work

We suggest a parametrization of LR fuzzy numbers u by the use of parametric monotonic (simple) functions to model the left and the right branches of u. The obtained parametrizations form a subspace of the space of fuzzy numbers and can be possibly be refined to become a dense subspace. Within the parametrizations, we define arithmetic operators for the basic arithmetic and for the fuzzy extension of functions by the application of Zadeh's extension principle.

Type-2 Fuzzy Arithmetic using Alpha-planes

Hussam Hamrawi Simon Coupland

Centre for Computational Intelligence, Faculty of Technology, De Montfort University
Leicester, UK
Email: hussamw@dmu.ac.uk, simonc@dmu.ac.uk

Abstract— This paper examines type-2 fuzzy arithmetic using interval analysis. It relies heavily on alpha-cuts and alpha-planes. Furthermore, we discuss the use of quasi type-2 fuzzy sets proposed by Mendel and Liu and define quasi type-2 fuzzy numbers. Arithmetic operations of such numbers are defined and a worked example is presented.

Keywords— Fuzzy Arithmetic, Type-2 Fuzzy Arithmetic, Type-2 Fuzzy Numbers, Quasi Type-2 Fuzzy Numbers.

1 Introduction

Zadeh introduced the concept of type-2 fuzzy sets in the first of a trio of papers in 1975 [1]. In these papers he also defined linguistic variables, interval-valued fuzzy sets and their representations using the resolution identity (later known as α-cuts). Type-2 fuzzy logic has gained much attention recently due to its ability to handle uncertainty [2], and many advances appeared in both theory and applications [3, 4, 5]. Type-2 fuzzy numbers and the associated arithmetic operations have not received the same attention, only two main contributions appear in the literature that specificly target arithmetic operations using the representation theorem and the extension principle [6, 7]. Recent work on fuzzy systems has proposed an extension to α-cuts for type-2 fuzzy sets through the notion of α-planes [8]. Further work by Mendel and Liu [9] defined a quasi type-2 fuzzy logic system as a restricted special case of a type-2 fuzzy logic system represented by its α-planes.

In this paper we examine type-2 fuzzy arithmetic through α-planes. We use arithmetic operations on type-1 and interval type-2 fuzzy sets through their α-cut representation, moreover, we define quasi type-2 fuzzy numbers and derive their arithmetic operations.

This paper is organised as follows: Section 2 reviews some basic type-2 fuzzy set definitions used in this paper; Section 3 defines type-2 fuzzy numbers and quasi type-2 fuzzy numbers; Section 4 derives the arithmetic operations for these numbers; Section 5 provides a worked example; finally Section 6 provides a conclusion.

2 Type-2 Fuzzy Sets

We present a review of the basic terminology used in this paper. A type-2 fuzzy set (**T2FS**) [2, 10] is defined by equation (1)

$$\widetilde{A} = \int_{\forall x \in X} \int_{\forall u \in J_x \subseteq [0,1]} \mu_{\widetilde{A}}(x,u)/(x,u) \qquad (1)$$

where $\int\int$ denotes the union over all admissible *domain values* x and *secondary domain values* u, and $\mu_{\widetilde{A}}(x,u)$ is a *type-2 membership function*, a T2FS is three dimensional (3D). The *Vertical Slice* (**VS**) is the two dimensional (2D) plane in the u and $\mu_{\widetilde{A}}(x,u)$ axes for a single value of $x = x^{'}$, then the VS is defined by equation (2).

$$VS(x^{'}) = \mu_{\widetilde{A}}(x^{'},u) \equiv \mu_{\widetilde{A}}(x^{'}) = \int_{u \in J_{x^{'}}} f_{x^{'}}(u)/u \qquad (2)$$

where $f_{x^{'}}(u) \in [0,1]$ is called the *secondary grade* and J_x represents the domain of the *secondary membership function* called the *secondary domain*, of course the VS is a *type-1 fuzzy set* (**T1FS**) in $[0,1]$. The *Vertical Slice Representation* (**VSR**) of T2FS is represented by the union of all the vertical slices

$$\widetilde{A} = \{(x, \mu_{\widetilde{A}}(x)) | \forall x \in X\} \qquad (3)$$

The *Footprint Of Uncertainty* (**FOU**) is derived from the union of all primary memberships

$$FOU(\widetilde{A}) = \int_{x \in X} J_x \qquad (4)$$

Another important notion is the *principal membership function* (**PrMF**) defined as the union of all the primary memberships having secondary grades equal to 1

$$Pr(\widetilde{A}) = \int_{x \in X} u/x | f_x(u) = 1 \qquad (5)$$

This notion allows us to view a T1FS as special case of T2FS in which its PrMF is obtained for only one primary membership having a secondary grade at unity [11, 12]. Based on [2] the FOU is described to be bounded by two membership functions a lower $\underline{\mu_{\widetilde{A}}(x)}$ and an upper $\overline{\mu_{\widetilde{A}}(x)}$. The FOU can be described in terms of its upper and lower membership functions (**MF**s)

$$FOU(\widetilde{A}) = \int_{x \in X} \left[\underline{\mu_{\widetilde{A}}(x)}, \overline{\mu_{\widetilde{A}}(x)}\right] \qquad (6)$$

Interval type-2 fuzzy set (**IT2FS**) is defined to be a T2FS where all its secondary grades are of unity $\forall f_x(u) = 1$. A IT2FS can be completely determined using its FOU given in equation (6). Recalling from Zadeh [1] an *α-level set*, A_α, that comprises of elements $x \in X$ of a type-1 fuzzy subset A of universe X

$$A_\alpha = \{x | \mu_A(x) \geq \alpha\} \qquad (7)$$

where $\alpha \in [0,1]$, the fuzzy set A can be represented (decomposed) as

$$A = \bigcup_{\alpha \in [0,1]} \alpha.A_\alpha \qquad (8)$$

ISBN: 978-989-95079-6-8

where $\mu_A(x) = \sup_{x \in A_\alpha} \alpha$ and (sup) denotes the supremum, this decomposition theorem [13] is called the *α-cut Representation*. The same analogy is used by Tahayori *et al.* [14]:

$$\widetilde{A}_{\widetilde{\alpha}} = \{(x,u) | f_x(u) \geq \widetilde{\alpha}\} \tag{9}$$

and the T2FS $\widetilde{A}$ can be represented (decomposed) as

$$\widetilde{A} = \bigcup_{\widetilde{\alpha} \in [0,1]} \widetilde{\alpha}.\widetilde{A}_{\widetilde{\alpha}} \tag{10}$$

where[1] $f_x(u) = \sup_{(x,u) \in \widetilde{A}_{\widetilde{\alpha}}} \widetilde{\alpha}$. Liu [8] calls equation (9) an *α-plane* due to its 2D nature and consequently equation (10) is called the *α-plane Representation*. Liu [8] and Wagner and Hagras [15] noted that when $\widetilde{\alpha} = 0$, $\widetilde{A}_{\widetilde{\alpha}}$ is actually the FOU and Liu and Mendel [9] generalise it to a footprint of uncertainty at plane $\widetilde{\alpha}$ denoted by $FOU(\widetilde{A}_{\widetilde{\alpha}})$. We are interested in the use of this representation as these α-planes can compute some of T2FS operations using IT2FS operations by applying Zadeh's extension principle [1] as follows

$$f(\widetilde{A}) = f(\bigcup_{\widetilde{\alpha} \in [0,1]} \widetilde{\alpha}.\widetilde{A}_{\widetilde{\alpha}}) = \bigcup_{\widetilde{\alpha} \in [0,1]} \widetilde{\alpha}.f(\widetilde{A}_{\widetilde{\alpha}}) \tag{11}$$

As Zadeh himself noted that this principle can be used with functions between sets, relations, etc. and it can extend any function from crisp sets to its fuzzy and obviously type-2 fuzzy counterparts. In [9] based on observations about the shape of the centroid Liu and Mendel defined the notion of *quasi type-2 fuzzy logic system* (QT2FLS). They propose approximating the T2FS using two α-planes ($\widetilde{A}_{\widetilde{\alpha}=0}$ and $\widetilde{A}_{\widetilde{\alpha}=1}$). Great use of these methods is made later in this paper.

3 Type-2 Fuzzy Numbers

A type-1 fuzzy number (T1FN) is defined as a fuzzy set that is both normal and convex [16, 17]. Normality is required in order to capture the concept of a fuzzy number being a set of real numbers close to a specific crisp number [13], in other words when all the uncertainty about a number disappears it reduces to a crisp number. Convexity is required as it allows meaningful arithmetic operations to be performed on fuzzy sets using the well established methods from interval analysis since α-level sets are closed intervals [13]. Coupland *et al.* [6, 7] define a type-2 fuzzy number (T2FN) as a type-2 fuzzy set having a numerical domain. Although no assumption for normality has been defined for these T2FN the examples used assumed normality. From another perspective within the framework of interval-valued fuzzy sets (IVFS) [18], which are equal to IT2FS [5, 19], interval-valued fuzzy numbers (IVFN) are defined to be convex and normal [20, 21]. Here it is desired to define a host of cases that may be conceived to qualify as T2FN. First normality is defined, recalling its definition within the context of T1FN.

Definition 3.1 (Normal T1FS) *A T1FS, A, is said to be normal if its height $h(A)$ is equal to 1 i.e. $\sup \mu_A(x) = 1$.*

Whenever a T1FS is not normal it is called *subnormal*. In IT2FS we differentiate between two cases of normality, one when both the upper and lower MFs are normal, and the other when only the upper T1FS is normal.

[1] Here $\widetilde{\alpha}$ is used instead of α to distinguish that these are α-cuts in the third dimension.

Definition 3.2 (Normal IT2FS) *A IT2FS, $\widetilde{A}$, is said to be normal if its upper MF is normal i.e. $\sup \overline{\mu_A(x)} = 1$.*

Note that there is a point in which a crisp number can be reached which is only depending on the upper MF, this can be seen as a less restrictive condition and is widely used in applications (e.g. Computing with words [22]).

Definition 3.3 (Perfectly Normal IT2FS) *A IT2FS, $\widetilde{A}$, is said to be perfectly[2] normal if both its upper and lower MFs are normal i.e. $\sup \overline{\mu_A(x)} = \sup \underline{\mu_A(x)} = 1$.*

Here the crisp number is reached when uncertainties about both the upper and lower MFs disappear, it is more restrictive, but conceptually more appealing since it generalises the concept of normal T1FS with only a single peak point where it is completely crisp. It can be seen as a special case of a normal IT2FS, this is clear in figure (1).

Definition 3.4 (Partially Normal T2FS) *A T2FS, $\widetilde{A}$, is said to be partially normal if its FOU is **a normal IT2FS.***

This is the weakest case in which a T2FS can qualify to be a number. There is an argument, this can not qualify to be a fuzzy number at all as the secondary membership function is clearly not about 1 at any point (i.e $f_x(u) \neq 1, \forall f_x(u)$).

Definition 3.5 (Normal T2FS) *A T2FS, $\widetilde{A}$, is said to be normal if its FOU is **a normal IT2FS** and it has a PrMF.*

Definition 3.6 (Perfectly Normal T2FS) *A T2FS, $\widetilde{A}$, is said to be perfectly normal if its FOU is a perfectly normal IT2FS and it has a PrMF which is normal (i.e. either a normal T1FS or a normal IT2FS).*

Second, recalling the general definition of a T1FN using piecewise-defined functions.

Definition 3.7 (T1FN[13]) *Let A be a fuzzy subset on real numbers. Then, A is a fuzzy number if and only if there exists a closed interval $[m_1, m_2] \neq \phi$ such that*

$$\mu_A(x) = \begin{cases} 1 & x \in [m_1, m_2] \\ l(x) & x \in [s, m_1) \\ r(x) & x \in (m_2, e] \\ 0 & x \in (-\infty, s); x \in (e, \infty) \end{cases} \tag{12}$$

where $l(x) \in [0,1]$ is monotonically increasing and continuous from the right; $r(x) \in [0,1]$ is monotonically decreasing and continuous from the left; $\langle s, m_1, m_2, e \rangle$ are the parameters that define the T1FN.

Observe that if A is subnormal it is not considered a number, but it is useful to define a *type-1 fuzzy sub-number* (T1FsN) which satisfies all the properties of a T1FN except it is subnormal, this can be defined for a fuzzy set A with height $h(A) = \sup_{\forall x} \mu_A(x) = h_A$ as follows

$$\mu_A(x) = \begin{cases} h_A & x \in [m_1, m_2] \\ l(x) & x \in [s, m_1) \\ r(x) & x \in (m_2, e] \\ 0 & x \in (-\infty, s); x \in (e, \infty) \end{cases} \tag{13}$$

[2] this term has been used by Kaufmann and Gupta [17] describing a perfectly triangular T2FN.

ISBN: 978-989-95079-6-8

Using equations (7) and (8) a T1FN can be represented as intervals using their α-cuts $A_\alpha = [a_1^\alpha, a_2^\alpha]$ as follows

$$A = \bigcup_{\forall\alpha} \alpha.[a_1^\alpha, a_2^\alpha] = \bigcup_{\forall\alpha} \alpha.[l^{-1}(\alpha), r^{-1}(\alpha)] \quad (14)$$

IT2FN can be represented by its lower and upper membership functions which themselves are T1FS. Here we use the terms above to define IT2FN. Let $FOU(\widetilde{A}) = [\underline{FOU(\widetilde{A})}, \overline{FOU(\widetilde{A})}]$ [3] to represent a perfectly normal IT2FS defined by its lower and upper membership functions, respectively. Then, using equation (14) individually for each of the memberships, it follows that

$$\underline{FOU(\widetilde{A})} = \bigcup_{\forall\alpha} \alpha.[\underline{a_1^\alpha}, \underline{a_2^\alpha}] = \bigcup_{\forall\alpha} \alpha.[\underline{l^{-1}}(\alpha), \underline{r^{-1}}(\alpha)]$$

$$\overline{FOU(\widetilde{A})} = \bigcup_{\forall\alpha} \alpha.[\overline{a_1^\alpha}, \overline{a_2^\alpha}] = \bigcup_{\forall\alpha} \alpha.[\overline{l^{-1}}(\alpha), \overline{r^{-1}}(\alpha)]$$

then

$$FOU(\widetilde{A}) = \bigcup_{\forall\alpha} \alpha.\left[[\overline{a_1^\alpha}, \underline{a_1^\alpha}], [\underline{a_2^\alpha}, \overline{a_2^\alpha}]\right] \quad (15)$$

for a normal IT2FS with lower membership function height, $h(FOU(\widetilde{A})) = h_l$, a IT2FN can be represented as

$$FOU(\widetilde{A}) = \begin{cases} \bigcup_{\forall\alpha} \alpha.\left[[\overline{a_1^\alpha}, \underline{a_1^\alpha}], [\underline{a_2^\alpha}, \overline{a_2^\alpha}]\right] & \alpha \le h_l \\ \bigcup_{\forall\alpha} \alpha.[\overline{a_1^\alpha}, \overline{a_2^\alpha}] & \alpha > h_l \end{cases} \quad (16)$$

Then a IT2FN can be defined by definition (3.8)

Definition 3.8 (IT2FN)
Let $FOU(\widetilde{A}) = [\underline{FOU(\widetilde{A})}, \overline{FOU(\widetilde{A})}]$ be an interval type-2 fuzzy subset on real numbers. Then, $FOU(\widetilde{A})$ is an interval type-2 fuzzy number if:

- *$\underline{FOU(\widetilde{A})}$ and $\overline{FOU(\widetilde{A})}$ are T1FNs, in this case it is called a perfectly normal IT2FN.*
- *$\underline{FOU(\widetilde{A})}$ is a T1FsN [4] and $\overline{FOU(\widetilde{A})}$ is a T1FN, in this case it is called a normal IT2FN.*

This definition can be seen in figure (1), observe that both IT2FSs are IT2FNs. We can also consider an interval type-2 fuzzy sub-number (IT2FsN) when bothe the upper and lower MFs are T1FsNs. Now, it is desired to define T2FN using the same terminology. From equation (10) a T2FS

$$\widetilde{A} = \bigcup_{\forall\widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{A}_{\widetilde{\alpha}})$$

and using equation (15) a perfectly normal T2FS

$$\widetilde{A} = \bigcup_{\forall\widetilde{\alpha}} \widetilde{\alpha}.(\bigcup_{\forall\alpha} \alpha.\left[[\overline{a_1^\alpha}, \underline{a_1^\alpha}], [\underline{a_2^\alpha}, \overline{a_2^\alpha}]\right]) \quad (17)$$

and using equation (16) a normal T2FS

$$\widetilde{A} = \begin{cases} \bigcup_{\forall\widetilde{\alpha}} \widetilde{\alpha}.(\bigcup_{\forall\alpha} \alpha.\left[[\overline{a_1^\alpha}, \underline{a_1^\alpha}], [\underline{a_2^\alpha}, \overline{a_2^\alpha}]\right]) & \alpha \le h_l \\ \bigcup_{\forall\widetilde{\alpha}} \widetilde{\alpha}.(\bigcup_{\forall\alpha} \alpha.[\overline{a_1^\alpha}, \overline{a_2^\alpha}]) & \alpha > h_l \end{cases} \quad (18)$$

A partially normal T2FS will only require $\forall\widetilde{\alpha}; \widetilde{\alpha} \in [0, \sup_{\forall(x,u)} f_x(u)]$.

[3] FOU is used here since the FOU fully describes the IT2FS.
[4] see equation (13).

Definition 3.9 (T2FN) *Let $\widetilde{A} = \bigcup_{\forall\widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{A}_{\widetilde{\alpha}})$ be a type-2 fuzzy subset on real numbers. Then, $\widetilde{A}$ is a type-2 fuzzy number if:*

- *$FOU(\widetilde{A}_{\widetilde{\alpha}=0})$ is a perfectly normal IT2FN, and $FOU(\widetilde{A}_{\widetilde{\alpha}=1}) = Pr(\widetilde{A})$ is normal (i.e. either a T1FN or a normal IT2FN), in this case it is called a perfectly normal T2FN.*
- *$FOU(\widetilde{A}_{\widetilde{\alpha}=0})$ is a normal IT2FN, and $FOU(\widetilde{A}_{\widetilde{\alpha}=1})$ ($Pr(\widetilde{A})$) exist, in this case it is called a normal T2FN.*
- *$FOU(\widetilde{A}_{\widetilde{\alpha}=0})$ is a normal IT2FN, in this case it is called a partially normal T2FN.*

Note that a special case of $FOU(\widetilde{A}_{\widetilde{\alpha}=1}) = Pr(\widetilde{A})$ is when all the vertical slices constructing $Pr(\widetilde{A})$ are triangular T1FN then $Pr(\widetilde{A})$ is T1FS, this is depicted in figures (2) and (3). We can also define a type-2 fuzzy sub-number (T2FsN) when its FOU is an IT2FsN. In some applications one may need to restrict a fuzzy set to a specific form, e.g. in computing with words Klir *et al.* [23, 24] defined a procedure to convert any given convex fuzzy set to a fuzzy interval that is expressed in some standard form using some specific criteria. We now examine a special form of T2FN based on some ideas from [9]. Some observations about the shape of a centroid led to the proposition of a quasi type-2 fuzzy logic system, similirly, a definition of a quasi T2FN (QT2FN) can be proposed.

Assumption 3.10 (QT2FS) *Consider the following propositions about a T2FN*

A1 The T2FN is Normal (i.e FOU is normal IT2FN and PrMF is normal).

A2 The FOU upper and lower membership functions, the PrMF, and the vertical slices are characterised by piecewise functions.

A3 All the vertical slices that construct PrMF are T1FN.

A4 As for the rest of the vertical slices, they are T1FsN in which their supremum lay on piece-wise functions between the sides of the upper membership function of the FOU and the PrMF denoted $\widetilde{l}(x)$ on the left side, and $\widetilde{r}(x)$ on the right side.

A5 All the mid points of the FOU upper and lower membership functions, and the PrMF are at the same domain value.

these assumptions allow a T2FN to be completely determined by its FOU and PrMF, just like a T1FS based on certain assumptions can be completely determined by its core and support.

Definition 3.11 (QT2FN) *Let $\widetilde{A} = \bigcup_{\forall\widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{A}_{\widetilde{\alpha}})$ be a type-2 fuzzy subset on real numbers. Then, $\widetilde{A}$ is a quasi type-2 fuzzy number if it is completely determined by its FOU and PrMF.*

Figures (3) and (4) are both QT2FNs.

4 Arithmetic using Alpha-planes

In Kaufmann and Gupta [17] a comprehensive discussion on fuzzy numbers and arithmetic operations which is formulated and mostly dependent upon the interval of confidence (α-level sets). Recalling operations on intervals, let $[a_1, a_2]$ and $[b_1, b_2]$ be two interval numbers, then

$$[a_1, a_2] \oplus [b_1, b_2] = [a_1 \oplus b_1, a_2 \oplus b_2]$$

$$[a_1, a_2] \otimes [b_1, b_2] = [\min(a_1 \otimes b_1, a_1 \otimes b_2, a_2 \otimes b_1, a_2 \otimes b_2) , \max(a_1 \otimes b_1, a_1 \otimes b_2, a_2 \otimes b_1, a_2 \otimes b_2)] \quad (19)$$

where $\oplus \in \{+, -\}$, $\otimes \in \{\times, \div\}$ and $0 \notin B$ if $\otimes = \div$. Interval operations are extended to T1FN. Let $A = \bigcup_{\forall \alpha} \alpha.[a_1^\alpha, a_2^\alpha]$ and $B = \bigcup_{\forall \alpha} \alpha.[b_1^\alpha, b_2^\alpha]$ be two T1FN, then

$$A \circ B = \bigcup_{\forall \alpha} \alpha.([a_1^\alpha, a_2^\alpha] \circ [b_1^\alpha, b_2^\alpha]) \quad (20)$$

where $\circ = \{+, -, \times, \div\}$. Also these operations are extended to IT2FN. Let $FOU(\widetilde{A}) = \bigcup_{\forall \alpha} \alpha. \left[\overline{[a_1^\alpha, a_1^\alpha]}, \underline{[a_2^\alpha, a_2^\alpha]}\right]$ and $FOU(\widetilde{B}) = \bigcup_{\forall \alpha} \alpha. \left[\overline{[b_1^\alpha, b_1^\alpha]}, \underline{[b_2^\alpha, b_2^\alpha]}\right]$ be two perfectly normal IT2FN, then [17]

$$FOU(\widetilde{A}) \circ FOU(\widetilde{B}) = \bigcup_{\forall \alpha} \alpha.(\left[\overline{[a_1^\alpha, a_1^\alpha]} \circ \overline{[b_1^\alpha, b_1^\alpha]}, \underline{[a_2^\alpha, a_2^\alpha]} \circ \underline{[b_2^\alpha, b_2^\alpha]}\right]) \quad (21)$$

If $FOU(\widetilde{A})$ and $FOU(\widetilde{B})$ are normal IT2FN with lower membership function heights $h_{\widetilde{A}}$ and $h_{\widetilde{B}}$ respectively, then the following changes are made to equation (21)

- if $0 \leq \alpha \leq \min(h_{\widetilde{A}}, h_{\widetilde{B}})$ no changes are made.
- if $h_{\widetilde{A}} < \alpha \leq h_{\widetilde{B}}$ then $\underline{a_1^\alpha} = \underline{a_1^{h_{\widetilde{A}}}}$; $\underline{a_2^\alpha} = \underline{a_2^{h_{\widetilde{A}}}}$, and if $h_{\widetilde{B}} < \alpha \leq h_{\widetilde{A}}$ then $\underline{b_1^\alpha} = \underline{b_1^{h_{\widetilde{B}}}}$; $\underline{b_2^\alpha} = \underline{b_2^{h_{\widetilde{B}}}}$.
- if $\max(h_{\widetilde{A}}, h_{\widetilde{B}}) < \alpha \leq 1$ then equation (21) becomes $FOU(\widetilde{A}) \circ FOU(\widetilde{B}) = \bigcup_{\forall \alpha} \alpha.([\overline{a_1^\alpha, a_2^\alpha}] \circ [\overline{b_1^\alpha, b_2^\alpha}])$.

Wu and Mendel [25] noticed that such methods that result in discontinuous or nonconvex sets are neither desirable nor technically correct. Similarly such results appear for normal IT2FN arithmetic operations. According to Wu and Mendel [25] the following changes are made to equation (21)

$$FOU(\widetilde{A}) \circ FOU(\widetilde{B}) = \begin{cases} \bigcup_{\forall \alpha} \alpha.(\left[\overline{[a_1^\alpha, a_1^\alpha]} \circ \overline{[b_1^\alpha, b_1^\alpha]}, \underline{[a_2^\alpha, a_2^\alpha]} \circ \underline{[b_2^\alpha, b_2^\alpha]}\right]) \\ \quad , \text{if } 0 \leq \alpha \leq \min(h_{\widetilde{A}}, h_{\widetilde{B}}) \\ \bigcup_{\forall \alpha} \alpha.([\overline{a_1^\alpha, a_2^\alpha}] \circ [\overline{b_1^\alpha, b_2^\alpha}]) \\ \quad , \text{if } \min(h_{\widetilde{A}}, h_{\widetilde{B}}) < \alpha \leq 1 \end{cases} \quad (22)$$

Clearly T2FN arithmetic can be extended, let $\widetilde{A} = \bigcup_{\forall \widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{A}_{\widetilde{\alpha}})$ and $\widetilde{B} = \bigcup_{\forall \widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{B}_{\widetilde{\alpha}})$ be two T2FNs, then

$$\widetilde{A} \circ \widetilde{B} = \bigcup_{\forall \widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{A}_{\widetilde{\alpha}}) \circ \bigcup_{\forall \widetilde{\alpha}} \widetilde{\alpha}.FOU(\widetilde{B}_{\widetilde{\alpha}})$$

using the extension principle in equation (11) it follows that

$$\widetilde{A} \circ \widetilde{B} = \bigcup_{\forall \widetilde{\alpha}} \widetilde{\alpha}.(FOU(\widetilde{A}_{\widetilde{\alpha}}) \circ FOU(\widetilde{B}_{\widetilde{\alpha}})) \quad (23)$$

then we can use equation (21) for perfectly normal T2FNs or equation (22) for normal T2FNs. Next we examine QT2FN, let $\widetilde{A}^Q$ and $\widetilde{B}^Q$ be QT2FN completely determined by the FOU and PrMF, $\langle FOU(\widetilde{A}^Q_{\widetilde{\alpha}=0}), Pr(\widetilde{A}^Q)\rangle$ and $\langle FOU(\widetilde{B}^Q_{\widetilde{\alpha}=0}), Pr(\widetilde{B}^Q)\rangle$, respectively. Then the result of basic arithmetic operations between them is a QT2FN

$$\widetilde{C}^Q = \widetilde{A}^Q \circ \widetilde{B}^Q \quad (24)$$

completely determined by $\langle FOU(\widetilde{C}^Q_{\widetilde{\alpha}=0}), Pr(\widetilde{C}^Q)\rangle$ where $FOU(\widetilde{C}^Q_{\widetilde{\alpha}=0}) = FOU(\widetilde{A}^Q_{\widetilde{\alpha}=0}) \circ FOU(\widetilde{B}^Q_{\widetilde{\alpha}=0})$ and $Pr(\widetilde{C}^Q) = Pr(\widetilde{A}^Q) \circ Pr(\widetilde{B}^Q)$. This operation can only be performed for addition and subtraction as the functions $\widetilde{l}(x)$ and $\widetilde{r}(x)$ are preserved. In the case of multiplication and devision an approximation for these functions should be used. It has to be mentioned that methods to approximate a T1FN to some standard form is used in the literature (see Grzegorzewski [26]). Providing approximation to QT2FN is still an open question.

5 Worked Example

In this example we only consider QT2FN as it gives sufficient insight on T2FN. Let us consider the following triangular QT2FN $\widetilde{3}^Q = \langle FOU(\widetilde{3}^Q_{\widetilde{\alpha}=0}), Pr(\widetilde{3}^Q)\rangle$ depicted in figure (5) with parameters[5] $FOU(\widetilde{3}^Q_{\widetilde{\alpha}=0}) = \langle 1.5, 2.25, 3, 3.45, 4.75\rangle$, $h_{\widetilde{3}} = 0.6$, and $Pr(\widetilde{3}^Q) = \langle 1.75, 3, 4.25\rangle$. And the QT2FN $\widetilde{12}^Q = \langle FOU(\widetilde{12}^Q_{\widetilde{\alpha}=0}), Pr(\widetilde{12}^Q)\rangle$ depicted in figure (6) with parameters $FOU(\widetilde{12}^Q_{\widetilde{\alpha}=0}) = \langle 10.25, 11.5, 12, 12.5, 14\rangle$, $h_{\widetilde{12}} = 0.7$, and $Pr(\widetilde{12}^Q) = \langle 10.75, 12, 13.5\rangle$. When computing the addition $\widetilde{3}^Q + \widetilde{12}^Q$, first, we determine a suitable number of α-cuts along u for both FOU and PrMF[6]. In our case and for the sake of clarity we discretised u into 25 α-cuts. Then, we apply equation (24) to the decomposed IT2FS. This gives the result depicted in figure (7) with parameters $FOU(\widetilde{15}^Q_{\widetilde{\alpha}=0}) = \langle 11.75, 13.75, 15, 15.95, 18.75\rangle$, $h_{\widetilde{15}} = 0.6$, and $Pr(\widetilde{15}^Q) = \langle 12.5, 15, 17.75\rangle$. This result we would expect, $\widetilde{3}^Q + \widetilde{12}^Q = \widetilde{15}^Q$.

6 Conclusions

In this paper we presented methods to perform type-2 fuzzy arithmetic operations using well known arithmetic operations on intervals. In order to better analyse our methods we defined a set of terms that describe different normality formations of IT2FS and T2FS, some of which, have already been used in the literature without a clear definition. Our methods relied heavily on interval analysis through α-cuts and α-planes that allow T2FSs be represented as a collection of intervals. Furthermore, we examined the use of quasi type-2 fuzzy sets proposed by Mendel and Liu and defined quasi type-2 fuzzy numbers as a special case of type-2 fuzzy numbers. Finally, we derived arithmetic operations for quasi type-2 fuzzy numbers and provided an illustration by a worked example.

[5] The parameters used here are $FOU(\widetilde{A}^Q_{\widetilde{\alpha}=0}) = \langle s_1, s_2, m_1, e_2, e_1\rangle$ derived from equation (12) where $\overline{FOU(\widetilde{A}^Q_{\widetilde{\alpha}=0})} = \langle s_1, m_1, e_1\rangle$ and $\underline{FOU(\widetilde{A}^Q_{\widetilde{\alpha}=0})} = \langle s_2, m_1, e_2\rangle$.

[6] In the case of T2FN we first discretise along $f_x(u)$ in order to determine a suitable number of α-planes, then, we discretise along u for each of the α-planes.

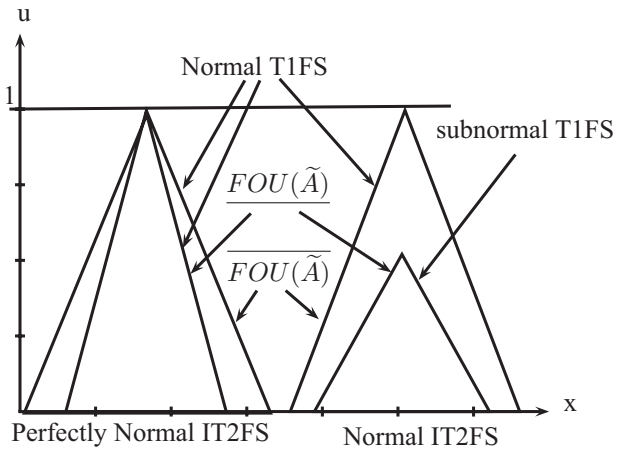

Figure 1: Different types of normal fuzzy sets

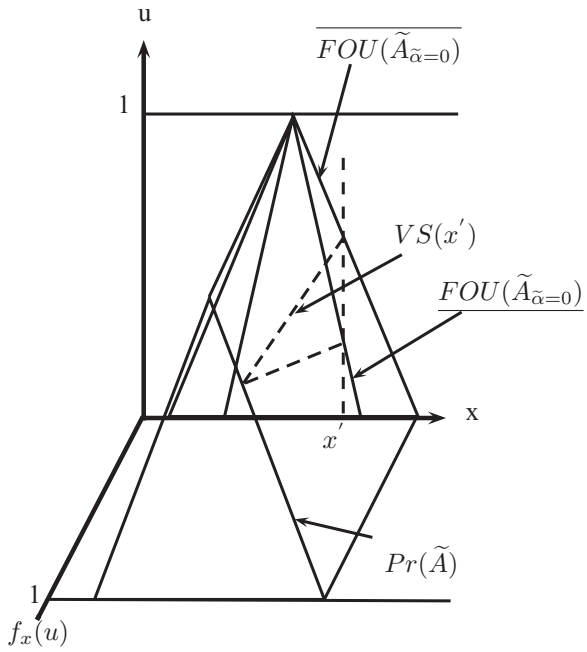

Figure 2: 3D representation of a perfectly normal T2FN, it is also a QT2FN.

We believe that this paper will form the basis for further work on type-2 fuzzy numbers and thier applications. Quasi type-2 fuzzy numbers may be viewed as a next step in the progress between IT2FN and T2FN. Arithmetic operations are already used in aggregation and averaging operations, measures that apply certain mathematical functions, and fusion functions between one system and another.

Further work with regards to the operations defined here will include approximation of standard forms of Quasi type-2 fuzzy numbers, and a thorough comparison between these methods and previous methods in terms of computational complexity, although, it is almost trivial that our methods are computationally sound as they are based on interval analysis.

Acknowledgment

The authors would like to thank the anonymous reviewers for their constructive comments which we believe have helped to improve this paper, and also would like to thank Mr. Simon Miller for his helpful discussions.

Operations for Real-Valued Bags and Bag Relations

Sadaaki Miyamoto
Department of Risk Engineering, University of Tsukuba
Email: miyamoto@risk.tuskuba.ac.jp

Abstract— *A generalization of bags is proposed and fundamental operations are described. That is, a real-valued bag is proposed which is a straightforward generalization of the traditional bags, but is necessary for complementation, and s-norm and t-norm operations. We mainly describe how complementation and s-norms are related. As a result a duality theorem between s-norm and t-norm is obtained. R-bag relations with max-s norm composition and max-t norm composition are also proposed. Further generalization that includes fuzzy bags and real-valued bags having membership of a region in a plane is moreover discussed.*

Keywords— bag relation, max-s composition, real-valued bag, set-valued bag, t-norm and conorm .

1 Introduction

Bags which are also called *multisets* have long been studied by computer scientists [5, 6]. In soft computing, Yager [19] have proposed fuzzy bags, and its theory and applications have been studied by several researchers [3, 4, 15, 16, 17, 18, 20]. In particular, the author [9, 10, 12] has redefined basic operations of the union and intersection for fuzzy bags. The definition anew by the authors is necessary in order to keep consistency between operations for ordinary fuzzy sets and those for fuzzy bags [12]. However, there are many problems that are left and should be studied.

One class of such problems is fundamental operations of bags including complementation and bag s-norms (and s-norms). Another class is bag relations that should have composition operations. In this paper we study these two problem classes. While studying these problems, we should generalize the traditional concept of bags, as described in this paper. We therefore introduce a generalization called R-bag which appears straightforward, but this generalization is necessary to consider complementation and bag t-norms. As a result, a duality theorem is derived using the complementation. Moreover a Minkwoski type bag s-norms are derived using a generating function.

Bag relations and their compositions for R-bags are then studied by introducing a max-s algebra and a max-t algebra. Here s and t stands for s-norm and t-norm.

Another generalization that includes R-bag and fuzzy bag is moreover mentioned and how the above consideration is extended to this generalized bag is suggested.

There are a number of propositions herein, but to prove propositions given in this paper is not difficult. Hence short notes on proofs are given in the appendix.

Although the purpose of this paper is to show theoretical properties of generalized bags, bags have many application possibilities, which are briefly mentioned in the conclusion.

2 Bags and R-Bags

The two terms of bags and multisets are used interchangeably, and we use *bags* throughout this paper.

2.1 Overview of crisp bags

Assume that the universal set $X = \{x_1, \ldots, x_n\}$ is finite for simplicity. A crisp bag M of $X = \{x_1, \ldots, x_n\}$ is characterized by a function $C_M(\cdot)$ (called count of M) whereby a natural number including zero $\boldsymbol{N} = \{0, 1, 2, \ldots\}$ corresponds to each $x \in X$ ($C_M : X \to \boldsymbol{N}$).

For a crisp bag, different expressions such as

$$M = \{k_1/x_1, \ldots, k_n/x_n\}$$

and

$$M = \{\overbrace{x_1, \ldots, x_1}^{k_1}, \ldots, \overbrace{x_n, \ldots, x_n}^{k_n}\}$$

are used. In such a way, an element of X may appear more than once in a bag. In the above example x_i appears k_i times in M ($i = 1, \ldots, n$).

Consider an example where $X = \{a, b, c, d\}$ and $C_M(a) = 2$, $C_M(b) = 1$, $C_M(c) = 3$, $C_M(d) = 0$. In other words, $M = \{a, a, b, c, c, c\}$. This means that a, b, c, and d are included 2, 1, 3, and 0 times, respectively, in M. We can write $M = \{2/a, 1/b, 3/c\}$ by ignoring an element of zero occurrence.

Basic relations and operations for crisp bags are as follows.

1. (inclusion):
   $M \subseteq N \Leftrightarrow C_M(x) \leq C_N(x), \quad \forall x \in X.$
2. (equality):
   $M = N \Leftrightarrow C_M(x) = C_N(x), \quad \forall x \in X.$
3. (union):
   $C_{M \cup N}(x) = \max\{C_M(x), C_N(x)\}.$
4. (intersection):
   $C_{M \cap N}(x) = \min\{C_M(x), C_N(x)\}.$
5. (addition or sum):
   $C_{M \oplus N}(x) = C_M(x) + C_N(x).$
6. (subtraction):
   $C_{M \ominus N}(x) = \max\{0, C_M(x) - C_N(x)\}.$
7. (scalar multiplication):
   $C_{\alpha M} = \alpha C_M(x)$, where α is a positive integer.
8. (Cartesian product):
   Let P is a bag of Y.
   $C_{M \times P}(x, y) = C_M(x) C_P(y).$

ISBN: 978-989-95079-6-8

We sometimes use $\vee$ and $\wedge$ for $\max$ and $\min$, respectively. We also note that the relations and operations are similar to those for fuzzy sets. However, bags have the addition which fuzzy sets do not have, and the Cartesian product for bags is different from that for fuzzy sets. Moreover, a complementation is not defined in general.

2.2 R-bags

An immediate generalization of crisp bag is to assume that $C_M(\cdot)$ has a nonnegative real-value instead of a natural number. For example, we admit $C_M(a) = 3.14$ or $C_N(a) = \pi$. Moreover we admit the value of infinity $+\infty$ for a technical reason. We thus assume $C_M : X \to [0, +\infty]$.

The above relations and operations 1–8 are used without any change except that α in the scalar multiplication can now be a positive real constant. For simplicity, a real-valued bag is called an R-bag here and the collection of all R-bags of X is denoted by $\mathcal{RB}(X)$.

Complementation of R-bags

A function $\mathcal{N} : [0, +\infty] \to [0, +\infty]$ with the next properties is used to define a complementation operation:

(i) $\mathcal{N}(0) = +\infty, \quad \mathcal{N}(+\infty) = 0.$

(ii) $\mathcal{N}(x)$ is strictly monotonically decreasing on $(0, +\infty)$.

A typical example is $\mathcal{N}(x) = const/x$ with $const > 0$.

Using this function, a natural operation for the complement is:

9.(complement):
$C_{\bar{M}}(x) = \mathcal{N}(C_M(x))$.

This operation justifies the generalization into R-bags. That is, even when we start crisp bags, the result of complementation is generally real-valued.

We immediately have the next two propositions of which the proof is easy and omitted.

Proposition 1 *For arbitrary $M, N \in \mathcal{RB}(X)$, the following properties hold:*

$$\overline{(\overline{M})} = M \tag{1}$$

$$\overline{M \cup N} = \bar{M} \cap \bar{N}, \qquad \overline{M \cap N} = \bar{M} \cup \bar{N}. \tag{2}$$

Proposition 2 *If we introduce an empty bag $\emptyset$ and the maximum bag* **Infinity** *in $\mathcal{RB}$ by*

$$C_{\emptyset}(x) = 0, \quad \forall x \in X, \tag{3}$$

$$C_{\mathbf{Infinity}}(x) = +\infty, \quad \forall x \in X. \tag{4}$$

Then we have

$$\bar{\emptyset} = \mathbf{Infinity}, \quad \overline{\mathbf{Infinity}} = \emptyset. \tag{5}$$

s-norms and t-norms of R-bags

There have been studies on t-norms for crisp bags [7, 1], but generalization into R-bags admits a broader class of s-norms and t-norms. For this purpose we introduce two functions $t(a, b)$ and $s(a, b)$ as those in fuzzy sets, but the definitions are different.

Definition 1 *Two functions $t : [0, +\infty] \times [0, +\infty] \to [0, +\infty]$ and $s : [0, +\infty] \times [0, +\infty] \to [0, +\infty]$ having the following properties (I)–(IV) are called a t-norm and an s-norm for bags, respectively. An s-norm is also called a t-conorm for bags.*

(I)[monotonicity] For $a \le c$, $b \le d$,

$$t(a, b) \le t(c, d),$$
$$s(a, b) \le s(c, d).$$

(II)[symmetry]

$$t(a, b) = t(c, d), \quad s(a, b) = s(b, a).$$

(III)[associativity]

$$t(t(a, b), c) = t(a, t(b, c)),$$
$$s(s(a, b), c) = s(a, s(b, c)).$$

(IV)[boundary condition]

$$t(0, 0) = 0, \quad t(a, +\infty) = t(+\infty, a) = a,$$
$$s(+\infty, +\infty) = +\infty, \quad s(a, 0) = s(0, a) = a.$$

A purpose to introduce such norms for bags is to generalize the intersection and union operations. First we note that $s(a, b) = a+b$ and $s(a, b) = \max\{a, b\}$ satisfy the above conditions. The norm $t(a, b) = \min\{a, b\}$ also satisfies (I)–(IV). Thus, s-norms and t-norms can represent the three operations of addition, union, and intersection.

We moreover introduce a generating function $g(x)$ for s-norm.

Definition 2 *A function $g : [0, +\infty] \to [0, +\infty]$ is called a generating function for s-norm if it satisfies the next (i)–(iii):*
(i) it is strictly monotonically increasing,
(ii) $g(0) = 0, \quad g(+\infty) = +\infty$,
(iii) $g(x + y) \ge g(x) + g(y), \quad \forall x, y \in [0, +\infty]$.
We have

Proposition 3 *Let*

$$s(a, b) = g^{-1}(g(a) + g(b)). \tag{6}$$

Then $s(a, b)$ is an s-norm.

An example of the generation function is

$$g(x) = x^p \quad (p \ge 1). \tag{7}$$

Moreover, note the following.

Proposition 4 *Let $s(a, b)$ is an s-norm and $\mathcal{N}$ is the complementation operator. Then*

$$t(a, b) = \mathcal{N}(s(\mathcal{N}(a), \mathcal{N}(b))) \tag{8}$$

is a t-norm. Suppose $t(a, b)$ is a t-norm, then

$$s(a, b) = \mathcal{N}(t(\mathcal{N}(a), \mathcal{N}(b))) \tag{9}$$

is an s-norm.

If a pair of t-norm and s-norm has the above property, we say (s, t) has the *duality* of norm and conorm. The duality has the next property.

ISBN: 978-989-95079-6-8

Proposition 5 *Suppose $s_0(a,b)$ is an s-norm and $t_0(a,b)$ is derived from $s_0(a,b)$ by the operation (8). Let*

$$s(a,b) = \mathcal{N}(t_0(\mathcal{N}(a),\mathcal{N}(b)))$$

Then $s(a,b) = s_0(a,b)$.

Suppose also that $t_0(a,b)$ is a t-norm and $s_0(a,b)$ is derived from $t_0(a,b)$ by the operation (8). Let

$$t(a,b) = \mathcal{N}(s_0(\mathcal{N}(a),\mathcal{N}(b)))$$

Then $t(a,b) = t_0(a,b)$. In summary, applying (8) and (9) (resp. (9) and (8)) successively, we have the original norm.

Note that s-norm and t-norm are applied to define bag operations $M\mathcal{S}N$ and $M\mathcal{T}N$, respectively, for $M, N \in \mathcal{RB}(X)$.

$$C_{M\mathcal{S}N}(x) = s(C_M(x), C_N(x)). \tag{10}$$
$$C_{M\mathcal{T}N}(x) = t(C_M(x), C_N(x)). \tag{11}$$

Let us consider examples of s-norms and t-norms.

Example 1 The standard operators

$$s(a,b) = \max\{a,b\} \tag{12}$$
$$t(a,b) = \min\{a,b\} \tag{13}$$

are an s-norm and a t-norm, respectively. This pair has the duality stated in Proposition 5. Note, however, that s-norm (12) does not have a generating function that satisfies (6).

Second example uses the generating function.

Example 2 Let $g(x)$ be given by (7). Then we have

$$s(a,b) = (a^p + b^p)^{\frac{1}{p}}, \tag{14}$$
$$t(a,b) = (a^{-p} + b^{-p})^{-\frac{1}{p}}. \tag{15}$$

are an s-norm and a t-norm, respectively. This pair has the duality stated in Proposition 5 when $\mathcal{N} = const/x$ is used.

The second example has interesting properties. First, $s(a,b) = a+b$ is a particular case of (14) for $p = 1$. Moreover $s(a,b) = \max\{a,b\}$ and $t(a,b) = \min\{a,b\}$ are obtained from (14) and (15) when $p \to +\infty$.

New findings are included in the above example. First, the dual t-norm derived from $s(a,b) = a + b$ is the harmonic mean:

$$t(a,b) = (a^{-1} + b^{-1})^{-1} = \frac{ab}{a+b}.$$

(Note that the arithmetic mean $\frac{a+b}{2}$ and the geometric mean $\sqrt{ab}$ are not t-norms). Second, $s(a,b) = (a^2 + b^2)^{\frac{1}{2}}$ with $p = 2$ which is similar to the Euclidean norm is an s-norm, and the dual t-norm is

$$t(a,b) = \frac{1}{\sqrt{\frac{1}{a^2} + \frac{1}{b^2}}}.$$

2.3 R-bags and fuzzy sets

Let us study what relations exist between fuzzy sets and R-bags. For this purpose we introduce another notation: the collection of all fuzzy sets of X is denoted by $\mathcal{FS}(X)$.

We introduce another function $h\colon [0,+\infty] \to [0,1]$ that is strictly monotonically increasing in $[0,+\infty)$ and

$$h(0) = 0, \quad h(+\infty) = 1.$$

An example of such a function is

$$h_0(x) = 1 - \exp(-K_0 x), \quad x \in [0,+\infty)$$

with constant $K_0 > 0$ and with the additional definition $h_0(+\infty) = 1$. Another example is

$$h_1(x) = 1 - \frac{K_1}{K_1 + K_2 x}, \quad x \in [0,+\infty)$$

with positive constants K_1, K_2 and with $h_1(+\infty) = 1$.

Since such a function has an inverse function $h^{-1}(y)$, we can define one to one correspondence between a fuzzy set and an R-bag:

$$\mu_{h(M)}(x) = h(C_M(x)). \tag{16}$$

For $M \in \mathcal{RB}(X)$, $h(M) \in \mathcal{FS}(X)$, and $h^{-1}(h(M)) = M$. Note that $h^{-1}(y)$ is also a strictly monotonically increasing.

We also have

$$h(\emptyset) = \emptyset, \quad h(\mathbf{Infinity}) = X;$$
$$h^{-1}(\emptyset) = \emptyset, \quad h^{-1}(X) = \mathbf{Infinity}.$$

Using these functions, we can generate operations for R-bags from those for fuzzy sets.

Proposition 6 *Let*

$$\mathcal{N}(x) = h^{-1}(1 - h(x)). \tag{17}$$

Then $\mathcal{N}(x)$ satisfies the properties of complementation operation. Hence for arbitrary $M \in \mathcal{RB}(X)$, $\bar{M}$ derived by

$$C_{\bar{M}}(x) = \mathcal{N}(C_M(x))$$

using (17) is a complement of M.

Note that this operation is derived from the complementation of fuzzy sets.

For the s-norm and t-norm, we have similar results. Let $s_F(a,b)$ and $t_F(a,b)$ are respectively an s-norm and a t-norm for *fuzzy sets*. We have the following.

Proposition 7 *For $a, b \in [0,+\infty]$, let*

$$s(a,b) = h^{-1}(s_F(h(a), h(b))) \tag{18}$$
$$t(a,b) = h^{-1}(t_F(h(a), h(b))) \tag{19}$$

Then $s(a,b)$ and $t(a,b)$ are an s-norm and a t-norm for R-bags.

we also have

Proposition 8 *Suppose $s(a,b)$ and $t(a,b)$ are an s-norm and a t-norm for R-bags. For $a, b \in [0,1]$, let*

$$s_F(a,b) = h(s(h^{-1}(a), h^{-1}(b))) \tag{20}$$
$$t_F(a,b) = h(t(h^{-1}(a), h^{-1}(b))) \tag{21}$$

Then $s_F(a,b)$ and $t_F(a,b)$ are an s-norm and a t-norm for fuzzy sets.

3 Bag Relations

What we consider in this section is a bag-relations and their composition. As a result we have max-s and max-t algebras for R-bags. The discussion in this section generalizes the max-plus algebra [2].

ISBN: 978-989-95079-6-8

3.1 max-s and max-t algebra

Let us use a particular notation of $\boxplus$ and $\boxdot$ for

$$a \boxplus b = \max\{a, b\}, \quad a \boxdot b = s(a, b) \tag{22}$$

where $s(a, b)$ is an s-norm for R-bags. We call this algebra as *max-s algebra*.

It is easy to see that the following properties hold.

$$a \boxplus b = b \boxplus a, \tag{23}$$
$$a \boxplus (b \boxplus c) = (a \boxplus b) \boxplus c, \tag{24}$$
$$a \boxplus 0 = a, \tag{25}$$
$$a \boxdot b = b \boxdot a, \tag{26}$$
$$a \boxdot (b \boxdot c) = (a \boxdot b) \boxdot c, \tag{27}$$
$$a \boxdot 0 = a. \tag{28}$$

Alternatively, we can define $\boxplus$ and $\boxdot$ for

$$a \boxplus b = \max\{a, b\}, \quad a \boxdot b = t(a, b) \tag{29}$$

where $t(a, b)$ is a t-norm for R-bags. We call this algebra as *max-t algebra*. We see that (23)–(27) hold, while (28) should be replaced by

$$a \boxdot +\infty = a. \tag{30}$$

We moreover note the next lemma.

Lemma 1 *Let a, b, c be real numbers. Then*

$$a \boxdot (b \boxplus c) = (a \boxdot b) \boxplus (a \boxdot c). \tag{31}$$

Thus the commutative, associative, and distributive properties hold for the max-s algebra. Noting Example 2, we observe that the max-t algebra includes the max-min algebra and the max-s algebra includes the max-plus algebra as particular cases.

3.2 Bag relations

We now define R-bag relations. The definition is simple. An R-bag relation R on $X \times Y$ is an R-bag R of $X \times Y$. The count function is denoted by $R(x, y)$ instead of $C_R(x, y)$ for simplicity. Sometimes an R-bag relation is also called bag relation for simplicity.

The reason why we call such a bag $R(x, y)$ a bag relation is that we can define composition operation.

Let X, Y, Z be three universes. Assume R is a bag relation of $X \times Y$ and S is a bag relation of $Y \times Z$. Then the max-s composition $R \circ S$ is defined as follows.

$$(R \circ S)(x, z) = \boxplus_{y \in Y}\{R(x, y) \boxdot S(y, z)\} \tag{32}$$

Note that

$$\boxplus_{y \in \{a_1, \ldots, a_L\}} = a_1 \boxplus a_2 \boxplus \cdots \boxplus a_L.$$

The max-t composition is defined by the same equation (32) except that $\boxdot$ uses a t-norm.

Note also that the addition is straightforward

$$(R_1 \boxplus R_2)(x, y) = R_1(x, y) \boxplus R_2(x, y), \tag{33}$$

for bag relations on $X \times Y$.

We have the following proposition.

Proposition 9 *The composition satisfies the associative property*

$$(R \circ S) \circ T = R \circ (S \circ T). \tag{34}$$

and the distributive property

$$(R_1 \boxplus R_2) \circ S = (R_1 \circ S) \boxplus (R_2 \circ S), \tag{35}$$
$$R \circ (S_1 \boxplus S_2) = (R \circ S_1) \boxplus (R \circ S_2). \tag{36}$$

We introduce the unit relations for the max-s and max-t compositions. Define O_X and Ω_X on $X \times X$:

$$O_X(x, y) = 0, \quad \forall x, y \in X, \tag{37}$$
$$\Omega_X(x, y) = +\infty, \quad \forall x, y \in X. \tag{38}$$

We define O_{XY} and Ω_{XY} on $X \times Y$ in the same way:

$$O_{XY}(x, y) = 0, \quad \forall (x, y) \in X \times Y, \tag{39}$$
$$\Omega_{XY}(x, y) = +\infty, \quad \forall (x, y) \in X \times Y. \tag{40}$$

Frequently we omit the subscripts like O and Ω when we have no ambiguity.

We then have

Proposition 10 *Assume that the max-s algebra is used. For arbitrary bag relation R on $X \times Y$,*

$$R \boxplus O = O \boxplus R = R, \tag{41}$$
$$R \circ O = O \circ R = R. \tag{42}$$

Proposition 11 *Assume that the max-t algebra is used. For arbitrary bag relation R on $X \times Y$,*

$$R \boxplus O = O \boxplus R = R, \tag{43}$$
$$R \circ \Omega = \Omega \circ R = R. \tag{44}$$

4 A Note on Further Generalization

The above generalization to R-bags does not include fuzzy bags [19, 10]. It appears that R-bags and fuzzy bags are inconsistent. However, there is further generalization discussed in [12] which uses a closed region in $\boldsymbol{R}^2$ as the count function for generalized bags. In this section we briefly note how the above discussion is extended into generalized bags which encompasses R-bags and fuzzy bags.

A generalized bag A has a count function as a region

$$\mathbf{N}(x, A) = C_A(x), \quad \forall x \in X \tag{45}$$

where $\mathbf{N}(x, A)$ is a closed set of $[0, +\infty)^2$. Let $\nu(y, z; x, A)$ is the characteristic function of the region $\mathbf{N}(x, A)$:

$$\nu(y, z; x, A) = \begin{cases} 1, & (y, z) \in \mathbf{N}(x, A), \\ 0, & (y, z) \notin \mathbf{N}(x, A). \end{cases}$$

This region should have the following properties:

(N1) For any $y \in [0, +\infty)$,

$$\eta(y) = \{z \in [0, +\infty) : \nu(y, z; x, A) = 1\}$$

is either an empty set or a closed interval $[0, \mu(y)]$ where $\mu(y) = \max\{y' : y' \in \eta(y)\}$.

ISBN: 978-989-95079-6-8

(N2) For all $y \in [0, +\infty)$, $\mu(y)$ is a monotonically decreasing function and $0 \leq \mu(y) \leq 1$.

(N3) For any $z \in [0, +\infty)$,

$$\theta(z) = \{y \in [0, +\infty) : \nu(y, z; x, A) = 1\}$$

is either an empty set or a closed interval $[0, \zeta(z)]$ where $\zeta(z) = \max\{z' : z' \in \theta(z)\}$.

(N4) For all $z \in [0, +\infty)$, $\zeta(z)$ is a monotonically decreasing function and $0 \leq \zeta(z) < +\infty$.

Roughly, a generalized bag is characterized by the pair $(\mu(y), \zeta(y))$ for each $x \in X$.

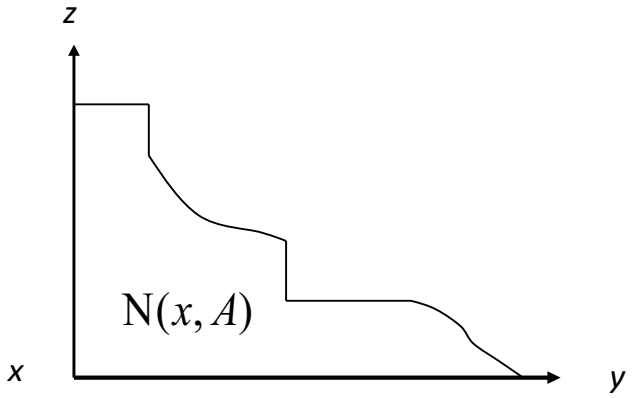

Figure 1: An illustration of $\mathbf{N}(x, A)$ as the count function for a generalized bag.

Two cuts which relate the generalized bag to R-bags and fuzzy sets are defined:

α-cut: Let $\alpha \in (0, 1]$. For the generalized bag A, $[A]_\alpha$ is an R-bag given by

$$C_{[A]_\alpha}(x) = \max\{z : \nu(\alpha, z; x, A) = 1\}.$$

ℓ-cut: Let $\ell \in (0, +\infty)$. For the generalized bag A, $\langle A \rangle_\ell$ is a fuzzy set given by

$$\mu_{\langle A \rangle_\ell}(x) = \max\{y : \nu(y, \ell; x, A) = 1\}.$$

It can be proved that the generalized bags are smallest generalization of fuzzy bags and R-bags [12]. Moreover, s-norms and t-norms can be used for the generalized bags using the α-cuts, while the complementation operation cannot be used for the generalized bags. Bag relations and their compositions can also be used for the generalized bags. The detailed consideration is too lengthy to give here and will be discussed elsewhere.

5 Conclusion

We have shown the operations of complementation and s-norm and t-norm for real-valued bags. Moreover R-bag relations and the max-s (or max-t) compositions are studied. Further generalization has moreover been proposed of which the details will be discussed in near future.

As seen herein, the theory of bags should be studied more deeply, since it has more ample mathematical structure than expected until now. More theoretical studies are thus needed. Relations between rough sets [14] and bags have been discussed [12], but there is much room for further studies. Application of bags such as those in information retrieval [8] and information mining [11, 13] will also be important.

Acknowledgment

This study has partly been supported by the Grant-in-Aid for Scientific Research, Japan Society for the Promotion of Science, No.19650052.

Appendix: Notes on Proofs

Since detailed proofs are too lengthy, we give short notes on how to prove the propositions given here. The proofs are mostly straightforward.

Notes on proofs of Propositions 1 and 2

These propositions are immediately proved by straightforward calculation using $\mathcal{N}$. The details are hence omitted.

Notes on proofs of Propositions 3 and 4

It is enough to check the conditions (I)–(IV) are satisfied.

Notes on proof of Proposition 5

$$\begin{aligned} s(a, b) &= \mathcal{N}(t_0(\mathcal{N}(a), \mathcal{N}(b))) \\ &= \mathcal{N}(\mathcal{N}(s_0(\mathcal{N}(\mathcal{N}(a)), \mathcal{N}(\mathcal{N}(b))))) \\ &= s_0(a, b). \end{aligned}$$

Notes on proof of Proposition 6

By a simple calculation, it is seen that $\mathcal{N}$ by (17) satisfies the conditions for the complementation.

Notes on proofs of Propositions 7 and 8

The conditions for s-norms and t-norms for fuzzy sets should be noted. Mostly it is easy to check that the conditions are satisfied, since the functions h and h^{-1} are monotone. The boundary conditions are satisfied from $h(0) = 0$ and $h(+\infty) = 1$.

Notes on proof of Lemma 1

Let $b \geq c$, then the left hand side is $s(a, b)$. The right hand side is

$$\max\{s(a, b), s(a, c)\} = s(a, b).$$

The case of $b < c$ is calculated likewise and we have the desired equality.

When we use a max-t algebra, we can prove the lemma in a similar way, since the monotone property is common to s-norm and t-norm. We omit the detail.

Notes on proof of Proposition 9

The detailed proof is lengthy, but the way to prove this proposition is just the same as the proof of the matrix properties for ordinary algebra, since those properties for ordinary algebra uses the commutative, associative, and distributive properties which are valid for the present algebra, since (23)–(28) (or (30)) and (31) are valid.

Notes on proofs of Propositions 10 and 11

Omitted as they are straightforward.

Abstract— *Kernel data analysis is now becoming standard in every application of data analysis and mining. Kernels are used to represent a mapping into a high-dimensional feature space, where an explicit form of the mapping is unknown. Contrary to this common understanding, we introduce an explicit mapping which we consider standard. The reason why we use this mapping is as follows. (1) the use of this mapping does not lose any fundamental information in kernel data analysis and we have the same formulas in every kernel methods. (2) Usually the derivation becomes simpler by using this mapping. (3) New applications of the kernel methods become possible using this mapping. As an application we consider an example of text mining where we use fuzzy c-means clustering and cluster centers in the high-dimensional space and visualize the centers using kernel principal component analysis.*

Keywords— Kernel data analysis, fuzzy clustering, explicit mapping, text mining

1 Introduction

Kernel functions [9] which are not very new but was noted in support vector machines[10] and now is a well-known technique and becoming standard in many applications of data analysis and data mining. An important point in the use of kernel functions is that although we consider a mapping from a data space into a high-dimensional feature space, we need not to know its explicit form but we should know the inner product of the feature space. Generally, the feature space is not uniquely determined. Accordingly every formula in data analysis using kernel functions should be described in terms of the inner product.

Although kernel functions are really useful, but the derivation is sometimes complicated when original formulas should be rewritten by the inner product forms. A typical example is kernel fuzzy c-means clustering [3] and kernel SOM [4] in which the cluster centers in a feature space should be eliminated using inner product forms.

Here is a question: can we have a useful and explicit mapping and explicit representation of a high-dimensional feature space? The answer is YES, and we will show the mapping that is simple enough and useful in the sense that it leads to the same formulas when transformed into the inner product forms. To summarize, this explicit mapping and associated feature space have all information that is used in kernel functions for data analysis.

Another question arises: what is useful in this explicit mapping? We will show a real application of an example of text analysis. A result of kernel fuzzy c-means clustering and cluster centers will be shown using kernel principal component analysis.

Proofs of propositions are mostly omitted to save the space but brief notes are given as appendix.

2 Kernel Functions and an Explicit Mapping

2.1 Preliminary consideration

Although we consider kernel fuzzy c-means (FCM) clustering [3] and kernel principal component analysis (KPCA)[9] later, we describe FCM and omit KPCA for simplicity.

Assume that a set of data $X = \{x_1, \ldots, x_n\} \subset \boldsymbol{R}^p$ is given. Each data unit is also called an object or an individual and it is a point in the p-dimensional real space $x_k = (x_k^1, \ldots, x_k^p)^T \in \boldsymbol{R}^p$. We consider a mapping into a high-dimensional feature space $\Phi\colon \boldsymbol{R}^p \to H$ and associated kernel function

$$\boldsymbol{K}(x, y) = \langle \Phi(x), \Phi(y) \rangle \tag{1}$$

where $\langle \cdot, \cdot \rangle$ is an inner product of H. We also assume $\| \cdot \|_H$ is a norm of H. Thus H is an inner product space. In this section suppose we do not know function $\Phi(\cdot)$ explicitly but we know $\boldsymbol{K}(x, y)$. Specifically, the Gaussian kernel is used frequently:

$$\boldsymbol{K}(x, y) = \exp(-\lambda \|x - y\|^2) \tag{2}$$

where $\lambda > 0$ and $\|x\|$ is the norm of $\boldsymbol{R}^p$.

An objective function of fuzzy c-means using the feature space H is the following.

$$J_H(U, W) = \sum_{i=1}^{c} \sum_{k=1}^{n} (u_{ki})^m \|\Phi(x_k) - W_i\|_H^2, \quad (m > 1) \tag{3}$$

where $U = (u_{ki})$ is $n \times c$ matrix representing membership of x_k to cluster i. U has the next constraint when it is optimized.

$$M = \{U = (u_{ki}) : \sum_{i=1}^{c} u_{ki} = 1,\ u_{ki} \geq 0, \forall k, i\}. \tag{4}$$

Moreover $W = (W_1, \ldots, W_c)$ shows cluster centers.

The iterative algorithm of fuzzy c-means clustering is basically an alternative minimization of $J_H(U, W)$ with respect to

ISBN: 978-989-95079-6-8

U and W until convergence. We have the next solutions.

$$u_{ki} = \left[\sum_{j=1}^{c} \left(\frac{D(x_k, W_i)}{D(x_k, W_j)} \right)^{\frac{1}{m-1}} \right]^{-1}, \tag{5}$$

$$W_i = \frac{\sum_{k=1}^{n} (u_{ki})^m \Phi(x_k)}{\sum_{k=1}^{n} (u_{ki})^m} \tag{6}$$

where we put

$$D(x_k, W_i) = \|\Phi(x_k) - W_i\|_H^2. \tag{7}$$

Equations (5) and (6) are repeated until convergence, but since $\Phi(x_k)$ is unknown, we should use another formula for kernel fuzzy c-means clustering.

The formula is derived by eliminating (6) from iteration, i.e., we substitute (6) into (7) to have an updating formula for $D(x_k, W_i)$[3]:

$$D(x_k, W_i) = \boldsymbol{K}(x_k, x_k) - \frac{2}{\sum_{k=1}^{n} (u_{ki})^m} \sum_{j=1}^{n} (u_{ji})^m \boldsymbol{K}(x_j, x_k) + \frac{1}{\{\sum_{k=1}^{n} (u_{ki})^m\}^2} \sum_{j=1}^{n} \sum_{\ell=1}^{n} (u_{ji} u_{\ell i})^m \boldsymbol{K}(x_j, x_\ell). \tag{8}$$

We hence repeat (5) and (8) until convergence when kernel fuzzy c-means clustering should be used.

2.2 An explicit mapping and its properties

We sometimes have applications in which we wish to have explicit cluster centers. Even if we cannot show them in a low-dimensional data space, there are ways to have approximate representations or visualizations, one of which is to show kernel principal components and another is to use SOM mapping.

To this end we use the following explicit mapping that is simple enough but seems unnoticed.

$$\Phi(x_k) = e_k \quad (k = 1, 2, \ldots, n) \tag{9}$$

where $H = \boldsymbol{R}^n$ and e_k is the k-th unit vector that has unity as ith component and all other components are zero. Note that $\Phi\colon X \to \boldsymbol{R}^n$, i.e., $\Phi(\cdot)$ is not defined on $\boldsymbol{R}^p$ but is limited to the finite set X. Moreover we assume that the inner product of $\boldsymbol{R}^n$ is

$$\langle e_k, e_\ell \rangle = \boldsymbol{K}(x_k, x_\ell) \tag{10}$$

instead of the usual $\langle e_k, e_\ell \rangle = \delta_{k\ell}$.

We have the next proposition.

Proposition 1. *If kernel $\boldsymbol{K}(x, y)$ is positive definite, $\langle e_k, e_\ell \rangle$ defined by (10) satisfy the axioms of the inner product of $\boldsymbol{R}^n$, that is, $\boldsymbol{R}^n$ with (10) is an inner product space.*

We now apply this mapping to fuzzy c-means clustering. It is sufficient to show the optimal solution of W_i. We then have the next proposition of which the proof is easy and omitted.

Proposition 2. *For all positive definite kernel $\boldsymbol{K}(x, y)$ and mapping Φ by (9), the cluster centers are the same and are given by*

$$W_i = \left(\frac{(u_{1i})^m}{\sum_{k=1}^{n} (u_{ki})^m}, \ldots, \frac{(u_{ni})^m}{\sum_{k=1}^{n} (u_{ki})^m} \right)^T, \quad i = 1, \ldots, c \tag{11}$$

The next proposition of which the proof is almost trivial shows an important result of the equivalence between the usual technique and the explicit mapping method.

Proposition 3. *Using the explicit mapping (11) to (7), we have (8).*

That is, (11) derived from the single mapping (9) has all necessary and sufficient information for kernel fuzzy c-means clustering.

As noted above, formulas in kernel principal component analysis are derived likewise. Since the derivation repeats what is described in textbooks [9], we omit the details. The mapping (9) is moreover useful for application to LVQ and SOM [2], where vectors for updating quantization vectors should be based on learning. The explicit mapping enables vector representations in $\boldsymbol{R}^n$, we can use every formulas in LVQ and SOM, while usual kernel methods should eliminate quantization vectors [6].

3 Analysis of Terms from a Set of Texts

We hereafter show an application in which mapping (9) has a natural interpretation. A typical example is analysis of terms from s set of texts. A well-known model for term analysis uses a vector-space model [8] which is also called a bag model. Mizutani and Miyamoto[6] generalize the model into fuzzy multiset model and use kernel based learning and clustering. Note that a term may occur many times in a text which we call here term occurrences, or simply occurrences. Term occurrences are handled as term frequencies or count in bags in the vector space model, or it is treated as fuzzy multisets in [6] when memberships are attached to each term occurrence. When c-means clustering is applied, cluster centers have implications as they are representatives of clusters.

In these models, however, a structure inside a text such as distances or topology between occurrences is not considered. Miyamoto and Kawasaki[5] propose a kernel-based model that handles fuzzy neighborhood. As a result, kernel-based data analysis can be applied but a drawback is that we cannot have cluster centers. We consider this model of fuzzy neighborhood here and uses the above explicit mapping and overcome the last drawback.

3.1 Fuzzy neighborhood model

Let us consider a model that consists of a quintuple:

$$< T, O, d, R, N >$$

where each element is as follows.

1. $T = \{t_1, \ldots, t_n\}$: a finite set of *terms* or *keywords*;
2. O and d: a metric space; O is a finite set of *term occurrences* where a metric d is defined;
3. R : a fuzzy relation of $T \times O$;
4. N : a fuzzy relation of $O \times O$ called *fuzzy neighborhood*.

ISBN: 978-989-95079-6-8

The relation $R(t,o)$ shows correspondence between a term and its occurrence. For simplicity we assume, for every $t \in T$, $R(t,\cdot) = \{o \in O : R(t,o) > 0\}$ is not empty. The most simple relation is

$$R(t,o) = \begin{cases} 1 & (o \text{ is an occurrence of } t), \\ 0 & (\text{otherwise}), \end{cases}$$

and this relation is assumed hereafter in this paper.

Moreover we impose the following conditions to N:

(i) $N(o,o) = 1$ for all $o \in O$;

(ii) $d(o,o') > d(o,o'') \Rightarrow N(o,o') \leq N(o,o'')$;

(iii) $N(o,o') \to 0$ as $d(o,o') \to \infty$;

(iv) $N(o,o') = N(o',o)$.

Our purpose is to define a natural inner product space on T using the structure of occurrence space. We define a proximity relation $p(t,t')$, $t,t' \in T$:

$$p(t,t') = \sum_{o\in O}\sum_{o'\in O} R(t,o)N(o,o')R(t',o'). \tag{12}$$

If the matrix $P = (p(t,t'))$ is positive-definite, we can define an inner product space. If P is positive definite, we can use a normalized relation

$$s(t,t') = \frac{p(t,t')}{\sqrt{p(t,t)p(t',t')}}. \tag{13}$$

which is also positive-definite.

Generally, the above equation (12) does not guarantee the positive definiteness. We hence consider conditions for the positive-definiteness. To obtain a general condition is not practically useful. We therefore describe a specific, but broad enough, application example.

3.2 A model of a text set

A set of texts where each term may occur many times is represented as a sequence. For example, let a term set is $T = \{a,b,c\}$. Then an example of O can be represented by

$$O = aabcbbcccabbccabab$$

or more precisely, we put suffixes:

$$O = a_1\, a_2\, b_1\, c_1\, b_2\, b_3\, c_2\, c_3\, c_4\, a_3\, b_4\, b_5\, c_5\, c_6\, a_4\, b_6\, a_5\, b_7 \tag{14}$$

in order to distinguish occurrences. Obviously, $R(a,\cdot) = \{a_1,\ldots,a_5\}$. What if two or more texts should be handled? We can connect those texts into a sequence using dummy terms. Hence a sequence is sufficient to represent a set of texts. A natural distance d on O is given by

$$d(o,o') = \{\text{the number of occurrences between } o \text{ and } o'\}+1 \tag{15}$$

Thus, $d(a_1,c_1) = 3$, $d(c_6,c_2) = 7$, *etc* in the above example.

Next, two specific examples of fuzzy neighborhood are considered.

Fuzzy neighborhood using a monotone function

Let us show and example of a fuzzy neighborhood. For this purpose we introduce a monotone-decreasing function $f\colon \boldsymbol{R} \to [0,1]$ such that

(I) $f(0) = 1$,

(II) $f(-x) = f(x)$,

(III) $\lim_{x\to\infty} f(x) = 0$.

We define

$$N(o,o') = f(d(o,o')). \tag{16}$$

We have

Proposition 4. *Fuzzy relation $N(o,o')$ defined by (16) satisfies the conditions (i)–(iv) for a fuzzy neighborhood.*

The next proposition is crucial to this model.

Proposition 5. *If function $f(x)$ is convex on $[0,\infty)$, then $P = (p(t,t'))$ is positive-definite. Namely, we can define an inner product space using P.*

Let us consider a simple example where a convex function

$$f(x) = \begin{cases} 1 - \frac{x}{3} & (0 \leq x \leq 3) \\ 0 & (x > 3) \end{cases}$$

is used and $f(-x) = f(x)$. For the example of (14), $N(a_1,b_1) = 1/3$, $N(a_2,b_1) = 2/3$, *etc*. we hence have

$$p(a,b) = \sum_{i=1}^{5}\sum_{j=1}^{7} N(a_i,b_j) = 4.$$

3.3 Fuzzy neighborhood using a hierarchical structure

Another class for fuzzy neighborhood uses a hierarchical structure of a text, that is, a text frequently has chapters, sections, subsections, and paragraphs. Hence the next distance can be induced using $0 < \alpha < \beta < \gamma$.

- If o and o' occurs in a same paragraph, $d(o,o') = \alpha$;
- else if o and o' occurs in a same subsection, $d(o,o') = \beta$;
- else if o and o' occurs in a same section, $d(o,o') = \gamma$;
- else $d(o,o') = \infty$.

Such a distance induced from a hierarchical classification satisfies

$$d(o,o'') \leq \max\{d(o,o'), d(o',o'')\}. \tag{17}$$

which is called ultra-metric property. It is also known that this property is equivalent to fuzzy equivalence that is also called fuzzy similarity. That is,

$$N(o,o') = f(d(o,o')) \tag{18}$$

is a fuzzy equivalence.

We have the next proposition.

Proposition 6. *If $d(o,o')$ satisfies (17) and $N(o,o')$ is defined by (18), then $P = (p(t,t'))$ is positive-definite. Namely, we can define an inner product space using this P.*

ISBN: 978-989-95079-6-8

Let us moreover consider a particular case of d when O consists of documents $D_1, \ldots, D_m$:

$$d(o, o') = \begin{cases} 0 & (o \text{ and } o' \text{ are in a same document}), \\ \infty & (o \text{ and } o' \text{ are in different documents}). \end{cases} \tag{19}$$

Suppose also that the frequency of occurrences of t in D_i is $F_i(t)$.

We have the next proposition.

Proposition 7. *If $d(o, o')$ is given by (19) and $N(o, o')$ is defined by (18). then*

$$p(t, t') = \sum_{i=1}^{m} F_i(t) F_i(t'), \tag{20}$$

which is used in the vector space model.

We thus note that the model in this section generalizes the vector space model.

Finally, we note that the above model can directly be applied to a document set $D = \{d_1, \ldots, d_m\}$ using

$$R_D(d, t) = \begin{cases} 1 & (\ t \text{ occurs in } d), \\ 0 & (\ t \text{ doe no not occur in } d). \end{cases}$$

Then we have a positive definite measure between two documents:

$$p_D(d, d') = \sum_{t, t' \in T} R_D(d, t) p(t, t') R_D(d', t'), \tag{21}$$

and a normalized measure

$$s_D(d, d') = \frac{p_D(d, d')}{\sqrt{p_D(d, d) p_D(d', d')}}, \tag{22}$$

which can be used as inner products of the document space.

4 Numerical Examples

We briefly show the results of kernel fuzzy c-means clustering (KFCM) with the kernel principal components (KPCA) applied to a set of documents extracted from a Japanese newspaper articles. Sixty articles from ASAHI Shinbun (ASAHI News) have been used. They are categorized by the publisher into three categories of 'Economics', 'Politics', and 'Social Affairs'; each category has 20 articles. Each of these categories are subdivided into subcategories of 'economic statistics', 'finance', and so on. Terms occurred more than twice were used and the number of terms is 556. The above measure (22) has been used throughout. The method of fuzzy c-means with $m = 1.2$ and with $c = 3$ has been applied. The following two neighborhood functions have been used.

- First type uses a convex function $f(x) = 1.2^{-d(o,o')}$.
- Second type uses a fuzzy equivalence: If two term occurrences are the same term, $N(o, o') = 1$; if they are in a same paragraph, $N(o, o') = 0.9$; if they are in a same document, $N(o, o') = 0.7$; if they are in a same subcategory: $N(o, o') = 0.5$; if they are in a same category: $N(o, o') = 0.3$.

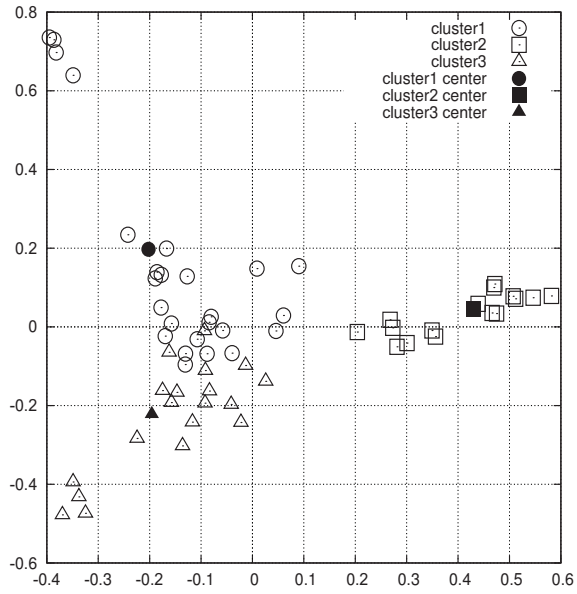

Figure 1: Two-dimensional display from KPCA with three clusters and cluster centers, where the first type of neighborhood function $f(x) = 1.2^{-d(o,o')}$ has been used.

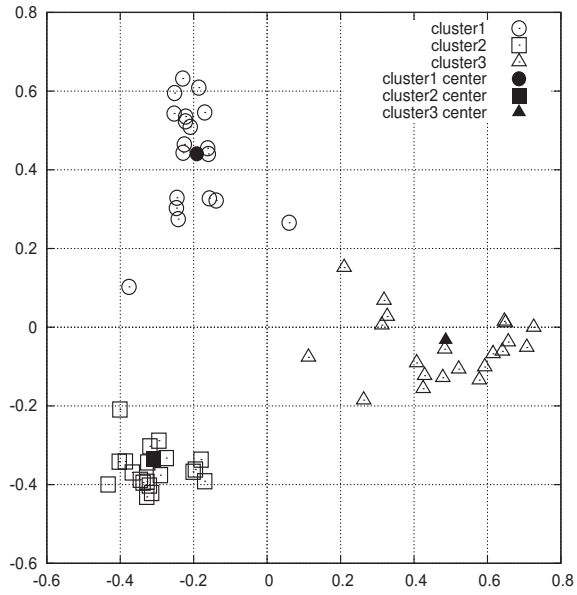

Figure 2: Two-dimensional display from KPCA with three clusters and cluster centers, where the second type of fuzzy equivalence has been used.

Figures 1 and 2 respectively show the two-dimensional figures of two-major axes from KPCA using the first and the second types of neighborhoods. The three symbols of white squares, triangles, and circles show the three clusters obtained from KFCM: fuzzy clusters have been made crisp by the maximum membership rule

$$x_k \to \textit{cluster } i \iff u_{ki} = \max_{1 \le j \le c} u_{kj}.$$

The black square, triangle, and circle are the cluster centers of the corresponding clusters. It seems that the second neigh-

ISBN: 978-989-95079-6-8

borhood of fuzzy equivalence divides more clearly the three clusters.

We have checked the correspondence of the obtained clusters with the actual classification provided from the publisher. The six correspondences have all been checked and the maximum correspondence percentages are given next. In the calculation 1000 trials with random initial values were used and the average numbers are shown below. That is, when we used the first type of neighborhood, the correct classification ratio was 73.5%, while the second type of fuzzy equivalence produced 97.9%.

We also tested a subclass of the above articles: 20 'Economics' and 20 'Politics' articles with the same conditions except that the number of clusters $c = 2$. The number of terms which occurred more than twice is 390. The results are shown as Figures 3 and 4. The separation was better than the previous case of three clusters. The correct classification ratio was 93.2% for the first type of neighborhood and 99.8 for the second neighborhood.

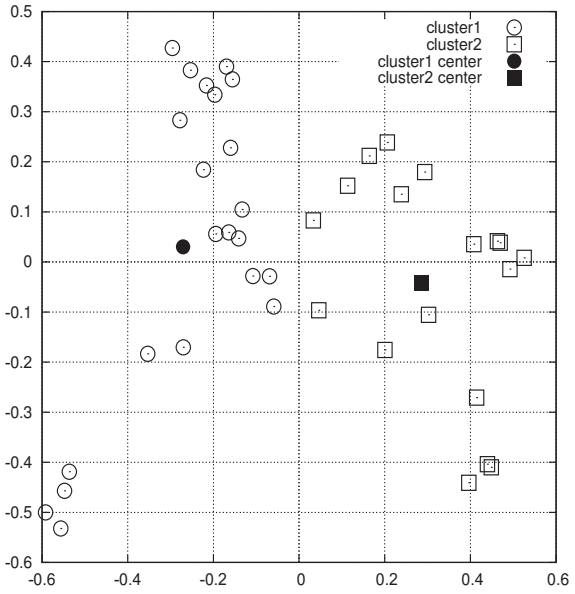

Figure 3: Two-dimensional display from KPCA with two clusters and cluster centers, where the first type of neighborhood function $f(x) = 1.2^{-d(o,o')}$ has been used.

5 Conclusion

We have proposed the use of an explicit mapping for kernel based data analysis. To summarize, we note the following advantages of the present method.

1. Using this mapping, we do not lose any fundamental information in kernel data analysis.
2. Generally the derivation becomes simpler using this mapping.
3. New applications of the kernel methods become easier using this mapping.

The last statement should be put into practice. In relation to fuzzy clustering, the method of fuzzy c-varieties should be

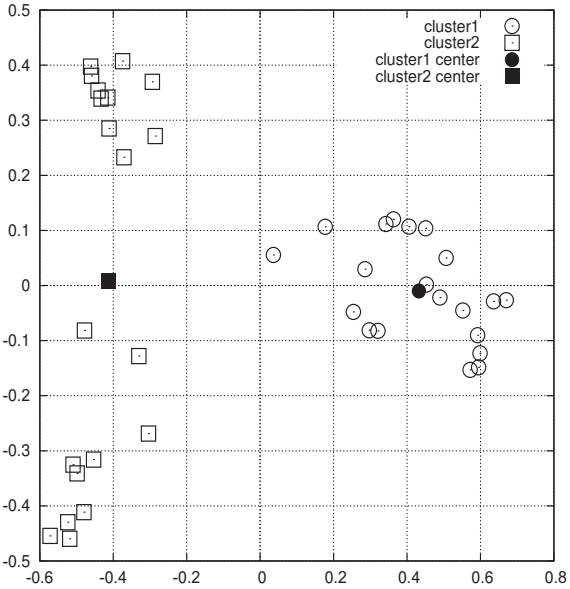

Figure 4: Two-dimensional display from KPCA with two clusters and cluster centers, where the second type of fuzzy equivalence has been used.

studied. We moreover have many research possibilities related to SOM.

This mapping invokes several problems to be solved. For example, when the number of objects are large, we have a problem of many dimensions which should be overcome using some handling large matrix techniques. We also should consider when and where such an explicit mapping become useless. Clarification of such a boundary between usefulness and uselessness is the ultimate objective of the present study.

Appendix: Notes on Proofs

Since detailed proofs are too lengthy, we give notes on how to prove the propositions given here. The proofs are mostly straightforward.

Note on proof of Proposition 1

The detailed proof is given in standard textbooks [9]. As a rough sketch of the proof, note that the Mercer condition[10]

$$\int \int \boldsymbol{K}(x,y)\eta(x)\eta(y)dxdy \geq 0$$

for all $\eta(x)$ guarantees

$$\sum_{i,j} \boldsymbol{K}(x_i,x_j)\zeta_i\zeta_j \geq 0$$

$\forall \zeta_i \in \boldsymbol{R}$, by putting $\eta(x) = \sum_i \zeta_i \delta(x - x_i)$. Thus the matrix $K = (\boldsymbol{K}(x_i,x_j))$ is positive semi-definite. The kernel function generally does not distinguish positive semi-definiteness

ISBN: 978-989-95079-6-8

and positive definiteness, while positive-definiteness is required for the definition of an inner product. For this purpose a simple trick is to use a regularization which means that we take

$$K \to K + \epsilon I \quad (\epsilon > 0)$$

where ϵ is sufficiently small. The matrix $K + \epsilon I$ is positive definite and approximates K when K is positive semi-definite. In this paper we thus assume positive-definiteness throughout, by using such a regularization when needed.

Note on proof of Proposition 2

The proof of this proposition is not difficult by observing closely (6). Note that W_i given by (6) is the solution of

$$\min_{W_i} \sum_k (u_{ki})^m \|x_k - W_i\|^2$$

where the space can be an arbitrary inner product space, since the derivation of (6) uses a general variational principle valid for any Hilbert space. Note moreover that we substitute (11) into (5) to have the optimal solution of U. It should be noted that although optimal W_i is the same for all positive definite kernel, optimal U differs because (10) give different values for different kernels.

Note on proof of Proposition 3

A straightforward calculation shows this proposition is valid.

Note on proof of Proposition 4

The proof is immediate and omitted here.

Note on proof of Proposition 5

Take an arbitrary $c \in O$. The conclusion is immediately obtained from the Pólya's theorem [7] which states that

$$\sum_{a,b} z_a z_b f(|x(a) - x(b)|) \geq 0$$

when f is convex on $[0, +\infty)$ and $f(x) \to 0$ as $x \to +\infty$. Note that $x(a)$ is the real value defined by $x(a) = D(a, c)$ when a is the left hand of c; $x(a) = -D(a, c)$ when a is right hand of c.

Note on proof of Proposition 6

To prove this proposition, we consider a partition matrix $U = (u_{ij})$. Namely, an $n \times n$ real matrix U is called a partition matrix iff there exists a partition $K_1, \ldots, K_c$ of $\mathbf{n} = \{1, 2, \ldots, n\}$ ($\bigcup_j K_j = \mathbf{n}$ and $K_i \cap K_j = \emptyset$, for $i \neq j$) such that

$$u_{ij} = 1 \quad \forall i, j \in K_h$$

for some h and

$$u_{ij} = 0 \quad \forall i \in K_\ell, j \in K_h$$

for $h \neq \ell$.

We have

Lemma: *A partition matrix U is positive semi-definite. It is positive definite if and only if U is identity matrix ($U = I$).*

The proof of the lemma is immediate by observing

$$x^t U x = \sum_{i=1}^{c} \left(\sum_{x_j \in K_i} x_j \right)^2 .$$

The proof of this proposition is now straightforward. We assume that O is a finite set for simplicity. Then an equivalence relation is represented by a partition matrix. Moreover a fuzzy equivalence relation F is represented by a finite collection $U_1, \ldots, U_k$ of partition matrix and positive $\beta_1, \ldots, \beta_k$:

$$F = \sum_{j=1}^{k} \beta_j U_j.$$

Consequently we have

$$x^t F x = \sum_{j=1}^{k} \beta_j x^t U_j x \geq 0.$$

Hence $N(a, b)$ is positive definite. From Proposition 6, $p(t, t')$ is also positive definite. The proposition is thus proved.

Note on proof of Proposition 7

By straightforward calculation, we see this proposition holds.

***Abstract*— *Distorted probabilities are an important family of fuzzy measures. In a recent paper we introduced m-dimensional distorted probabilities, which generalize the former and permit us to have a smooth transition from distorted probabilities to unconstrained ones.*

In this paper we introduce the union condition and the strict union condition, and we show that when these conditions hold for a fuzzy measure, the fuzzy measure is a distorted probability. In addition, we present a few results that establish some relationships between other fuzzy measures.

Keywords: Fuzzy measures, distorted probabilities, m-dimensional distorted probabilities, m-symmetric fuzzy measures, union condition, strict union condition.

1 Introduction

Aggregation operators [28] are used in a large number of applications to combine information from different sources. Although the weighted mean is probably the most well known aggregation operator, other operators exist. E.g., the OWA, the WOWA and some fuzzy integrals. Choquet and Sugeno integrals are examples of such fuzzy integrals.

Fuzzy integrals permits the user to combine information when the sources supplying the information are not independent. To express this a priori knowledge about the sources, fuzzy integrals combine the input data with the information about the sources. Formally, the integrals integrate a function, which represents the data being aggregated, with respect to a fuzzy measure, which represents the a priori information about the sources.

A major difficulty for applying fuzzy integrals in real applications is that they are set functions, and thus, for any aggregation problem with n inputs, 2^n values should be defined. In fact, properly speaking, boundary conditions on the measure reduce this number to $2^n - 2$.

Real applications try to reduce the number of $2^n - 2$ required values using constrained measures. That is, measures that require less than $2^n - 2$ parameters. Sugeno λ-measures are probably the most used ones [22, 23, 20, 21]. Such measures solely require n values as well as an additional parameter λ, which can be deduced from the n values as [10] shows. k-order additive fuzzy measures are another family of measures with reduced complexity. This family, that has been extensively studied, is of special interest because the parameter k permits us to find a trade-off between expressiveness and complexity. In short, when $k = 1$ the measure has the lowest complexity (only $n - 1$ values are required) but it corresponds to a probability distribution. Instead, when $k = n$, any unconstrained fuzzy measure can be represented but at the cost of the highest complexity ($2^n - 2$ values should be defined).

In this paper we study m-dimensional distorted probabilities, another family of measures, introduced in [16], that generalizes distorted probabilities. Informally, distorted probabilities are measures that can be expressed in terms of a probability distribution and a function that distorts this distribution. Such measures, which were originated in psychology [19, 4, 5], have been extensively used. See, for example, the book by Aumann and Shapley (1974) [1] and their recent use in game theory. Recent research on such measures is on their determination either from examples (as in [27]) or from interviews [9]. Nevertheless, the modeling capabilities of distorted probabilities are limited. In [16] it was shown that the number of such measures with respect to the number of unconstrained ones is very small. Moreover, the larger is n, the smaller is the proportion of distorted probabilities. So, in most cases, fuzzy measures cannot be represented using distorted probabilities. To overcome this problem, we introduced in [16] m-dimensional distorted probabilities.

In this work we present some new results with respect to this family of measures. We show some conditions that, when fulfilled, imply distorted probabilities.

Other families of fuzzy measures have been studied in the literature. Two of them, that are relevant for the present paper, are the m-symmetric fuzzy measures [11, 12] and the hierarchically decomposable ones [26]. Some results establishing some relationships between these measures and distorted probabilities will be given.

The structure of the paper is as follows. In Sections 2, we review some concepts that are needed later on. In Section 3, we present the results establishing the connections among different kinds of fuzzy measures. The paper finishes with some conclusions.

2 Preliminaries

This section reviews some previous results in the literature that are needed in the rest of the paper. We start by defining fuzzy measures, and some of their families. Among them, we review m-dimensional distorted probabilities and a few results concerning these measures. The section finishes with a review of a few aggregation operators that are relevant for the purpose of this paper.

ISBN: 978-989-95079-6-8

2.1 Fuzzy measures

In this paper we will consider fuzzy measures on a finite universal set $X = \{x_1, \ldots, x_n\}$. For the sake of simplicity, when possible, we will consider $X := \{1, \ldots, n\}$. Now, we review the definition of fuzzy measure.

Definition 1 *A set function $\mu : 2^X \to [0, 1]$ is a fuzzy measure if it satisfies the following axioms:*

(i) $\mu(\emptyset) = 0$, $\mu(X) = 1$ *(boundary conditions)*

(ii) $A \subseteq B$ *implies* $\mu(A) \leq \mu(B)$ *(monotonicity)*

In order to distinguish measures satisfying (i) and (ii) with others that also satisfy some additional constraints (*e.g.* additivity $\mu(A \cup B) = \mu(A) + \mu(B)$ when $A \cap B = \emptyset$), we use the terms *unconstrained* fuzzy measures for the former ones and *constrained* fuzzy measures for the others.

2.2 m-symmetric fuzzy measures

The definition of these measures is based on the concept of *set of indifference*. Roughly speaking, a set of indifference is defined by elements that do not affect the value of the measure. That is, the elements of a set are indistinguishable with respect to the fuzzy measure.

Definition 2 *[11, 12] Given a subset A of X, we say that A is a set of indifference if and only if:*

$$\forall B_1, B_2 \subseteq A, |B_1| = |B_2|,$$

$$\forall C \subseteq X \setminus A \quad \mu(B_1 \cup C) = \mu(B_2 \cup C)$$

In this definition $|\cdot|$ corresponds to the cardinality of a set. We now consider m-symmetric fuzzy measures for the particular case of $m = 2$ and, then, we give the general definition.

Definition 3 *[11, 12] Given a fuzzy measure μ, we say that μ is an at most 2-symmetric fuzzy measure if and only if there exists a partition of the universal set $\{X_1, X_2\}$, with $X_1, X_2 \neq \emptyset$ such that both X_1 and X_2 are sets of indifference. An at most 2-symmetric fuzzy measure is 2-symmetric if X is not a set of indifference.*

Definition 4 *[11, 12] Given a fuzzy measure μ, we say that μ is an at most m-symmetric fuzzy measure if and only if there exists a partition of the universal set $\{X_1, \ldots, X_m\}$, with $X_1, \ldots, X_m \neq \emptyset$ such that $X_1, \ldots X_m$ are sets of indifference.*

The next proposition follows from this definition.

Proposition 1 *Every fuzzy measure μ is an at most n-symmetric fuzzy measure for $n = |X|$.*

So, all fuzzy measures can be considered as m-symmetric for a value of m large enough.

Definition 5 *[11, 12] Given two partitions $\{X_1, \ldots, X_p\}$ and $\{Y_1, \ldots, Y_r\}$ on the finite universal set X, we say that $\{X_1, \ldots, X_p\}$ is coarser than $\{Y_1, \ldots, Y_r\}$ if the following holds:*

$$\forall X_i \exists Y_j \text{ such that } Y_j \subseteq X_i$$

Definition 6 *Given a fuzzy measure μ, we say that μ is m-symmetric if and only if the coarsest partition of the universal set in sets of indifference contains m non empty sets. That is, the coarsest partition is of the form: $\{X_1, \ldots, X_m\}$, with $X_i \neq \emptyset$ for all $i \in \{1, \ldots, m\}$.*

Proposition 2 *[11, 12] Let μ be an m-symmetric measure with respect to the partition $\{X_1, \ldots, X_m\}$. Then, the number of values that are needed in order to determine μ is:*

$$\big[(|X_1| + 1) \cdots (|X_m| + 1)\big] - 2$$

An m-symmetric fuzzy measure can be represented in a $(|X_1| + 1) \cdots (|X_m| + 1)$ matrix M.

2.3 Hierarchically S-Decomposable Fuzzy Measures

[26] introduced Hierarchically S-Decomposable Fuzzy Measures. These measures (HDFM for short) can be seen as a generalization of S-decomposable measures. An important characteristic of S-decomposable fuzzy measures, is that the measure for any subset of X can be built from the measures on the singletons and a t-conorm S. When interactions among information sources are considered, such construction means that the interactions among pairs (or subsets) of sources can be expressed in a single and unique way. In particular, all interactions are modeled using the t-conorm S.

The so-called hierarchically S-decomposable fuzzy measures define a more general family of fuzzy measures as they permit us to express different kind of interactions between different subsets. This is achieved permitting us the use of different t-conorms for combining the measures of different singletons (and of different subsets).

This is obtained as follows: (i) the elements in X are structured in a hierarchy that gathers together elements that are *similar* (from the interactions point of view); (ii) each node of the hierarchy has associated a t-conorm to be used to *combine* the interactions. In this way, a richer variety of interactions can be expressed.

For example, if we have a fuzzy measure $\mu : 2^X \to [0, 1]$ with $X = \{x_1, x_2, x_3, x_4, \ldots, x_n\}$ such that $\mu(\{x_1\}) = 0.2$, $\mu(\{x_2\}) = 0.4$, $\mu(\{x_3\}) = 0.3$ and $\mu(\{x_4\}) = 0.3$. Then, we have a negative interaction between x_1 and x_2 defining $\mu(\{x_1, x_2\}) = \max(\mu(\{x_1\}), \mu(\{x_2\}))$. Instead, for a positive interaction between x_3 and x_4 we define $\mu(\{x_3, x_4\}) = \min(1, \mu(\{x_3\}) + \mu(\{x_4\}))$. Both situations can be modeled with the t-conorms $S_1(x, y) = \max(x, y)$ and $S_2(x, y) = \min(1, x + y)$.

We give below the definition for the particular case of 2-level HDFM. That is, a measure where the hierarchy has only two levels.

Definition 7 *[26] Given a fuzzy measure μ, we say that μ is a 2-level Hierarchically Decomposable Fuzzy Measure (2-level HDFM) if there is a partition $\{X_1, \ldots, X_m\}$ on X (we denote the elements in X_i by $X_i = \{x_{i,1}, \ldots, x_{i,m_i}\}$) and t-conorms S, S_1, …, S_m such that:*

$$\mu(A) = S(r_1(A), \ldots, r_m(A))$$

where

$$r_i(A) = S_i(\mu(\{x_{i,1}\} \cap A), \ldots, \mu(\{x_{1,m_i}\} \cap A))$$

ISBN: 978-989-95079-6-8

In the general case of HDFM, not presented here, a complete hierarchy is permitted and, then, the measure is defined recursively for each node using the t-conorm attached to the node, and the partition associated to the node.

2.4 Distorted probabilities

As briefly described in the introduction, distorted probabilities correspond to fuzzy measures that can be represented by a probability distribution and a distortion function. We formalize these measures as well as the required concepts below:

Definition 8 *Let $P : 2^X \to [0,1]$ be a probability measure. Then, we say that a function f is strictly increasing with respect to P if and only if*

$$P(A) > P(B) \text{ implies } f(P(A)) > f(P(B))$$

Remark: Since we suppose that X is a finite set, when there is no restriction on the function f, a strictly increasing function f with respect to P can be regarded as a strictly increasing function on $[0,1]$. Note that with respect to increasingness only the points in $\{P(A)|A \in 2^X\}$ are essential, the others are not considered by $f(P(A))$.

Definition 9 *[1, 2] Let μ be a fuzzy measure. We say that μ is a distorted probability if there exists a probability distribution P and a strictly increasing function f with respect to P such that $\mu = f \circ P$.*

The next theorem gives the necessary and sufficient condition for a fuzzy measure μ to be a distorted probability. The theorem is based on *Scott's condition*:

Definition 10 *[16] Let μ be a fuzzy measure, μ satisfies* Scott's condition *when for all $A_i, B_i \in 2^X$ such that $\sum_{i=1}^n 1_{A_i} = \sum_{i=1}^n 1_{B_i}$ the condition below holds:*
$\mu(A_i) \leq \mu(B_i)$ for $i = 2, 3, \ldots, n$ implies $\mu(A_1) \geq \mu(B_1)$.

Here 1_A represents the characteristic function of the set A. That is $1_A(x) = 1$ if and only if $x \in A$.

Using this condition, we can characterize distorted probabilities as follows:

Theorem 1 *[16] Let μ be a fuzzy measure; then, μ is a distorted probability if and only if Scott's condition holds.*

2.5 m-dimensional distorted probabilities

m-dimensional distorted probabilities were presented in [16] to overcome the limited expressiveness of distorted probabilities. They are defined as follows:

Definition 11 *[16] Let $\{X_1, X_2, \cdots, X_m\}$ be a partition of X; then, we say that μ is an at most m dimensional distorted probability if there exists a function f on $\mathbb{R}^m$ and probabilities P_i on $(X_i, 2^{X_i})$ such that:*

$$\mu(A) = f(P_1(A \cap X_1), P_2(A \cap X_2), \cdots, P_m(A \cap X_m)) \quad (1)$$

where f on $\mathbb{R}^m$ is strictly increasing with respect to each variable.

We say that an at most m dimensional distorted probability μ is an m dimensional distorted probability if μ is not an at most $m-1$ dimensional.

The next proposition follows from the definition above.

Proposition 3 *Every fuzzy measure is an at most n-dimensional distorted probability with $n = |X|$.*

Note that for $n = |X|$, we are considering the following partition of X: $\{X_1 = \{x_1\}, \ldots, X_n = \{x_n\}\}$. So, $f(a_1, \ldots, a_n) = \mu(A)$ when $a_i = 1$ if and only if $x_i \in A$.

Also, we can prove that m-dimensional distorted probabilities define a family of measures with increasing complexity with respect to m. This means that increasing the value of m, the number of measures representable increases. The following proposition establishes this property.

Proposition 4 *Let $\mathcal{M}_k$ be the set of all fuzzy measures that are k-dimensional distorted probabilities and let $\mathcal{M}_0$ be the empty set. Then $\mathcal{M}_{k-1} \subset \mathcal{M}_k$ for all $k = 1, 2, \ldots, |X|$.*

Corollary 1 *Given a fuzzy measure μ, there exists a $k \in \{1, 2, \ldots, |X|\}$ such that $\mu \in \mathcal{M}_k$ and $\mu \notin \mathcal{M}_{k-1}$.*

Therefore, the proposed family of fuzzy measures permits us to cover the whole set of fuzzy measures.

2.6 Aggregation operators

Now we define the OWA and the WOWA operators. They will be of relevance in this work. As explained in detail in [25], the OWA operator permits to give importance to the data (with respect to their position) while the WOWA permits to give importance to the data (as the OWA operator) and also to the information sources (as the weighted mean does).

Definition 12 *[29, 30] Let $\mathbf{w}$ be a weighting vector of dimension n (*i.e.*, $w_i \geq 0$ and $\sum_{i=1}^n w_i = 1$), then a mapping OWA: $\mathbb{R}^n \to \mathbb{R}$ is an* Ordered Weighted Averaging (OWA) operator *of dimension n if*

$$OWA_{\mathbf{w}}(a_1, ..., a_n) = \sum_{i=1}^{n} w_i a_{\sigma(i)}$$

where $\{\sigma(1), ..., \sigma(n)\}$ is a permutation of $\{1, ..., n\}$ such that $a_{\sigma(i-1)} \geq a_{\sigma(i)}$ for all $i = \{2, ..., n\}$ (i.e. $a_{\sigma(i)}$ is the i-th largest element in the collection $a_1, ..., a_n$).

Definition 13 *[25] Let $\mathbf{p}$ and $\mathbf{w}$ be two weighting vectors of dimension n, then a mapping WOWA: $\mathbb{R}^n \to \mathbb{R}$ is a* Weighted Ordered Weighted Averaging (WOWA) operator *of dimension n if*

$$WOWA_{\mathbf{p},\mathbf{w}}(a_1, ..., a_n) = \sum_{i=1}^{n} \omega_i a_{\sigma(i)}$$

where σ is defined as in the case of the OWA, and the weight ω_i is defined as:

$$\omega_i = w^*(\sum_{j \leq i} p_{\sigma(j)}) - w^*(\sum_{j<i} p_{\sigma(j)})$$

with w^* being a non-decreasing function that interpolates the points $\{(i/n, \sum_{j \leq i} w_j)\}_{i=1,\ldots,n}$ together with the point $(0,0)$. The function w^* is required to be a straight line when the points can be interpolated in this way.

ISBN: 978-989-95079-6-8

Alternatively, it is possible to define the WOWA operator directly using the function w^*. This will be denoted by $WOWA_{\mathbf{p},w^*}(a_1,\ldots,a_n)$ or $WOWA_{\mathbf{p},w^*}(f)$ when f is a function $f : X \to \mathbb{R}$ such that $f(x_i) = a_i$. In this latter case, we will read $WOWA_{\mathbf{p},w^*}(f)$ as the $WOWA$ of f with respect to $\mathbf{p}$ and w^*.

We finish the section with the definition of the Choquet integral.

Definition 14 *[3] Let μ be a fuzzy measure, then the* Choquet integral *of a function $f : X \to \mathbb{R}^+$ with respect to the fuzzy measure μ is defined by:*

$$(C)\int f d\mu (= C_\mu(f)) = \sum_{i=1}^{n} [f(x_{s(i)}) - f(x_{s(i-1)})]\mu(A_{s(i)})$$

where $x_i \in X$ and where $f(x_{s(i)})$ indicates that the indices have been permuted so that
$0 \le f(x_{s(1)}) \le \cdots \le f(x_{s(n)}) \le 1$,
$A_{s(i)} = \{x_{s(i)},\ldots,x_{s(n)}\}$ *and* $f(x_{s(0)}) = 0$.

3 Distorted probabilities and symmetric fuzzy measures

3.1 A sufficient condition for distorted probablity

We have discussed above Scott's condition: Definition 10 for distorted probability. Nevertheless, this condition is not easy to check. We present below another condition under which a fuzzy measure is a distorted probability. The new condition is easier to check.

Definition 15 *We say that a fuzzy measure μ satisfies a union condition (for short UC), if $A \cap C = \emptyset, B \cap D = \emptyset$,*

$$\mu(A) \ge \mu(B), \mu(C) \ge \mu(D) \Rightarrow \mu(A \cup C) \ge \mu(B \cup D).$$

The next proposition is obvious from the definition.

Proposition 5 *Suppose that a fuzzy measure μ satisfies UC. We have $A \cap C = \emptyset, B \cap D = \emptyset$,*

$$\mu(A) = \mu(B), \mu(C) = \mu(D) \Rightarrow \mu(A \cup C) = \mu(B \cup D).$$

Definition 16 *We say that a fuzzy measure μ satisfies a strict union condition (for short SUC), if $A \cap C = \emptyset, B \cap D = \emptyset$,*

$$\mu(A) > \mu(B), \mu(C) \ge \mu(D) \Rightarrow \mu(A \cup C) > \mu(B \cup D).$$

Proposition 6 *Suppose that a fuzzy measure μ satisfies SUC. We have $A \cap C = \emptyset, B \cap C = \emptyset$,*

$$\mu(A) > \mu(B) \Rightarrow \mu(A \cup C) > \mu(B \cup C).$$

Applying Proposition 5,6,we have the next proposition.

Proposition 7 *Suppose that a fuzzy measure μ satisfies UC. There exists a function F on*

$$\{(x,y) | x = \mu(A), y = \mu(B), A \cap B = \emptyset, A, B \in 2^X\}$$

such that

$$\mu(A \cup B) = F(\mu(A), \mu(B))$$

for $A, B \in 2^X, A \cap B = \emptyset$, and

$$F(x,0) = x, F(F(x,y),z) = F(x,F(y,z)).$$

Moreover if μ satisfies both UC and SUC, F is strictly monotone with respect to each variable.

Suppose that a fuzzy measure μ satisfies both UC and SUC. Since F is strictly monotone on

$$\{(x,y) | x = \mu(A), y = \mu(B), A \cap B = \emptyset, A, B \in 2^X\},$$

the domain of F can be extended to $[0,1] \times [0,1]$ and F is monotone with respect to each variable and F is continuous. Then F can be represented by strictly monotone function φ on [0,1] as

$$F(x,y) = \varphi^{-1}(\varphi(x) + \varphi(y)).$$

That is,

$$F(\mu(A), \mu(B)) = \varphi^{-1}(\varphi(\mu(A)) + \varphi(\mu(B)))$$

for $A \cap B = \emptyset$. Therefore we have

$$\varphi(\mu(A \cup B)) = \varphi(\mu(A)) + \varphi(\mu(B)).$$

Let $P(A) := \varphi(\mu(A))$. Then, P is a probability and we have $\mu(A) = \varphi^{-1}(P(A))$. Therefore we have the next theorem.

Theorem 2 *A fuzzy measure μ is distorted probability if μ satisfies both UC and SUC.*

3.2 Symmetric fuzzy measure

We start showing that a 1-Symmetric fuzzy measure is a special case of distorted probabilities.

Proposition 8 *Let $\mu = f \circ P$ be a distorted probability. Then, μ is a 1-symmetric fuzzy measure if and only if $P(A) = |A|/|X|$.*

Now we show that all m-symmetric fuzzy measures are m-dimensional distorted probabilities. This implies that 1-symmetric fuzzy measures are distorted probabilities.

Proposition 9 *Let μ be an m-symmetric fuzzy measure with respect to the partition $\{X_1,\ldots,X_m\}$. Then, μ is an m-dimensional distorted probability.*

Although the reversal of this proposition is not true, the next proposition characterizes one case in which m-dimensional distorted probabilities are m-symmetric fuzzy measures.

Proposition 10 *Let μ be an m-dimensional distorted probability. If, $p_i(x_j) = p_i(x_k)$ for all $x_j, x_k \in X_i$ and for all $i = 1,\ldots,m$, then μ is an m-symmetric fuzzy measure.*

It is known that OWA operators are equivalent to Choquet integrals with respect to symmetric fuzzy measures. Therefore, m-symmetric fuzzy measures permit us to define a generalization of OWA operators. The m-dimensional OWA is defined below:

Definition 17 *The m-dimensional OWA is defined as the Choquet integral with respect to an m-symmetric fuzzy measure.*

As proven in [24], a Weighted OWA (WOWA) operator is equivalent to a Choquet integral with respect to a distorted probability. Therefore, a Choquet integral with an m-dimensional probability can be seen as a generalization of the WOWA operator. We define an m-dimensional WOWA as follows:

ISBN: 978-989-95079-6-8

Definition 18 *The m-dimensional WOWA is defined as the Choquet integral with respect to an m-dimensional distorted probability.*

Then, considering Definitions 17 and 18 above, we have the following corollary from Proposition 9:

Corollary 2 *An m-dimensional OWA is a particular case of an m-dimensional WOWA. In other words, a Choquet integral with respect to an m-symmetric fuzzy measure is a particular case of a Choquet integral with respect to an m-dimensional distorted probability.*

3.3 m-separable fuzzy measure

As shown in Proposition 9, m-symmetric fuzzy measures are one special class of the m-dimensional distorted probabilities. We present another special class of fuzzy measure

Definition 19 *Let μ be a fuzzy measure. Then, we say that μ is a m-separable fuzzy measure if there exists a function g and a partition $\{X_1, \ldots, X_m\}$ of X such that*

$$\mu(A) = g(\mu(A \cap X_1), \ldots, \mu(A \cap X_m)) \tag{2}$$

where g is a m-dimensional function on $\mathbb{R}^m$. We say that g is a generating function for μ. We say that a generating function g is induced by h on $[0,1] \times [0,1]$ if $g(x_1, \ldots, x_m) = h(h(\ldots h(x_1, x_2), \ldots, x_{m-1}), x_m)$, $g(x_1, x_2, 0, \ldots, 0) = h(x_1, x_2)$.

Example 1 *Let $\{X_1, \ldots, X_m\}$ be a partition of X.*

1. *Suppose $g(x_1, \ldots, x_m) = x_1 + \cdots + x_m$, so g is induced by $h(x, y) = x + y$. Then we have*

$$\mu(A) = \mu(A \cap X_1) + \cdots + \mu(A \cap X_m).$$

This is an interadditivity defined in [14].

2. *Suppose $g(x_1, \ldots, x_m) = x_1 \vee \cdots \vee x_m$, so g is induced by $h(x, y) = x \vee y$. Then we have*

$$\mu(A) = \mu(A \cap X_1) \vee \cdots \vee \mu(A \cap X_m).$$

3. *Suppose $g(x_1, \ldots, x_m) = (x_1^2 + \cdots + x_m^2)^{1/2}$, so g is induced by $h(x, y) = (x^2 + y^2)^{1/2}$. Then we have*

$$\mu(A) = (\mu(A \cap X_1)^2 + \cdots + \mu(A \cap X_m)^2)^{1/2}.$$

Suppose that μ is a m-separable fuzzy measure generated by g and that g is induced by h. We say that h is associative if $h(h(x, y), z) = h(x, h(y, z))$. Suppose that h is strictly monotone and associative. Since g is symmetric, then h is symmetric, that is $h(x, y) = h(y, x)$. Then there exists a strictly monotone function φ such that $h(x, y) = \varphi^{-1}(\varphi(x) + \varphi(y))$. Define φ- Möbius inverse m^φ by

$$m^\varphi(A) := \sum_{B \subset A} (-1)^{|A \setminus B|} \varphi(\mu(B)).$$

Let $\mathcal{P}$ be a partition of X for a m-separable fuzzy measure. Applying theorem in [14], $m^\varphi(A) = 0 \Rightarrow A \not\subset C, C \in \mathcal{P}$. Let $M := \{A | m^\varphi(A) \neq 0\}$ We have $\mathcal{P} \subset M$. Define $A_l := \{A | A \in M, x_l \in A\}$ for $X = \{x_1, \ldots, x_l, \ldots, x_n\}$ and $M_l := \max\{|A| | A \in A_l\}$. Since $A \subset C, C \in \mathcal{P}$ for $A \in A_l$, we have the next proposition.

Proposition 11 *Let μ be a m - separable fuzzy measure generated by g, and g be induced by a strict monotone and associative h on $[0,1]$. Then we have*

$$m \times \min_{l \in |1,\ldots,n|} M_l \leq n.$$

We say that a fuzzy measure μ is a φ $k-$order additive if $max\{|A| | A \in M\} = k$. If $\varphi(x) = x$, a φ $k-$order additive fuzzy measure is a k-order additive fuzzy measure [6, 7].

Proposition 12 *Let μ be a m-separable fuzzy measure generated by g, and g be induced by strict monotone and associative h on $[0,1]$. If μ is k- additive, then we have $m \times k \geq n$.*

Now, we consider the relationship between the m-separable fuzzy measures and some other families of measures.

Proposition 13 *2-level HDFMs with S_i Archimedean t-conorms are a m-separable fuzzy measures.*

Theorem 3 *Let $\{X_1, \ldots, X_m\}$ be a partition of X and μ_i $i = 1, \ldots m$ be distorted probabilities represented by f_i and P_i (i.e., $\mu_i = f_i \circ P_i$). Then, there exists a m-separable fuzzy measure μ such that*

$$\sum_{i=1}^{m} ((C) \int f df_i \circ P_i) = (C) \int f d\mu \tag{3}$$

for all measurable function f.

As a corollary of this theorem, we have that the Choquet integral with respect to a m-separable fuzzy measure μ with $g(x_1, \ldots, x_m) = x_1 + \cdots + x_m$ can be represented as a two step Choquet integral.

Corollary 3 *Let μ be a m-separable fuzzy measure μ with $g(x_1, \ldots, x_m) = x_1 + \cdots + x_m$. Then the Choquet integral with respect to μ is represented as a two step Choquet integral of a 1st step integral with respect to a probability on $(1, \ldots, m)$. That is,*

$$(C) \int f d\mu = \int ((C) \int f df_i \circ P_i) dP(i). \tag{4}$$

4 Conclusions

In this paper we have introduced two new conditions, the Union Condition (UC) and the Strict Union Condition (SUC), and we have studied distorted probability under these conditions. We have shown that a fuzzy measure is a distorted probability when both UC and SUC conditions are satisfied.

***Abstract*—** This paper presents a continuation of the study on a mathematical morphology based on left-continuous conjunctive uninorms given in [1]. Experimental results are displayed using the morphological Top-Hat transformation, used to highlight certain components of the image, and on the reduction and elimination of noise using alternate filters that are generated with the operators of opening and closing associated with these morphological operators

***Keywords*—** Mathematical morphology, Top-Hat, alternate filters, uninorms, representable uninorms, idempotent uninorm.

1 Introduction

The fuzzy mathematical morphology is a generalization of binary morphology [2] using techniques of fuzzy sets [3, 4, 5, 6]. The basic tools of mathematical morphology are the so-called morphological operations that are applied to an image A, which is modified through a structural element B, whose size and shape are chosen in order to study the structure of the image A. The basic morphological operations are: erosion, dilation, opening and closing. Other fuzzy extensions have been introduced by others authors, see fo example [7, 6].

The fuzzy operators used to build a fuzzy morphology are conjunctors and implications. Among them, the most commonly used are the t-norms and their residual implications. Recently conjunctive uninorms, as a particular case of conjunctors, have also been used in this area [8, 9, 1]. In these two last recent works the authors use two kinds of conjunctive uninorms in order to obtain a mathematical morphology with "good" properties, including duality between the morphological operators.

This work can be seen as a continuation of [1] where the authors made a comparative study of the results obtained using the morphology based on uninorms with those obtained using t-norms and using the classical umbra approach. In that work, it is checked out that uninorms detect the edges of the images better than other approaches. Also, in [1], properties of idempotence and generalized idempotence for opening and closing operators based on uninorms are shown. Thus, the aim of this paper is to extend this study to " Top-Hat" operators (residual between openings and closings, a morphological gradient) based on uninorms, as well as to the so-called alternate filters (alternate compositions of openings and closings). The Top-Hat is used to highlight certain components of the image, while the alternate filters are used in elimination and reduction of noise.

The residuals and morphological gradients are still under study and have applications in image analysis. Thus, in [10], it is proposed a directional transition detection algorithm based on morphological residues, considering linear structurant elements. In 2002, T. Chen et al. in [11], design on the basis of mathematical morphology, a new detector of soft edges in dark regions called "Pseudo Top-Hat" which provides, in the case of the classical image of the video cameraman (see Figure 1), a better performance than those achieved by other edge detection methods used to compare the results. In [12], morphological gradients based on openings and closings were used to detect edges in CT medical images altered by noise. The results were compared with other contours detectors, improving the obtained edge images. More recently, in [13, 14] gradient operators are applied again to edge detection and image segmentation, respectively. Thus, in [13], an edge detector is developed for obtaining thin edges in regions or images with low-contrast. Tested with multiple images, even some of them disturbed by noise type salt and pepper and Gaussian noise of mean zero and variance 0.02, the method performs very well in comparison with the other four methods with which they work. In [14] operators were designed based on multiscale morphological gradients, addressing the segmentation problem of images to Computed Axial Tomography (CAT). All these works show that the morphological gradients remain relevant and useful in the analysis and image processing.

The removal, reduction and smoothing of noise is one of the key tasks of analysis and image processing as a preliminary step to artificial vision. Mainly because many techniques of interpretation, measurement, segmentation, detection of structures, among others, fail or diminish its effectiveness in presence of noise. In [12, 13] the designed gradient operators are robust in the presence of noise. Many efforts have been devoted in the literature, and also are currently devoted, to the smoothing, reduction and elimination of noise, from both points of view: crisp and fuzzy. Some examples can be seen in [15, 16, 17]. More specifically, we can find a good job on fuzzy filters in [18] and more recently, in [19], where noise reduction is handled. The design of basic and fast filters remains a subject of interest. In this work it will be studied the feasibility of alternate filters, from opening and closing of the fuzzy morphology based on uninorms, in order to use them in the elimination and reduction of noise.

This work is organized as follows. In the next section we will introduce the fuzzy morphological operators based on left-continuous conjunctive uninorms and their basic properties. Section 3 analyzes the Top-Hat and filtering based on this morphology and shows some experimental results together with their interpretations. Finally, Section 4 is devoted to conclusions and future work.

2 Fuzzy morphological operators and its properties

We assume known the basics facts on uninorms used in this work which, in any case, can be found in [20, 21, 22]. We will use the following notation: $\mathcal{I}$ is an implication, $\mathcal{C}$ a conjunction, $\mathcal{N}$ a strong negation, U a conjunctive uninorm with a neutral element e, $\mathcal{I}_U$ its residual implication, and finally A a gray-scale image and B a gray-scale structural element.

We recall the definitions of fuzzy morphological operators following the ideas of De Baets in [3]. The method consists in fuzzify the logical operations, i.e. the Boolean conjunction and the Boolean implication, to obtain fuzzy operators. An n-dimensional gray-scale image is modeled as an $\mathbb{R}^n \longrightarrow [0,1]$ function. The values of an image must be in $[0,1]$ in order to consider it as a fuzzy object. Then, we will proceed to explain this method from the following definitions and propositions.

Definition. The *fuzzy dilation* $D_{\mathcal{C}}(A,B)$ and *fuzzy erosion* $E_{\mathcal{I}}(A,B)$ of A by B are the gray-scale images defined by

$$D_{\mathcal{C}}(A,B)(y) = \sup_x \mathcal{C}(B(x-y), A(x)) \quad (1)$$

$$E_{\mathcal{I}}(A,B)(y) = \inf_x \mathcal{I}(B(x-y), A(x)). \quad (2)$$

Note that the reflection $-B$ of a fuzzy image B is defined by $-B(y) = B(-y)$, for all $y \in \mathbb{R}^n$. Given two images B_1, B_2, we will say that $B_1 \subseteq B_2$ when $B_1(y) \leq B_2(y)$ for all $y \in \mathbb{R}^n$.

Definition. The *fuzzy closing* $C_{\mathcal{C},\mathcal{I}}(A,B)$ and *fuzzy opening* $O_{\mathcal{C},\mathcal{I}}(A,B)$ of A by B are the gray-scale images defined by

$$C_{\mathcal{C},\mathcal{I}}(A,B)(y) = E_{\mathcal{I}}(D_{\mathcal{C}}(A,B), -B)(y) \quad (3)$$

$$O_{\mathcal{C},\mathcal{I}}(A,B)(y) = D_{\mathcal{C}}(E_{\mathcal{I}}(A,B), -B)(y). \quad (4)$$

In this paper, we use as conjunction two types of left-continuous conjunctive uninorms and as implication, their residual implications. Specifically these two types of uninorms are the following.

- The representable uninorms: Let $e \in]0,1[$ and let $h : [0,1] \longrightarrow [-\infty, \infty]$ be a strictly increasing, continuous function with $h(0) = -\infty$, $h(e) = 0$ y $h(1) = \infty$. Then $U_h(x,y) =$

$$\begin{cases} h^{-1}(h(x)+h(y)), & \text{if } (x,y) \notin \{(1,0),(0,1)\}, \\ 0, & \text{in other case,} \end{cases}$$

  is a conjunctive representable uninorm with neutral element e, see [20], and its residual implication $\mathcal{I}_{U_h}$ is given by $\mathcal{I}_{U_h}(x,y) =$

$$\begin{cases} h^{-1}(h(y)-h(x)), & \text{if } (x,y) \notin \{(0,0),(1,1)\}, \\ 1, & \text{in other case.} \end{cases}$$

  Moreover, U_h satisfies self duality (except at the points (0,1) and (1,0)) with respect to the strong negation $\mathcal{N}(x) = h^{-1}(-h(x))$, see [21].

- A specific type of idempotent uninorms: Let $\mathcal{N}$ be a strong negation. The function given by

$$U^{\mathcal{N}}(x,y) = \begin{cases} \min(x,y), & \text{if } y \leq \mathcal{N}(x), \\ \max(x,y), & \text{in other case,} \end{cases}$$

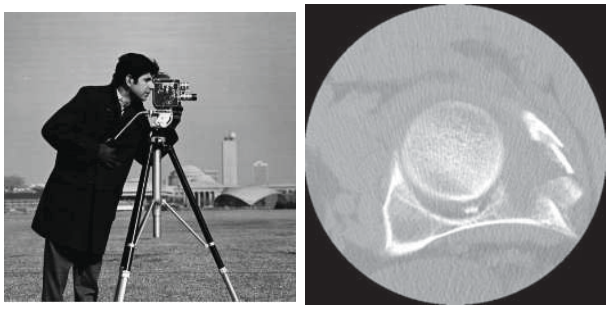

Figure 1: Original images used in experiments.

is a conjunctive idempotent uninorm. Its residual implication is given by (see [22])

$$\mathcal{I}_{U^{\mathcal{N}}}(x,y) = \begin{cases} \min(\mathcal{N}(x), y), & \text{if } y < x, \\ \max(\mathcal{N}(x), y), & \text{if } y \geq x. \end{cases}$$

These two types of conjunctive uninorms guarantees most of the good algebraic and morphological properties associated with the morphological operators obtained from them ([1, 9, 21, 22]). Among them, we highlight those described below. In all properties, U is a left-continuous conjunctive uninorm with neutral element $e \in]0,1[$, $\mathcal{I}_U$ its residual implication, A is a gray-level image and B a gray-scale structural element.

- The fuzzy dilation D_U is increasing in both arguments, the fuzzy erosion $E_{\mathcal{I}}$ is increasing in their first argument and decreasing in their second one, the fuzzy closing $C_{U,\mathcal{I}_U}$ and the fuzzy opening $O_{U,\mathcal{I}_U}$ are both increasing in their first argument.
- If $B(0) = e$ the fuzzy dilation is extensive and the fuzzy erosion is anti-extensive $E_{\mathcal{I}_U}(A,B) \subseteq A \subseteq D_U(A,B)$.
- Moreover, the fuzzy closing is extensive and the fuzzy opening is anti-extensive: $O_{U,\mathcal{I}_U} \subseteq A \subseteq C_{U,\mathcal{I}_U}(A,B)$.
- The fuzzy closing and the fuzzy opening are idempotent, i.e.: $C_{U,\mathcal{I}_U}(C_{U,\mathcal{I}_U}(A,B),B) = C_{U,\mathcal{I}_U}(A,B)$, and $O_{U,\mathcal{I}_U}(O_{U,\mathcal{I}_U}(A,B),B) = O_{U,\mathcal{I}_U}(A,B)$.
- If $B(0) = e$, then $E_{\mathcal{I}_U}(A,B) \subseteq O_{U,\mathcal{I}_U}(A,B) \subseteq A \subseteq C_{U,\mathcal{I}_U}(A,B) \subseteq D_U(A,B)$.
- For the two previous conjunctives uninorms of type U_h and $U^{\mathcal{N}}$, the duality between fuzzy morphological operators is guaranteed.

3 Residuals and basic filters

In the following experiments, the idempotent uninorm $U^{\mathcal{N}}$ with $\mathcal{N}(x) = 1 - x$ and the representable uninorm U_h with $h(x) = \ln\left(\frac{x}{1-x}\right)$ have been used. The obtained results are compared with the Łuckasiewicz t-norm and the classic development based on *umbra approach* (see [7]). In particular, the structural element used by the morphological operators is given by the following matrix:

$$B = e \cdot \begin{pmatrix} 0.86 & 0.86 & 0.86 \\ 0.86 & 1.00 & 0.86 \\ 0.86 & 0.86 & 0.86 \end{pmatrix}$$

ISBN: 978-989-95079-6-8

Figure 2: Left: closing. Right: opening. Top, an idempotent uninorm is used. Down, a representable uninorm is used.

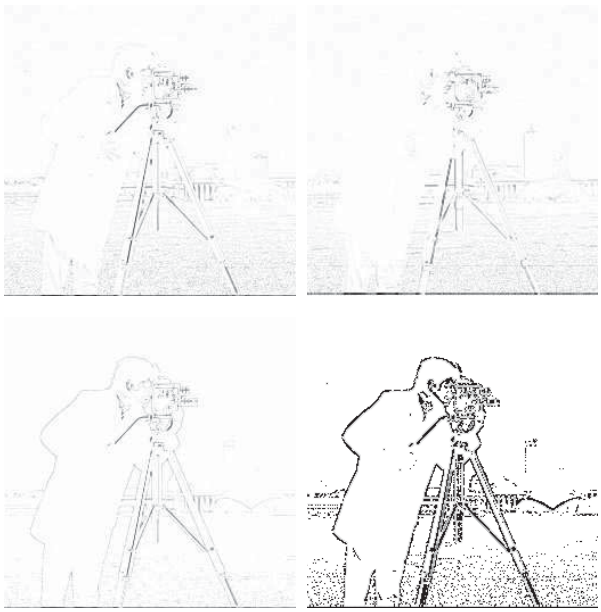

Figure 3: Left: Top-Hat. Right: Dual Top-Hat. Top: *umbra approach*. Down: Łuckasiewicz t-norm.

where e is the neutral element of the considered uninorm. The original images used in the experiments are shown in Figures 1 and 6 (they are represented by A in the fuzzy morphological operators). Two gray level original images are shown in Figure 1; one of them with size 256×256 is the classical image of a cameraman, and the other one of size 512×512 is the medical image of a hip.

The residual of two morphological operations or transformations is their difference. The first residual that can be defined in mathematical morphology is the morphological gradient, which is used as an edge detector and as a first approximation to a morphological segmentation. The morphological gradient, known in morphology as the Beucher gradient, is the difference between a dilation and an erosion, a dilation and the original image or the difference between the original image and its erosion. When we use the dilation and the erosion of a fuzzy set A by the structural element B, where the uninorm U is considered as a conjunctor and $\mathcal{I}_U$ as the residual implicator, the gradients are given by:

$$\nabla^{-}_{U,\mathcal{I}_U}(A,B) = A \setminus E_{\mathcal{I}_U}(A,B), \quad (5)$$

$$\nabla^{+}_{U,\mathcal{I}_U}(A,B) = D_U(A,B) \setminus A, \quad (6)$$

$$\nabla_{U,\mathcal{I}_U}(A,B) = D_U(A,B) \setminus E_{\mathcal{I}_U}(A,B), \quad (7)$$

where expression (5) represents the gradient by erosion, (6) the gradient by dilation and (7) the symmetrical gradient. From the point of view of the fuzzy inclusion, $\nabla^{-}_{U,\mathcal{I}_U}(A,B) \subseteq \nabla_{U,\mathcal{I}_U}(A,B)$ and $\nabla_{U,\mathcal{I}_U}(A,B) \supseteq \nabla^{+}_{U,\mathcal{I}_U}(A,B)$ are satisfied.

The goal of the gradients is the detection of the edges and/or the perimeter of the objects of the image. The correct choice of the structural element and the gradient will depend on the geometry of the objects. The application of the symmetrical gradient based on uninorms to the edge detection can be seen in [1], where the obtained results are better than those obtained by the gradients using t-norms or the classic approach.

The opening and closing defined in the previous section are the most elementary morphological filters, which are called *basic filters*. As we have seen in the previous section, the opening is an antiextensive morphological filter and the closing is an extensive morphological filter. So, in a first step, they can be used to remove non desired objects in an image. We can observe that the opening of a gray level image by a structural element removes the light zones of less size than the element and makes the light objects darker. The morphological closing helps to remove dark structures of less size than the structural element, toning down the dark objects. The size and shape of the used structurant element in the opening must agree with the image structures that we want to remove. Sometimes, structurant element of great size will remove the non desired shapes of an image, but also they can remove others shapes and the rest of the structures can be affected. Reduced sizes will be optimal when the images have small details. The effect of the closing and the opening on the cameraman's image can be observed in Figure 2, using the idempotent uninorm (top) and the representable uninorm (down).

The opening and the closing are morphological transformations and they are sensitive to compute the associated residuals, which are called *Top-Hat* transformations. The Top-Hat transformation, initiated by F. Meyer in 1977 (see [2]), finds structures of the images that have been removed by the opening or closing filter. If we choose the appropriated size and shape of the structural element, it is possible to filter and to remove some elements in the original image. The difference operation between the original map and the filtered map increases considerably the contrast of the removed zones.

The Top-Hat transformations are defined as a residual between the identity and the opening, which is called opening Top-Hat or white Top-Hat, or between the closing and the identity, which is called dual Top-Hat or black Top-Hat. They

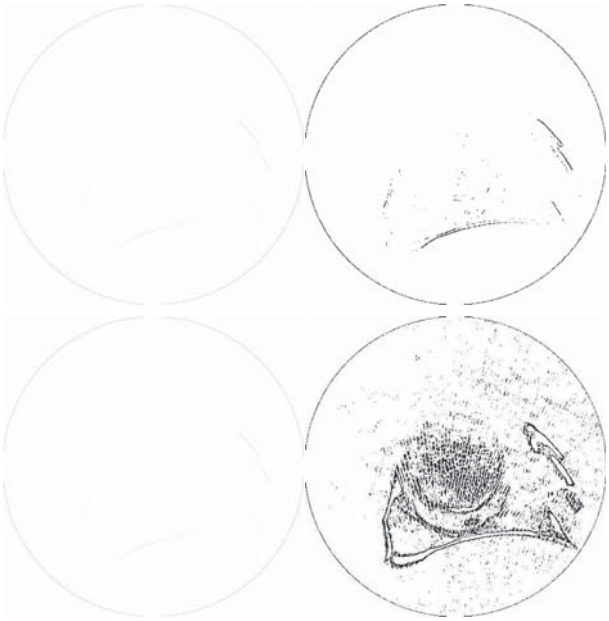

Figure 5: Left: Top-Hat. Right: Dual Top-Hat. Top, Łuckasiewicz t-norm. Down, representable uninorm.

are defined by:

$$\rho_{U,\mathcal{I}_U}(A,B) = A \setminus O_{U,\mathcal{I}_U}(A,B) \text{ (Top-Hat)}$$
$$\rho^d_{U,\mathcal{I}_U}(A,B) = C_{U,\mathcal{I}_U}(A,B) \setminus A \text{ (dual Top-Hat)}$$

The Top-Hat enhances the light objects that have been removed by the opening and it is used to extract contrasted components from the background, while the dual Top-Hat extracts the dark components that have been removed by the closing. Usually, the Top-Hat removes the soft trends, making thus an enhanced contrast. The detection of light objects is improved with an opening Top-Hat, in the same way with the dual Top-Hat does with the dark objects. The size of the structurant element is a deciding factor in order to apply the Top-Hat transformations.

The Top-Hat is idempotent (but it is not increasing) and it is antiextensive. The dual Top-Hat is neither increasing nor idempotent.

The obtained edges using the Top-Hat and the dual Top-Hat can be seen in Figures 3 and 4 for the cameraman image. The collected information using the idempotent uninorm is similar to the classical approach, and in the case of the representable uninorm, we can obtain (with the dual approach) more information than in the rest of the cases. Both top-hats are shown in Figure 5 for the hip image and it can be observed that the representable uninorm shows again more information.

It has been indicated that opening and closing are the basic filters of the fuzzy mathematical morphology. In order to build new mophological filters ([2]), we start with the basic filters and using composition or combination with other operations. New filters as sequential filters, center operators, contrast filters, etc. can be implemented. The basic applications of the morphological filters are the noise reduction and the selected extraction of image objects. Both applications are important in artificial vision since interpretation or measure techniques will fail in presence of noise, whereas the structure and the object selection are fundamental in segmentation processes.

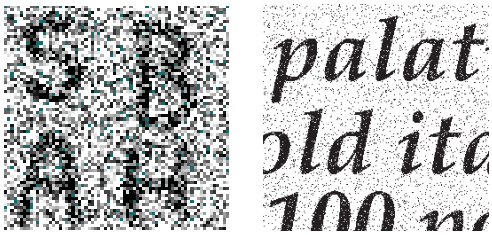

Figure 6: Original images with noise.

The first built filters from opening and closing are the so called *alternate filters*. Let $\xi(A,B)$ and $\psi(A,B)$ be the opening and closing, respectively, of a fuzzy object A by the structural element B using uninorm U as a conjuctor and $\mathcal{I}_U$ as a residual implicator. Using these two filters, four idempotent and growing filters can be generated: $\xi\,\psi$, $\psi\,\xi$, $\psi\,\xi\,\psi$ and $\xi\,\psi\,\xi$. These filters have similar properties to the classical morphological filters. Due to the idempotent property, the composition of more of three operators doesn't provide a new filter, except that we change the structural element.

In Figure 6, two binary images with added noise are shown. In the left image of size 70×74 the 60% of the points have been substituted by random graylevel noise[1]. In the right image of size 256×256, a gaussian noise has been added. Figure 7 shows the results obtained when we apply, from left to right, the alternate filters ψ, $\xi\,\psi$ and $\psi\,\xi\,\psi$, respectively. From top to bottom, the obtained results are shown using the different approaches. We can see that the uninorms remove the noise of the image in such a way that the *original* image is discernible. The same structure is shown in Figure 8.

The filtered image using the filter $\psi\,\xi$ and using the idempotent uninorm (very similar to the obtained image using the representable uninorm), Łuckasiewicz t-norm and *umbra approach* are shown in Figure 9. The filtered image with the

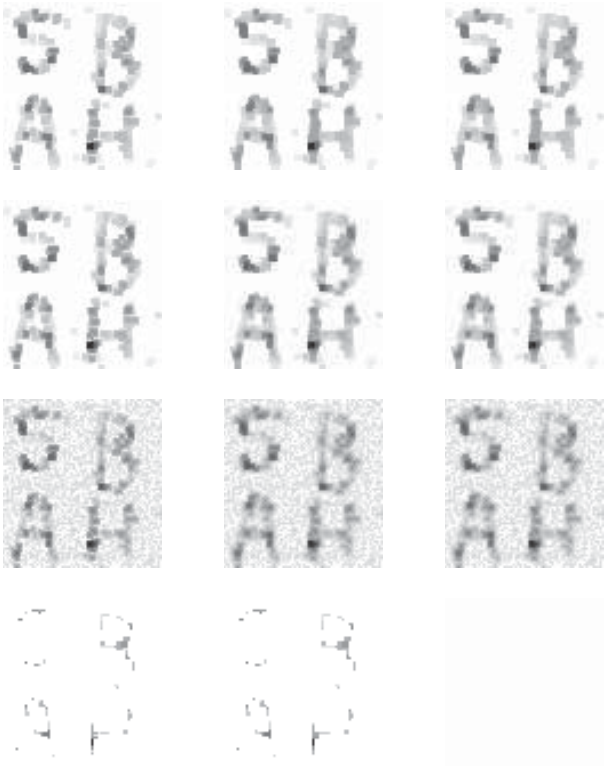

Figure 7: From left to right: filtered image using ξ, $\xi\,\psi$ and $\psi\,\xi\,\psi$, respectively. Top to bottom: idempotent uninorm, representable uninorm, Łuckasiewicz t-norm and *umbra approach*.

Figure 8: From left to right: filtered image using ξ, $\xi\,\psi$ and $\psi\,\xi\,\psi$, respectively. From top to bottom: idempotent uninorm, representable uninorm, Łuckasiewicz t-norm and *umbra approach*.

structure $\psi\,\xi\,\psi$ is very similar, except in the classical approach where the image gets smudged and in the case of the t-norm, the noise is softer.

A chest CT image of size 425×334 with "salt and pepper" added noise is shown in Figure 10 using 0.02 as a parameter. The results obtained using filter $\psi\,\xi\,\psi$ are shown in Figure 11. In the top left image, the Łuckasiewicz t-norm has been used and most of the noise remains. In the right image, the filtered image using the *umbra approach* is shown, a lot of "salt" noise is magnified. In the bottom images, the results obtained using uninorms are shown. The results using an idempotent uninorm are shown in the left image and the results using a representable uninorm are shown in the right image. The function generator of the representable uninorm is $h(x) = \frac{x-0.5}{x(1-x)}$. In the cases using uninorms the results are better than the ones using t-norms and umbra approach, because the noise is practically removed.

These type of filters have been used in the industrial control of pieces with partial occlusions or even in edge detection with noise elimination.

4 Conclusions and future work

In this work we have shown how the alternate filters based on opening and closing morphological operators using uninorms can remove the noise of an image preserving their structure. The obtained results improve the obtained results using t-norms and *umbra approach*. Also, we have obtained images very similar to the original ones without noise. So, the alternate filters based on uninorms are suitable to remove different

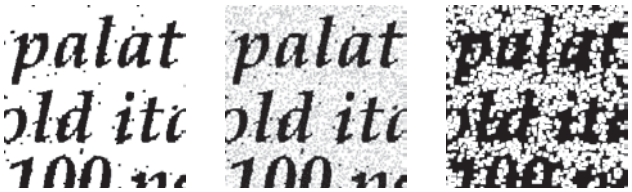

Figure 9: From left to right: filtered image using $\psi\,\xi$, an idempotent uninorm, Łuckasiewicz t-norm and *umbra approach*.

types of noise. The future work will consist on the construction of new filters. Also, we have shown the usefullness of the opening and closing filters in the edge detection. The future work includes the study of the effect of the choice of the structural element too. We have used isotropic structural elements in the experiments. That is, they have the same effect in all directions where they can be applied. We think that in some images, the use of anisotropic structural elements would improve the results.

We also want to apply the previous techniques to a more extended set of gray level images, even color images.

Abstract— *This paper provides a new value (solution concept or allocation rule) of cooperative games via posets induced by graphs. Several values in a graph-restricted communication situation have been proposed or introduced by Myerson, Borm, and Hamiache... However, these values have been subjected to some criticisms in certain types of games. The value proposed in this paper withstands these criticisms. Moreover, these existing values have been defined only in situations represented by undirected graphs, while the notion of the value proposed in this paper can be extended to situations represented by directed graphs.*

Keywords— graph-restricted situations, communication situations, values, posets, cooperative games.

1 Introduction and Preliminaries

Throughout the paper, N denotes the universal set of n elements. For convenience, we often number the elements such that the universal set is $N = \{1, 2, \ldots, n\}$. A real-valued function $v : 2^N \to \mathbb{R}$ with $v(\emptyset) = 0$ is called a *game*. A monotone game (i.e., $v(A) \leq v(B)$ whenever $A \subseteq B \subseteq N$) is called a *capacity* or *a fuzzy measure*. We often call the pair (N, v), rather than v, a game or a capacity. The set of all games on N is denoted by $\mathcal{G}^N$. A real vector-valued function $\Phi : \mathcal{G}^N \to \mathbb{R}^{|N|}$ is called a *value*. In cooperative game theory, N is considered to be the set of all players. For every subset S of N, often called a *coalition*, $v(S)$ represents the (transferable) utility/profits that players in S can obtain if they decide to cooperate. For every game (N, v), the value $\Phi(N, v)$ represents an allocation rule, which provides an assessment of the benefits for each player from participating in a game v. For the sake of simplicity, we mainly discuss games in terms of various set functions (e.g., games, capacities, fuzzy measures, and so forth.) on N.

To avoid cumbersome notations, we often omit braces for singletons, e.g., by writing $v(i)$, $U \setminus i$ instead of $v(\{i\})$, $U \setminus \{i\}$. Similarly, for pairs, we write ij instead of $\{i, j\}$. Furthermore, cardinalities of subsets $S, T, \ldots$, are often denoted by the corresponding lower case letters $s, t, \ldots$, otherwise by the standard notation $|S|, |T|$,...

1.1 Games and capacities with graph restricted situations

In ordinary cooperative game theory it is implicitly assumed that all coalitions of N can be formed; however, this is generally not the case. For players to coordinate their actions, they must be able to communicate. The bilateral communication channels between players in N are described by a *communication network*. Such a network can be represented by an *undirected graph* (N, L), which has the set of players as its *nodes* $S \subseteq N$ and in which the players are connected by the set of *links* $L \subseteq \{ij \mid i, j \in N, i \neq j\}$; i.e., players i and j can communicate (directly) with each other if $ij \in L$. This paper will deals with only situations induced by communication networks described by undirected graphs. Many other approaches to the situations can be seen via the literatures [1, 2].

Definition 1.1 (communication situation)
The triple (N, v, L), which reflects a situation consisting of a game v on N and a communication network (N, L), is called a *communication situation*. We denote the set consisting of all communication situations on N by CS^N. For a coalition $T \subseteq N$, the restriction of (N, L) to T is denoted by $(T, L(T))$ and defined by $L(T) := \{ij \in L \mid ij \subseteq T\}$.

Definition 1.2 (feasible coalition) We say that players j and k are *connected in* $S \subseteq N$ if $j = k$ or there exists a subset $\{i_1, \cdots, i_m\} \subseteq S$ such that $j = i_1$, $k = i_m$, and $\{i_t, i_{t+1}\} \in L$ for all $t \in \{1, \cdots, m-1\}$. Then we denote $j \sim_S k$. Clearly, this relation $\sim_S$ is an equivalence relation. Hence, the notion of connectedness in S induces a partition $S/L := S/\sim_S$ of S. A coalition $S \subseteq N$ is said to be *feasible* in the communication network (N, L) if any two players, $j \in S$ and $k \in S$, are connected in S (i.e., $S/L = \{S\}$).

Example 1.1
Consider the communication situation (N_1, v, L_1) with $N_1 = \{1, 2, 3, 4, 5, 6, 7\}$ and $L_1 = \{12, 15, 26, 37, 47, 56\}$ (Fig.1). Then, all the players in $\{1, 2, 6\}$ can communicate with other;

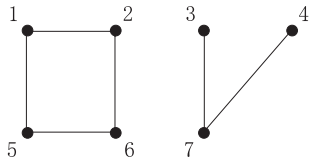

Figure 1: Communication network(N, L_1).

i.e., the coalition $\{1, 2, 6\}$ is feasible. Hence, they can fully coordinate their actions and obtain the value $v(\{1, 2, 6\})$. On the other hand, in the coalition $\{1, 2, 3, 4\}$, players 1 and 2 can communicate with each other, but players 3 and 4 cannot communicate with any other players in $\{1, 2, 3, 4\}$. Thus, feasible subcoalitions of $\{1, 2, 3, 4\}$ are $\{1, 2\}$, $\{3\}$, and $\{4\}$ (i.e., forming the coalition $\{1, 2, 3, 4\}$ is unfeasible). Hence, the value attainable by the players in $\{1, 2, 3, 4\}$ should be $v(\{1, 2\}) + v(\{3\}) + v(\{4\})$. In general, the value attainable by the players in $S \in N$ under a communication situation (N, v, L) is represented by

$$\sum_{T \in S/L} v(T). \tag{1}$$

ISBN: 978-989-95079-6-8

Definition 1.3 (network-restricted game [3]) The *network-restricted game* (N, v^L) associated with (N, v, L) is defined as

$$v^L(S) := \sum_{T \in S/L} v(T) \quad \text{for each } S \subseteq N. \tag{2}$$

Note that if (N, L) is the complete graph (i.e., $L = \{ij \mid i, j \in N, i \neq j\}$), the network-restricted game v^L is equal to the original game v.

The network-restricted game evaluates the possible gains from cooperation in a communication situation from the viewpoint of the players. The next example focuses on the importance of communication channels and links in a communication situation.

Example 1.2 In the communication situation L_1 depicted in Fig.1, the value obtainable by the players in the grand coalition N is

$$v^{L_1}(N) = v(\{1, 2, 5, 6\}) + v(\{3, 4, 7\}), \tag{3}$$

since $N/L_1 = \{\{1, 2, 5, 6\}, \{3, 4, 7\}\}$. If for some reason the communication link between players 4 and 7 is lost, the communication network L_1 becomes the new communication network $L_2 = \{12, 15, 26, 37, 56\}$. Then, $N/L_2 = \{\{1, 2, 5, 6\}, \{4\}, \{3, 7\}\}$ and the value obtainable by the players in the grand coalition N becomes

$$v^{L_2}(N) = v(\{1, 2, 5, 6\}) + v(\{4\}) + v(\{3, 7\}). \tag{4}$$

Then,

$$v^{L_1}(N) - v^{L_2}(N) \tag{5}$$

can be interpreted as a type of marginal contribution of the link $\{4, 7\} \in L_1$ to the communication network L_1.

Definition 1.4 (link game [4]) The *link game* (L, γ^v) associated with (N, v, L) consisting of a zero-normalized game v is a game on L defined by

$$\gamma^v(M) := v^M(N) = \sum_{T \in N/M} v(T) \quad \text{for each } M \subseteq L. \tag{6}$$

Note that, for an ordinary game v, γ^v is not a game on L since $\gamma^v(\emptyset) = \sum_{T \in N/\emptyset} v(T) = \sum_{i \in N} v(\{i\}) \neq 0$.

The link game $\gamma^v(M)$ represents the worth of the communication network $M \subseteq L$ as the worth of the grand coalition in the communication situation (N, v, M) through the network-restricted game v^M.

Definition 1.5 (Möbius Transform [5]**)** The *Möbius transform* of a game $v : 2^N \to \mathbb{R}$ (resp. $\gamma : 2^L \to \mathbb{R}$) is a game on N (resp. L) denoted by $\Delta^v : 2^N \to \mathbb{R}$ (resp. $\Delta^\gamma : 2^L \to \mathbb{R}$) and is defined by

$$\Delta^v(S) := \sum_{T \subseteq S} (-1)^{|S \setminus T|} v(T) \quad \text{for each } S \in 2^N. \tag{7}$$

$$(resp.\ \Delta^\gamma(M) := \sum_{K \subseteq M} (-1)^{|M \setminus K|} \gamma(K) \quad \text{for each } M \in 2^L). \tag{8}$$

Equivalently, we have that

$$v(S) = \sum_{T \subseteq S} \Delta^v(T) \quad \forall S \in 2^N. \tag{9}$$

$$(resp.\ \gamma(M) = \sum_{K \subseteq M} \Delta^\gamma(K) \quad \forall M \in 2^L). \tag{10}$$

Thus, the worth $v(S)$ (resp. $\gamma(M)$) of a coalition S (resp. communication network M) is equal to the sum of the Möbius transform of all its subcoalitions (subnetworks). This gives a recursive definition of the Möbius transform. The Möbius transform of every singleton is equal to its worth, while recursively, the Möbius transform of every coalition (resp. communication network) of at least two players (resp. links) is equal to its worth minus the sum of the Möbius transform of all its proper subcoalitions (resp. subnetworks). In this sense, the Möbius transform of a coalition S (resp. communication network M) can be interpreted as the extra contribution of the cooperation/synergy among the players in S (resp. links in M) that they did not already achieve by smaller coalitions (resp. networks). In fact, in the context of *interaction indices* (e.g.,[6, 7]), the Möbius transform $\Delta^v(S)$ is called the *internal interaction index* of S, which represents the magnitude of a type of interaction among the elements in S. The Möbius transform is also occasionally called the *Harsanyi dividends*[8].

Definition 1.6 (unanimity game) The *unanimity game* for a non-empty coalition $T \subseteq N$ is denoted by u_T and defined by

$$u_T(S) = \begin{cases} 1 & \text{if } S \supseteq T, \\ 0 & \text{otherwise.} \end{cases} \tag{11}$$

For any game $v : 2^N \to \mathbb{R}$, v can be represented as

$$v(S) = \sum_{T(\neq \emptyset) \in 2^N} \Delta^v(T) \cdot u_T(S) \quad \forall S(\neq \emptyset) \in 2^N. \tag{12}$$

2 Values for communication situations

In this section, we briefly introduce the Shapley value for ordinary cooperative games and three existing values for communication situations that appear in the literatures [3, 4, 9], *the Myerson value, the position value, and the Hamiache value*.

Definition 2.1 (the Shapley value [10]) The *Shapley value* $\Phi : \mathcal{G}^N \to \mathbb{R}^{|N|}$ for a game $(N, v) \in \mathcal{G}^N$ is defined by

$$\Phi_i(N, v) := \sum_{T \ni i} \frac{1}{|T|} \Delta^v(T) \quad \text{for each } i \in N. \tag{13}$$

Definition 2.2 (the Myerson value [3]) The *Myerson value* $\Psi : CS^N \to \mathbb{R}^{|N|}$ for a communication situation $(N, v, L) \in CS^N$ is defined by

$$\Psi(N, v, L) := \Phi(N, v^L). \tag{14}$$

The Myerson value is the allocation rule that assigns to every communication situation (N, v, L) the Shapley value of the network-restricted game (N, v^L). Note that $\Psi(N, v, L) = \Phi(N, v)$ if (N, L) is the complete graph.

Definition 2.3 (position value [4]) The *position value* $\pi : CS^N \to \mathbb{R}^{|N|}$ for a communication situation $(N, v, L) \in CS^N$ is defined by

$$\pi_i(N, v, L) := \frac{1}{2} \sum_{\substack{l \in L \\ l \ni i}} \Phi_l(L, \gamma^v) \quad \text{for each } i \in N. \tag{15}$$

ISBN: 978-989-95079-6-8

The Shapley value $\Phi_l(L,\gamma^v)$ of a link $l \in L$, which is induced via (13) for the link game (L,γ^v), can be interpreted as a type of *expected marginal contribution* of the link l to all communication networks containing l. Then, the value is divided equally between the two players at the ends of the considered link $l \in L$. The position value of a given player $i \in N$ is obtained as the sum of all these shares.

We focus to a third value for communication situations, introduced by Hamiache [9]. Given a communication situation (N,v,L) and $S \subseteq N$, we denote by S^* the set of all nodes of the communication network (N,L) that are adjacent to at least one of the nodes of S,

$$S^* := \{i \in N \mid \exists j \in S \text{ such that } ij \in L\}. \tag{16}$$

Definition 2.4 (associated game [9]) For a value ϕ on CS^N (i.e., $\phi : CS^N \to \mathbb{R}^{|N|}$), the *associated game* v^*_ϕ of v with respect to ϕ is defined for $S \subseteq N$, by

$$v^*_\phi(S) := \begin{cases} v(S) + \displaystyle\sum_{j \in S^* \setminus S} \Big(\phi_i(S^{+j}, v|_{S^{+j}}, L(S^{+j})) - v(j)\Big) & \text{if } |S/L| = 1, \\ \displaystyle\sum_{T \in S/L} v^*_\phi(T) & \text{otherwise,} \end{cases} \tag{17}$$

where $S^{+j} := S \cup \{j\}$ and $v|_{S^{+j}}$ is the restriction of v to S^{+j}.

Hamiache [9] claims that there is a unique value ϕ, the so-called *Hamiache value*, for communication situations satisfying the following five properties, *component-efficiency*, *linearity w.r.t. games*, *independence of irrelevant players*, *positivity*, and *associated consistency*:

Component-efficiency :
For any (N,v,L) and any $S \in N/L$,

$$\sum_{i \in S} \phi_i(N,v,L) = v(S). \tag{18}$$

Linearity w.r.t. games :
For any $\alpha,\beta \in \mathbb{R}$ and $(N,v,L),(N,w,L) \in CS^N$,

$$\phi(N,\alpha v + \beta w, L) = \alpha\phi(N,v,L) + \beta\phi(N,w,L). \tag{19}$$

Independence of irrelevant players :
For any (N,L) and for any two feasible coalitions $R \subseteq T$,

$$\phi_i(N,u_R,L) = \phi_i(T,u_R,L(T)) \ \ \forall i \in T. \tag{20}$$

Positivity :
For any feasible coalition $T \subseteq N$,

$$\phi_i(T,u_T,L(T)) \geq 0 \ \ \forall i \in T. \tag{21}$$

Associated consistency:
For any $(N,v,L) \in CS^N$,

$$\phi(N,v,L) = \phi(N,v^*_\phi,L). \tag{22}$$

Note that $\phi(N,v,L) = \Phi(N,v)$ if (N,L) is the complete graph.

3 Posets induced by communication networks

3.1 Communication networks and posets

In this subsection, we consider and introduce a subposet of $B(n) := (2^N, \subseteq)$ induced by a communication network (N,L).

For a communication network (N,L), the set of all feasible coalitions in (N,L) is denoted by $P(N,L)$. i.e.,

$$P(N,L) := \{S \subseteq N \mid |S/L| = 1\}. \tag{23}$$

The set $P(N,L)$, together with set inclusion $\subseteq$ as an order on $P(N,L)$, is called the *poset induced by the communication network* (N,L).

Example 3.1 Let $N = \{1,2,3\}$, $L_a = \{12,13,23\}$, $L_b = \{13,23\}$, and $L_c = \{12\}$. Then the posets induced by communication networks (N,L_a), (N,L_b), and (N,L_c), as shown in (a) – (c) in Fig. 2, are represented as shown in (a) – (c) in Fig. 3, respectively.

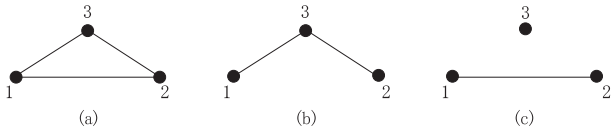

Figure 2: Communication networks on $N = \{1,2,3\}$.

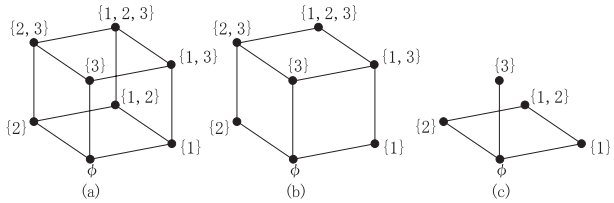

Figure 3: Posets corresponding to networks in Fig. 2.

Definition 3.1 (Möbius transform on posets)
Let $P := (N,\leq)$ be a poset. For a function $v : P \to \mathbb{R}$, the *Möbius transform* Δ^v of v is a function on P satisfying the following equation:

$$v(x) = \sum_{y \leq x} \Delta^v(y) \quad \forall x \in P. \tag{24}$$

Definition 3.2 (representation functions)
The *representation function of a communication situation* (N,v,L) is a function v^P on the poset $P(N,L)$ defined by

$$v^P(S) = v(S) \quad \text{for each } S \in P(N,L). \tag{25}$$

Then, the Möbius transform Δ^{v^P} of v^P is represented as

$$\Delta^{v^P}(S) := \sum_{\substack{T \in P(N,L) \\ T \subseteq S}} (-1)^{|S \setminus T|} v^P(T) \quad \forall S \in P(N,L). \tag{26}$$

Conversely,

$$v^P(S) := \sum_{\substack{T \in P(N,L) \\ T \subseteq S}} \Delta^{v^P}(T) \quad \forall S \in P(N,L). \tag{27}$$

Definition 3.3 (poset representation) The *poset representation of a communication situation* (N,v,L) is the pair $(P(N,L),\Delta^{v^P})$ of the poset induced by (N,v,L) and the Möbius transform Δ^{v^P} of representation function v^P of (N,v,L).

4 A new value in communication situations

In this section, we introduce a new value for communication situations.

4.1 An interpretation of the Shapley value

Now, we consider the case $N = \{1,2\}$; the Shapley value $\Phi_1(N,v)$ of player 1 in a game v is obtained, from (13), as

$$\Phi_1(N,v) = \frac{1}{1}\Delta^v(\{1\}) + \frac{1}{2}\Delta^v(\{1,2\}). \tag{28}$$

This can be interpreted as an allocation rule of *Harsanyi dividends* (i.e., the Möbius transform) described as follows:

Allocation rule of Harsanyi dividends : We consider a process to form the coalition $\{1,2\}$. Then, there are two shortest paths from $\emptyset$ to $\{1,2\}$ in Fig. 2. One is the path $\emptyset \to \{1\} \to \{1,2\}$; another is the path $\emptyset \to \{2\} \to \{1,2\}$. The path $\emptyset \to \{1\} \to \{1,2\}$ can be interpreted as follows: *Player 1 makes an offer to player 2 for forming the coalition* $\{1,2\}$. *Player 2 accepts the offer and adds to the coalition* $\{1\}$ *to form the new coalition* $\{1,2\}$. Among these two paths, the only path that passes through $\{1\}$ is $\emptyset \to \{1\} \to \{1,2\}$. That is, the number of paths from $\emptyset$ to $\{1,2\}$ is 2, while of the number of paths via $\{1\}$ is 1. Then player 1 obtains $\frac{1 \text{ path}}{2 \text{ paths}}$ of the amount of the Harsanyi dividend $\Delta^v(\{1,2\})$ (i.e., $\frac{1}{2}\Delta^v(\{1,2\})$). In the same way, player 1 obtains $\frac{1}{1}\Delta^v(\{1\})$ and $\frac{0}{1}\Delta^v(\{2\})$. The Shapley value of player 1 is obtained as the sum of all these shares.

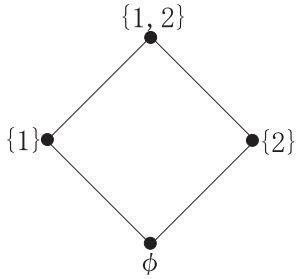

Figure 4: The Boolean lattice $B(2)$ on $N = \{1,2\}$.

This allocation rule can be extended to the case $N = \{1,2,3\}$ (Fig. 5).

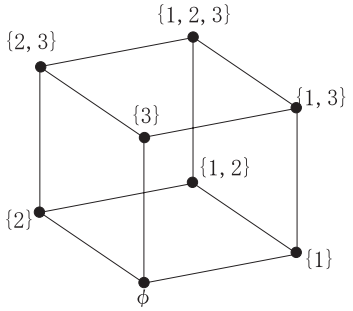

Figure 5: The Boolean lattice on $N = \{1,2,3\}$.

Indeed,

$$\begin{aligned}\Phi_1(N,v) &= \frac{1}{1}\Delta^v(\{1\}) + \frac{1}{2}\Delta^v(\{1,2\}) + \frac{1}{2}\Delta^v(\{1,3\}) \\ &+ \frac{0}{2}\Delta^v(\{2,3\}) + \frac{2}{6}\Delta^v(\{1,2,3\}).\end{aligned} \tag{29}$$

For instance, there are six shortest paths from $\emptyset$ to $\{1,2,3\}$. Among them, two paths pass through $\{1\}$, as shown in Fig. 6.

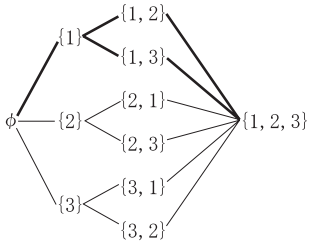

Figure 6: Shortest paths from $\emptyset$ to $\{1,2,3\}$.

4.2 An interpretation of the Myerson value

The Myerson value of (N,v,L) is the Shapley value of the network-restricted game (v^L,N). That is, the Myerson value is obtained by applying the above allocation rule to Harsanyi dividends $\{\Delta^{v^L}\}$ of v^L. Then Δ^{v^L} is given as follows:

Proposition 4.1 Let $(N,v,L) \in CS^N$ be a communication situation and $(B(n),\Delta^{v^L})$ the poset representation of the network-restricted game (N,v^L) associated with (N,v,L). Then,

$$\Delta^{v^L}(S) = \begin{cases} \Delta^v(S) & \text{if } S \in P(N,L), \\ 0 & \text{otherwise.} \end{cases} \tag{30}$$

4.3 Criticisms of existing values

Each of the existing values for communication situations, the Myerson value, the position value, and the Hamiache value, has been subject to criticisms, as follows.

The Myerson value :

$$\Psi_i(N,u_S,L) = \Psi_i(N,u_S,M) = \frac{1}{|S|} \quad \forall i \in N \tag{31}$$

whenever S is a feasible coalition in both (N,L) and (N,M). For example, consider the communication situation with $L = \{ij \subseteq N \mid j \in N \setminus i\}$ (i.e., L is a star with a central player i); then every player receives the same value (see Example $\Psi(N,v,L_e)$ in Example 5.3).

The position value :

Irrelevant null players often have positive values (see Example 5.2), where a null player $i \in N$ of the game (N,v) is a player satisfying $v(S \cup i) = v(S)$ for any $S \subseteq N$.

The Hamiache value :

It is very complex to compute the Hamiache value. Not only that, associated consistency is rather technical.

ISBN: 978-989-95079-6-8

4.4 A new value in communication situations

In this section, we propose a new value for communication situations that withstands all these criticisms.

Definition 4.1 (chain, saturated chain) A *chain* (or a *totally ordered set* or *linear ordered set*) is a poset in which any two elements are comparative. That is, a subset C of $P(N,L)$ is called a chain if $S \subseteq T$ or $T \subseteq S$ for any $S, T \in C$. The chain C of $P(N,L)$ is *saturated* (or *unrefinable*) if there does not exist $W \in P(N,L) \setminus C$ such that $S \subsetneq W \subsetneq T$ for some $S, T \in C$ and that $C \cup W$ is a chain.

Definition 4.2 (shortest path) For two feasible coalitions S, $T \in P(N,L)$, a saturated chain $\mathcal{P}$ of $P(N,L)$ is called a *shortest path* from S to T if $S, T \in \mathcal{P}$ and $S \subseteq W \subseteq T$ for any $W \in \mathcal{P}$. Then, we denote the set of all shortest paths from S to T by $\{S \to T\}$.

In the following, we propose a new value in communication situations, based on the interpretation of the Shapley value mentioned in Subsection 4.1.

Definition 4.3 We now propose a new value $\sigma(N,v,L)$ of a communication situation (N,v,L), as follows.

$$\sigma_i(N,v,L) := \sum_{S \in P(N,L)} \frac{|\{i \to S\}|}{|\{\emptyset \to S\}|} \Delta^{v^P}(S) \quad \text{for each } i \in N. \tag{32}$$

The number $|\{\emptyset \to S\}|$ of all shortest paths from $\emptyset$ to S indicates the number of all processes in which the feasible coalition S is formed. Also, $|\{i \to S\}|$ indicates the number of all processes in which the feasible coalition S is formed by the initiator $i \in N$. Then, the player $i \in N$ obtains $\frac{|\{i \to S\}|}{|\{\emptyset \to S\}|}$ of the amount of $\Delta^{v^P}(S)$ if $\Delta^{v^P}(S)$ is allocated in proportion to the frequency with which the player i initiates the formation of the feasible coalition S. The value proposed here of a given player $i \in N$ is obtained as the sum of all these shares.

Now we show an example that supports the naturalness of the definition of this value.

Example 4.1 We consider the communication situation (N,v,L) with $N = \{1,2,3\}$, $L = \{13,23\}$, and $\Delta^{v^P}(S) \geq 0$ for any $S \in P(N,L)$. The value $\sigma_i(N,v,L)$ proposed here of player $i \in N$ is represented as the values of the ammeters A_i in the electric circuit with current sources $I_S = \Delta^{v^P}(S)$, as shown in Fig.7.

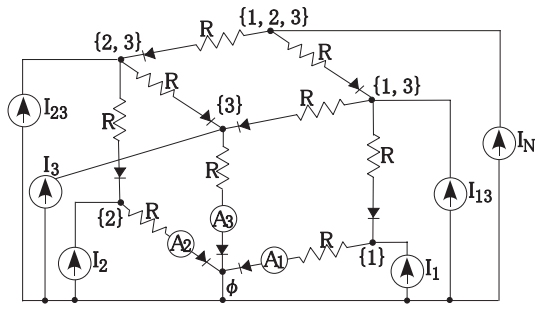

Figure 7: Electric circuit representing (N,v,L).

Property 1 The value σ proposed here satisfies *component-efficiency*, *linearity w.r.t. games*, *independence of irrelevant players*, and *positivity*.

Property 2 Let (N,u_N,L_c^*) be a communication situation with $L_c^* = \{cj \mid j \in N \setminus c\}$, $c \in N$. Then,

$$\sigma_i(N,u_N,L_c^*) = \begin{cases} \dfrac{1}{2} & \text{if } i = c, \\ \dfrac{1}{2(n-1)} & \text{otherwise.} \end{cases} \tag{33}$$

That is, if the communication network (N,L) is a star-graph with central player $c \in N$, in the unanimity game u_N, the central player obtains a half of the total amount of $u_N(N) = 1$ and the rest of the amount are shared out equally among the other players (see L_b, L_e in example 5.3).

However, we have not found any axiomatic characterization of the value proposed in this paper yet.

5 Comparison of existing values

In this section, we compare the existing four values (the Shapley, Myerson, position, and Hamiache values) and the value proposed in this paper. Examples 5.1 and 5.2 not only compare them but also illustrate the criticisms against the Shapley, Myerson, and position values, respectively.

Example 5.1 Consider the communication situation (N,v,L) with $N = \{1,2,3\}$, $L = \{13,23\}$ ((b) in Fig. 2), and

$$v(S) = \begin{cases} 0 & \text{if } |S| \leq 1 \\ 30 & \text{if } |S| = 2 \\ 36 & \text{if } S = N. \end{cases} \tag{34}$$

Then,

$$\Phi(N,v) = (12,12,12), \quad \Psi(N,v,L) = (7,7,22),$$
$$\pi(N,v,L) = (9,9,18), \quad \phi(N,v,L) = (9,9,18),$$
$$\sigma(N,v,L) = (9,9,18).$$

Example 5.2 Consider the communication situation (N,v,L) with $N = \{1,2,3\}$, $L = \{12,13,23\}$ (L_d in Fig. 8), and

$$v(S) = \begin{cases} 12 & \text{if } S \supseteq \{1,2\} \\ 0 & \text{otherwise.} \end{cases} \tag{35}$$

Then,

$$\Phi(N,v) = (6,6,0), \quad \Psi(N,v,L) = (6,6,0),$$
$$\pi(N,v,L) = (5,5,2), \quad \phi(N,v,L) = (6,6,0),$$
$$\sigma(N,v,L) = (6,6,0).$$

Example 5.3 Consider communication situations (N,u_N,L) with $2 \leq |N| \leq 4$, $|N/L| = 1$ (i.e., (N,L) is connected). Fig.8 shows all connected graphs (up to isomorphism) with $2 \leq n \leq 4$ nodes. Then, for any such communication situations (N,u_N,L),

$$\Phi_i(N,u_N,L) = \Psi_i(N,u_N,L) = \frac{1}{|N|} \quad \forall i \in N. \tag{36}$$

Table 1 shows comparisons of the remaining values (i.e., the position value π, the Hamiache value ϕ, and the value σ proposed in this paper), and illustrates that the value σ does not always coincide with the Hamiache value ϕ.

Ranking of fuzzy numbers, some recent and new formulas

Saeid Abbasbandy

Department of Mathematics, Science and Research Branch
Islamic Azad University, Tehran, 14778, Iran
Email: abbasbandy@yahoo.com

Abstract— *Ranking of fuzzy numbers plays a very important role in linguistic decision making and some other fuzzy application systems. Several strategies have been proposed for ranking of fuzzy numbers. Each of these techniques has been shown to produce non-intuitive results in certain cases. In this paper, some new approaches for ranking of trapezoidal fuzzy numbers are introduced.*

Keywords— Magnitude of fuzzy number, Parametric form of fuzzy number, Ranking of fuzzy numbers, Trapezoidal fuzzy number.

1 Introduction

Ranking of fuzzy numbers is an important component of the decision process in many applications. More than 30 fuzzy ranking indices have been proposed since 1976. In 1976 and 1977, Jain [1, 2] proposed a method using the concept of maximizing set to order the fuzzy numbers. Jain's method is that the decision maker considers only the right side membership function. A canonical way to extend the natural ordering of real numbers to fuzzy numbers was suggested by Bass and Kwakernaak [3] as early as 1977. Dubios and Prade 1978 [4], used maximizing sets to order fuzzy numbers. In 1979, Baldwin and Guild [5] indicated that these two methods have some disturbing disadvantages. Also, in 1980, Adamo [6] used the concept of α-level set in order to introduce α-preference rule. In 1981 Chang [7] introduced the concept of the preference function of an alternative. Yager in 1981 [8, 9] proposed four indices which may be employed for the purpose of ordering fuzzy quantities in $[0, 1]$. Bortolan and Degani have been compared and reviewed some of these ranking methods [10]. Chen and Hwang [11] thoroughly reviewed the existing approaches, and pointed out some illogical conditions that arise among them. Chen [12], Choobineh [13], Cheng [14] have presented some methods , and also more recently numerous ranking techniques have been proposed and investigated by Chu, Tsao [15] and Ma, Kandel and Friedman [16]. Nowadays many researchers have developed methods to compare and to rank fuzzy numbers. Some of those methods are counter-intuitive and non discriminating [18, 19, 20, 21, 22] and recently some methods based on different distance functions have been introduced for ranking of fuzzy numbers [23, 24, 25, 26, 27].

2 Preliminaries

Though there are a number of ways of defining fuzzy numbers, for the purposes of this paper we adopt the following definition, we will identify the name of the number with that of its membership function for simplicity. Throughout this paper, $\mathbb{R}$ stands for the set of all real numbers, E stands the set of fuzzy numbers, $u(x)$ for the membership function of every $u \in E$ and $x \in \mathbb{R}$.

Definition 2.1 *[28] A fuzzy number is a fuzzy set like $u : \mathbb{R} \to I = [0, 1]$ which satisfies:*

1. *u is upper semi-continuous,*
2. *$u(x) = 0$ outside some interval $[a, d]$,*
3. *There are real numbers $a,\ b$ such that $a \le b \le c \le d$ and*
   a. *$u(x)$ is monotonic increasing on $[a, b]$,*
   b. *$u(x)$ is monotonic decreasing on $[c, d]$,*
   c. *$u(x) = 1,\ b \le x \le c$.*

The membership function u can be expressed as

$$u(x) = \begin{cases} u_L(x), & a \le x \le b, \\ 1, & b \le x \le c, \\ u_R(x), & c \le x \le d, \\ 0, & otherwise, \end{cases}$$

where $u_L : [a, b] \longrightarrow [0, 1]$ and $u_R : [c, d] \longrightarrow [0, 1]$ are left and right membership functions of fuzzy number u. An equivalent parametric form is also given in [29] as follows:

Definition 2.2 *[29] A fuzzy number u in parametric form is a pair $(\underline{u}, \overline{u})$ of functions $\underline{u}(r), \overline{u}(r),\ 0 \le r \le 1$, which satisfy the following requirements:*

1. *$\underline{u}(r)$ is a bounded monotonic increasing left continuous function,*
2. *$\overline{u}(r)$ is a bounded monotonic decreasing left continuous function,*
3. *$\underline{u}(r) \le \overline{u}(r),\ 0 \le r \le 1$.*

The trapezoidal fuzzy number $u = (x_0, y_0, \sigma, \beta)$, with two defuzzifier x_0, y_0, and left fuzziness $\sigma > 0$ and right fuzziness $\beta > 0$ is a fuzzy set where the membership function is as

$$u(x) = \begin{cases} \dfrac{1}{\sigma}(x - x_0 + \sigma), & x_0 - \sigma \le x \le x_0, \\ 1 & x \in [x_0, y_0], \\ \dfrac{1}{\beta}(y_0 - x + \beta), & y_0 \le x \le y_0 + \beta, \\ 0, & otherwise, \end{cases}$$

and its parametric form is

$$\underline{u}(r) = x_0 - \sigma + \sigma r, \quad \overline{u}(r) = y_0 + \beta - \beta r.$$

ISBN: 978-989-95079-6-8

Let E_{TR} be the set of all trapezoidal fuzzy numbers on the real line. Provided that, $x_0 = y_0$ then u is a triangular fuzzy number, and we write $u = (x_0, \sigma, \beta)$. The support of fuzzy number u is defined as follows:

$$supp(u) = \overline{\{x \mid u(x) > 0\}},$$

where $\overline{\{x \mid u(x) > 0\}}$ is closure of set $\{x \mid u(x) > 0\}$.

The addition and scalar multiplication of fuzzy numbers are defined by the extension principle and can be equivalently represented in [30, 31, 32] as follows. For arbitrary $u = (\underline{u}, \overline{u})$, $v = (\underline{v}, \overline{v})$ we define addition $(u + v)$ and multiplication by scalar $k > 0$ as

$$(\underline{u+v})(r) = \underline{u}(r) + \underline{v}(r), \ \ (\overline{u+v})(r) = \overline{u}(r) + \overline{v}(r), \quad (1)$$

$$(\underline{ku})(r) = k\underline{u}(r), \ \ (\overline{ku})(r) = k\overline{u}(r). \quad (2)$$

To emphasis the collection of all fuzzy numbers with addition and multiplication as defined by (1) and (2) is denoted by E, which is a convex cone. The image (opposite) of $u = (x_0, y_0, \sigma, \beta)$, can be defined by $-u = (-y_0, -x_0, \beta, \sigma)$ (see [32, 33]).

Definition 2.3 *For arbitrary fuzzy numbers $u = (\underline{u}, \overline{u})$ and $v = (\underline{v}, \overline{v})$ the quantity*

$$D(u,v) = \left[\int_0^1 (\underline{u}(r) - \underline{v}(r))^2 \,\mathrm{dr} + \int_0^1 (\overline{u}(r) - \overline{v}(r))^2 \,\mathrm{dr}\right]^{1/2},$$

is the distance between u and v, [16, 17, 34]. The function $D(u, v)$ is a metric in E and (E, D) is a complete metric space.

The ordering indices are organized into three categories by Wang and Kerre [35] as follows:

1- **Defuzzification method**: Each index is associated with a mapping from the set of fuzzy quantities to the real line. In this case fuzzy quantities are compared according to the corresponding real numbers.

2- **Reference set method**: In this case a fuzzy set as a reference set is set up and all the fuzzy quantities to be ranked are compared with the reference set.

3- **Fuzzy relation method**: In this case a fuzzy relation is constructed to make pairwise comparisons between the fuzzy quantities involved.

Let M be an ordering method on E. The statement "two elements u and v in E satisfy that u has a higher ranking than v when M is applied" will be written as "$u \succ v$ by M". "$u \sim v$" and "$u \succeq v$" are similarly interpreted. The following reasonable properties for the ordering approaches are introduced by Wang and Kerre [35].

Reasonable properties (axioms)

A_1 : For an arbitrary finite subset Γ of E and $u \in \Gamma, u \succeq u$.

A_2 : For an arbitrary finite subset Γ of E and $(u, v) \in \Gamma^2, u \succeq v$ and $v \succeq u$, we should have $u \sim v$.

A_3 : For an arbitrary finite subset Γ of E and $(u, v, w) \in \Gamma^3, u \succeq v$ and $v \succeq w$, we should have $u \succeq w$.

A_4 : For an arbitrary finite subset Γ of E and $(u, v) \in \Gamma^2$, $\inf supp(u) \geq \sup supp(v)$, we should have $u \succeq v$.

A'_4 : For an arbitrary finite subset Γ of E and $(u, v) \in \Gamma^2$, $\inf supp(u) > \sup supp(v)$, we should have $u \succ v$.

A_5 : Let Γ and Γ' be two arbitrary finite subsets of E also u and v are in $\Gamma \cap \Gamma'$. We obtain the ranking order $u \succ v$ by M on Γ' if and only if $u \succ v$ by M on Γ.

A_6 : Let $u,\ v$, $u + w$ and $v + w$ be elements of E. If $u \succeq v$, then $u + w \succeq v + w$.

A'_6 : Let $u,\ v$, $u + w$ and $v + w$ be elements of E. If $u \succ v$, then $u + w \succ v + w$, when $w \neq 0$.

A_7 : Let $u,\ v,\ uw$, and vw be elements of E and $w \geq 0$. If $u \succeq v$ then $uw \succeq vw$.

3 Some new and recent methods

3.1 Method of D-distance

Let all of fuzzy numbers are positive or negative. Without less of generality assume that all of them are positive. The membership function of $a \in R$ is $u_a(x) = 1$, if $x = a$; and $u_a(x) = 0$, if $x \neq a$. Hence if $a = 0$ we have the following

$$u_0(x) = \begin{cases} 1 & x = 0, \\ 0 & x \neq 0. \end{cases}$$

Since $u_0(x) \in E$, left fuzziness σ and right fuzziness β are 0, so for each $u \in E$

$$D(u, u_0) = \left[\int_0^1 (\underline{u}(r)^2 + \overline{u}(r)^2)\mathrm{dr}\right]^{1/2}.$$

Thus we have the following definition.

Definition 3.1 *For u and $v \in E$, define the ranking of u and v by saying*

$$u > v \ \ iff \ \ d(u, u_0) > d(v, u_0),$$
$$u < v \ \ iff \ \ d(u, u_0) > d(v, u_0),$$
$$u \approx v \ \ iff \ \ d(u, u_0) = d(v, u_0).$$

Property 3.1. Suppose u and $v \in E$ are arbitrary there

(I) If $u = v$ then $u \approx v$.

(II) If $v \subseteq u$ and $\underline{u}(r)^2 + \overline{u}(r)^2 > \underline{v}(r)^2 + \overline{v}(r)^2$ for all $r \in [0, 1]$ then $v < u$.

Remark 3.1. (I) The distance triangular fuzzy number $u = (x_0, \sigma, \beta)$ of u_0 is defined as following

$$d(u, u_0) = \left[2x_0^2 + \sigma^2/3 + \beta^2/3 + x_0(\beta - \sigma)\right]^{1/2}.$$

(II) The distance trapezoidal fuzzy number $u = (x_0, y_0, \sigma, \beta)$ of u_0 is defined as following

$$d(u, u_0) = \left[2x_0^2 + \sigma^2/3 + \beta^2/3 - x_0\sigma + y_0\beta\right]^{1/2}.$$

(III) If $u \approx v$, it is not necessary that $u = v$. Since if $u \neq v$ and $(\underline{u}(r)^2 + \overline{u}(r)^2)^{1/2}$=$(\underline{v}(r)^2 + \overline{v}(r)^2)^{1/2}$ then $u \approx v$.

3.2 Method of min distance

In this subsection, we will propose the ranking of fuzzy numbers associated with the metric D in E.

Definition 3.2 *Let $\gamma = \{v_1, v_2, \ldots, v_n\} \subseteq E$ be is set of fuzzy numbers, we define a ranking on γ by min distance as*

$$v_i \succ v_j \ \text{ iff } \ D(v_i, \tilde{M}) > D(v_j, \tilde{M}),$$

ISBN: 978-989-95079-6-8

$$v_i \prec v_j \text{ iff } D(v_i, \tilde{M}) < D(v_j, \tilde{M}),$$
$$v_i \sim v_j \text{ iff } D(v_i, \tilde{M}) = D(v_j, \tilde{M}),$$

where $\tilde{M} = \tilde{min}\{v_1, \ldots, v_n\}$.

Dubois and Prade [30] present rules for computing $\tilde{min}$ and also comment on the properties of $\tilde{min}$.

Remark 3.2. The min distance, has the properties $A_1, A_2, \ldots, A_4'$.

3.3 Method of sign distance

Definition 3.3 *For arbitrary fuzzy numbers* $u = (\underline{u}, \overline{u})$ *and* $v = (\underline{v}, \overline{v})$*,the function*

$$D_p(u,v) = \left[\int_0^1 |\underline{u}(r) - \underline{v}(r)|^p \mathrm{dr} + \int_0^1 |\overline{u}(r) - \overline{v}(r)|^p \mathrm{dr}\right]^{1/p}, \quad (p \geq 1)$$

is the distance between u *and* v.

Definition 3.4 *Let* $\gamma : E \longrightarrow \{-1, 1\}$ *be a function that is defined as follows:*

$$\forall\, u \in E : \gamma(u) = sign\left[\int_0^1 (\underline{u}(r) + \overline{u}(r))\mathrm{dr}\right],$$

where

$$\gamma(u) = \begin{cases} 1 & \text{if } sign\left(\int_0^1 (\underline{u} + \overline{u})(r)\mathrm{dr}\right) \geq 0, \\ -1 & \text{if } sign\left(\int_0^1 (\underline{u} + \overline{u})(r)\mathrm{dr}\right) < 0. \end{cases}$$

Remark 3.3. (I) If $\inf supp(u) \geq 0$ or $\inf \underline{u}(r) \geq 0$ then $\gamma(u) = 1$.

(II) If $\sup supp(u) < 0$ or $\sup \overline{u}(r) < 0$ then $\gamma(u) = -1$.

Definition 3.5 *For* $u \in E$,

$$d_p(u, u_0) = \gamma(u) D_p(u, u_0),$$

is called sign distance.

Definition 3.6 *For* u *and* $v \in E$*, define the ranking of* u *and* v *by* d_p *on* E*, i.e.*

$$u \succ v \text{ iff } d_p(u, u_0) > d_p(v, u_0),$$
$$u \prec v \text{ iff } d_p(u, u_0) < d_p(v, u_0),$$
$$u \sim v \text{ iff } d_p(u, u_0) = d_p(v, u_0).$$

Remark 3.4. (I) The function d_p, sign distance, has the properties $A_1, A_2, \ldots, A_5$.

(II) The function d_p, sign distance, for $p = 1$ has the properties A_6, A_6' if

$$\inf\{supp(u), supp(v), supp(u+w), supp(v+w)\} \geq 0$$

or

$$\sup\{supp(u), supp(v), supp(u+w), supp(v+w)\} \leq 0.$$

(III) Suppose u and $v \in E$ are arbitrary, then

(a) If $u = v$ then $u \sim v$,

(b) If $v \subseteq u$ and $\gamma(u)\left(|\underline{u}(r)|^p + |\overline{u}(r)|^p\right) > \gamma(v)\left(|\underline{v}(r)|^p + |\overline{v}(r)|^p\right)$ for all $r \in [0,1]$ then $v \prec u$.

(IV) If $u \sim v$, it is not necessary that $u = v$. Since if $u \neq v$ and $\gamma(u)(|\underline{u}(r)|^p + |\overline{u}(r)|^p) = \gamma(v)(|\underline{v}(r)|^p + |\overline{v}(r)|^p)$ then $u \sim v$.

(V) If $u \preceq v$ then $-u \succeq -v$.

Therefore we can simply rank the fuzzy numbers by the defuzzification of $d_p(u, u_0)$. By Remark 3.4(V) we can logically infer ranking order of the images of the fuzzy numbers.

3.4 Method of H-distance

Definition 3.7 *A continuous function* $s : [0,1] \longrightarrow [0,1]$ *with the following properties is a* source *function*

1. $s(0) = 0$,
2. $s(1) = 1$,
3. $s(r)$ *is increasing.*
4. $\int_0^1 s(r)\mathrm{dr} = \frac{1}{2}$.

In fact, a reducing has the reflect of weighting the influence of the different r-cuts and diminishes the contribution of the lower r-levels. This is reasonable since these levels arises from values of membership function for which there is a considerable amount of uncertainty. For example, we can use $s(r) = r$.

Definition 3.8 *The Value and Ambiguity of a fuzzy number* $\widetilde{u}$ *are defined as follows, [36],*

$$Val_s(\widetilde{u}) = \int_0^1 s(r)[\overline{u}(r) + \underline{u}(r)]\mathrm{dr},$$
$$Amb_s(\widetilde{u}) = \int_0^1 s(r)[\overline{u}(r) - \underline{u}(r)]\mathrm{dr}.$$

Definition 3.9 *For* $\widetilde{u}, \widetilde{v} \in E$*, we define* ***H-distance*** *of* $\widetilde{u}$ *and* $\widetilde{v}$ *by*

$$D_H^s(\widetilde{u}, \widetilde{v}) = \frac{1}{2}\big\{\, |Val_s(\widetilde{u}) - Val_s(\widetilde{v})| + |Amb_s(\widetilde{u}) - Amb_s(\widetilde{v})| + d_H([\widetilde{u}]^1, [\widetilde{v}]^1)\big\},$$

where d_H *is the Hausdorff metric between intervals, and* $[.]^1$ *is the 1-cut representation of a fuzzy number.*

Property 3.2. The source distance, D_H^s, is a metric on E_{TR} and a pseudo-metric on E.

Remark 3.5. By the metric D_H^s and an arbitrary reference fuzzy set (like subsection 3.1 or 3.2), we can define a new ordering for fuzzy numbers.

3.5 Method of source distance

Definition 3.10 *For* $\widetilde{u}, \widetilde{v} \in E$*, we define* ***source distance*** *of* $\widetilde{u}$ *and* $\widetilde{v}$ *by*

$$D_s(\widetilde{u}, \widetilde{v}) = \frac{1}{2}\big\{\, |Val_s(\widetilde{u}) - Val_s(\widetilde{v})| + |Amb_s(\widetilde{u}) - Amb_s(\widetilde{v})| + \max\big\{\, |t_v - t_u|, |m_v - m_u|\big\}\big\},$$

where $[m_u, t_u]$ *and* $[m_v, t_v]$ *are the cores of fuzzy numbers* $\widetilde{u}$ *and* $\widetilde{v}$ *respectively.*

ISBN: 978-989-95079-6-8

Property 3.3. The source distance, D_s, is a metric on E_{TR} and a pseudo-metric on E.

Remark 3.6. By the metric D_s and an arbitrary reference fuzzy set (like subsection 3.1 or 3.2), we can define a new ordering for fuzzy numbers.

3.6 Method of magnitude

For an arbitrary trapezoidal fuzzy number $u = (x_0, y_0, \sigma, \beta)$, with parametric form $u = (\underline{u}(r), \overline{u}(r))$, we define the *magnitude* of the trapezoidal fuzzy number u as

$$Mag(u) = \frac{1}{2}\Big(\int_0^1 (\underline{u}(r) + \overline{u}(r) + x_0 + y_0) f(r) \mathrm{dr} \Big),$$

where the function $f(r)$ is a non-negative and increasing function on $[0, 1]$ with $f(0) = 0$, $f(1) = 1$ and $\int_0^1 f(r)\mathrm{dr} = \frac{1}{2}$. For example, we can use $f(r) = r$. The resulting scalar value is used to rank the fuzzy numbers. In the other words $Mag(u)$ is used to rank fuzzy numbers. The larger $Mag(u)$, the larger fuzzy number. Therefore for any two trapezoidal fuzzy numbers u and $v \in E$, we define the ranking of u and v by the $Mag(.)$ on E as follows:

1. $Mag(u) > Mag(v)$ if and only if $u \succ v$,
2. $Mag(u) < Mag(v)$ if and only if $u \prec v$,
3. $Mag(u) = Mag(v)$ if and only if $u \sim v$.

Then we formulate the order $\succeq$ and $\preceq$ as $u \succeq v$ if and only if $u \succ v$ or $u \sim v$, $u \preceq v$ if and only if $u \prec v$ or $u \sim v$. In the other words, this method is placed in the first class of Kerre's categories [35].

Remark 3.7. **(I)** If $\inf supp(u) \geq 0$ or $\inf \underline{u}(r) \geq 0$ then $Mag(u) \geq 0$.

(II) If $\sup supp(u) \leq 0$ or $\sup \overline{u}(r) \leq 0$ then $Mag(u) \leq 0$.

(III) For two arbitrary trapezoidal fuzzy numbers u and v, we have

$$Mag(u + v) = Mag(u) + Mag(v).$$

(IV) For all symmetric trapezoidal fuzzy numbers $u = (-x_0, x_0, \sigma, \sigma)$,

$$Mag(u) = 0.$$

(V) For any two symmetric trapezoidal fuzzy numbers $u = (x_0, y_0, \sigma, \sigma)$ and $v = (x_0, y_0, \beta, \beta)$,

$$Mag(u) = Mag(v).$$

Property 3.4. The function $Mag(.)$ has the properties $A_1, A_2, A_3, \ldots, A_6'$.

4 Conclusions

In spite of many ranking methods, no one can rank fuzzy numbers with human intuition consistently in all cases. The proposed methods can effectively rank various fuzzy numbers and their images. These methods have some mathematical properties. Moreover some pseudo metric on the set of fuzzy numbers and metric on trapezoidal fuzzy numbers are introduced. We may conclude that these ordering methods are relatively reasonable for fuzzy numbers based on the introduced axioms.

Email: {jaume.casasnovas,jvicente.riera}@uib.es

Abstract— *This paper proposes to study the lattice properties of two closed binary operations in the set of discrete fuzzy numbers. Using these operations to represent the meet and the join, we prove that the set of discrete fuzzy numbers whose support is a set of consecutive natural numbers is a distributive lattice. Finally, we demonstrate that the subsets of discrete fuzzy numbers, which have the same support, are distributive lattices too.*

Keywords— Fuzzy numbers, discrete fuzzy numbers, distributive lattice.

1 Introduction

It is possible to approach the theory of fuzzy numbers in different directions: theoretical[8, 9, 10, 13], geometric [1, 2], applications in engineering [13], social science [12], lattice theory[13, 20], etc.. Voxman [18] introduced the concept of a discrete fuzzy number as a fuzzy subset of real numbers with discrete support and analogous properties to a fuzzy number (convexity, normality). Also, like fuzzy numbers, it is possible to consider discrete fuzzy numbers from different points of view: theoretical [16, 18], applications in engineering [11, 19], social sciences [17], etc.

It is well known that, the arithmetic and lattice operations such as maximum and minimum on fuzzy numbers can be approached either by the direct use of the membership function (by the Zadeh's extension principle) or by the equivalent use of the *r-cuts* representation, for instance, [13, 14, 20].

Nevertheless, in the discrete case using the same methods, this process can yield a fuzzy subset that does not satisfy the conditions to be a discrete fuzzy number [3, 19]. In previous works [3, 4], we have presented a technique that allows us to obtain a closed addition on the set of discrete fuzzy numbers, DFN, and moreover, we focus on the addition of discrete fuzzy numbers whose support is an arithmetic sequence and even a subset of consecutive natural numbers. This type of numbers arise mainly when a fuzzy cardinality of a fuzzy set [5, 6] or a fuzzy multiset [15] is considered.

In [7] we define two closed binary operations in the set of discrete fuzzy numbers to obtain the maximum and the minimum of discrete fuzzy numbers. We prove as well that in the set $\mathcal{A}_1$, of discrete fuzzy numbers whose support is a set of consecutive natural numbers, these operations coincide with the function maximum and minimum obtained using the Zadeh's extension principle.

The aim of this paper is to continue studying the properties of these operations and if it is possible to obtain a structure of lattice using them. We will see that, in general, these binary operations only fulfill the associative, commutative and idempotent laws. We show as well that the triplets ($\mathcal{A}_1$,MAX_w,MIN_w) and (F_A,MIN_w,MAX_w) are distributive lattices, where F_A is the subset of discrete fuzzy numbers whose support is the support of A, with $A \in DFN$.

2 Preliminaries

In this section, we recall some definitions and the main results about discrete fuzzy numbers which will be used later.

Definition 2.1 *[13] A fuzzy subset u of $\mathbb{R}$ with membership mapping $u : \mathbb{R} \to [0,1]$ is called* fuzzy number *if its* support *is an interval $[a,b]$ and there exist real numbers s,t with $a \leq s \leq t \leq b$ and such that:*

1. *$u(x)$=1 with $s \leq x \leq t$*
2. *$u(x) \leq u(y)$ with $a \leq x \leq y \leq s$*
3. *$u(x) \geq u(y)$ with $t \leq x \leq y \leq b$*
4. *$u(x)$ is upper semi-continuous.*

We will denote the set of fuzzy numbers by FN.

Definition 2.2 *[18] A fuzzy subset u of $\mathbb{R}$ with membership mapping $u : \mathbb{R} \to [0,1]$ is called* discrete fuzzy number *if its support is finite, i.e., there are $x_1, ..., x_n \in \mathbb{R}$ with $x_1 < x_2 < ... < x_n$ such that $supp(u) = \{x_1, ..., x_n\}$, and there are natural numbers s,t with $1 \leq s \leq t \leq n$ such that:*

1. *$u(x_i)$=1 for any natural number and i with $s \leq i \leq t$ (*core*)*
2. *$u(x_i) \leq u(x_j)$ for each natural number i,j with $1 \leq i \leq j \leq s$*
3. *$u(x_i) \geq u(x_j)$ for each natural number i,j with $t \leq i \leq j \leq n$*

From now on, we will denote the set of discrete fuzzy numbers by DFN and $DFN(\mathbb{N})$ will stand for the set of discrete fuzzy numbers whose support is a subset of the set of Natural Numbers. Finally, a discrete fuzzy number will be denoted by *dfn*.

In general, the operations on fuzzy numbers f, g can be approached either by the direct use of their membership function, $\mu_f(x), \mu_g(x)$, as fuzzy subsets of $\mathbb{R}$ and the Zadeh's extension principle:

$$O(f,g)(z) = sup\{\mu_f(x) \wedge \mu_g(y) | O(x,y) = z\}$$

or by the equivalent use of the α-*cuts* representation[13]:

ISBN: 978-989-95079-6-8

$$O(f,g)^{\alpha} = O(f^{\alpha}, g^{\alpha}) = \{O(x,y) | x \in f^{\alpha}, y \in g^{\alpha}\}$$

and

$$O(f,g)(z) = sup\{\alpha \in [0,1] | z \in O(f,g)^{\alpha}\}$$

Nevertheless, in the discrete case, this process can yield a fuzzy subset that does not satisfy the conditions to be a discrete fuzzy number [3, 19]. For example, let $u = \{0.3/1, 1/3, 0.5/7\}$ and $v = \{0.4/2, 1/5, 1/6, 0.8/9\}$ be two discrete fuzzy numbers. If we use the Zadeh's extension principle to obtain their addition, it results the fuzzy subset $S = \{0.3/3, 0.4/5, 0.3/6, 0.3/7, 1/8, 1/9, 0.3/10, 0.8/12, 0.5/13, 0.5/16\}$ which doesn't fulfill the conditions to be a discrete fuzzy number, because the third property of the definition 2.2 fails. In a previous work [3, 4] we have presented an approach to a closed extended addition ($\oplus$) of discrete fuzzy numbers after associating suitable non-discrete fuzzy numbers, which can be used like a carrier to obtain the desired addition.
In a recent paper [4] we proved that a suitable carrier can be a discrete fuzzy number whose support is an arithmetic sequence and even a subset of consecutive natural numbers. Thus, we obtained the following results:

Proposition 2.3 *[4]*
Let $\mathcal{A}_r$ be the set $\{f \in DFN\ (\mathbb{N})$, such that supp(f) is the set of terms of an arithmetic sequence with r as common difference$\}$. If $f, g \in \mathcal{A}_r$. The following facts:

1. $f \oplus g \in DFN(\mathbb{N})$
2. $f \oplus g \in \mathcal{A}_r$

hold.

Remark 2.4 *[4] Note that the set $\mathcal{A}_1$ is the set of discrete fuzzy numbers whose support is a set of consecutive natural numbers.*

Finally, we will use a kind of representation in the study of discrete fuzzy numbers:

Theorem 2.5 *[19] Let u be a dfn and let u^r be the r-cut $=\{x \in \mathbb{R} | u(x) \geq r\}$ for any $r \in (0,1]$. Let's u^0 denote the support of u. Then the following statements (1)-(4) hold:*

1. *u^r is a nonempty finite subset of $\mathbb{R}$, for any $r \in [0,1]$*
2. *$u^{r_2} \subset u^{r_1}$ for any $r_1, r_2 \in [0,1]$ with $0 \leq r_1 \leq r_2 \leq 1$*
3. *For any $r_1, r_2 \in [0,1]$ with $0 \leq r_1 \leq r_2 \leq 1$, if $x \in u^{r_1} - u^{r_2}$ we have $x < y$ for all $y \in u^{r_2}$, or x>y for all $y \in u^{r_2}$*
4. *For any $r_0 \in [0,1]$, there exist some real numbers $r_0^{'}$ with $0 < r_0' < r_0$ such that $u^{r_0'} = u^{r_0}$ (i.e. $u^r = u^{r_0}$ for any $r \in [r_0', r_0]$).*

And conversely, if for any $r \in [0,1]$, there exist $A^r \subset \mathbb{R}$ satisfying the following conditions (1)-(4):

1. *A^r is a nonempty finite for any $r \in [0,1]$*
2. *$A^{r_2} \subset A^{r_1}$, for any $r \in [0,1]$ with $0 \leq r_1 \leq r_2 \leq 1$*
3. *For any $r_1, r_2 \in [0,1]$ with $0 \leq r_1 \leq r_2 \leq 1$, if $x \in A^{r_1} - A^{r_2}$ we have $x < y$ for all $y \in A^{r_2}$, or x>y for all $y \in A^{r_2}$*
4. *For any $r_0 \in [0,1]$, there exists a real number $r_0^{'}$ with $0 < r_0^{'} < r_0$ such that $A^{r_0'} = A^{r_0}$ (i.e. $A^r = A^{r_0}$, for any $r \in [r_0', r_0]$)*

then there exists a unique $u \in DFN$ such that $u^r = A^r$ for any $r \in [0,1]$.

3 Maximum and Minimum of discrete fuzzy numbers

It's well known, for example [13], that the set of fuzzy numbers is a distributive lattice using the following operations

$$MIN(u,v)(z) = \sup_{z=\min(x,y)} \min(u(x), v(y)), \forall z \in \mathbb{R} \quad (1)$$

$$MAX(u,v)(z) = \sup_{z=\max(x,y)} \min(u(x), v(y)), \forall z \in \mathbb{R} \quad (2)$$

for each couple $u, v \in FN$. If we use the same operations to obtain a similar structure in the set of discrete fuzzy numbers we see that this result is not possible. For instance, if we consider the discrete fuzzy numbers $u = \{0.3/1, 0.4/3, 1/4\}$ and $v = \{0.5/2, 1/5, 1/6\}$ and we use the previous definition to calculate the $MIN(u,v)$, we obtain the fuzzy subset $M = \{0.3/1, 0.5/2, 0.4/3, 1/4\}$ which doesn't satisfy the conditions of the definition 2.2. In [7], the authors study this drawback and we propose a new method to calculate them. Using this method, we will see later that, it is possible to provide different subsets of the set DFN with a structure of distributive lattice.

Definition 3.1 *[7] Let u, v be two dfn. For each $\alpha \in [0,1]$, let's consider the α-cut sets: $u^{\alpha} = \{x_1^{\alpha}, ..., x_p^{\alpha}\}, v^{\alpha} = \{y_1^{\alpha}, ..., y_k^{\alpha}\}$ for u and v respectively and the set $supp(u) \bigvee supp(v) = \{x \vee y | x \in supp(u), y \in supp(v)\}$. Let's define the set:*

$$A^{\alpha} = \{z \in supp(u) \bigvee supp(v) \text{ such that}$$

$$\min(u^{\alpha} \vee v^{\alpha}) \leq z \leq \max(u^{\alpha} \vee v^{\alpha})\} =$$

$$= \{z \in supp(u) \bigvee supp(v) \text{ such that}$$

$$(\min u^{\alpha} \vee \min v^{\alpha}) \leq z \leq (\max u^{\alpha} \vee \max v^{\alpha})\}$$

i.e.:

$$A^{\alpha} = \{z \in supp(u) \bigvee supp(v) | (x_1^{\alpha} \vee y_1^{\alpha}) \leq z \leq (x_p^{\alpha} \vee y_k^{\alpha})\}$$

Proposition 3.2 *[7] The finite set A^{α}, as defined above, satisfies the properties 1,2,3 and 4 of theorem 2.5 and a discrete fuzzy number, $MAX_w(u,v)$, whose α-cuts are the finite set A^{α} exists and $MAX_w(u,v)(z) = \sup\{\alpha \in [0,1]$ such that $z \in A^{\alpha}\}$.*

Proposition 3.3 *[7] If $u, v \in \mathcal{A}_1$, then $MAX(u,v)$, defined through the extension principle, coincides with $MAX_w(u,v)$. So, if $u, v \in \mathcal{A}_1$, $MAX(u,v)$ is a discrete fuzzy number and $MAX(u,v) \in \mathcal{A}_1$.*

ISBN: 978-989-95079-6-8

Definition 3.4 *[7] Let u, v be two dfn. For each $\alpha \in [0,1]$, let's consider the α-cut sets: $u^\alpha = \{x_1^\alpha, ..., x_p^\alpha\}$,$v^\alpha = \{y_1^\alpha, ..., y_k^\alpha\}$ for u and v respectively and the set $supp(u) \bigwedge supp(v) = \{x \wedge y | x \in supp(u), y \in supp(v)\}$. Let's define the set:*

$$B^\alpha = \{z \in supp(u) \bigwedge supp(v) \text{ such that}$$

$$\min(u^\alpha \wedge v^\alpha) \leq z \leq \max(u^\alpha \wedge v^\alpha)\} =$$

$$= \{z \in supp(u) \bigwedge supp(v) \text{ such that}$$

$$(\min u^\alpha \wedge \min v^\alpha) \leq z \leq (\max u^\alpha \wedge \max v^\alpha)\}$$

i.e.:

$$B^\alpha = \{z \in supp(u) \bigwedge supp(v) | (x_1^\alpha \wedge y_1^\alpha) \leq z \leq (x_p^\alpha \wedge y_k^\alpha)\}$$

Remark 3.5 *In general, if "$*$" is a binary operation the equalities*

- $\min(u^\alpha * v^\alpha) = \min u^\alpha * \min v^\alpha$
- $\max(u^\alpha * v^\alpha) = \max u^\alpha * \max v^\alpha$

do not hold. For example, if we consider the sets $u^\alpha = \{-10, -9, -8, -7, -6, -1\}$, $v^\alpha = \{0, 1, 2, 3, 4\}$ and the usual product of real numbers as binary operation then $\min(u^\alpha \cdot v^\alpha) = -40$ and $\min(u^\alpha) \cdot \min(v^\alpha) = -10 \cdot 0 = 0$, and $\max(u^\alpha \cdot v^\alpha) = 0$ and $\max(u^\alpha) \cdot \max(v^\alpha) = -1 \cdot 4 = -4$

Proposition 3.6 *[7] The finite set B^α, as defined above, satisfies the properties 1,2,3 and 4 of Proposition 2.5 and a discrete fuzzy number, $MIN_w(u, v)$, whose α-cuts are the finite set B^α exists and $MIN_w(u, v)(z) = \sup\{\alpha \in [0, 1]$ such that $z \in B^\alpha\}$.*

Proposition 3.7 *[7] If $u, v \in \mathcal{A}_1$, then $MIN(u, v)$, defined through the extension principle, coincides with $MIN_w(u, v)$. So, if $u, v \in \mathcal{A}_1$, $MIN(u, v)$ is a discrete fuzzy number and $MIN(u, v) \in \mathcal{A}_1$.*

We have seen, in the previous propositions, that the operations $MAX_w(u, v)$ and $MIN_w(u, v)$ are discrete fuzzy numbers.

Example 3.8 *If we use the method, as explained above, to calculate the minimum of $u = \{0.3/1, 0.4/3, 1/4\}$ and $v = \{0.5/2, 1/5, 1/6\}$, we obtain the following discrete fuzzy number $MIN_w(u, v) = \{0.3/1, 0.5/2, 0.5/3, 1/4\}$ where*

$$B^{0.3} = \{z \in \{1, 2, 3, 4\} \text{ such that } 1 \leq z \leq 4\} = \{1, 2, 3, 4\}$$

$$B^{0.4} = \{z \in \{1, 2, 3, 4\} \text{ such that } 2 \leq z \leq 4\} = \{2, 3, 4\}$$

$$B^{0.5} = \{z \in \{1, 2, 3, 4\} \text{ such that } 2 \leq z \leq 4\} = \{2, 3, 4\}$$

$$B^1 = \{z \in \{1, 2, 3, 4\} \text{ such that } 4 \leq z \leq 4\} = \{4\}$$

Proposition 3.9 *Let A, B and C be three dfn such that their supports are $supp(A)$,$supp(B)$ and $supp(C)$ respectively. The following properties hold:*

1. *Commutativity*

$$supp(A) \bigwedge supp(B) = supp(B) \bigwedge supp(A)$$

and

$$supp(A) \bigvee supp(B) = supp(B) \bigvee supp(A)$$

2. *Associativity*

$$(supp(A) \bigwedge supp(B)) \bigwedge supp(C) =$$

$$= supp(A) \bigwedge (supp(B) \bigwedge supp(C))$$

and

$$(supp(A) \bigvee supp(B)) \bigvee supp(C) =$$

$$= supp(A) \bigvee (supp(B) \bigvee supp(C))$$

3. *Idempotence*

$$supp(A) \bigwedge supp(A) = supp(A)$$

and

$$supp(A) \bigvee supp(A) = supp(A)$$

4. *If the supports of A and B are the same or $supp(B) \subseteq supp(A)$ or $A, B \in \mathcal{A}_1$ then the next absorption laws*

$$supp(A) \bigwedge (supp(A) \bigvee supp(B)) = supp(A)$$

$$supp(A) \bigvee (supp(A) \bigwedge supp(B)) = supp(A)$$

hold.

5. *If the supports of A, B and C are the same or $A, B, C \in \mathcal{A}_1$ then the following distributive properties*

$$supp(A) \bigwedge (supp(B) \bigvee supp(C)) =$$

$$= (supp(A) \bigwedge supp(B)) \bigvee (supp(A) \bigwedge supp(C))$$

and

$$supp(A) \bigvee (supp(B) \bigwedge supp(C)) =$$

$$= (supp(A) \bigvee supp(B)) \bigwedge (supp(A) \bigvee supp(C))$$

hold.

6. *For any $A, B \in DFN$ then*

$$supp(A) \bigwedge (supp(B) \bigvee supp(C))) \subseteq$$

$$\subseteq (supp(A) \bigwedge supp(B)) \bigvee (supp(A) \bigwedge supp(C))$$

and

$$supp(A) \bigvee (supp(B) \bigwedge supp(C))) \subseteq$$

$$\subseteq (supp(A) \bigvee supp(B)) \bigwedge (supp(A) \bigvee supp(C))$$

7. *For any $A, B \in DFN$ then*

$$supp(A) \subseteq supp(A) \bigwedge (supp(A) \bigvee supp(B))$$

$$supp(A) \subseteq supp(A) \bigvee (supp(A) \bigwedge supp(B))$$

ISBN: 978-989-95079-6-8

Proof From the definition 2.2, the support of a discrete fuzzy number is a finite linearly ordered subset of real numbers. Moreover, it is well known that the set of real numbers is a distributive lattice with the usual operations maximum(max) and minimum(min). Let X, Y and Z denote the supports of $A, B, C \in DFN$ respectively.

1. Using the commutative property of the real functions maximum and minimum the proof is trivial.

2. Associativity

   If $z \in (X \bigwedge Y) \bigwedge Z$ then $z = \min(x, c)$ where $x = \min(a, b)$, $a \in X$, $b \in Y$ and $c \in Z$. So $z = \min(\min(a, b), c)$. Using the associativity of the function minimum, $z = \min(\min(a, b), c) = \min(a, \min(b, c))$. Then $z \in X \bigwedge (Y \bigwedge Z)$. Therefore

   $$(X \bigwedge Y) \bigwedge Z \subseteq X \bigwedge (Y \bigwedge Z)$$

   If $z \in X \bigwedge (Y \bigwedge Z)$ then $z = \min(a, x)$ where $x = \min(b, c)$, $a \in X$, $b \in Y$ and $c \in Z$. So $z = \min(a, \min(b, c))$. Using the associativity of the function minimum, $z = \min(a, \min(b, c)) = \min(\min(a, b), c)$. Then $z \in (X \bigwedge Y) \bigwedge Z$. Therefore

   $$X \bigwedge (Y \bigwedge Z) \subseteq (X \bigwedge Y) \bigwedge Z$$

   The proof of the other associative law is analogous.

3. Idempotence

   If $z \in X \bigwedge X$ then $z = \min(a, a')$ with $a, a' \in X$. Therefore $z = a \in X$ or $z = a' \in X$. This means that $z \in X$ and so $X \bigwedge X \subseteq X$. On the other hand, it is evident that $X \subseteq X \bigwedge X$ because the function minimum is idempotent and then for each $z \in X$, $z = \min(z, z)$.

   The proof of the other idempotence law is similar.

4. Absorption

   If $z \in X \bigwedge (X \bigvee Y)$ then $z = \min(a, \max(a', b))$ where $a, a' \in X$ and $b \in Y$. Then if $z = a$ or $z = a'$ obviously $z \in X$. But if $z = b$ we have that $a' \leq b \leq a$. Using the hypothesis of the proposition we obtain that $b \in X$. Therefore $X \bigwedge (X \bigvee Y) \subseteq X$.

   If $z \in X$ then $z = \min(z, \max(z, b))$ for all $b \in Y$. Because if $\max(z, b) = b$ then $\min(z, b) = z$. And, if $\max(z, b) = z$ then $\min(z, z) = z$. So, $X \subseteq X \bigwedge (X \bigvee Y)$

5. Distributivity

   Let's $A, B, C \in \mathcal{A}_1$ where $supp(A) = \{x_1, \cdots, x_n\}$,$supp(B) = \{y_1, \cdots, y_m\}$ and $supp(C) = \{z_1, \cdots, z_k\}$ respectively. Then

   $$supp(A) \bigwedge (supp(B) \bigvee supp(C))$$

   is the set of natural numbers z such that they belong to the set

   $$\{x_1, \cdots, x_n\} \bigwedge \{\max(y_1, z_1), \cdots, \max(y_m, z_k)\}$$

   , i.e., it's the set of natural numbers z such that $z \in \{\min(x_1, \max(y_1, z_1)), \cdots, \min(x_n, \max(y_m, z_k))\} =$ (using the distributive property of natural numbers with the usual order)

   $$= \{z \in \{\max(\min(x_1, y_1), \min(x_1, z_1)), \cdots$$
   $$\cdots, \max(\min(x_n, y_m), \min(x_n, z_k))\}\}$$

   Where the previous set is an interval of consecutive natural numbers. On the other hand,

   $$(supp(A) \bigwedge supp(B)) \bigvee (supp(A) \bigwedge supp(C)) =$$
   $$= \{z \in \{\{\min(x_1, y_1), \cdots, \min(x_n, y_m)\} \bigvee$$
   $$\{\min(x_1, z_1), \cdots, \min(x_n, z_k)\}\} =$$
   $$= \{z \in \{\max(\min(x_1, y_1), \min(x_1, z_1)), \cdots$$
   $$\cdots, \max(\min(x_n, y_m), \min(x_n, z_k))\}.$$

   The proof of the second distributive law is analogous.

6. If $z \in X \bigwedge (Y \bigvee Z))$ then $z = \min(a, \max(b, c))$ where $a \in X$, $b \in Y$ and $c \in Z$. Using the distributive property of the minimum and the maximum of real numbers, $z = \max(\min(a, b), \min(a, c))$. Then we obtain that $z \in (X \bigwedge Y) \bigvee (X \bigwedge Z)$ and so $X \bigwedge (Y \bigvee Z)) \subseteq (X \bigwedge Y) \bigvee (X \bigwedge Z)$.

   Analogously for the other inclusion.

7. If $z \in X$ then $z = \max(z, \min(z, b))$ for all $b \in Y$. Because if $\min(z, b) = b$ then $\max(z, b) = z$. And, if $\min(z, b) = z$ then $\max(z, z) = z$. So, $X \subseteq X \bigvee (X \bigwedge Y)$

Remark 3.10 *In general, the absorption and the distributive laws of the supports do not hold. For example, if* $X = \{4, 7, 9\}$,$Y = \{4, 6, 7\}$ *and* $Z = \{8, 9, 10\}$ *represent the supports of the discrete fuzzy numbers* A, B *and* C *respectively, then*

a) $X \bigwedge (X \bigvee Y) = \{4, 6, 7, 9\}$ *but* $X = \{4, 7, 9\}$.

b) $X \bigwedge (Y \bigvee Z) = \{4, 7, 8, 9\}$, *but* $(X \bigwedge Y) \bigvee (X \bigwedge Z) = \{4, 6, 7, 8, 9\}$.

The following theorem establishes some properties of the binary operations MAX_w and MIN_w using the same conditions and results that the previous proposition 3.9:

Theorem 3.11 *Let* MAX_w *and* MIN_w *be the binary operations on* DFN *defined by the propositions 3.2 and 3.6, respectively. Then, for any,* $A, B, C \in DFN$ *the following properties hold:*

1. Commutativity: $MIN_w(A, B) = MIN_w(B, A)$, $MAX_w(A, B) = MAX_w(B, A)$

2. Associativity:

$$MIN_w(MIN_w(A, B), C) =$$
$$= MIN_w(A, MIN_w(B, C))$$

and

$$MAX_w(MAX_w(A, B), C) =$$
$$= MAX_w(A, MAX_w(B, C))$$

ISBN: 978-989-95079-6-8

3. Idempotence: $\begin{array}{l} MIN_w(A,A)=A \\ MAX_w(A,A)=A \end{array}$

If the supports of A and B are the same or $A,B,C \in \mathcal{A}_1$ then

4. Absorption: $\begin{array}{l} MIN_w(A, MAX_w(A,B))=A \\ MAX_w(A, MIN_w(A,B))=A \end{array}$

5. Distributivity:

$$MIN_w(A, MAX_w(B,C)) =$$
$$= MAX_w(MIN_w(A,B), MIN_w(A,C))$$

And

$$MAX_w(A, MIN_w(B,C)) =$$
$$= MIN_w(MAX_w(A,B), MAX_w(A,C))$$

Proof Let A, B and C be three dfn. Let's consider the α-cut sets: $A^\alpha = \{x_1^\alpha, ..., x_p^\alpha\}$, $B^\alpha = \{y_1^\alpha, ..., y_k^\alpha\}$, $C^\alpha = \{w_1^\alpha, ..., w_l^\alpha\}$ for A, B and C respectively.

1. We want to show that $MIN_w(A,B) = MIN_w(B,A)$

It is enough to prove that the discrete fuzzy numbers $MIN_w(A,B)$ and $MIN_w(B,A)$ are the same α-cut sets for each $\alpha \in [0,1]$.

By definition 3.4

$$MIN_w(A,B)^\alpha =$$
$$= \{z \in supp(A) \bigwedge supp(B) \text{ such that}$$
$$(\min A^\alpha \wedge \min B^\alpha) \le z \le (\max A^\alpha \wedge \max B^\alpha)\} =$$
$$= \{z \in supp(A) \bigwedge supp(B) | (x_1^\alpha \wedge y_1^\alpha) \le z \le (x_p^\alpha \wedge y_k^\alpha)\} =$$
$$= \{z \in supp(A) \bigwedge supp(B) | (y_1^\alpha \wedge x_1^\alpha) \le z \le (y_p^\alpha \wedge x_k^\alpha)\} =$$
$$= MIN_w(B,A)^\alpha$$

Analogously for the other commutative law.

2. We want to see that

$$MIN_w(MIN_w(A,B),C) = MIN_w(A, MIN_w(B,C))$$

By definition 3.4

$$MIN_w(MIN_w(A,B),C)^\alpha =$$
$$= \{z \in supp(MIN_w(A,B)) \bigwedge supp(C) \text{ such that}$$
$$\min MIN_w(A,B)^\alpha \wedge \min C^\alpha \le z \le \max MIN_w(A,B)^\alpha \wedge \max C^\alpha\} =$$
$$= \{z \in supp(MIN_w(A,B)) \bigwedge supp(C) \text{ such that}$$
$$(x_1^\alpha \wedge y_1^\alpha) \wedge w_1^\alpha \le z \le (x_p^\alpha \wedge y_k^\alpha) \wedge w_l^\alpha\} =$$
$$= \{z \in (supp(A) \bigwedge supp(B)) \bigwedge supp(C) \text{ such that}$$
$$(x_1^\alpha \wedge y_1^\alpha) \wedge w_1^\alpha \le z \le (x_p^\alpha \wedge y_k^\alpha) \wedge w_l^\alpha\} =$$
$$= \{z \in (supp(A) \bigwedge supp(B)) \bigwedge supp(C) \text{ such that}$$
$$x_1^\alpha \wedge (y_1^\alpha \wedge w_1^\alpha) \le z \le x_p^\alpha \wedge (y_k^\alpha \wedge w_l^\alpha\}) =$$
$$= \{z \in supp(A) \bigwedge (supp(B) \bigwedge supp(C)) \text{ such that}$$
$$x_1^\alpha \wedge (y_1^\alpha \wedge w_1^\alpha) \le z \le x_p^\alpha \wedge (y_k^\alpha \wedge w_l^\alpha\}) =$$
$$= MIN_w(A, MIN_w(B,C))^\alpha$$

The proof of the other associative law is similar.

3. We want to demonstrate that

$$MIN_w(A,A) = A$$

By definition 3.4

$$MIN_w(A,A)^\alpha =$$
$$= \{z \in supp(A) \bigwedge supp(A) \text{ such that}$$
$$(\min A^\alpha \wedge \min A^\alpha) \le z \le (\max A^\alpha \wedge \max A^\alpha)\} =$$
$$= \{z \in supp(A) | (x_1^\alpha \wedge x_1^\alpha) \le z \le (x_p^\alpha \wedge x_p^\alpha)\} =$$
$$= \{z \in supp(A) | x_1^\alpha \le z \le x_p^\alpha\} =$$
$$= A^\alpha$$

It is the same for the other idempotence law.

4. We want to demonstrate that

$$MIN_w(A, MAX_w(A,B)) = A$$

By definition 3.4

$$MIN_w(A, MAX_w(A,B))^\alpha =$$
$$= \{z \in supp(A) \bigwedge supp(MAX_w(A,B)) \text{ such that}$$
$$\min A^\alpha \wedge \min MAX_w(A,B)^\alpha \le z \le \max A^\alpha \wedge \max MAX_w(A,B)^\alpha\} =$$
$$= \{z \in supp(A) \bigwedge supp(MAX_w(A,B)) \text{ such that}$$
$$x_1^\alpha \wedge (x_1^\alpha \vee y_1^\alpha) \le z \le x_p^\alpha \wedge (x_p^\alpha \vee y_k^\alpha\}) =$$

(using the absorption law of real numbers)

$$= \{z \in supp(A) \bigwedge supp(MAX_w(A,B)) \text{ such that}$$
$$x_1^\alpha \le z \le x_p^\alpha\} = \{z \in supp(A) \text{ such that } x_1^\alpha \le z \le x_p^\alpha\} =$$
$$= A^\alpha.$$

(The previous equality is only possible if we use the same hypotheses and results of the proposition 3.9)

5. We want to show the first distributive law, ie,

$$MIN_w(A, MAX_w(B,C)) = MAX_w(MIN_w(A,B), MIN_w(A,C))$$

By definition 3.4

$$MIN_w(A, MAX_w(B,C))^\alpha =$$
$$= \{z \in supp(A) \bigwedge supp(MAX_w(B,C)) \text{ such that}$$
$$\min A^\alpha \wedge \min MAX_w(B,C)^\alpha \le z \le \max A^\alpha \wedge \max MAX_w(A,B)^\alpha\} =$$
$$= \{z \in supp(A) \bigwedge supp(MAX_w(B,C)) \text{ such that}$$
$$x_1 \wedge (y_1^\alpha \vee w_1^\alpha) \le z \le x_p^\alpha \wedge (y_k^\alpha \vee w_l^\alpha)\} =$$

(using the distributive law of real numbers)

$$= \{z \in supp(A) \bigwedge supp(MAX_w(B,C)) \text{ such that}$$
$$(x_1^\alpha \wedge y_1^\alpha) \vee ((x_1^\alpha \wedge w_1^\alpha) \le z \le (x_p^\alpha \wedge y_k^\alpha) \vee (x_p^\alpha \wedge w_l^\alpha)\} =$$
$$= \{z \in supp(A) \bigwedge (supp(B) \bigvee supp(C)) \text{ such that}$$
$$(x_1^\alpha \wedge y_1^\alpha) \vee ((x_1^\alpha \wedge w_1^\alpha) \le z \le (x_p^\alpha \wedge y_k^\alpha) \vee (x_p^\alpha \wedge w_l^\alpha)\} =$$
$$= \{z \in (supp(A) \bigwedge supp(B)) \bigvee (supp(A) \bigwedge supp(C))$$
$$\text{such that } (x_1^\alpha \wedge y_1^\alpha) \vee ((x_1^\alpha \wedge w_1^\alpha) \le z \le (x_p^\alpha \wedge y_k^\alpha) \vee (x_p^\alpha \wedge w_l^\alpha)\} =$$
$$= MAX_w(MIN_w(A,B), MIN_w(A,C))^\alpha$$

Analogously for the other distributive law. □

ISBN: 978-989-95079-6-8

Corollary 3.12 *The triplet ($\mathcal{A}_1$,MIN_w,MAX_w) is a distributive lattice, in which MIN_w and MAX_w represent the meet and join, respectively.*

Remark 3.13 *The lattice ($\mathcal{A}_1$,MIN_w,MAX_w) can also be expressed as the pair ($\mathcal{A}_1$,$\preceq$), where $\preceq$ is a partial ordering defined as:*

$A \preceq B$ if and only if $MIN_w(A, B) = A$
or, alternatively,
$A \preceq B$ if and only if $MAX_w(A, B) = B$
for any $A, B \in \mathcal{A}_1$.

Remark 3.14 *We can also define the partial ordering in terms of α-cuts:*

$A \preceq B$ if and only if $\min(A^\alpha, B^\alpha) = A^\alpha$
$A \preceq B$ if and only if $\max(A^\alpha, B^\alpha) = B^\alpha$
for any $A, B \in \mathcal{A}_1$ and $\alpha \in (0, 1]$, where A^α and B^α are finite sets (say , $A^\alpha = \{x_1^\alpha, \cdots, x_p^\alpha\}$,$B^\alpha = \{y_1^\alpha, \cdots, y_k^\alpha\}$). Then,

$$\min(A^\alpha, B^\alpha) = \{z \in supp(A) \bigwedge supp(B) \text{ such that}$$

$$\min(x_1^\alpha, y_1^\alpha) \leq z \leq \min(x_p^\alpha, y_k^\alpha)\} = A^\alpha \text{ and}$$

$$\max(A^\alpha, B^\alpha) = \{z \in supp(A) \bigvee supp(B) \text{ such that}$$

$$\max(x_1^\alpha, y_1^\alpha) \leq z \leq \max(x_p^\alpha, y_k^\alpha)\} = B^\alpha$$

Example 3.15
Let $u = \{0.4/1, 1/2, 0.8/3, 0.6/4, 0.5/5, 0.4/6, 0.3/7\}$ and $v = \{0.3/4, 0.6/5, 0.7/6, 0.8/7, 1/8, 0.8/9\}$ be two discrete fuzzy numbers. It is easy to prove that $u \preceq v$ because $MAX_w(u, v) = v$ or equivalently $MIN_w(u, v) = u$.

Corollary 3.16 *For each finite subset X of real numbers, let's consider the subset F_X of DFN such that any element of F_X has as support X. Then, the triplet (F_X,MIN_w,MAX_w) is a distributive lattice, in which MIN_w and MAX_w represent the meet and join, respectively.*

Example 3.17 *Let $u = \{0.3/3, 0.4/5, 1/7, 0.7/8\}$ and $v = \{0.3/3, 1/5, 0.7/7, 0.6/8\}$ be two discrete fuzzy numbers. It is easy to prove that $v \preceq u$ because $MAX_w(u, v) = u$ or equivalently $MIN_w(u, v) = v$.*

Remark 3.18 *It is possible to find two discrete fuzzy numbers $A, B \in \mathcal{A}_1$ such that $MAX_w(A, B) \neq A$ and $MAX_w(A, B) \neq B$ or equivalenty $MIN_w(A, B) \neq A$ and $MIN_w(A, B) \neq B$. This means that the two discrete fuzzy numbers, A and B, are not comparable. For example, let's consider $A = \{0.3/4, 0.5/5, 0.8/6, 1/7, 0.9/8, 0.7/9\}, B = \{0.5/6, 1/7, 0.9/8, 0.6/9, 0.5/10\} \in \mathcal{A}_1$. Then, $MIN_w(A, B) = \{0.3/4, 0.5/5, 0.8/6, 1/7, 0.9/8, 0.6/9\} \neq A, B$.*

***Abstract*— *In this paper we introduce and describe two classes of aggregation functions with members that are migrative. First continuous triangular norms are studied that own the migrative property with respect to another fixed t-norm, in particular to the three prototypes minimum, product, and the Łukasiewicz t-norm. For classes of nilpotent and strict migrative t-norms the characterization and construction is carried out by solving functional equations for the generators. For the third case when the fixed t-norm is the minimum, an ordinal-sum-like construction is resulted. Then we formulate and study the migrative property for quasi-arithmetic means. The results are less permissive than for t-norms: we can hardly escape from the classical arithmetic mean.*

***Keywords*—** Triangular norms, quasi-arithmetic means, functional equations, migrative property.

1 Introduction

In this paper we study the migrative property for some classes of binary *aggregation functions*. These are increasing functions $F\colon [a,b]\times[a,b]\to[a,b]$ such that $F(a,a)=a$ and $F(b,b)=b$.

It is well-known that some operations in fuzzy logic (like t-norms, t-conorms, uninorms, nullnorms) can be considered aggregation functions on the closed unit interval in the above sense. In addition, these operations own a characteristic property of associativity that can be formulated as a well-known functional equation. A function $F\colon [a,b]\times[a,b]\to[a,b]$ is called *associative* if

$$F(x,F(y,z))=F(F(x,y),z),\quad x,y,z\in[a,b]. \tag{1}$$

Under some additional conditions, the above-mentioned logical operations are the general solutions of the associativity equation (1).

Another important class of aggregation functions consists of *means*. One of the first authors who introduced the term "mean" in a mathematical sense was Cauchy [1]. In that spirit, a function $F\colon [a,b]\times[a,b]\to[a,b]$ is called a *mean* in the interval $[a,b]\subset\mathbb{R}$ if

$$\min(x,y)\le F(x,y)\le\max(x,y)$$

for all $x,y\in[a,b]$. Well-known examples are the median, the arithmetic mean, the geometric mean, the root-power mean, the harmonic mean and the like.

Although these means and t-norms, t-conorms, uninorms, nullnorms have rather different properties, there is one particular common property they all share. This is called *bisymmetry*, introduced by Aczél [2], and is defined for a function $M\colon [a,b]\times[a,b]\to[a,b]$ by

$$F(F(x,y),F(u,v))=F(F(x,u),F(y,v)), \tag{2}$$

for all $x,y,u,v\in[a,b]$.

It is easy to see that if a function $F\colon [a,b]\times[a,b]\to[a,b]$ is symmetric (i.e., $F(x,y)=F(y,x)$ for all $x,y\in[a,b]$) and associative then F is bisymmetric. The converse statement is not true in general. If, however, F is symmetric and has a neutral element, then bisymmetry of F implies that F is associative [3].

We give the definition of α-migrative two-variable functions in Definition 1 just as it was proposed originally in [5]. Since that notion has something to do, in essence, with triangular norms, first we attempt to catch hold of the very meaning of it for t-norms. This is expressed by equation (6), and two more equivalent forms in Theorem 2. That is, for t-norms we can choose any of the three forms of (8), (9) or (10). Equation (8) is obtained by considering the classical associativity functional equation, then fixing the t-norm (T_0) inside the equation, and finally fixing one of the variables' value at α. Equation (9) can be obtained similarly: the only difference is that we fixed the t-norm outside the equation. Equation (10) is just equivalent to (8) and (9) for t-norms.

Therefore, when we realized that Definition 1 can never hold for t-conorms, and it is very restrictive for quasi-arithmetic means, we tried to develop new definitions that are context dependent. The idea is to use the characteristic composite functional equation of the function class under study (e.g., the bisymmetry equation for means), then fix the function inside (or outside), and finally fix one of the variables at some α. Or alternatively, consider the equation that corresponds to (10). While for t-norms these three approaches are equivalent, for quasi-arithmetic means this is not the case at all.

According to our sketched ideas and investigations, in this paper we introduce and describe two classes of aggregation functions (triangular norms and quasi-arithmetic means) with members that are migrative. The underlying compact interval is $[0,1]$ in the study. In our formulation the migrative property is context-dependent. First we show the original property and its extensions for triangular norms. Then migrativity is reformulated and studied for quasi-arithmetic means. In the conclusions we highlight the essential differences between the two classes.

2 The migrative property for t-norms

In this section we highlight some essential aspects and consequences of the original α-migrative property and its possible extensions.

A *triangular norm* (t-norm for short) $T:[0,1]^2\to[0,1]$ is an associative, commutative, non-decreasing function such that $T(1,x)=x$ for all $x\in[0,1]$. Prototypes of t-norms are

ISBN: 978-989-95079-6-8

the minimum $T_{\mathbf{M}}(x,y)=\min(x,y)$, the product $T_{\mathbf{P}}(x,y)=xy$, and the Łukasiewicz t-norm $T_{\mathbf{L}}(x,y)=\max(x+y-1,0)$. Obviously, the product t-norm $T_{\mathbf{P}}$ is α-migrative for any $\alpha\in]0,1[$.

As it is well-known, each continuous Archimedean t-norm T can be represented by means of a continuous additive generator (see e.g. [4]), i.e., a strictly decreasing continuous function $t\colon[0,1]\to[0,\infty]$ with $t(1)=0$ such that

$$T(x,y)=t^{(-1)}(t(x)+t(y)), \tag{3}$$

where $t^{(-1)}\colon[0,\infty]\to[0,1]$ is the pseudo-inverse of t, and is given by

$$t^{(-1)}(u)=t^{-1}(\min(u,t(0))).$$

2.1 The Class of α-Migrative Functions

In [5] the authors introduced a new term – α-migrative – for a class of two-variable functions (binary operations) as follows.

Definition 1. Let α be in $]0,1[$. A binary operation $T\colon[0,1]^2\to[0,1]$ is said to be *α-migrative* if we have

$$T(\alpha x,y)=T(x,\alpha y)\quad\text{for all } x,y\in[0,1]. \tag{4}$$

Although this definition seems to be rather general, the paper [5] deals with triangular norms and subnorms. Further progress can be seen in [6], where the authors studied a slightly modified definition of migrativity. They discussed also the associativity and bisymmetry of migrative aggregation functions.

Notice also that Definition 1 does not provide a meaningful notion for triangular conorms. Indeed, if S is a t-conorm then it is α-migrative if and only if $S(\alpha x,y)=S(x,\alpha y)$ holds for all $x,y\in[0,1]$. If we choose $y=0$ then we must have $\alpha x=x$ for all $x\in[0,1]$, because S is α-migrative. This is impossible when $\alpha\neq 1$. Similarly, if $y=1$ then we must have $S(x,\alpha)=1$ for all $x\in[0,1]$, which is again impossible unless $\alpha=1$. Therefore, even the correct definition of α-migrative t-conorms needs special care.

Obviously, the product t-norm $T_{\mathbf{P}}$ is α-migrative for any $\alpha\in]0,1[$. The following non-continuous t-norm T_β is also α-migrative:

$$T_\beta(x,y)=\begin{cases}\min(x,y) & \text{if } \max(x,y)=1,\\ \beta xy & \text{otherwise.}\end{cases} \tag{5}$$

It was provided in [8] as a counterexample to the question: Is a strictly monotone t-norm always continuous?

We provide all *continuous* solutions of the equation (4) in Theorem 1. More details and proofs can be found in our paper [7].

Theorem 1. *Let α be in $]0,1[$. Suppose T is a continuous t-norm. Then the following statements hold.*

(a) T is α-migrative if and only if we have

$$T(\alpha,y)=\alpha y\quad \textit{for all } y\in[0,1]. \tag{6}$$

(b) If T is α-migrative then T is strict.

(c) Suppose t is an additive generator of T. Then T is α-migrative if and only if there exists a continuous, strictly decreasing function t_0 from $[\alpha,1]$ to the non-negative reals with $t_0(0)<+\infty$ and $t_0(1)=0$ such that

$$t(x)=k\cdot t_0(\alpha)+t_0\left(\frac{x}{\alpha^k}\right)\quad \textit{if } x\in]\alpha^{k+1},\alpha^k], \tag{7}$$

where k is any non-negative integer.

In the next subsection we extend the above definition by allowing any fixed t-norm instead of the product in the defining equation.

2.2 The Class of (α,T_0)-Migrative Functions

Following our plan, the next definition extends the migrative property as follows. Some more details can be found in [9] and in [10] with proofs.

Definition 2. Let α be in $]0,1[$ and T_0 a fixed triangular norm. A binary operation $T\colon[0,1]^2\to[0,1]$ is said to be *α-migrative with respect to T_0* (shortly: (α,T_0)-migrative) if we have

$$T(T_0(\alpha,x),y)=T(x,T_0(\alpha,y)) \tag{8}$$

for all $x,y\in[0,1]$.

Obviously, Definition 1 is a particular case of Definition 2 with $T_0=T_{\mathbf{P}}$.

In the next theorem we give a simple but very useful characterization of (α,T_0)-migrative t-norms.

Theorem 2. *Let α be in $]0,1[$ and T_0 a fixed triangular norm. Then the following statements are equivalent for a t-norm $T\colon[0,1]^2\to[0,1]$.*

(i) T is α-migrative with respect to T_0;

(ii) T satisfies the following equation for all $x,y\in[0,1]$:

$$T_0(T(\alpha,x),y)=T_0(x,T(\alpha,y)); \tag{9}$$

(iii) T satisfies the following equation for all $x\in[0,1]$:

$$T(\alpha,x)=T_0(\alpha,x). \tag{10}$$

We do not recall the case when $T_0=T_{\mathbf{L}}$. The interested reader can find the related results in [9, 10].

For illustrating the non-representable case $T_0=T_{\mathbf{M}}$, we consider $(\alpha,T_{\mathbf{M}})$-migrative continuous triangular norms. In the present case the $(\alpha,T_{\mathbf{M}})$-migrative property is read as follows:

$$T(\min(\alpha,x),y)=T(x,\min(\alpha,y)),\ x,y\in[0,1]. \tag{11}$$

By Theorem 2 we know that the $(\alpha,T_{\mathbf{M}})$-migrative property is equivalent to the following functional equation:

$$T(\alpha,y)=\min(\alpha,y),\quad y\in[0,1]. \tag{12}$$

The description of all $(\alpha,T_{\mathbf{M}})$-migrative continuous triangular norms, as solutions to the equation (12), is given in the following theorem. For the proof see [10].

ISBN: 978-989-95079-6-8

Theorem 3. *A continuous t-norm T is $(\alpha, T_{\mathbf{M}})$-migrative if and only if there exist two continuous t-norms T_1 and T_2 such that T can be written in the following form:*

$$T(x,y) = \begin{cases} \alpha T_1\left(\frac{x}{\alpha}, \frac{y}{\alpha}\right) & x,y \in [0,\alpha], \\ \alpha + (1-\alpha)T_2\left(\frac{x-\alpha}{1-\alpha}, \frac{y-\alpha}{1-\alpha}\right) & x,y \in [\alpha,1], \\ \min(x,y) & \textit{otherwise}. \end{cases}$$

Notice that equations (8) and (10) has something to do with the *generalized associativity equation* that has also been studied and solved under some additional conditions, see [11, 12]. It can be written as follows:

$$F(G(x,y),z) = H(x,K(y,z)). \tag{13}$$

In this general framework the particular form of $H = F$ and $K = G$ in (13) correspond to (8).

3 The class of α-migrative quasi-arithmetic means

Let $[a,b]$ be a compact real interval. Aczél [2] proved that a function $M : [a,b]^2 \to [a,b]$ is continuous, symmetric, strictly increasing in each argument, idempotent and fulfils the bisymmetry equation (2) if and only if

$$M(x,y) = f^{-1}\left(\frac{f(x)+f(y)}{2}\right), \quad x,y \in [a,b] \tag{14}$$

with some continuous strictly monotonic function f. We also know that this result still holds for intervals of the form $]a,b]$, $[a,b[$, $]a,b]$ or even for any unbounded interval of the real line (see [13], pp 250–251, 280). A function M having a representation (14) is called a *quasi-arithmetic mean*.

When one tries to extend migrativity for quasi-arithmetic means, there are several options. One possibility is to choose a particular quasi-arithmetic mean M_0 (for instance, the arithmetic mean $M_{\mathbf{A}}(x,y) = \frac{x+y}{2}$), and consider the bisymmetry equation (2) extended in the following forms, with a fixed argument (say $y = \alpha$):

$$M(M_0(x,\alpha), M_0(u,v)) = M(M_0(x,u), M_0(\alpha,v)) \tag{15}$$
$$M_0(M(x,\alpha), M(u,v)) = M_0(M(x,u), M(\alpha,v)) \tag{16}$$

For motivations of these equations we refer to Theorem 2 and formulas (8)–(10) in case of t-norms.

We indeed chose the arithmetic mean, because of its key role in the representation of quasi-arithmetic means (14). In this case equations (15) and (16) are of the following respective forms:

$$M\left(\frac{x+\alpha}{2}, \frac{u+v}{2}\right) = M\left(\frac{x+u}{2}, \frac{\alpha+v}{2}\right), \tag{17}$$

$$\frac{M(x,\alpha)+M(u,v)}{2} = \frac{M(x,u)+M(\alpha,v)}{2}, \tag{18}$$

for a fixed $\alpha \in]0,1[$ and for all $x,u,v \in [0,1]$.

First we state that equation (18) is extremely restrictive: under the condition of idempotency, M must be the arithmetic mean.

Theorem 4. *Assume that an idempotent function $M\colon [0,1]^2 \to [0,1]$ satisfies equation (18). Then M is equal to the arithmetic mean.*

Therefore, if we want to define α-migrativity in a way that allows not only the arithmetic mean owning this property, we should try the other equation (17).

Lemma 1. *Let α be in $]0,1[$. Then*

$$M(\alpha,x) = \frac{\alpha+x}{2} \textit{ for all } x \in [0,1] \tag{19}$$

is a necessary condition for having (17) satisfied by an idempotent M.

This simple observation suggests that an appropriate definition of α-migrative quasi-arithmetic means might be the following one.

Definition 3. Let α be in $]0,1[$. A quasi-arithmetic mean $M\colon [0,1]^2 \to [0,1]$ is said to be *α-migrative* if (19) holds for all $x \in [0,1]$.

We solve equation (19) first, than we relate the solution to (17).

3.1 Quasi-Arithmetic Means that Satisfy (19)

Consider a quasi-arithmetic mean M in the form of (14) with a strictly increasing, continuous generator function f defined on $[0,1]$. Suppose M satisfies (19). That is, we have

$$f^{-1}\left(\frac{f(\alpha)+f(x)}{2}\right) = \frac{\alpha+x}{2} \quad \text{for all } x \in [0,1]. \tag{20}$$

Equation (20) implies that $f(0) = \lim_{x \downarrow 0} f(x)$ and $f(1) = \lim_{x \uparrow 1} f(x)$ are finite. Indeed, for instance, if $f(0) = -\infty$ then the left-hand side of (20) equals 0, while the right-hand side is $\frac{\alpha}{2}$, a contradiction. The other cases lead to a contradiction in a similar manner.

Therefore, (20) can be written in an equivalent form as

$$\frac{f(\alpha)+f(x)}{2} = f\left(\frac{\alpha+x}{2}\right) \quad \text{for all } x \in [0,1]. \tag{21}$$

The general solution of (21) is given in the next theorem.

Theorem 5. *Assume that $f : [0,1] \to \mathbb{R}$ is a strictly increasing, continuous function. Then f satisfies (21) if and only if there exist real numbers f_0, f_α, f_1 such that f can be written in the following form:*

$$f(x) = \begin{cases} \frac{f_\alpha - f_0}{\alpha} \cdot x + f_0 & \textit{if } x \in [0,\alpha] \\ \frac{f_1 - f_\alpha}{1-\alpha} \cdot x + \frac{f_\alpha - \alpha f_1}{1-\alpha} & \textit{if } x \in]\alpha,1] \end{cases}. \tag{22}$$

That is, the most general quasi-arithmetic means that satisfy (19) are generated by a piece-wise linear generator function. It is linear on $[0,\alpha]$ and on $[\alpha,1]$.

Next we show that the piecewise linear solution of (21) becomes linear when we feed it back into (17).

Theorem 6. *Let M be a quasi-arithmetic mean that satisfies (17). Then $M(x,y) = \frac{x+y}{2}$, i.e., M equals the arithmetic mean.*

Notice that this result is somewhat disappointing: we returned back again to quasi-arithmetic means.

ISBN: 978-989-95079-6-8

4 Conclusions

It is worth comparing results presented in this paper for t-norms and for quasi-arithmetic means. For t-norms a general form of (α, T_0)-migrativity resulted in two other equivalent formulations, and also infinite families of t-norms owning that property could be obtained. For quasi-arithmetic means idempotency alone implied the arithmetic mean as the only solution in (18). When we looked for quasi-arithmetic mean solutions of (17), it was also the arithmetic mean that satisfied the equation. The only exceptions are quasi-arithmetic mean solutions to (19) with piece-wise linear generator functions.

Notice that the general case when the fixed quasi-arithmetic mean $M_0(x,y) = f_0^{-1}\left(\frac{f_0(x)+f_0(y)}{2}\right)$ differs from the arithmetic mean can be handled in a similar way.

It might be worth studying other types of composite functional equations in the spirit of the present paper.

Abstract— *In the present paper, an effective support method for equipment operation under a dynamic environment is proposed. The proposed method presents operation instructions that the driver should be preparing to follow in the future. Using this method, the current and future states of the surrounding environment can be considered. The time change fuzzy set, which considers the state and time, to be universe of discourse. The time change fuzzy set is used for a computer as a buildup method with expert knowledge concerning the time change in the state. Experiments to support a lane change operation were conducted using a driving simulator. The obtained results indicated that the proposed method safely supports a lane change operation, and the time lag between the instruction being given by the system and operation being performed by the driver is decreased.*

Keywords— Dynamic environment, fuzzy inference, operation support, safety, time change fuzzy sets.

1 Introduction

When a human operates equipment in a dynamic environment, in which the surrounding conditions change with time, the operator should correctly understand complex changes in the surrounding environment. In addition, the operator must judge whether an operation is appropriate within a limited time. Therefore, an equipment operation support system is necessary in order to reduce the load on the operator and to achieve safe operation.

The equipment operation support system causes a time lag between the instruction by system and the operation by the driver. This is a significant problem in a dynamic environment, into which surrounding circumstances change with time.

Fuzzy sets can quantitatively manage human subjective assessments, such as ”He is *young*,” and thought processes, such as ”IF x is *small*, THEN y is *very large*” [1, 2]. Mamdani applied fuzzy control, which is an intelligent control, experimentally to a steam engine for the first time [3]. Yasunobu achieved the selection of the control order based on a multipurpose evaluation of an expert driver using the predictive fuzzy control and applied to the automatic train operation (ATO) system [4, 5, 6]. These fuzzy sets and control methods are applied to numerous intelligent cooperative control systems based on ”fuzzy instruction” [7, 9] and a ”fuzzy target”[8]. However, in fuzzy sets, it is difficult to build in expert knowledge concerning the time change. High-performance computers that have recently been developed have enabled equipment operation support, including expert knowledge, in real time.

In the present study, we construct an effective support method for use in a dynamic environment. When operating equipment in a dynamic environment, experts perform appropriate operations by considering not only the present state but also potential future states. In the present paper, time change fuzzy sets, which considers the state and time, to be universe of discourse. Time change fuzzy sets are used to provide expert knowledge to the computer regarding the time change of the states. Time change fuzzy sets can provide a sense of time change, such as ”Speed is continuous high” and ”Temperature change to cold from hot” to a computer.

The proposed method is applied to support a lane change operation using a driving simulator.

2 Support method in a dynamic environment

In this section, an effective support method for a dynamic environment is considered. The process of the proposed system is shown in Fig. 1.

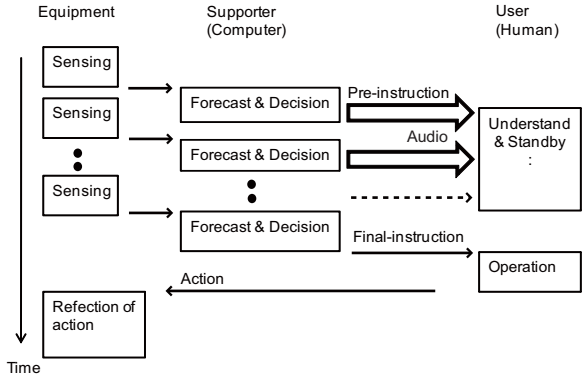

Figure 1: Process of the proposed operation support method.

The support (system) consists of 1) sensing equipment and surrounding states, 2) forecasting of future states, 3) instruction decision, and 4) presentation of instruction in advance and sending of a pre-instruction via audio. The driver (human) is 5) perceives the pre-instruction, and 6) interprets the intention of the system and waits for the final/pre-instruction. The support (system) continues 7) sensing the surrounding state and sends a final short signal. The driver (human) 8) starts an operation.

In the proposed method, the driver can confirm the operation instructions in advance. In addition, the time of 4) presentation of instruction in advance, 5) perception of instruction, 6) interpreting the intention of the system, can be sufficiently secured. The time lag can be related only to 8) operation.

The proposed method 2) forecasts future states and 3) decides pre-instruction or final-instruction, and the manner of action 2) and 3) is important.

3 Fuzzy inference that considers future time

A computer can be made to emulate man's interpretive ability by building expert knowledge into a system using the fuzzy theory and fuzzy inference.

In a dynamic environment, an expert operates equipment by considering not only present states but also forecasting future states. It is necessary to define fuzzy sets concerning the change of states in order to build expert knowledge about the change of states and to perform inference by considering future states.

3.1 Time change fuzzy sets

In the present paper, we define a fuzzy set that changes with time. A fuzzy set to which a time axis has been added is referred to herein as a time change fuzzy set.

The total set of the state is assumed as R. The time change fuzzy set $\widetilde{X}fn$ in state $x(t)$ of the object is defined by the following expression (1):

$$\widetilde{X}_{fn(x,p)} = \int_{R\times P} \mu_{\widetilde{X}fn(x,p)}/(x,p), \quad x \in R, p \in (0,P). \tag{1}$$

Here, $\mu_{\widetilde{X}_{fn(x,p)}}$ is the membership value in universe of discourse the state x and the following time p, and P is the maximum following time.

An example of a time change fuzzy set is shown in Fig. 2. This fuzzy set describes a "change in distance from far to near". The axes of this figure indicate distance, x, the following time, p, and the membership degree of the fuzzy set μ.

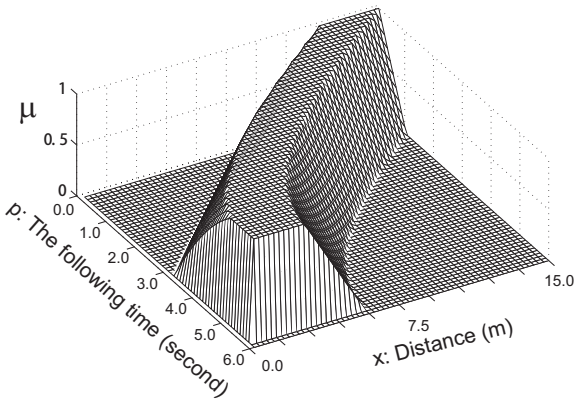

Figure 2: Example of a time change fuzzy set: change in distance from far to near.

Figure 3 shows the time change fuzzy set at $p = 0$ sec, $p = 3$ sec, and $p = 6$ sec.

Time change fuzzy sets indicate how a fuzzy set changes with time. Time change fuzzy sets can be used to build expert knowledge concerning the time change of states into a computer.

3.2 Fuzzy inference rules

Time change fuzzy sets are used to if-part and to then-part of fuzzy inference. To simplify explanation, three fuzzy rules for lane change support are described below.

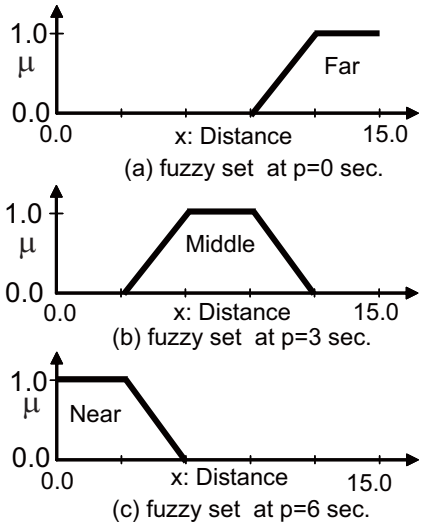

Figure 3: Time-sliced fuzzy sets of the time change fuzzy set: change in distance from far to near.

Rule 1: If forward vehicle (x) is *continuous far* and following vehicle (y) is *continuous far*, then lane change (z) is *continuous safe.*

Rule 2: If forward vehicle (x) is *continuous far* and following vehicle (y) is *change from far to near*, then lane change (z) is *change from safe to danger.*

Rule 3: If forward vehicle (x) is *change from near to far* and following vehicle (y) is *change from far to near*, then lane change (z) is *continuous middle.*

The terms x, y, and z in the above rules are defined by time change fuzzy sets, as shown in (1) . The above rules are then described as follows:

r1: $\widetilde{X}_{1(x,p)}$ *and* $\widetilde{Y}_{1(y,p)} \Rightarrow \widetilde{Z}_{1(z,p)}$,

r2: $\widetilde{X}_{2(x,p)}$ *and* $\widetilde{Y}_{2(y,p)} \Rightarrow \widetilde{Z}_{2(z,p)}$,

r3: $\widetilde{X}_{3(x,p)}$ *and* $\widetilde{Y}_{3(y,p)} \Rightarrow \widetilde{Z}_{3(z,p)}$.

3.3 Fuzzy inference process

Figure 4 shows an example of the fuzzy inference process. The if-part is given by time change fuzzy sets $\widetilde{X}_{(x,p)}$ and $\widetilde{Y}_{(x,p)}$, and the then-part is given by time change fuzzy set $\widetilde{Z}_{(x,p)}$. These fuzzy sets are in the form of time functions, as shown in Fig. 4. The input functions $\widehat{x}_{(p)}$ and $\widehat{y}_{(p)}$ are calculated by forecasting the future states from the present states.

The degree of membership of the input value to the time change fuzzy sets $\widetilde{X}'_{i(p)}$ and $\widetilde{Y}'_{i(p)}$ as shown in (2) and (3), respectively, is calculated by minimum operation, whereby time change fuzzy sets are removed by the input value. For example, when the time change fuzzy set $\widetilde{X}_{i(x,p)}$ is removed by the input value of $\widehat{x}_{(p)}$, the section area becomes $\widetilde{X}'_{i(p)}$.

$$\widetilde{X}'_{i(p)} = \widetilde{X}_{i(x,p)} \wedge \widehat{x}_{(p)} = \widetilde{X}_{i(\widehat{x}_{(p)},p)} \quad i = 1,3, \tag{2}$$

$$\widetilde{Y}'_{i(p)} = \widetilde{Y}_{i(y,p)} \wedge \widehat{y}_{(p)} = \widetilde{Y}_{i(\widehat{y}_{(p)},p)} \quad i = 1,3. \tag{3}$$

Each rule ri is evaluated to $\widetilde{Z}'_{i(z,p)}$, as shown in (4).

ISBN: 978-989-95079-6-8

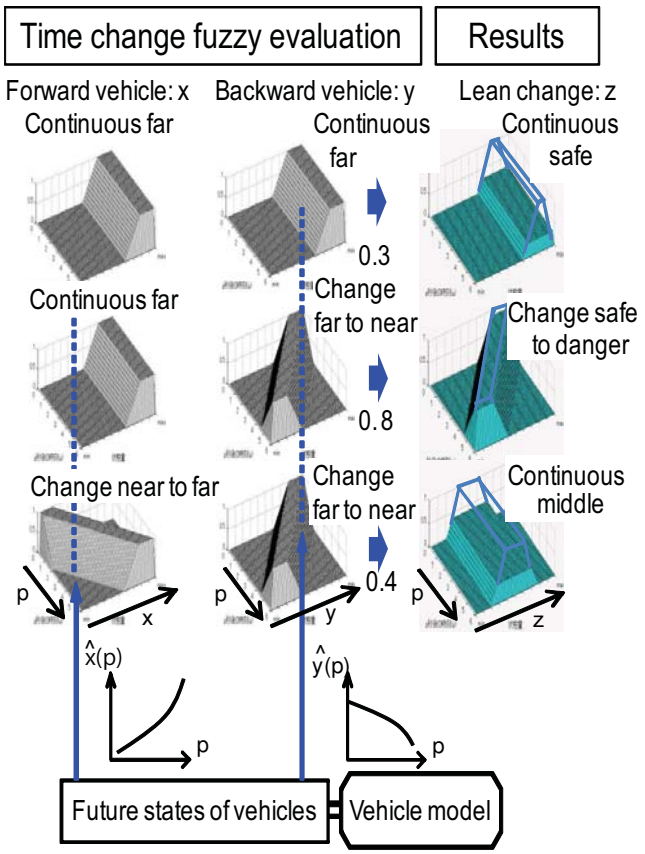

Figure 4: Fuzzy inference using time change fuzzy sets.

$$\widetilde{Z}'_{i(z,p)} = \widetilde{Z}_{i(z,p)} \wedge \widetilde{X}'_{i(p)} \wedge \widetilde{Y}'_{i(p)} \quad i = 1, 3. \tag{4}$$

3.4 *Result of fuzzy inference*

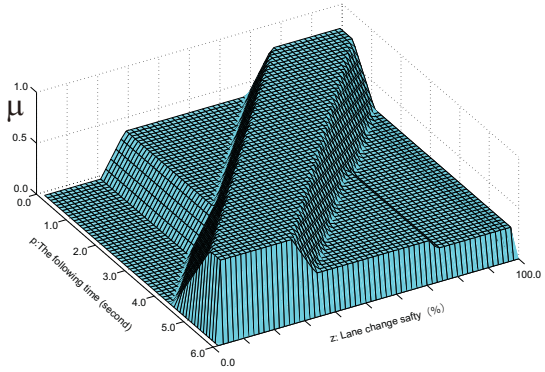
When the evaluation values of rules $\widetilde{Z}'_1$, $\widetilde{Z}'_2$, and $\widetilde{Z}'_3$ are 0.3, 0.8, and 0.4, respectively, as shown in Fig. 4, the result of fuzzy inference, i.e., $\widetilde{Z}_{ans(z,p)}$, as given by (5), is as shown in Fig. 5(a).

$$\widetilde{Z}_{ans(z,p)} = \widetilde{Z}'_{1(z,p)} \cup \widetilde{Z}'_{2(z,p)} \cup \widetilde{Z}'_{3(z,p)}. \tag{5}$$

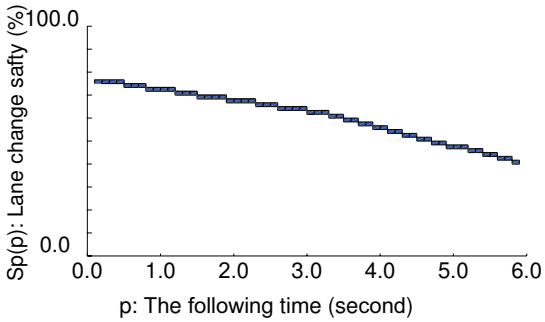
In the present study, $Sp_{(p)}$ is the lane change safety at time p obtained using the center of gravity method (defuzzification), as given by (6). Figure 5(b) shows the lane change safety at time p.

$$Sp_{(p)} = \frac{\int z \cdot \mu_{\widetilde{Z}ans(z,p)} dz}{\int \mu_{\widetilde{Z}ans(z,p)} dz} \tag{6}$$

Thus, the future output states are inferred from the future states of input, which are forecast from the present states. The system determines the operation that the driver should perform in the future based on the results of inference. The operation instruction is presented to the driver in advance, and the support method described in Section 2 is achieved. The shape of this fuzzy set looks like a type-2 fuzzy set[10]. The type-2 fuzzy set extends the membership grade to fuzzy value. Other side, this time change fuzzy set based on universe of discourse time and dynamic state, and simple membership grade from 0.0 to 1.0.



(a) Fuzzy set of lane change safety: $\widetilde{Z}_{ans}$



(b) Lane change safety at p: $Sp_{(p)}$

Figure 5: Result of fuzzy inference.

4 Application supporting a vehicle lane change

4.1 *Outline of the support system*

The support method proposed in Section 2 and fuzzy inference that considers the time change proposed in Section 3 are applied to support the lane change of a vehicle.

An expert driver can forecast the future states of other vehicles and judge intuitively whether a lane change can be performed safely.

In the present study, the knowledge of the expert driver is referred to as driving knowledge. A support system is constructed that forecasts future traffic states from present traffic states, judges whether a lane change can be performed safely and presents instructions to the driver.

It is preferable to maintain the velocity of the vehicle constant during a lane change so that the driver can operate the vehicle safely. Therefore, constant velocity is a requirement for safe lane changing. In addition, it is necessary to keep safety from the presentation of system's instruction to the operation of driver. This requirement is judged based on whether a sufficient distance between the driver's vehicle and the other vehicles will be maintained during a lane change.

The lane change support process is as follows. (a) Assume that the velocity of one's own vehicle is constant, (b) Forecast changes in the relative positions of the other vehicles, and (c) Present the instruction to change lanes if it appears that safety will be maintained.

4.2 *Forecast future states*

Other vehicles are assumed to maintain their velocities. The relative positions of the other vehicles are calculated as follows based on assumption (a) above.

ISBN: 978-989-95079-6-8

Predictive states after p seconds are as follows:

$$\widehat{x}_{(p)} = \widetilde{x}_{(t)} + v_x p \quad (7)$$

$$\widehat{y}_{(p)} = \widetilde{y}_{(t)} + v_y p, \quad (8)$$

where $\widetilde{x}_{(t)}$ and $\widetilde{y}_{(t)}$ denote the relative position of forward and backward vehicle at the present time, t, and v_x and v_y denote the relative velocity of these vehicles respectively.

4.3 Judge lane change appropriateness

In order to judge whether a lane change is possible based on the prediction of future states, expert knowledge concerning the future state of traffic is necessary. In the present study, the appropriateness of the lane change is referred to as the lane change appropriateness and is expressed as a number from 0 to 10. These numbers correspond to the following meanings: 0; dangerous(unsafe), 5; will be safe soon, and 10; safe.

Fuzzy inference is performed by using the predictive values of the relative positions of other vehicles as the input calculated in Section 4.2, and the lane change appropriateness is given as the output. The instruction to change lanes is presented to the driver based on the lane change appropriateness.

4.4 Presentation of audio instructions

In the proposed system, the driver is presented with audio instructions. The instruction is decided according to the lane change appropriateness and the change. In the present study, the instruction is output as follows.

Audio instruction:

· Present: Safety is high. Future: Safety is high.
⟶ Instruction: ”You can safely change lanes.”

· Present: Safety is high. Future: Safety is low.
⟶ Instruction: ”It’s getting dangerous.”

· Present: Safety is low. Future: Safety is high.
⟶ Instruction: ”You will be able to change lanes soon.”
After a few seconds.
⟶ Instruction: ”Change lanes now.” = Go signal

· Present: Safety is low. Future: Safety is low.
⟶ Instruction: ”You can’t change lanes.”

5 Driving simulator experiments

Experiments using the lane change support system are performed using proposed support method. The case in which the vehicle in the left-hand lane on a two-lane roadway enters the right-hand lane is assumed. The only vehicle in the left-hand lane is the driver’s own vehicle, and two or more other vehicles are driving in the right-hand lane. Fig. 6 shows a photograph of the driving simulator. The test drivers are three men in their twenties.

The following two situations are assumed in the experiments.

Situation 1) Approach from the rear: A vehicle approaches from the rear (Fig. 7(a)).

Figure 6: Driving simulator.

Situation 2) Nearby vehicle moves away: A nearby vehicle moves away gradually (Fig. 8(a)).

First, an experiment is performed using the support method in which only the present state is considered. Then, the experiment is performed using the proposed method (Section 2) in which the future states are considered. In the proposed method, time change fuzzy sets (Section 3) are used. Audio instructions are presented as described in Section 4.4.

5.1 Situation 1: Approach from the rear

5.1.1 Results obtained by considering only the present state

The results of an experiment conducted with one test driver in Situation 1 without considering future states is shown in Fig. 7(b). In this method, in which only the present state is considered, the experimental system can only judge whether the present state is ”safe” or ”unsafe”, and the safety of future states cannot be predicted. Fig. 7(b) indicates that when the driver started to operate the steering wheel, the system reported that the state changed from safe to unsafe. In this example, the time lag between the instruction of the system and the operation by the driver caused a problem.

5.1.2 Result obtained by considering the future states

The results of an experiment conducted with one test driver in Situation 1 considering future states is shown in Fig. 7(c). As the results indicate, the experimental system did not indicate that the state became safe, and driver did not operate the steering wheel. In Situation 1, the experimental system can predict the safety of future states. In addition, the experimental system judges that indicating that the state will become safe is not appropriate considering the time of driver’s perception, understanding, and operation.

5.2 Situation 2: Nearby vehicle moves away

5.2.1 Results obtained by considering only the present state

The results of an experiment conducted with one test driver in Situation 2 are shown in Fig. 8(b). This figure shows the time lag between the time at which the “safe” message is provided by the system and the time at which the driver begins to operate the steering wheel. The average of time lag of the three testers is $1.70sec.$

ISBN: 978-989-95079-6-8

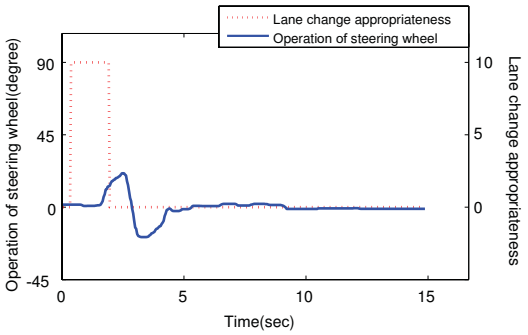
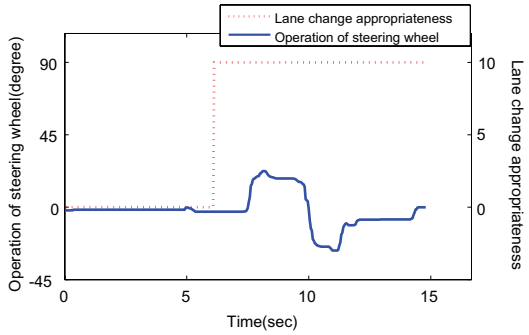
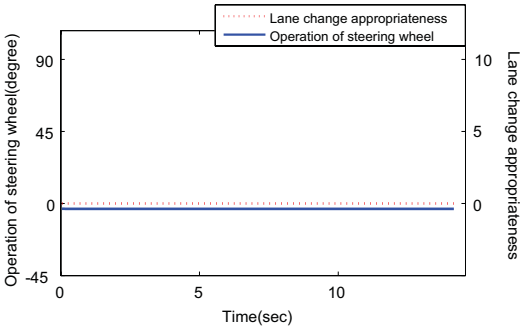
(a) Situation 2:Nearby vehicle moves away



(b) Results obtained by considering only the present state: Situation 1

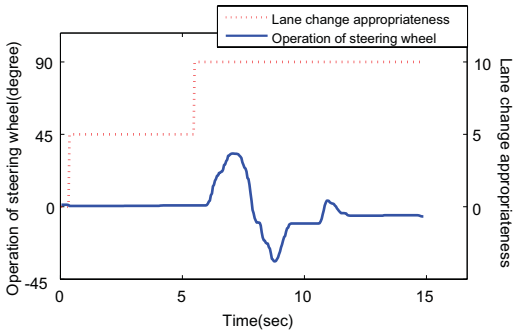


(b) Results obtained by considering only the present state: Situation 2



(c) Results obtained by considering future states: Situation 1

Figure 7: Experiments results obtained for Situation 1.



(c) Results obtained by considering future states: Situation 2

Figure 8: Experiments results obtained for Situation 2.

5.2.2 *Results obtained by considering future states*

The results of an experiment conducted with one test driver considering future states in Situation 2 are shown in Fig.8(c). The difference from Fig. 8(b) is that the message "It will be safe to change lanes soon" is presented to the driver, because this method considers not only the present state but also predicts future states. The "safe" message is then presented at the time when system judges that it will be safe to change lanes for a while. The final signal is then presented to the driver.

In this way, the driver is presented with the knowledge that he will be able change lanes soon, and can prepare to change lanes. In addition, the time required to provide the audio instruction can be shortened by using a signal to indicate that it is safe to change lanes.

As shown in Fig. 8(c), the time lag between the time at which the "safe" message is provided by the system and the time at which the driver begins to operate the steering wheel became shorter. The average time lag of three testers is $0.63sec$.

5.3 *Discussion*

The results of the experiments reveal the following.

- In Situation 1, the proposed support system can predict danger in future states, whereas the system that considers only the present state cannot predict danger in future states.
- In Situation 2, in the proposed support system, the time lag between the time at which the system provides an instruction and the time at which the driver performs an operation is shorter than that in the system that considers only the present state.

ISBN: 978-989-95079-6-8

Therefore, the effectiveness of the proposed system as a support system for use in a dynamic environment is demonstrated.

6 Conclusions

An effective support method for use in a dynamic environment is proposed in the present paper. The proposed method forecasts future states that are calculated from present states, and the driver is provided in advance with instructions to perform various operations. In order to achieve the proposed method, time change fuzzy sets are proposed as a method of building expert knowledge concerning the time change of the states into a computer.

The proposed method was applied to a lane change support system and experiments were performed. The obtained results indicate that it is possible to achieve a safety support system that can predict danger in future states and can reduce the time lag between the system providing an instruction and the driver performing an operation. In addition, the results indicate the effectiveness of the proposed support method.

Semantical evaluators

Antoon Bronselaer[1] Guy De Tré[1]
1. Department of Telecommunications and Information Processing, Ghent University
Ghent, Belgium
Email: {antoon.bronselaer,guy.detre}@ugent.be

Abstract— *In the context of a possibilistic framework for detection of object co-reference, evaluators have been defined as operators that compare two values and express the belief that such values are co-referent. Hereby, co-reference of two values means that these values describe the same entity in the real world. In this paper, a class of evaluators is investigated that determines the belief of co-reference based on semantical connections between values of the universe. These semantical connections are modeled by means of binary relations. In case these binary relations are not a-priori given, they can be (partially) learned in an iterative co-reference detection schema.*

Keywords— Possibility theory, co-reference, binary relations

1 Introduction

In order to deal with the increasing amount of (partially) independent information sources, detection of duplicate information storage is of key importance to avoid inefficient storage management and inconsistencies. In the context of this paper, data are discussed in terms of *objects*. An object is a structured description of a real world entity. Hereby, structured refers to a complex user defined data structure that is used to model data. Such is the case with, among others, relational databases, XML-documents and Object Oriented environments. Objects that refer to the same entity are called *co-referent* objects. A typical property of an object is that it can be decomposed into sub-objects with a *well-defined* domain. These sub-objects are called *attributes*. Note that attributes are not bound to have an atomic data structure, i.e. any collection type is a valid datatype for an attribute. In case of relational databases, the attributes are the tuple fields.

As a running example throughout this paper, the 'restaurant' dataset [1] is used, which is a table from a relational database that describes restaurants. Each restaurant is represented by an object that has four attributes: name, address, city and type. Next to the attributes, the dataset contains a source field, which indicates the restaurant guide from which the information was taken ('fodor' or 'zagat') and an identifier field 'oid'. The goal of this dataset is to find the co-referent restaurants. The dataset is chosen as an example in this paper because syntactical evaluators are not suited for attributes 'city' and 'type'. It is shown in this paper how semantical evaluators can be used for these attributes. A sample of the dataset is shown in Table 1, where objects 1 and 3 have source 'fodor' and objects 2 and 4 have source 'zagat'. Objects 1 and 2 are co-referent objects and so are objects 3 and 4.

In a possibilistic setting, an evaluator E_U determines the possibility (or belief) of (non) co-reference about two values from a universe U. This universe can be the domain of complex objects or the domain of less complex attributes. The subject of this paper is to investigate a special class of evaluators called *semantical evaluators*. These evaluators use binary relations on the universe of interest to determine the belief that two values are co-referent. The transfer of knowledge from a relational level to a comparative level has already been studied in literature. The first notion of semantical connections between linguistic terms is pointed out by Quillian [2]. Resnik uses a network of semantical connections to construct a *semantical similarity measure* [3]. The key idea in this model is to compare the information that is held by two concepts in order to compute the similarity between two words. Further on, Resnik uses an existing taxonomy as knowledge base. This interesting approach has led to several further enhancements, which are all based on information theory [4, 5]. The knowledge base T reflects relations between elements of a universe of concepts. Each approach then uses T to construct a similarity measure. The research presented in this paper is in line of these approaches and provides a theoretical framework for semantical evaluators. The case in which the the taxonomy T is not a-priori known, will be treated in this paper, leading to an unsupervised schema for construction of binary relations. Unsupervised approaches for co-reference have been studied in [6, 7, 8]. The idea proposed here is in fact complementary with the key idea behind these approaches. In recent research, the term co-reference has become relevant in the field of computational linguistics [9, 10, 11]. The search for co-referent *non-structured* objects, i.e. flat text documents, has important applications in text clustering and information aggregation. In this recent field, semantics is of crucial importance to obtain good cluster accuracy. However, it is emphasized that semantical evaluators as introduced in this paper operate in a framework for *structured* objects, in contradiction to the frameworks for *non-structured* objects in [9, 10, 11]. The remainder of the paper is structured as follows. Section 2 summarizes some basic notations and preliminary knowledge. In Section 3, semantical evaluators are defined and properties are investigated. Section 4 introduces the iterative co-reference

ISBN: 978-989-95079-6-8

detection scheme, which is an unsupervised learning schema in which binary relations used by semantical evaluators are increasingly constructed. Finally, Section 5 summarizes the main contributions of this paper.

2 Preliminaries

Within the context of this paper, a (structured) object is a (structured) description of a real world entity that is decomposable into *attributes* and *co-referent* objects are objects that describe the same entity. The possibilistic model for detection of co-referent objects is based on the concept of *possibilistic truth values* [12, 13, 14]. A possibilistic truth value $\tilde{p}$ is a normalized possibility distribution over the domain $\mathbb{B} = \{T, F\}$ and represents uncertainty about the truth value of a proposition p. Hence $\tilde{p} = \{(T, \mu_{\tilde{p}}(T)), (F, \mu_{\tilde{p}}(F))\}$. A short notation thereof is $\tilde{p} = (\mu_{\tilde{p}}(T), \mu_{\tilde{p}}(F))$. The domain of all possibilistic truth values is denoted $\tilde{\wp}(\mathbb{B})$ which is complete lattice. Total order relations $\tilde{R}$ on this domain are defined as follows, with R a total order relation on the unit interval $[0, 1]$:

$$\tilde{p}_1 \ \tilde{R} \ \tilde{p}_2 \Leftrightarrow \begin{cases} \mu_{\tilde{p}_2}(F) \ R \ \mu_{\tilde{p}_1}(F), & \mu_{\tilde{p}_1}(T) = \mu_{\tilde{p}_2}(T) = 1 \\ \mu_{\tilde{p}_1}(T) \ R \ \mu_{\tilde{p}_2}(T), & \text{otherwise} \end{cases}$$

Possibilistic truth values describe available knowledge (or belief) about a proposition. It is emphasized that they do not describe a state of graded truth. The most important operators for knowledge aggregation in the domain of possibilistic truth values are generalized *conjunction*

$$\tilde{\wedge} : \tilde{\wp}(I)^2 \to \tilde{\wp}(I) : \tilde{p} \tilde{\wedge} \tilde{q} \mapsto \{ \ (T, \min\left(\mu_{\tilde{p}}(T), \mu_{\tilde{q}}(T)\right)), \\ (F, \max(\mu_{\tilde{p}}(F), \mu_{\tilde{q}}(F))) \ \}$$

and *disjunction*

$$\tilde{\vee} : \tilde{\wp}(I)^2 \to \tilde{\wp}(I) : \tilde{p} \tilde{\vee} \tilde{q} \mapsto \{ \ (T, \max(\mu_{\tilde{p}}(T), \mu_{\tilde{q}}(T))), \\ (F, \min(\mu_{\tilde{p}}(F), \mu_{\tilde{q}}(F))) \ \}$$

In the context of co-reference detection, possibilistic truth values are generated by *evaluators*. These are formally defined as follows:

Definition 1 (Evaluator)
Assume a universe U of values describing entities in the real world. An evaluator on U is a commutative function E_U such that:

$$E_U : U^2 \to \tilde{\wp}(\mathbb{B}) : (u, v) \mapsto E_U(u, v) = \tilde{p} \qquad (1)$$

with $p =$"u and v are co-referent", $\mu_{\tilde{p}}(T)$ is the possibility that p is true and $\mu_{\tilde{p}}(F)$ is the possibility that p is false.

An evaluator is *reflexive* if $\forall (u, u') \in U^2 : u = u' \Rightarrow E_U(u, u') = \{(T, 1)\}$ and is *strong reflexive* if $\forall (u, u') \in U^2 : u = u' \Leftrightarrow E_U(u, u') = \{(T, 1)\}$.

This paper deals with evaluators that extract knowledge from binary relations. A binary relation R on U is a subset of the Cartesian product $U \times U$. The elements of R are thus couples of elements from U. $(u, v) \in R$ is also denoted as $u \ R \ v$. An equivalence relation is a binary relation that is *reflexive* ($\forall u \in U : u \ R \ u$), *symmetrical* ($\forall (u, v) \in U^2 : u \ R \ v \Leftrightarrow v \ R \ u$) and *transitive* ($\forall (u, v, w) \in U^3 : (u \ R \ v \wedge v \ R \ w) \Rightarrow u \ R \ w$). A partial order relation is a binary relation that is reflexive, transitive and anti-symmetrical ($\forall (u, v) \in U^2 : (u \ R \ v) \wedge (v \ R \ u) \Rightarrow (u = v)$). A *strict* partial order relation is anti-reflexive ($\forall u \in U : \neg(u \ R \ u)$), anti-symmetric and transitive.

3 Semantical evaluators

3.1 Definitions

Evaluators have been introduced and investigated in [15]. In general, three classes of evaluators are distinguished: syntactical, semantical and hybrid evaluators. *Syntactical* evaluators determine possibility based on syntactical differences and are useful to deal with typographical errors in string data and inaccuracies with numerical data. *Semantical* evaluators are based on *binary relations* between elements of a universe U. The name 'semantical evaluator' reflects that in many cases, such binary relations model a semantical connection between elements of the universe. However, the use of the framework presented here is not restricted to semantical connections only. In fact, binary relations can very well express a syntactical connection, rather than a semantical one, for example the *equality* relation. Nevertheless, the applications of interest assume in most cases relations that are semantical in nature, which explains the name of this type of evaluators. *Hybrid* evaluators are a combination of several evaluators on the same domain. Syntactical evaluators are studied in [15], whereas semantical evaluators are the subject of this paper.

The rationale of a semantical evaluator emerges from the fact that co-reference of objects is nothing more than equality of the entities described by the objects. As such it can be seen that co-reference of objects can in fact be modeled by a symmetrical reflexive binary relation (say R_c for convenience) in the domain $O \times O$ with O the set of objects. Moreover, the domain O can be decomposed into sub-domains U_i which are the domains of attributes a_i. Hence, if a binary relation R_i is defined in $U_i \times U_i$, a key question is then how the information given by relation R_i can be translated into information about R_c. It is thus studied in this paper how a given binary relation R on a universe U can be used to generate the possibility that elements of U belong to co-referent objects. An important assumption hereby made is that R contains *positive* knowledge about co-reference, which means that connection of two elements u and v through a binary relation is regarded as evidence for their co-reference. If elements are not connected through R, it is concluded that u and v are not co-referent. This is formalized as follows.

Definition 2 (Semantical evaluator)
Assume a universe U and a binary relation R. A semantical evaluator $E_{U,R}$ is defined by means of a function f_R called the knowledge transfer function, such that $\forall (u, v) \in U^2 : E_{U,R}(u, v) = f_R(u, v)$ with:

$$f_R : U^2 \to \tilde{\wp}(\mathbb{B}) \qquad (2)$$

such that

$$f_R(u, v) = \begin{cases} \tilde{p}_{u,v} & u \ R \ v \vee v \ R \ u \\ (0, 1) & \neg(u \ R \ v) \wedge \neg(v \ R \ u) \end{cases} \qquad (3)$$

The condition $u \ R \ v \vee v \ R \ u$ in Definition 2 is a consequence of the assumption of commutativity in the definition of evaluators. As an example, let $\mathcal{S}$ be the domain of strings and consider the relation R='city-part-of'. If, for the sake of simplicity, it is assumed that $\tilde{p}_{u,v}$ is independent of u and v and equal to $(1, 0.3)$, then:

$$E_{\mathcal{S},R}(\text{"Manhattan"}, \text{"New York"}) = (1, 0.3)$$
$$E_{\mathcal{S},R}(\text{"New York"}, \text{"Chicago"}) = (0, 1)$$

ISBN: 978-989-95079-6-8

The assignment of possibilities by a semantical evaluator is constrained by the specificity of the relation R. Assume two binary relations R_1 and R_2 on universe U such that $R_1 \subset R_2$, then R_2 applies for more couples of elements than does R_1. In an extreme case, a relation R can apply for each couple of elements, which means that R is an equivalence relation on U with 1 equivalence class. Clearly such a relation offers no information about co-reference at all, which means that:

$$R = U^2 \Rightarrow \forall (u, v) \in U^2 : E_R(u, v) = (1, 1) \quad (4)$$

Thus, if more couples satisfy a relation R, R is less specific and less knowledge about co-reference can be derived from R. Hence, a knowledge transfer function must satisfy:

$$(R_1 \subseteq R_2) \Rightarrow \forall (u, v) \in R_1 : f_{R_1}(u, v) \tilde{\geq} f_{R_2}(u, v) \quad (5)$$

The principle of specificity can also be applied inside a relation R. Consider a binary relation R defined over the universe U. The projection of R over an element $u \in U$ is given by:

$$\text{Proj}_u(R) = \{(x, y) | x \; R \; y \wedge (x = u \vee y = u)\} \quad (6)$$

The knowledge transfer from R to $\tilde{\wp}(\mathbb{B})$ modeled by f_R is *monotone* if and only if for any triple $(u, v, w) \in U^3$ that satisfies $uRw \vee wRu$ and $vRw \vee wRv$, we have that:

$$|\text{Proj}_u(R)| \geq |\text{Proj}_v(R)| \Leftrightarrow f_R(u, w) \tilde{\leq} f_R(v, w) \quad (7)$$

It can be verified that monotone knowledge transfer is obtained if f_R is constructed as follows:

$$\begin{array}{l} u \; R \; v \vee v \; R \; u \Rightarrow \\ f_R(u, v) = \left(1, g\left(\frac{|\text{Proj}_u(R)|}{2|R|-1}, \frac{|\text{Proj}_v(R)|}{2|R|-1}\right)\right) \end{array} \quad (8)$$

with g a monotonic increasing, commutative function such that $g(1, 1) = 1$. Monotone transfer knowledge implies that it is *more* certain that u and v are co-referent if they are connected by R and if there is *less* evidence that u or v are co-referent with other elements.

A common problem with semantical evaluators is that relations are a-priori information. In other words, relations are constructed without observing the actual values on which the evaluator must operate. It is possible that the values on which R is constructed are not *equal* to values of an observed problem, but rather co-referent. This is caused by the fact that values considered for a-priori construction of R are typically standardized, which is not the case for values that are the subject of co-reference detection. For example, with R='city-part-of', it is known that "Manhattan" R "New York". Nevertheless:

$$E_{\mathcal{S},R}(\text{"Manhatan"}, \text{"New York"}) = (0, 1)$$

due to the spelling error in "Manhatan". To deal with such a situation, an evaluator can be used to detect co-references between values from an observed problem and values from the a-priori universe on which R is constructed. Typically, such an evaluator will be *syntactical*. A semantical evaluator is then used in a *chain* of evaluators.

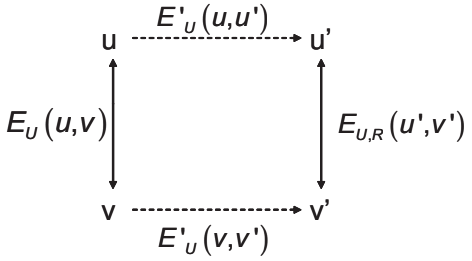

Figure 1: Evaluator chain

Definition 3 (Evaluator chain)
Assume a universe U equipped with a semantical evaluator $E_{U,R}$ and a reflexive evaluator E'_U. An evaluator chain is an evaluator E_U such that:

$$E_U(u, v) = \max_{(u', v')} E'_U(u, u') \tilde{\wedge} E_{U,R}(u', v') \tilde{\wedge} E'_U(v', v) \quad (9)$$

The principle of chaining is schematically depicted in Figure 1. Due to reflexivity of E'_U it can be seen that:

$$(u \; R \; v \vee v \; R \; u) \Rightarrow E_U(u, v) = E'_U(u, v) \quad (10)$$

Moreover, if E'_U is strong reflexive:

$$(u \; R \; v \vee v \; R \; u) \Leftrightarrow E_U(u, v) = E'_U(u, v) \quad (11)$$

In the context of iterative co-reference detection (Section 4), an important concept is that of a hybrid evaluator.

Definition 4 (Hybrid evaluator)
Assume a universe U and a set of evaluators $\mathcal{E} = \{E_{U,1}, ..., E_{U,n}\}$ on U. A hybrid evaluator is an evaluator on U such that:

$$E_U = c(E_{U,1}, ..., E_{U,n}) \quad (12)$$

with c a commutative, associative and monotonic increasing function called the combinatory function.

3.2 Examples

The most obvious example of a semantical evaluator is an evaluator that is based on the equality relation. In many cases, reflexivity of an evaluator is required which means that $\forall (u, v) \in U^2 : u = v \Rightarrow E_U(u, v) = (1, 0)$. Hence, in order to support this constraint, equality of elements must imply full impossibility of non co-reference. As mentioned in Section 3.1, this evaluator can be regarded as syntactical evaluator, because the binary relation is not semantical in nature. A related case is a semantical evaluator where R is relaxed to an *equivalence* relation, which has interesting applications such as detection of synonyms, i.e. words with the same meaning. Another example is the case where two words don't have the same meaning, but they both fully qualify for description of a given entity. This is because the entity can not be described exactly and more descriptions are possible. In that case, words are equivalent with respect to their appropriateness for description of an entity, despite the fact that these words do not have the same meaning. This is the case with the attribute 'type' of the 'restaurant' dataset, where for example 'steakhouse' and 'american' are possible (and thus equivalent) descriptions of the type of restaurant.

ISBN: 978-989-95079-6-8

Assume a universe U and assume a partition of U into n disjunct subsets U_i. Consider $n-1$ relations R_i such that each R_i is a surjective function between U_i and U_{i+1}. The set of relations $\{R_i\}_{i=1,2,...,n-1}$ is called a *hierarchy* on U. It can be seen that, by definition, each R_i from a hierarchy is anti-reflexive and anti-symmetrical. Due to the fact that $\forall i \in \{1,...,n-1\} : im(R_i) = dom(R_{i+1})$, it is possible to compose relations R_i and R_{i+1}.

$$\forall (u,w) \in U^2 : u\ R_1R_2\ w \Leftrightarrow (\exists v \in U : u\ R_1\ v \wedge v\ R_2 w) \tag{13}$$

Hence, $R_1R_2...R_n$ denotes the n-ary composition of n relations and thus, elements of non subsequent partitions are related through composition. For each hierarchy $\{R_i\}_{i=1,2,...,n-1}$, consider the set of relations $\{R_i^*\}$ such that:

$$u\ R_i^*\ v \Leftrightarrow \exists k \leq l \leq i : u\ R_k...R_l v \tag{14}$$

By definition:

$$\forall i,j \leq n : i < j \Rightarrow R_i^* \subset R_j^* \tag{15}$$

It is then possible to construct $n-1$ semantical evaluators with knowledge transfer function $f_{R_i^*}$. Due to the consistency constraint:

$$\forall i,j \leq n : i < j \Rightarrow f_{R_i^*} \tilde{\geq} f_{R_j^*} \tag{16}$$

It can be seen that composing all relations, leads to a strict partial order relation. Hence, each partial order relation can be decomposed into relations with higher granularity and thus higher belief of co-reference. This principle can be applied on the 'city' attribute of the restaurant dataset, because the values are connected by a strict partial order relation.

4 Iterative co-reference detection

4.1 Approach

In this Section, attention is given to the case where R is not a-priori given. This is the case when dealing with subjective information, for example the 'type' attribute of the restaurant dataset. There is no a-priori information about which types can be used to denote the same restaurant. In that case a semantical evaluator can be (partially) constructed based on a training set. However, in what follows a method is proposed to construct a semantical evaluator in cases where no training set is given. Assume objects consisting of n attributes a_i. For each attribute a_i, an evaluator $E_{dom(a_i)} = E_i$ must be constructed. The set of attributes can thus be partitioned into attributes that require a syntactical evaluator (A_{syn}) and attributes that require a semantical evaluator (A_{sem}), such that $A = A_{syn} \cup A_{sem}$ and $A_{syn} \cap A_{sem} = \emptyset$. For the 'restaurant' dataset, $A_{syn} = \{$'name', 'street'$\}$ and $A_{sem} = \{$'type', 'city'$\}$.

The key idea of iterative co-reference detection, is to find the co-referent objects in m iterations. Semantical evaluators for which no binary relation R is available are gradually constructed throughout the different iterations. An evaluator is called *unavailable* if it is a semantical evaluator for which the binary relation R is unknown. In each iteration j, a subset of the available evaluators is selected. With these evaluators, a candidate set C_j of co-referent object couples is generated. For each attribute a_i that requires a semantical evaluator, a binary relation R_j is constructed by projecting each object couple from C_j over the attribute a_i. In other words, if the object couple (o_1, o_2) is contained in the candidate set C_j and attribute a_i requires a semantical evaluator, then the couple $(\text{Proj}_{a_i}(o_1), \text{Proj}_{a_i}(o_2))$ is considered as a couple of co-referent values for attribute a_i. As a consequence, this couple of values is added to the binary relation R_j. For each attribute a_i that requires semantical evaluation, a novel relation is R_j is constructed in each iteration j. The reason to do this is explained next. Typically, the generation of the first candidate set is based on very stringent criteria. If this is not the case, many false positives are included in the candidate set, which implies that constructed binary relations contain a large amount of couples. As explained before, a binary relation with large cardinality implies inferred knowledge with much uncertainty (Eq. 4, Eq. 5). Throughout sequential iterations, the candidate set is expanded by (i) relaxation of syntactical evaluators and (ii) additional knowledge of semantical evaluators. As a consequence, there is a high probability that for $k \leq l$, $C_k \subset C_l$. If this is true, relations constructed in iteration k are subsets of the corresponding relations in iteration l. Due to the consistency constraint (Eq. 5), relations constructed in iteration l imply more uncertainty. Therefor, in order to preserve the level of (un)certainty in relations constructed in early iterations, each iteration constructs a new relation. Hence, for each attribute a_i that requires a semantical evaluator, m binary relations are constructed. Each of these relations $R_{i,j}$ yields a semantical evaluator $E_{i,R_{i,j}}$. The constructed evaluator for attribute a_i is a hybrid evaluator (Eq. 12) with $\tilde{\vee}$ as combinatory function:

$$E_i(u,v) = E_{i,R_{i,1}}(u,v)\tilde{\vee}...\tilde{\vee}E_{i,R_{i,m}}(u,v) \tag{17}$$

Hence, the constructed evaluator tries to find the most stringent binary relation by which the values are connected as this relation yields the most belief in co-reference. After iteration m, the last candidate set C_m of co-referent couples is generated which gives us the possible co-referent objects. It is noted that iterative co-reference detection is a stand-alone comparison process: it produces a set of possible co-referent couples. However, it can also be used to construct evaluators and their corresponding binary relations. In other words, the proposed method can be used to find co-referent objects, but it's purpose

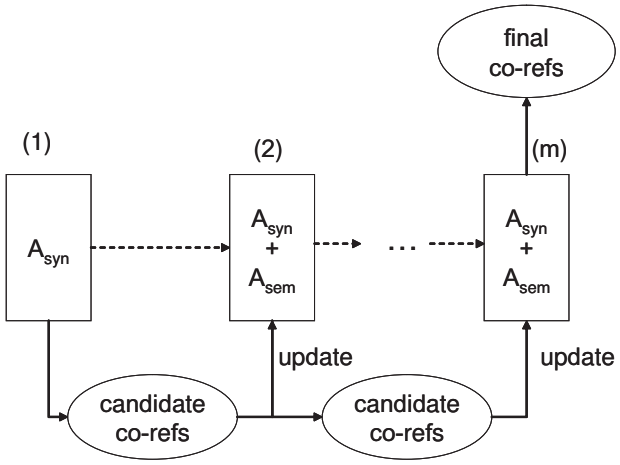

Figure 2: Iterative learning of semantical evaluators

ISBN: 978-989-95079-6-8

Table 2: Statistics of restaurant test

'type' evaluator	Co-refs	Non Co-refs
Equality	22	5018
Equality + R	100	27811

can also be limited to construction of binary relations, which makes it compatible with other (possibilistic) frameworks for co-reference detection. Figure 2 shows a schematical representation of iterative co-reference detection.

4.2 Example

The idea of iterative co-reference detection is illustrated on the 'restaurant' dataset. The focuss in this example lies on illustrating the construction of binary relations. The dataset consists of two lists ($|L_1| = 533$ and $|L_2| = 331$). Among the 176423 couples of restaurants, 112 couples are co-referent. For convenience, only two attributes are initially considered: 'name' and 'type'. It is assumed that a syntactical evaluator is used for 'name' and a semantical evaluator must be constructed for 'type'. For the first iteration, consider an evaluator for attribute 'name' based on equality (i.e. values are co-referent if they are equal). Among all possible couples, 83 couples have an equal name, of which 82 are identified as co-referent, based on ground truth (i.e. equal oid's). Hence, candidate set C_1 contains 83 couples of restaurants. Projecting this candidate set over the 'type' attribute and filtering identical couples out, yields 40 couples of possible co-referent restaurant types. These couples determine the binary relation R_1. Table 2 learns how R_1 allows for assignment of belief to 100 co-referent couples (89.3% of all co-referent couples). However, 27811 non-coreferent couples are also assigned belief (15.8% of all non co-referent couples). This is partially due to the type of data. As can be seen, 5018 non-coreferent couples have equal values for type, which is an indication that the 'type' attribute is prone to many false positives. It must be remembered that the goal is to construct an evaluator that is used in a larger object comparison system. Hence, the contribution of semantical evaluators lies in the assignment of belief to co-referent values, thereby trying to minimize the belief attached to non co-referent values. As can be seen in Table 2, the fraction of non-coreferent values that are assigned belief can still be large in absolute numbers. However, this fraction can be filtered out using an intelligent aggregation function to combine the belief assigned by the different evaluators. The constructed relation for 'type' assigns belief to 89.3% of the co-referent couples, after one iteration. Assume in a second iteration, that the 'street' attribute is involved, which requires a syntactical evaluator. For the sake of simplicity, assume an evaluator for 'street' based on equality. If the evaluations for 'name' and 'street' are combined through disjunction, i.e. two restaurants are co-referent if their names are equal *or* their streets are equal, then the candidate set C_2 contains 106 object couples of which 101 are actually co-referent. Suppose that iteration 2 would be the last iteration, then the model can be refined by adding semantical evaluation of the 'type' attribute, i.e. two restaurants are co-referent if their types are connected by R_1 *and* (names are equal *or* their streets are equal). Using this model results in a candidate set of 95 couples of which 94 are co-referent, which means that 83.9% of all co-referent couples are detected with a precision of 98.95%. If iteration 2 is not the last iteration, then C_2 can be used to construct a second binary relation R_2. Note that by construction $R_1 \subset R_2$.

An advantage of iterative co-reference detection is that the binary relations R are dynamically adapted throughout the different iterations. If an approach with a training set is used, the relation R can be partially constructed only on the observations in the training set. With iterative co-reference detection, binary relations are constructed by generating a candidate set from *all* known observations. Hence, the relations constructed in an iterative co-reference detection scheme will be more complete.

5 Conclusion

In the possibilistic framework for detection of complex co-referent objects, a central concept is that of an evaluator, which is a function that estimates belief/uncertainty about co-reference of (sub)-objects. This paper introduces a formal framework for *semantical* evaluators E_U that model the transfer of knowledge from binary relations on the universe, to knowledge about co-reference of elements. This transfer is modeled by means of a knowledge transfer function f_R. It is shown that, depending on the application, such a function must satisfy consistency constraints. It is also shown how semantical evaluators can be used in an evaluator chain and how to combine evaluators in a hybrid evaluator. Finally, when relations on U are unknown, it is investigated how to (partially) construct such relations without use of a pre-labeled training set. This construction process is called iterative co-reference detection.

Abstract— *We present a fuzzy version of the efficient portfolio selection problem which adds to the Markowitz's classical model the vagueness of the investor's preferences about the assumed risk. This is done by adapting some techniques previously applied by the authors in other logistic problems. We provide several procedures to solve it: an exact one and a hybrid meta-heuristic procedure more adequate for medium and large-sized problems. To show the usefullness of the model and the algorithms, we provide an example based on data from the Spanish index IBEX35.*

Keywords— Fuzzy programming, Heuristic strategies, Portfolio selection.

1 Introduction

The modern portfolio selection problem is a classical model for determining the optimal composition of a portfolio according to the preferences of an investor. The model is credited to Markowitz [17, 18], who is rightfully regarded as the founder of modern portfolio theory [6].

In a first approach, given n securities S_1, $S_2, \cdots, S_n$ in which we can invest non-negative quantities $x_1, x_2, \cdots, x_n$, a portfolio consists of a subset of securities in which all the capital should be invested satisfying investor's preferences. These preferences must take into account the risk that the investor is willing to assume, the expected return and, to a lesser extent, some diversification criteria.

One possibility is taking the return as objective function and including the risk as a constraint, i.e.

$$\begin{array}{ll} \text{Max.} & \text{Portfolio return} \\ \text{s.t.} & \text{Risk of portfolio} \leq R \\ & \sum_{i,=1}^{n} x_i = 1, \\ & l_i \leq x_i \leq u_i, \qquad i = 1, \ldots, n. \\ & l_i \geq 0 \qquad\qquad i = 1, \ldots, n. \end{array} \tag{1}$$

where R is the maximum risk accepted by the investor, and the last constraints express that all the capital must be invested as well as diversification conditions.

However, we could also consider the dual version (in an economic sense) in which the risk is minimized taking the expected return as a constraint.

Obviously, the portfolio selection, like most financial problems, is related with uncertainty because it consists in taking a decision about future events. Therefore, we do not have at our disposal more than historical data which usually are managed with statistical methods [18, 6]. Moreover, it is not easy to model the investor's preferences. After the seminal work by Markowitz, attention has been given in the study of alternative models [13, 14]. Most of these models are based on probability distributions, which are used to characterize risk and return. For instance, in the Markowitz model, variance and mean were generally deemed satisfactory measures of risk and return, respectively [18, 21, 7, 12]. However, according to the chosen modellization of the expected risk and return, different models coexist to select the best portfolio. Some of them propose to describe the risk by means of mean-absolute deviation ([11], [24]), other authors propose linear programming [22] or multiobjective [15] models.

Another way of dealing with uncertainty is working with models based on soft computing. This can be done by means of vague goals for the expected return rate and risk [23, 16], or by using possibility distributions to model the returns. This fact permits the incorporation of expert knowledge by means of a possibility grade, to reflect the degree of similarity between the future state of stock markets and the state of previous periods.

In this paper, we present several ways of dealing with the uncertainty associated to the portfolio selection problem. Namely, we are going to show that the techniques used by the authors in logistic problems[2, 3, 4] can be generalized to deal with the risk and return fuzziness in the portfolio selection problem. These techniques allows us to include in our fuzzy model the vagueness related with the fact that the investor fixes arbitrarily the risk that he/she will assume. The uncertainty concerning to the valuation of risk and returns is modellized by means of the usual variance and mean.

To solve our model, meta-heuristic techniques are often needed because of the size of the problem or because a quick solution is required in order to reflect real-time cases. Therefore, we propose a hybrid meta-heuristic procedure.

The paper is organized as follows: The next section introduces the framework for portfolio selection used in this paper. Section 3 examines the portfolio selection with flexible constraints, incorporating this flexibility in a fuzzy model. In section 4, we present a hybrid meta-heuristic to solve the portfolio selection problem with flexible constraints. Finally, Section 5 outlines the most important conclusions.

ISBN: 978-989-95079-6-8

2 Portfolio selection

We could consider the problem of an investor who intends to invest some money in securities in such a way that the rate of return is maximized and a given level of risk cannot be surpassed. If we have n securities, r_i is the return of the i-th security and x_i is the proportion of total investment funds devoted to the i-th security, then we have the constraint

$$\sum_{i=1}^{n} x_i = 1.$$

The risk of investment can be measured by the variance $x^t S x$, where $S = [s_{ij}]$ is the variance-covariance matrix. If R is the maximum risk accepted by the investor, we have the constraint

$$\sum_{i,j=1}^{n} s_{ij} x_i x_j \leq R.$$

Then, one of the simplest models for the portfolio selection problem is:

$$\begin{array}{rl} \text{Max.} & \displaystyle\sum_{i=1}^{n} r_i x_i \\ \text{s.t.} & \displaystyle\sum_{i=1}^{n} x_i = 1, \\ & \displaystyle\sum_{i,j=1}^{n} s_{ij} x_i x_j \leq R, \\ & x_i \geq 0, \;\; i = 1, \ldots, n. \end{array} \tag{2}$$

However, choosing the best investment options for a portfolio is a difficult task due to economic environment uncertainty and the problem of suitably reflecting decision maker desires in the model. Both stochastic and fuzzy programming provide different ways of handling the first kind of uncertainty [9]. This paper presents a fuzzy approach for the second kind, in which the portfolio problem includes the subjective criteria of the decision maker to determine the level of risk that he or she is able to support and the level of satisfaction to be assigned to a possible increase in return.

3 Flexible Portfolio selection

The portfolio selection problem has two data concerning decision maker preferences, namely the capital to be invested and the risk to be assumed. The investor can be assumed to know with certainty the capital that he/she would like to consider, and in fact, in the model this quantity has been normalized to the unit. However, determining the risk to be assumed could be more flexible. As a result, it is worth incorporating this flexibility in a fuzzy model.

The main idea is to consider partially feasible solutions involving slightly greater risk than that fixed by the decision maker, and to study the possibilities that they offer in order to improve the expected return. When compared with the logistic models (actually with the p-median case [2, 3, 4]), this problem happens to be more complicated, because the p-median problem is linear whereas the risk constraint in the portfolio model is quadratic. Moreover, in the p-median case, a small reduction in covered demand affected optimal cost in a simple linear way, whereas the way in which the maximum expected return depends on the accepted risk is rather more complicated.

A fuzzy set $\tilde{S}$ of partially feasible solutions is defined so that portfolio selection belongs to $\tilde{S}$ with a degree of membership that depends on how much it exceeds the risk R_0 fixed by the investor. On the other hand, a second fuzzy set $\tilde{G}$ is defined, whose membership function reflects the improvement of the return provided by a partially feasible solution with respect to the optimal crisp return z^*. In practice, we consider piecewise linear membership functions

$$\mu_{\tilde{S}}(x) = \begin{cases} 1 & \text{if } r \leq R_0, \\ 1 - \frac{r - R_0}{p_f} & \text{if } R_0 < r < R_0 + p_f, \\ 0 & \text{if } r \geq R_0 + p_f, \end{cases}$$

$$\mu_{\tilde{G}}(x) = \begin{cases} 0 & \text{if } z \leq z^*, \\ \frac{z - z^*}{p_g} & \text{if } z^* < z < z^* + p_g, \\ 1 & \text{if } z \geq z^* + p_g, \end{cases}$$

where r and z are the risk and the return provided by the portfolio x (which is assumed to satisfy the constraints of (2), except the second one); the parameter p_f is the maximum increment in the risk that the decision maker can accept, and p_g is the increment of the return that the decision maker would consider completely satisfactory. From this, we can define a global degree of satisfaction

$$\lambda(x) = \min\{\mu_{\tilde{G}}(x), \mu_{\tilde{S}}(x)\},$$

which is the membership degree to the fuzzy intersection of $\tilde{S} \cap \tilde{G}$. The fuzzy portfolio model becomes

$$\begin{array}{rl} \text{Max.} & \lambda(x) \\ \text{s.t.} & x \in \tilde{S}. \end{array} \tag{3}$$

In order to solve it, the optimal solution of (2) will be calculated for each risk level R. Therefore, we solve explicitly the Kuhn-Tucker conditions for the problem. To carry out the computations in a generic framework, we start making a change of variables to diagonalize the risk matrix. As we are interested in small variations of R, the variables x_i that are zero in the optimal crisp portfolio can be removed and hence assume that non-negative conditions are not active. We can also assume that the risk constraint is active.

Standard linear algebra theory ensures us that we can decompose

$$S = A^t D A, \tag{4}$$

where the matrix D is diagonal and A is regular. Then the change of variables $y = Ax$ transforms the problem to

$$\begin{array}{rl} \text{Max.} & \displaystyle\sum_{i=1}^{n} r'_i y_i \\ \text{s.t.} & \displaystyle\sum_{i=1}^{n} b_i y_i = 1, \\ & \displaystyle\sum_{i=1}^{n} d_i y_i^2 = R, \\ & A^{-1} y \geq 0, \end{array} \tag{5}$$

where $r' = r^t A^{-1}$, $b = (1, \ldots, 1) A^{-1}$.

ISBN: 978-989-95079-6-8

As nonnegative conditions are inactive, the optimal solution must satisfy

$$\sum_{i=1}^{n} b_i y_i = 1, \quad \sum_{i=1}^{n} d_i y_i^2 = R, \quad r'_i - b_i\lambda - 2d_i y_i \mu = 0,$$

where λ and μ are the Lagrange multipliers of the capital and risk constraints respectively. Hence:

$$y_i = \frac{r'_i - b_i\lambda}{2d_i\mu},$$

and, from the first constraint, we get:

$$\sum_{i=1}^{n} \frac{b_i r'_i}{2d_i} - \sum_{i=1}^{n} \frac{b_i^2}{2d_i}\lambda = \mu.$$

Call

$$K = \sum_{i=1}^{n} \frac{b_i r'_i}{2d_i}, \qquad L = \sum_{i=1}^{n} \frac{b_i^2}{2d_i},$$

so that $\mu = K - L\lambda$. Hence:

$$y_i(\lambda) = \frac{r'_i - b_i\lambda}{2d_i(K - L\lambda)}.$$

The second constraint gives us:

$$\sum_{i=1}^{n} \frac{(r'_i - b_i\lambda)^2}{4d_i} = R(K - L\lambda)^2$$

or

$$\sum_{i=1}^{n} \frac{r'^2_i}{4d_i} - \sum_{i=1}^{n} \frac{r'_i b_i}{2d_i}\lambda + \sum_{i=1}^{n} \frac{b_i^2}{4d_i}\lambda^2 = R(K^2 - 2KL\lambda + L^2\lambda^2),$$

$$\sum_{i=1}^{n} \frac{r'^2_i}{4d_i} - K\lambda + \frac{L}{2}\lambda^2 = R(K^2 - 2KL\lambda + L^2\lambda^2).$$

If

$$M = \sum_{i=1}^{n} \frac{r'^2_i}{4d_i} \tag{6}$$

we get

$$(RL^2 - L/2)\lambda^2 + (K - 2KLR)\lambda + RK^2 - M = 0.$$

This is a second degree equation on λ with discriminant

$$\Delta(R) = K^2 - 2ML + (4ML^2 - 2K^2L)R.$$

Hence,

$$\lambda(R) = \frac{2KLR - K \pm \sqrt{\Delta(R)}}{2L^2R - L},$$

and so

$$\mu(R) = K - L\lambda(R) = \frac{\pm\sqrt{\Delta(R)}}{1 - 2LR}.$$

The sign must be chosen so that $\mu(R) \geq 0$ (the Kuhn-Tucker sign condition). Once the right sign is chosen, this function $\lambda(R)$ allows us to calculate $y_i(R)$ and, from this, we get the optimal portfolio $x_i(R)$ for each R such that $x_i(R) > 0$. This reduces the range of R to a certain interval that can be computed. When we reach one end point of this interval, we need to start again with the problem corresponding to the new set of positive variables.

We can also compute the return

$$F(R) = \sum_{i=1}^{n} r'_i y_i(R).$$

Since

$$y_i(\lambda) = \frac{r'_i - b_i\lambda}{2d_i\mu} = \mp\frac{2LR-1}{2d_i\sqrt{\Delta(R)}}\left(r'_i - b_i\frac{2KLR - K \pm \sqrt{\Delta(R)}}{2L^2R - L}\right), \quad 1 \leq i \leq n,$$

we have

$$F(R) = \mp\frac{2LR-1}{2\sqrt{\Delta(R)}}\sum_{i=1}^{n}\left(\frac{r'^2_i}{d_i} - \frac{r'_i b_i}{d_i}\frac{2KLR - K \pm \sqrt{\Delta(R)}}{2L^2R - L}\right).$$

This expression allows us to calculate the degree of improvement of the goal $\mu_g(R)$ of the best portfolio with risk R, whereas its degree of feasibility $\mu_f(R)$ is trivially computed.

Now we can determine the risk R^* such that $\mu_f(R^*) = \mu_g(R^*)$, which is easily shown to be the risk of the portfolio maximizing λ. The portfolio $x(R^*)$ corresponding to $y(R^*)$ by the change of variables is the optimal solution of (3).

4 A hybrid meta-heuristic to solve the Portfolio Selection problem

When the size of the problem increases, traditional methods become useless as they would need too much time, due to the combinatorial explosion in the solution space. Genetic Algorithms [19, 5] are meta-heuristic methods that have already shown their kindness to solve optimization problems.

In this section we describe a hybrid meta-heuristic for the portfolio selection problem with flexible constraints, called GAFUZ-PF (Genetic algorithm + simulated Annealing + FUZzy PortFolio). This meta-heuristic uses a hybrid scheme, mixing the ideas of Simulated Annealing technique with the classic Genetic Algorithm. Note that we need the optimal crisp return z^* of the portfolio selection problem (2) because $\mu_{\tilde{G}}(x)$ depends on it. Hence, solving the crisp problem must be considered as a part of the process of solving the fuzzy problem (this means to solve two NP-hard problems). In order to realize this idea, we use three different populations on three stages of the genetic algorithm. First of all, it uses a population to achieve feasible solutions to the problem (with a risk less than or equal to R fixed) which will be part of the population of the algorithm. Once feasible solutions are found, in the second stage, the algorithm uses other population that evolves searching the best return. The third stage uses another population, which looks for the best fitness $\lambda(x)$.

Simulated Annealing [1, 10] is a meta-heuristic used for optimization problems. This heuristic replaces the current solution by a random "nearby" solution, chosen with a probability that depends on the difference between the corresponding

ISBN: 978-989-95079-6-8

function values and a global parameter T (called the temperature), that is gradually decreased during the process. The use of this idea with Genetic Algorithm is suggested by Mitchell [19], using it with the individual selection function. We apply Simulated Annealing to mutation function. Having a mutation function with a big mutation rate helps us to keep diversity in the population, but it introduces distortion on the population when the algorithm approaches to the optimum. So, it seems a good idea to use Simulated Annealing with a temperature depending on the number of generations and the fitness of the solution in order to make possible a big mutation rate at the beginning, and reduce it while increasing the number of generations and the fitness. Now we specify our options and we give a general outline of our approach. Figure 1 shows the scheme of `GAFUZ-PF` hybrid meta-heuristic.

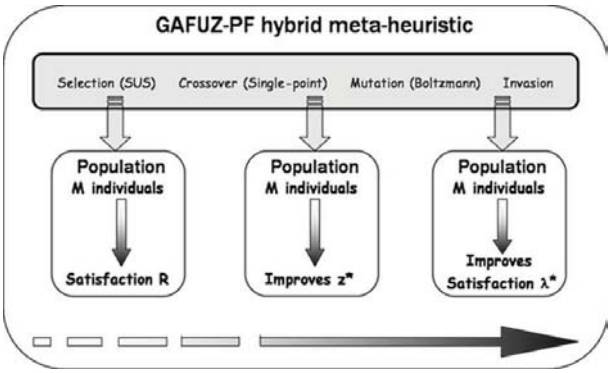

Figure 1: Scheme of hybrid meta-heuristic

4.1 Encoding, Fitness function and Population size

Each element of the population of the algorithm represents a solution to the described portfolio problem. The population encoding is made having an array of n-elements, where each gene represents the invest on one asset. The size of the population is fixed to 50 individuals, as it is known to be the best average size to avoid a too slow algorithm [19]. Furthermore, we use three different populations against time: the first one evolves searching for individuals to satisfy the second constraint of the problem 2. When it founds a suitable solution, it changes to the second stage, where it improves the return of the portfolio, taking account of the flexible constraint of R. Once the algorithm gets a state with $\lambda(x) > 0$, it changes the population and evolves taking into account p_f and p_g. The fitness function is the objective function of the problem (3).

The algorithm scheme is the classical one, with selection, crossover, mutation, invasion and having the number of generations as stop criteria.

4.2 Selecting the individuals

In order to select individuals for the crossover operator, we use the Stochastical Universal Sampling (SUS), as it has been shown to be better than Roulette Wheel [5]. Based on their fitness, SUS places the individuals on a Roulete and spuns it once with n selectors equally separated to select n individuals.

4.3 Crossover: generating new individuals

The crossover operator is the single-point crossover [19] adapted to the problem constraints: there is a fixed part from one parent that goes directly to the son; the genes from the second part (from the second parent) are added to the son (choosing them randomly) while the sum of its genes is ≤ 1.

4.4 Mutation

When we talk about mutation, there are some parameters used. The mutation rate (MUR) refers to the percentage of population individuals that will be mutated. On the other hand, we have the number of genes that will change (NR). As a mutation scheme we use Boltzmann mutation which is based on Simulated Annealing [5], with the following annealing function:

$$r = 1 - e^{-1/(n*max(\lambda(x)))}$$

It defines the mutation rate across the algorithm, reducing it as the algorithm evolves in order not to disturb the good solutions achieved when the algorithm is finishing. This rate specifies the percentage of individuals that would be mutated, since the number of mutations per individual is 1, as it is known to be the best choice [20]. A mutation consists in substract a random value from a gene and add this amount to other gene, both of them choose randomly.

4.5 Invasion

Finally, invasion is another genetic operator that helps to keep diversity in the population. It introduces a number of new randomly generated individuals, which replace some individuals at random in the population (except the best one). This helps to introduce new genes in the population, like mutation does. The invasion rate (IR) selected is 1% .

4.6 Stop criteria

The detention criterion is the number of generations (NG).

4.7 General outline of the `GAFUZ-PF` meta-heuristic

Now we have shown the configuration of the algorithm, we will see its general outline in algorithm 1.

4.8 Experiments

To test `GAFUZ-PF` hybrid meta-heuristic we have used various test problems. The PC used for the executions has the following features: Intel Pentium IV 3.00 GHz 2048 MB RAM.

• We have considered the returns on 20 assets from the Spanish index IBEX35. The set of assets included in the experiment represents Acesa (ACE), Arcelor (ACR), ACS, Altadis (ALT), BBVA, Bankinter (BKT), Dragados (DRC), Endesa (ELE), FCC, Iberdrola (IBE), Metrovacesa (MVC), NH Hoteles (NHH), Banco Popular (POP), Repsol (REP), SCH (SAN), Telefónica (TEF), Unión Fenosa (UNF), Vallermoso (VAL), Acerinox (ACX), Acciona (ANA) data respectively. We have considered the observations of the Wednesday prices as an estimate of the weekly prices. Hence, the return on the j- th asset during the k-th week is defined as $r_{kj} = (p_{(k+1)} - p_{kj})/p_{kj}$, where p_{kj} is the price of the j-th asset on the Wednesday of the k-th week. The used data base covers the period from January 1998 to March 2003. Table 1 contains the obtained results for two different risk levels R

end

with the same parameters p_f and p_g. The first column contains the assets apearing either in the crisp or the fuzzy solution. The other four columns contain the crisp and the fuzzy solution in both cases. The first one has a medium satisfaction level ($\lambda = 0.45$) whereas the second one has a very low one ($\lambda = 0.14$). This means that, in the first case, the fuzzy solution is an alternative solution that the investor should take into account, whereas, in the second one, the crisp solution cannot be substantially improved. The last two rows of the table contain the crisp and fuzzy returns and risks for the two cases. These risks measure also the efficiency of our metaheuristic: the optimal crisp solution should have a risk equal to the given one, and the near-optimal crisp solutions given by our metaheuristic have a risk level differing by a 0.54% and 0.19%, respectively, from the optimal one. The time used for the algorithm to obtain the solution to this problem is 1.61 seconds on average.

5 Conclusions

In this paper we have presented the problem of portfolio selection, which is a difficult problem to solve due to economic environment uncertainty and the problem of suitably reflecting decision maker desires in the model. We present an approach where the problem of fuzzy portfolio includes the subjective criteria of the decision maker to determine the level of risk that he or she is able to support and the level of satisfaction to be assigned to a possible increase in return.

We have proposed an exact method to solve the fuzzy model of the portfolio problem with the main idea of finding partially

feasible solutions involving slightly greater risk than that fixed by the decision maker, and to study the possibilities that they offer in order to improve the expected return.

We have also proposed a hybrid meta-heuristic to solve the fuzzy model for problems with medium or big size where the traditional methods become useless as they would need too much time due to the combinatorial explosion in the solution space. The proposed meta-heuristic uses a hybrid scheme, which combines ideas from the Simulated Annealing technique and genetic algorithms. To test the proposed meta-heuristic we have used several test problems based on dates of IBEX35, the best-known index of Spanish Stock Markets. The results allow us to verify that with the small problems the solutions are very similar to those obtained with the exact model. Moreover, our proposal allows us to work with big problems (large time series, intra-day data, etc.) and the time taken to get the results is about 1.6 seconds, achieving the goal we wanted to get with that meta-heuristic.

Abstract— *The Spanish National Agency for Quality Assessment and Accreditation as part of its evaluation activities has established a procedure for evaluating both teaching and institutions, by means of the Institutional Assessment Programme. In this communication we shall focus on the external assessment phase for qualifications in the field of Industrial Engineering and specifically on the structures of the database for a Decision Support System on the universities' rankings. In particular, this paper will focus on obtaining the weight of the criteria and definition of the linguistic labels used in the external assessment phase.*

Keywords— Analytical Hierarchy Process (AHP), Linguistic Labels, Qualification evaluation, Weighting Criteria

1 Introduction

The university rankings which just 20 years ago were an innovation are today a normal characteristic in the majority of countries with extensive systems of higher education [7, 13, 16, 17, 18]. These lists have an increasing impact not only between the universities themselves, but also between different social sectors.

University rankings are lists of certain groups of institutions, classified in comparative form, and according to a common set of indicators, in descending order.

Likewise, the reorganisation at European scale of university studies as a result of the Bologna Process, will contribute in an active way to the harmonisation of basic European academic aspects. This aspect will allow, on the one hand, for a better connection between universities and on another hand, for an easier comparison between them; for which certain indicators of functioning will be necessary.

All the above leads us to think about the need for the existence of global rankings of universities as an instrument to measure their quality rigorously [7, 16]. In this context, the Decision Support Systems (DSS), seem to be useful for the evaluation of the qualifications in the universities' ranking.

In this paper, we shall focus on the area of industrial engineering within the Spanish university system and on the structure of the Database as a fundamental element of the DSS.

The aim of the paper is the use of the fuzzy AHP process to obtain the weight of the criteria within a DSS in order to facilitate the process of evaluation on the universities' rankings.

Another aim is to obtain the fuzzy numbers associated with the linguistic labels used to evaluate the ANECA in the external assessment phase.

The paper is organised as follows: The next section introduces the ANECA process. Section 3 introduces the linguistic variables and fuzzy sets. In section 4, the framework for the AHP method is defined. Section 5 describes the database. Section 6 shows the aggregation results and finally we outline the most important conclusions.

2 The ANECA Process

In this sense and within the framework of the Institutional Assessment Programme (*Programa de Evaluación Institucional*, "PEI"), the Spanish National Agency for Quality Assessment and Accreditation (*Agencia Nacional de Evaluación de la Calidad y Acreditación "*ANECA") presents this Guide [2] with the purpose of showing the steps in the Process of Institutional Assessment

The primary objective of the Institutional Assessment Programme is to facilitate an assessment process to officially improve the quality of education leading to obtain university degrees throughout the national territory, through self-diagnosis and the external view brought by experts.

The development of this programme is intended to promote assessment processes favouring the establishment or continuity of processes guaranteeing quality in teaching, as well as providing information to the students and their families, to society, to the governing bodies of the universities and to public administrations, regarding the quality of university teaching and their action plans.

This process is organised in three phases, see figure 1:

- *Self-assessment:* the "Self-assessment Report" describes and evaluates the situation of the assessed degree with respect to the criteria established, identifying strengths and weaknesses and enhancement proposals forming the basis of execution of the action plans that must be initiated on conclusion of the entire process. The report is written by the Self-assessment Committee.

ISBN: 978-989-95079-6-8

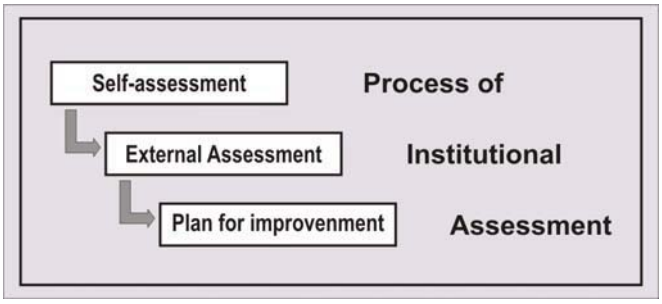

Figure 1: Phases of the Institutional Assessment Programme

- *External Assessment:* a group of external assessors to the teaching institution assessed, appointed by ANECA, and under its guidelines and supervision, analyzes the Self-Assessment Report, both through the study of documents and by means of a visit to the unit assessed, issues its recommendations, and proposes improvements. The result of this phase is the "External Assessment Report."

- *Plan for improvement*: it collects the main results of the Assessment process. This phase concludes with the plan for improvements of the degree, describing the proposed improvement actions in the Self-assessment and External Assessment phases, once their viability is analyzed. The tasks to be performed are determined according to their accomplishment, the persons responsible, resources involved, deadlines for their implementation, the indicators monitoring the actions proposed, and the benefits expected from them.

3 Linguistic variable and fuzzy sets

3.1 Linguistic variable

Most of the times, the decision-maker is not able to define the importance of the criteria or the goodness of the alternatives with respect to each criterion in a strict way. In many situations, we use measures or quantities which are not exact but approximate.

Since Zadeh [19] introduced the concept of fuzzy set and subsequently went on to extend the notion via the concept of linguistic variables, the popularity and use of fuzzy sets has been extraordinary. We are particularly interested in the role of linguistic variables as an ordinal scale and their associated terms, in this case triangular fuzzy number, as used in the multi-criteria decision making.

By a *linguistic variable,* [20,21,22], we mean a variable whose values are words or sentences in a natural or artificial language. For example *Age* is a linguistic variable if its values are linguistic rather than numerical, i.e., *young, not young, very young, quite young, old, not very old and not very young*, etc., rather than numbers as 20, 21,22, 23,.... .

Definition.1- A linguistic variable is characterized by a quintuple

$$\{X;T(X);U;G;M\}$$

in which

1. X is the name of the variable,
2. $T(X)$ is the term set of X, that is, the collection of its linguistic values
3. U is a universe of discourse,
4. G is a syntactic rule for generating the elements of $T(X)$ and
5. M is a semantic rule for associating meaning with the linguistic values of X.

In general for the decision-maker it is easier when he/she evaluates their judgments by means of linguistic terms. In those cases, the concept of fuzzy number is more adequate than that of real number.

3.2 Fuzzy sets

Then we have identified the linguistic variable with a fuzzy set [3,10,11]. The fuzzy set theory, introduced by Zadeh [19] to deal with vague, imprecise and uncertain problems has been used as a modelling tool for complex systems that can be controlled by humans but are hard to define precisely. A collection of objects (universe of discourse) X has a fuzzy set A described by a membership function f_A with values in the interval $[0,1]$.

$$f_A : X \to [0,1]$$

Thus A can be represented as $A = \{f_A(x) \mid x \in X\}$. The degree that u belongs to A is the membership function $f_A(x)$.

The basic theory of the triangular fuzzy number is described in Klir [12].

With regard to the fuzzy numbers, we will show only the mathematical operations that will be used throughout the development of the paper.

Definition 2. If T_1 and T_2 are two triangular fuzzy numbers defined by the triplets (a_1,b_1,c_1) and (a_2,b_2,c_2), respectively. Then, for this case, the necessary arithmetic operations with positive fuzzy numbers are:

a) Addition

$$T_1 \oplus T_2 = [a_1 + a_2, b_1 + b_2, c_1 + c_2] \quad (1)$$

b) Subtraction

$T_1 \Theta T_2 = T_1 + (-T_2)$ when the opposite

$-T_2 = (-c_2, -b_2, -a_2)$

$$\text{then} \quad T_1 \Theta T_2 = [a_1 - c_2, b_1 - b_2, c_1 - a_2] \quad (2)$$

c) Multiplication

$$T_1 \otimes T_2 = [a_1 \times a_2, b_1 \times b_2, c_1 \times c_2] \quad (3)$$

d) Division

$$T_1 \varnothing T_2 = [[a_1,b_1,c_1] \cdot [1/c_2, 1/b_2, 1/a_2]], \quad 0 \neq [a_2,b_2,c_2] \quad (4)$$

e) Scalar Multiplication

$$k \circ T_1 = (k \circ a_1, k \circ b_1, k \circ c_1) \quad (5)$$

ISBN: 978-989-95079-6-8

4 The Analytic Hierarchy Process Method (AHP)

The Analytic Hierarchy Process (AHP methodology [14,15] has been accepted by the international scientific community as a robust and flexible multi-criteria decision making tool for dealing with complex decision problems. AHP has been applied to numerous decision problems such as energy policy [1,7], project selection [6], measuring business performance [1], and evaluation of advanced manufacturing technology [4,5].

- Basically, AHP has three underlying concepts: Structuring the complex decision problem as a hierarchy of goal, criteria and alternatives,
- Pair-wise comparison of elements at each level of the hierarchy with respect to each criterion on the preceding level,
- and finally vertically synthesizing the judgements over the different levels of the hierarchy.

AHP attempts to estimate the impact of each one of the alternatives on the overall objective of the hierarchy. In this case, we only apply the method in order to obtain the criteria's weights.

We assume that the quantified judgements provided by the decision-maker on pairs of criteria (C_i, C_j) are represented in an *nxn* matrix as in the following:

$$C = \begin{array}{c} \\ C_1 \\ C_2 \\ . \\ . \\ C_n \end{array} \begin{array}{c} \begin{array}{cccc} C_1 & C_2 & \cdots & C_n \end{array} \\ \begin{bmatrix} c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & c_{22} & \ldots & c_{2n} \\ . & . & \ldots & . \\ . & . & \ldots & . \\ c_{n1} & c_{n2} & \ldots & c_{nn} \end{bmatrix} \end{array} \quad (6)$$

The c_{12} value is supposed to be an approximation of the relative importance of C_1 to C_2, i.e., $c_{12} \approx (w_1/w_2)$. This can be generalized and the statements below can be concluded:

1. $c_{ij} \approx (w_i/w_j)$ $i,j=1, 2, ..., n$
2. $c_{ii}=1$, $i=1,2,...,n$
3. If $c_{ij}=\alpha$, $\alpha \neq 0$, then $c_{ji}=1/\alpha$, $i=1,2,...,n$
4. If C_i is more important than C_j then $c_{ij} \cong (w_i/w_j)>1$

This implies that matrix *A* should be a positive and reciprocal matrix with 1's in the main diagonal and hence the decision-maker needs only to provide value judgements in the upper triangle of the matrix. The values assigned to c_{ij} according to Saaty scale are usually in the interval of 1-9 or their reciprocals.

It can be shown that the number of judgements (*L*) needed in the upper triangle of the matrix are:

$$L = n(n-1)/2 \quad (7)$$

where *n* is the size of the matrix *C*.

The matrixes associated to the AHP approach are reciprocal, thus:

- The maximum eigenvalue (λ_{max}) is a positive real number and such that $\lambda_{max} \geq n$.
- Associated with this eigenvalue is a vector whose components are also positive. If this vector is normalized the vector of weights associated with the matrix is obtained.

Where the values are fuzzy, not crisp; instead of using lambda as an estimator to the weight, we will use the geometric normalized average, expressed by the following expression:

$$w_i = \frac{\prod_{j=1}^{n}(a_{ij}, b_{ij}, c_{ij})}{\sum_{i=1}^{m}\prod_{j=1}^{n}(a_{ij}, b_{ij}, c_{ij})} \quad (8)$$

where, (a_{ij}, b_{ij}, c_{ij}) is a fuzzy number.

5 The database

The Database has two parts. The first part consists of the summary of the different Reports of External Evaluation, published by ANECA. These reports are given by the members of the External Assessment Committee who are persons qualified by ANECA; the valuation given by the external assessors is impartial.

The second part of the database, which is the focus of this paper, corresponds with obtaining the weights of the criteria, as well as the numerical representation of the labels. See Figure 2.

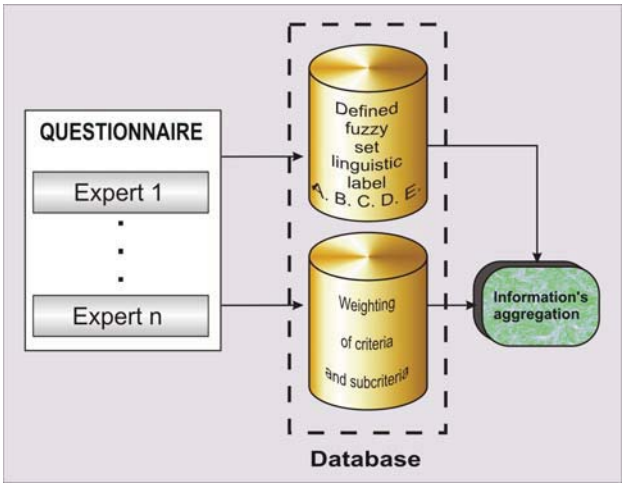

Figure 2: The database corresponding to this part of the work.

The study carried out has been based on a questionnaire designed to such effect. ANECA itself sent the questionnaire to the experts that it determined as proper assessors. The questionnaire was sent / answered by e-mail.

This questionnaire consists of two clearly differentiated parts;

- The first one has been produced on the basis of the hierarchic structure of the criteria and subcriteria (Table 1), using the AHP methodology to do so.
- The second part refers to the linguistic labels used in the ANECA survey for the external evaluation of university qualifications.

Likewise, we will take into account the possible valuations of the experts, expressed in linguistic terms (A, B, C, D) These labels are arranged from largest to smallest as follows: A > B > C > D and with the semantics that we will see later.

It should be remembered that the results obtained correspond to a problem of group decision-making, formed by *n* experts, from whom we will obtain:

1.-The criteria weight as a result of the consensus

2.- The membership functions of the fuzzy numbers that represent the linguistic labels A,B,C and D.

5.1 Obtaining the weightings of the criteria/subcriteria

According to Table 1, the hierarchy structure has three levels. Considering expression (7), the large number of questions might lead to the survey not being answered, since L = 74, as we have 6 in 1st level criteria, subcriteria 16 in 2nd level and 37 in 3rd level indicators. This results in a questionnaire which is not feasible for experts to answer.

For this, and since the influence of the third level on the weight of the previous ones is practically null, a uniform distribution on them was supposed.

ISBN: 978-989-95079-6-8

For the first and second level, the procedure is as follows: firstly, we ask if all the criteria/subcriteria have the same weight, if so, we pass to the following level.

On the contrary, if they do not have the same weight, it will be continued by the following question of the questionnaire.

In this part, there is a question that asking about the order of importance of the criteria/subcritera; and finally, using the linguistic labels defined by Saaty [14], the criteria/subcriteria are compared at the same level, taking into account the order established before.

We chose to ask only for one row of the pairwise matrix and from here to generate the rest of the information matrix, which was carried out completely consistently. Thus, this part of the questionnaire had only 21 questions.

5.2 Obtaining the linguistic evaluations

The second part of the questionnaire is based on the semiquantitative survey of the Evaluation of the Education inside the protocol to elaborate the Report of External Evaluation developed by ANECA, in which the following labels are used: A: Excellent, B: Good, C: Average, D: Deficient. For the valuation of these labels we use the interval [0, 10].

These linguistic variables, by the uncertainty of their nature, justified the use of fuzzy numbers associated with each linguistic term.

6 The results of the aggregation for the group decision experts

By means of a primary group decision-making process, it is possible to see the results of the weighting of the criteria and sub-criteria for all the experts (Table 1).

Table 2. Fuzzy numbers associated with the labels A,B,C and D.

Semi quantitative labels	General
A: Excellent	(8.1354, 9.4054, 10.0000)
B: Good	(5.8108, 7.1081, 8.4054)
C: Average	(3.5090, 4.8108, 6.1126)
D: Deficient	(0.7355, 2.5135, 4.2916)

Now, taking these weightings as the base; and the definition of semiquantitative labels (Table 2), obtained by ANECA's own experts, it is possible for us, attending to these six criteria, to order the different Universities. We make reference, in this case, only to the area of industrial engineering.

For the evaluation of the alternatives the methodology used has been the fuzzy weighted sum model as:

$$FWSM = \sum_{j=1}^{n} \tilde{w}_j \cdot \tilde{a}_{ij} \qquad (9)$$

where, $\tilde{w}_j$ and $\tilde{a}_{ij}$ are fuzzy numbers.

The defuzzification method used is described in [8] when:

$$I_{\beta,\lambda}(A_i) = \beta S_M(A_i) + (1-\beta)\lambda S_R(A_i) + (1-\beta)(1-\lambda) S_L(A_i)$$

In this way, we have defined a fuzzy number as a function of the three integrals, $S_L(A_i)$, $S_M(A_i)$ and $S_R(A_i)$, where $S_R(A_i)$ represents the upper mean value associated with the inverse function of $f_A^R(x)$, $S_L(A_i)$ is the lower mean value of the $g_A^L(x)$ function and $S_M(A_i)$ is the area of the core of the fuzzy number, $\beta \in [0,1]$ is the index of modality that represents the importance of the central value against the extreme values, and $\lambda \in [0,1]$ is the degree of optimism of the decision maker.

We have considered the case in which the three areas have the same weight and it would correspond to the neutral decision maker, when $\alpha = 1/2$ y $\beta = 1/3$

Taking as an example (Table 3), the outcome results of the DSS, for the real case of the evaluation of five universities in the qualifications of industrial engineering, where we have obtained results both for the principal criteria and for the global evaluation.

Table 3: Ranking result for five Universities.

Criteria	C1 Educational Programme	C2 Teaching Organizatio	C3 Human Resources	C4 Material Resources	C5 Educational Process	C6 Results	IAP Gobal
U1	0.062	0.033	0.071	0.040	0.042	0.056	0.306
U2	0.100	0.067	0.106	0.049	0.055	0.089	0.466
U3	0.129	0.086	0.105	0.067	0.098	0.119	0.604
U4	0.118	0.080	0.088	0.038	0.075	0.081	0.482
U5	0.125	0.089	0.105	0.047	0.082	0.100	0.548

7 Conclusions

For the assessors/experts it is simpler to express their knowledge by means of linguistic labels, instead of having to do so by means of numerical values. For that reason, it is preferable to prepare a questionnaire to obtain the experts' knowledge, in which the answers are in the form of linguistic variables. These linguistic variables have been modelized by means of fuzzy triangular numbers and from a methodology widely accepted by the scientific community, since it is the Analytical Hierarchic Process; developed by Saaty in 1980.

Taking Table 1into account, we conclude that in general the most important criterion is the Educational Programme and that the lowest weighting is obtained for the Material Resources.

For future work, it would be interesting to carry out a study of the aggregation of the information as a secondary process. In this process the weight of the criteria and subcriteria are obtained for every expert. Later all this information would be aggregated.

Moreover, a comparative primary and secondary study of both types of processes would be desirable.

ISBN: 978-989-95079-6-8

Similarly, as future work, it would be interesting to make a comparative study of the evaluation criteria according to the area of the different experts. It is possible that the valuation of an expert from the area of engineering does not value the criteria in the same way as another from the humanities.

Multiple-Criteria Fuzzy Evaluation: The FuzzME Software Package

Jana Talašová[1] Pavel Holeček[2]

1., 2. Faculty of Science, Palacký University Olomouc
tř. Svobody 26, 771 46 Olomouc, Czech Republic
Email: talasova@inf.upol.cz, holecekp@inf.upol.cz

Abstract— *This paper introduces a new software product FuzzME. It was developed as a tool for creating fuzzy models of multiple-criteria evaluation and decision making. The type of evaluations employed in the fuzzy models fully corresponds with the paradigm of the fuzzy set theory; the evaluations express the (fuzzy) degrees of fulfillment of corresponding goals. The FuzzME software takes advantage of linguistic fuzzy modeling to the maximum extent. In the FuzzME software, both quantitative and qualitative criteria can be used. The basic structure of evaluation is described by a goals tree. Within the goals tree, aggregation of partial fuzzy evaluations is done either by one of fuzzified aggregation operators (fuzzy weighted average, ordered fuzzy weighted average) or by a fuzzy expert system.*

The paper contains an illustrative example of the software usage. The application concerns a soft-fact-rating problem that was solved in one of Austrian banks.

Keywords— Fuzzy expert system, Fuzzy OWA operator, Fuzzy weighted average, Multiple-criteria fuzzy evaluation, Normalized fuzzy weights, Software.

1 Introduction

In practice, sophisticated models of multiple-criteria evaluation are required (e.g. rating of clients in banks, evaluation of hospitals or universities, comparison of alternative solutions to ecological problems). For creating the evaluating models, setting some of their input data and interpreting their outputs, expert's knowledge is needed (e.g. evaluations of alternatives according to qualitative criteria, partial evaluating functions for quantitative criteria, a choice of a suitable type of aggregation, criteria weights, or eventually, a rule base describing the relation between criteria values, the overall evaluation and a linguistic description of obtained results). Because uncertainty is the typical feature of any expert information, the fuzzy set theory is a suitable mathematical tool for creating such models. For the practical use of the fuzzy models of multiple-criteria evaluation, their user-friendly software implementation is necessary. But a good theoretical basis of the used models is crucial, too. The clear and well-elaborated theory of multiple-criteria fuzzy evaluation makes it possible to create an understandable methodics for the software user. And a good methodics is essential for correct application of any software to solving real problems.

There is a large number of papers and books dealing with the theory and methods of multiple-criteria evaluation that make use of the fuzzy approach (e.g. [1], [2], [3], [4]). Multiple-criteria evaluation (as a basis of decision making) was even one of the earliest applications of fuzzy sets (see [1]). In more than 40 years of existence of the fuzzy sets theory, several software products for multiple-criteria decision making, which use the fuzzy modeling principles in different degrees and in different ways, have been developed. In practice, FuzzyTECH (see [5]) is probably the best-known of these. It enables to use the specific instruments of the fuzzy set theory for solving multiple-criteria evaluation and decision making problems. Generally, FuzzyTECH is a universal software product which makes it possible to create and use fuzzy expert systems (or fuzzy controllers). It also includes the possibility to derive fuzzy rule bases from given data by means of neural network algorithms. In the book [6], there were described many successful applications of this software to solving multiple-criteria evaluation and decision making problems in the areas of business and finance. Similarly, fuzzy toolboxes of general mathematical systems such as Matlab can be used for multiple-criteria decision making.

The FuzzME software (**Fuzz**y models of **M**ultiple-criteria **E**valuation), presented in this paper, is based on a theoretical concept of evaluation which is very close to the original Zadeh's ideas. Similarly to his paper [1], the evaluations of alternatives according to particular criteria represent their degrees of fulfillment of the corresponding partial goals. Besides evaluations expressed by real numbers in $[0, 1]$, fuzzy evaluations modeled by fuzzy numbers on the same interval are employed in the software. They represent, analogously, the fuzzy degrees of fulfillment of the partial goals which are connected to the criteria. Resulting fuzzy evaluations, which are obtained by aggregation, have a similar clear interpretation. This theoretical approach to (fuzzy) evaluation was published in the book [7] and in the paper [8].

The predecessor of the FuzzME software package in terms of the used theoretical basis was the NEFRIT software. This software for multiple-criteria evaluation and decision making, which is also based on fuzzy technologies, was developed in about 2000 by the Czech software company TESCO SW Inc. The fuzzy model of evaluation applied there is described in detail in [8] and in the book [7] (a demo version of NEFRIT is enclosed in the book). NEFRIT makes it possible to work with expert fuzzy evaluations of alternatives according to qualitative criteria. Values of the quantitative criteria can either be crisp or fuzzy. Evaluating functions for quantitative criteria represent membership functions of corresponding partial goals. The main evaluation structure is expressed by a goals tree. For aggregation of the partial fuzzy evaluations the weighted average method is used. The weights (crisp only, not fuzzy) express the shares of partial evaluations in the

ISBN: 978-989-95079-6-8

aggregated one. Fuzzy evaluations on all levels of aggregation express the fulfillment of the corresponding goals. The NEFRIT software was originally developed for the Czech National Bank (decision making about granting a credit). Further, it was used e.g. by the Czech Tennis Association, the Czech Basketball Association and in other institutions. Nowadays it is tested by the Supreme Audit Office of the Czech Republic.

In contrast to NEFRIT, the FuzzME software makes it possible to use also uncertain weights in the aggregation by means of the weighted average method. The theory of normalized fuzzy weights, procedures for their setting, and an effective algorithm for calculation of fuzzy weighted average are taken from [9], [10] and [11]. Another fuzzy aggregation operator, available in the FuzzME software, is a fuzzified OWA operator. Again, it works with normalized fuzzy weights. The fuzzy OWA operator and the used algorithm for its calculation are described in [12]. In the FuzzME software, multiple-criteria evaluating functions can also be defined by means of fuzzy rule bases. In accordance with [7], two algorithms are offered for the approximate reasoning - the standard Mamdani algorithm and a modified Sugeno algorithm.

There are also software tools for multiple-criteria decision making based on other mathematical methods. But they are usually designed for solving a particular assignment. Our investigation by means of Internet did not result software fully comparable to FuzzME. Its universality and comprehensiveness make it unique.

2 Preliminaries

A fuzzy set A on a universal set X is characterized by its membership function $A : X \to [0,1]$. $Ker\ A$ denotes a kernel of A, $Ker\ A = \{x \in X \mid A(x) = 1\}$. For any $\alpha \in [0,1]$, A_α denotes an α-cut of A, $A_\alpha = \{x \in X \mid A(x) \geq \alpha\}$. A support of A is defined as $Supp\ A = \{x \in X \mid A(x) > 0\}$. The symbol $hgt\ \ A$ denotes a height of the fuzzy set A, $hgt\ A = \sup\{A(x) \mid x \in X\}$. An intersection and a union of the fuzzy sets A and B on X are defined for all $x \in X$ by the following formulas: $(A \cap B)(x) = \min\{A(x), B(x)\}$, $(A \cup B)(x) = \max\{A(x), B(x)\}$.

A fuzzy number is a fuzzy set C on the set of all real numbers $\Re$ which satisfies the following conditions: a) the kernel of C, $Ker\ C$, is not empty, b) the α-cuts of C, C_α, are closed intervals for all $\alpha \in (0,1]$, c) the support of C, $Supp\ C$, is bounded. A fuzzy number C is called to be defined on $[a,b]$, if $Supp\ C \subseteq [a,b]$. Real numbers $c^1 \leq c^2 \leq c^3 \leq c^4$ are called significant values of the fuzzy number C if the following holds: $[c^1, c^4] = Cl(Supp\ C), [c^2, c^3] = Ker\ C$, where $Cl(Supp\ C)$ denotes a closure of $Supp\ C$.

Any fuzzy number C can be characterized by a pair of functions $\underline{c} : [0,1] \to \Re$, $\overline{c} : [0,1] \to \Re$ which are defined by the following formulas: $C_\alpha = [\underline{c}(\alpha), \overline{c}(\alpha)]$ for all $\alpha \in (0,1]$, and $Cl(Supp\ C) = [\underline{c}(0), \overline{c}(0)]$. The fuzzy number C is called to be linear if both the functions $\underline{c}$, $\overline{c}$ are linear. A linear fuzzy number is fully determined by its significant values because $\underline{c}(\alpha) = (c_2 - c_1) \cdot \alpha + c_1$, $\overline{c}(\alpha) = (c_3 - c_4) \cdot \alpha + c_4$. For that reason, we can denote it as $C = (c^1, c^2, c^3, c^4)$.

An ordering of fuzzy numbers is defined as follows: a fuzzy number C is greater than or equal to a fuzzy number D, if $C_\alpha \geq D_\alpha$ for all $\alpha \in (0,1]$.

A fuzzy scale makes it possible to represent a closed interval of real numbers by a finite set of fuzzy numbers. Let $T_1, T_2, ..., T_s$ be fuzzy numbers defined on $[a,b]$, forming a fuzzy partition on the interval, i.e., for all $x \in [a,b]$ the following holds

$$\sum_{i=1}^{s} T_i(x) = 1, \tag{1}$$

then the set of the fuzzy numbers can be linearly ordered (see [7]). If the fuzzy numbers $T_1, T_2, ..., T_s$ are defined on $[a,b]$, form a fuzzy partition on the interval and are numbered according to their linear ordering, then they are said to form a fuzzy scale on $[a,b]$.

An uncertain division of the whole into m parts can be modeled by normalized fuzzy weights. Fuzzy numbers $V_1, ..., V_m$ defined on $[0,1]$ are normalized fuzzy weights if for any $i \in \{1, ..., m\}$ and any $\alpha \in (0,1]$ it holds that for any $v_i \in V_{i\alpha}$ there exist $v_j \in V_{j\alpha},\ j = 1, ..., m,\ j \neq i$, such that

$$v_i + \sum_{j=1, j\neq i}^{m} v_j = 1. \tag{2}$$

3 The FuzzME software

The mathematical models of the FuzzME software are based primarily on the theory and methods of multiple-criteria evaluation that were published in [7] and [8]. The theory of normalized fuzzy weights, the definition of fuzzy weighted average, and the algorithm for its computation were taken from [9], [10] and [11]. The fuzzified OWA operator and the algorithm for its calculation published in [12] are also used in the software.

In the FuzzME software, the basic structure of the fuzzy model of multiple-criteria evaluation is expressed by a goals tree. The root of the tree represents the overall goal of evaluation and each branch corresponds to a partial goal. The goals at the ends of branches are connected either with quantitative or qualitative criteria.

When an alternative is evaluated, evaluations with respect to criteria connected with the terminal branches are calculated first. Independently of the criterion type, each of the evaluations is described by a fuzzy number defined on the interval $[0,1]$. It expresses the fuzzy degree of fulfillment of the corresponding partial goal.

These partial fuzzy evaluations are then aggregated according to the defined type of the tree node. Three types of aggregation are available: a fuzzy weighted average (fuzzy WA), an ordered fuzzy weighted average (fuzzy OWA) or aggregation by means of a fuzzy expert system. For aggregation by fuzzy weighted average or ordered fuzzy weighted average, normalized fuzzy weights must be set. The weights express uncertain shares of the partial evaluations in the aggregated one. For the fuzzy expert system, the fuzzy rule base must be defined and an inference algorithm must be chosen (either the Mamdani algorithm or the generalized Sugeno algorithm of approximate reasoning).

The overall evaluation reflects the degree of fulfillment of the main goal. A verbal description of the overall evaluation can be obtained by means of the implemented linguistic approximation algorithm.

ISBN: 978-989-95079-6-8

The overall evaluations can be compared within the frame of a given set of alternatives. By this comparison the best of the alternatives can be chosen. That is why the FuzzME software can be also used as a decision support system.

The import and export of data is supported by the software, too. The FuzzME software is available in the Czech and English versions.

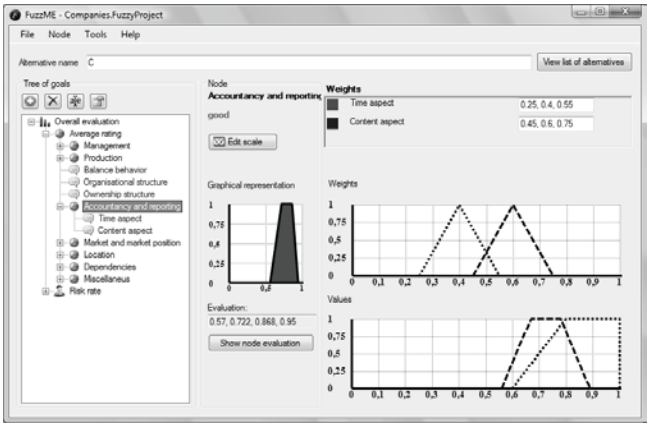

Figure 1: The main window of the software

3.1 Goals tree

Goals trees represent the basic structure of fuzzy models of multiple-criteria evaluation in the FuzzME software. When a goals tree is designed, the main goal is consecutively divided into goals of progressively lower levels. The process of division is stopped when such goals are reached whose fulfillment can be assessed by means of some known characteristics of alternatives (i.e. quantitative or qualitative criteria).

The design of a tree structure in the goals-tree editor is the first step in forming a fuzzy evaluation model in FuzzME. In the next step, the type of each node in the tree must be specified. For the nodes at the ends of tree branches the user defines if the node is connected with a quantitative or qualitative criterion. For the other nodes he/she sets the type of aggregation - fuzzy weighted average, ordered fuzzy weighted average or fuzzy expert system. An example of a goals tree is illustrated in Fig. 2.

3.2 Criteria of evaluation

In the models of evaluation created by the FuzzME software, qualitative and quantitative criteria can be combined arbitrarily.

3.2.1 Qualitative criteria

According to qualitative criteria, alternatives are evaluated verbally, by means of values of linguistic variables of special kinds - linguistic scales, extended linguistic scales and linguistic scales with intermediate values.

A linguistic variable is defined as a quintuple $(\mathcal{V}, \mathcal{T}(\mathcal{V}), X, G, M)$, where $\mathcal{V}$ is a name of the variable, $\mathcal{T}(\mathcal{V})$ is a set of its linguistic values, X is a universal set on which the meanings of the linguistic values are defined, G is a syntactic rule for generating values in $\mathcal{T}(\mathcal{V})$, and M is a semantic rule which maps each linguistic value $\mathcal{C} \in \mathcal{T}(\mathcal{V})$ to its mathematical meaning, $C = M(\mathcal{C})$, which is a fuzzy set on X.

A linguistic scale on $[a, b]$ is a special case of the linguistic variable $(\mathcal{V}, \mathcal{T}(\mathcal{V}), X, G, M)$, where $X = [a, b]$, $\mathcal{T}(\mathcal{V}) = \{\mathcal{T}_1, \mathcal{T}_2, ..., \mathcal{T}_s\}$ and the meanings of the linguistic values $\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_s$ are modeled by fuzzy numbers $T_1, T_2, \ldots, T_s$ which form a fuzzy scale on $[a, b]$. As the set of linguistic values of the scale is defined explicitly, it is not necessary to include the grammar G into the scale notation.

In the FuzzME software, the user defines a linguistic scale for each qualitative criterion in the fuzzy-scale editor. For example, the linguistic scale *quality of a product* can contain linguistic values *poor*, *substandard*, *standard*, *above standard* and *excellent*. The evaluating linguistic scale is usually defined on $[0, 1]$; in other cases, it has to be transformed to this interval.

The extended linguistic scale contains, besides elementary terms of the original scale, $\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_s$, also derived terms in the form $\mathcal{T}_i$ *to* $\mathcal{T}_j$, where $i < j, i, j \in \{1, 2, \ldots, s\}$. For example, the user can evaluate *quality of a product* by the linguistic term *standard to excellent*. The meaning of the linguistic value $\mathcal{T}_i$ *to* $\mathcal{T}_j$ is modeled by $T_i \cup_L T_{i+1} \cup_L \cdots \cup_L T_j$, where $\cup_L$ denotes the union of fuzzy sets based on the Lukasiewicz disjunction; e.g. $(T_i \cup_L T_{i+1})(x) = \min\{1, T_i(x) + T_{i+1}(x)\}$ for all $x \in \Re$.

The linguistic scale with intermediate values is the original linguistic scale enriched with derived terms *between* $\mathcal{T}_i$ *and* $\mathcal{T}_{i+1}$, $i \in \{1, 2, \ldots, s-1\}$. The meaning of the derived term *between* $\mathcal{T}_i$ *and* $\mathcal{T}_{i+1}$ is modeled by the arithmetic average of the fuzzy numbers T_i and T_{i+1}.

In the FuzzME software, the user evaluates a given alternative according to a qualitative criterion by selecting a proper linguistic evaluation from a drop-down list box. He/she can choose the value from a standard linguistic scale, extended scale or scale with intermediate values.

The three mentioned structures of linguistic values are also applied when resulting fuzzy evaluations are approximated linguistically.

3.2.2 Quantitative criteria

The evaluation of an alternative with respect to a quantitative criterion is calculated from the measured value of the criterion by means of the evaluating function expertly defined for the criterion. The evaluating function is the membership function of the corresponding partial goal. The FuzzME software admits both crisp and fuzzy values of quantitative criteria. The fuzzy values represent inaccurate measurements or expert estimations of the criteria values. In the case of a fuzzy value, the corresponding partial fuzzy evaluation is calculated by the extension principle.

In the FuzzME software, the evaluating function of a quantitative criterion is formally set by means of a fuzzy number. For example, if the evaluating function is defined by a linear fuzzy number $F = (f_1, f_2, f_3, f_4)$, then f_1 is the lower limit of all at least partly acceptable values of the criterion, f_2 is the lower limit of its fully satisfactory values, f_3 is the upper limit of the fully satisfactory values, and f_4 is the upper limit of the acceptable values.

For example, when a bank evaluates expected profitability of projects, the evaluating function can be defined by a linear fuzzy number with significant values 10, 30, 500, 500. In that case, values lower than 10% are not satisfying at all (the client

ISBN: 978-989-95079-6-8

would not be able to pay the money back to the bank). For the values from 10% to 30% the satisfaction of the bank is growing linearly. Values greater than 30% are fully satisfactory from the bank's point of view. Values greater than 500% are not supposed to occur. This way we can define a monotonous evaluating function, which is the most common in the evaluating models, by a fuzzy number.

3.3 Methods of aggregation of partial evaluations

The calculated partial fuzzy evaluations are then consecutively aggregated according to the structure of the goals tree. With respect to the defined type of the tree node, the fuzzy weighted average method, the ordered fuzzy weighted average method or the fuzzy expert system method is used for the aggregation. Each of the aggregation methods is suitable for a different situation:

The fuzzy weighted average is used if the goal corresponding with the node of interest is fully decomposed into disjunctive goals of the lower level. The normalized fuzzy weights represent uncertain shares of these lower-level goals in the goal corresponding with the considered node.

Again, the ordered fuzzy weighted average requires that the goal corresponding with the given node is decomposed into disjunctive goals of the lower level. In contrast to the fuzzy weighted average, the usage of this aggregation operator supposes special user's requirements concerning the structure of partial fuzzy evaluations. The normalized fuzzy weights again represent uncertain shares of the partial evaluations in the aggregated one. But the normalized fuzzy weights are not linked to the individual partial goals; the correspondence between the weights and the partial evaluations is given by the ordering of partial evaluations of the alternative of interest. It means, evaluations with respect to the same partial goal can have different weights for different alternatives.

If the relationship between the evaluations of the lower level and the evaluation corresponding with the given node is more complex (if neither of the two previous methods can be used), and if expert knowledge about the relationship is available, then the aggregation function is described by a fuzzy rule base of a fuzzy expert system. The approximate reasoning is used to calculate the resulting evaluation. In particular, evaluating function described by a fuzzy expert system is used if the fulfillment of a goal at the end of a tree branch depends on several mutually dependent criteria (i.e., if combinations of criteria values bring synergic or disynergic effects to the resulting multiple-criteria evaluation).

3.3.1 Fuzzy weighted average

If the fuzzy weighted average is used for aggregation of partial fuzzy evaluations, then the uncertain weights of the corresponding partial goals, which express their shares in the superior goal, must be set. To define consistent uncertain weights, a special structure of fuzzy numbers, normalized fuzzy weights, must be used.

In the FuzzME software, both real and fuzzy normalized weights can be used. Normalized real weights, i.e., real numbers $v_1, ..., v_m$, $v_j \geq 0$, $j = 1, ..., m$, $\sum_{j=1}^{m} v_j = 1$, represent a special case of the normalized fuzzy weights.

The fuzzy weighted average of the partial fuzzy evaluations, i.e., of fuzzy numbers $U_1, ..., U_m$ defined on $[0, 1]$, with the normalized fuzzy weights $V_1, \ldots, V_m$, is a fuzzy number U on $[0, 1]$ whose membership function is defined for any $u \in [0, 1]$ as follows

$$U(u) = \max\{\min\{V_1(v_1), ..., V_m(v_m), U_1(u_1), ..., U_m(u_m)\} \mid \sum_{i=1}^{m} v_i u_i = u,\ \sum_{i=1}^{m} v_i = 1,\ v_i, u_i \in [0, 1], i = 1, ..., m\}. \quad (3)$$

For an expert who sets the fuzzy weights, it is not so easy to satisfy the condition of normality. That is why the FuzzME software allows to set only an approximation to the normalized fuzzy weights - fuzzy numbers $W_1, ..., W_m$ on $[0, 1]$ satisfying the following weaker condition

$$\exists w_i \in Ker\ W_i,\ i = 1, ..., n : \sum_{i=1}^{n} w_i = 1. \quad (4)$$

The software removes the potential inconsistence in $W_1, ...,$ W_m and derives the normalized fuzzy weights $V_1, ..., V_m$ from them.

The structure of normalized fuzzy weights and the fuzzy weighted average operation are studied in detail in [9], [10] and [11]. Conditions for verifying normality of fuzzy weights, an algorithm for normalization of fuzzy weights satisfying the condition (4), and an algorithm for calculating fuzzy weighted average, which are all used in the FuzzME software, can be found there. Let us notice, that the used algorithm of fuzzy weighted average calculation is very effective.

3.3.2 Ordered fuzzy weighted average

The fuzzy OWA operator is used in case that the evaluator has special requirements concerning the structure of the partial evaluation. For example, he/she does not want any partial goal to be satisfied poorly. Then the weight of the minimum partial evaluation of any alternative equals 1, and the weights of all its other partial evaluations equal 0. The aggregated fuzzy evaluations then represent the guaranteed fuzzy degrees of fulfillment of all the partial goals (the fuzzy MINIMAX method). Another example of the fuzzy OWA operator usage could be the evaluation of subjects who can choose in which of the three areas they will be mostly involved. The evaluation algorithm should take into account their right of choice. Then, e.g., the results in the area where the subject performs best contribute to the overall evaluation by about one half, results from the second area by one third and results from the area in which the subject was least involved contribute to the overall evaluation only by one sixth. A practical application of such a fuzzy evaluation model could be the overall evaluation of the academic staff with respect to their results in the areas of research, education, and management of education and science.

The ordered fuzzy weighted average represents a fuzzification of the crisp OWA operator by means of the extension principle. Uncertain weights are modeled by normalized fuzzy weights as in the case of fuzzy weighted average.

The following notation will be used to define the ordered fuzzy weighted average: if $(x_1, ..., x_m)$ is a vector of real numbers, then $(x^{(1)}, ..., x^{(m)})$ is a vector in which for all $j \in \{1, \ldots, m\}$, $x^{(j)}$ is the j-th greatest number of $x_1, ..., x_m$.

The ordered fuzzy weighted average of the partial fuzzy evaluations, i.e., of fuzzy numbers $U_1, ..., U_m$ defined on

ISBN: 978-989-95079-6-8

$[0,1]$, with the normalized fuzzy weights $V_1, \ldots, V_m$, is a fuzzy number U on $[0,1]$ whose membership function is defined for any $u \in [0,1]$ as follows

$$U(u) = \max\{\min\{V_1(v_1), ..., V_m(v_m), U_1(u_1), ..., U_m(u_m)\} \mid \sum_{i=1}^{m} v_i u^{(i)} = u,\ \sum_{i=1}^{m} v_i = 1,\ v_i, u_i \in [0,1], i = 1, ..., m\}. \quad (5)$$

The algorithm used to calculate the ordered fuzzy weighted average in the FuzzME software was taken from [12], where fuzzification of the OWA operator is described in detail. The used algorithm is an analogy to the one used for the fuzzy weighted average.

3.3.3 Fuzzy expert system

The fuzzy expert system is used if the relationship between the criteria (or the partial evaluations) and the overall evaluation is complicated. Theoretically, it is possible to model, with an arbitrary precision, any Borel measurable function by means of a fuzzy rule base (properties of Mamdani and Sugeno fuzzy controllers, see e.g. [13]) In reality, the quality of the approximation is limited by the expert's knowledge of the relationship.

If the fuzzy rule base models the relation between values of criteria and the fulfillment of the corresponding partial goal, then the evaluation function is of the following form

$$\begin{aligned} &\text{If } \mathcal{C}_1 \text{ is } \mathcal{A}_{1,1} \text{ and } \ldots \text{ and } \mathcal{C}_m \text{ is } \mathcal{A}_{1,m}, \text{then } \mathcal{E} \text{ is } \mathcal{U}_1 \\ &\text{If } \mathcal{C}_1 \text{ is } \mathcal{A}_{2,1} \text{ and } \ldots \text{ and } \mathcal{C}_m \text{ is } \mathcal{A}_{2,m}, \text{then } \mathcal{E} \text{ is } \mathcal{U}_2 \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ &\text{If } \mathcal{C}_1 \text{ is } \mathcal{A}_{n,1} \text{ and } \ldots \text{ and } \mathcal{C}_m \text{ is } \mathcal{A}_{n,m}, \text{then } \mathcal{E} \text{ is } \mathcal{U}_n \end{aligned} \quad (6)$$

where for $i = 1, 2, \ldots, n$, $j = 1, 2, \ldots, m$, $(\mathcal{C}_j, \mathcal{T}(\mathcal{C}_j), V_j, M_j)$ are linguistic scales representing the criteria, $\mathcal{A}_{i,j} \in \mathcal{T}(\mathcal{C}_j)$ are their linguistic values, $(\mathcal{E}, \mathcal{T}(\mathcal{E}), [0,1], M_e)$ is a linguistic scale representing the evaluation of alternatives and $\mathcal{U}_i \in \mathcal{T}(\mathcal{E})$ are its linguistic values.

In the FuzzME software, rule bases are defined expertly. The user defines such a rule base by assigning a linguistic evaluation to each possible combination of linguistic values of criteria.

For given values of criteria, a resulting fuzzy evaluation is calculated either by the Mamdani fuzzy inference algorithm or by the generalized Sugeno inference.

In the case of the Mamdani fuzzy inference, the degree h_i of correspondence between the given m-tuple of fuzzy values $(A_1', A_2', \ldots, A_m')$ of criteria and the mathematical meaning of the left-hand side of the *i*-th rule is calculated for any $i = 1, \ldots, n$ in the following way

$$h_i = \min\{hgt(A_1' \cap A_{i,1}), \ldots, hgt(A_m' \cap A_{i,m})\}. \quad (7)$$

Then for each of the rules, the output fuzzy value U_i', $i = 1, \ldots, n$, corresponding to the given input fuzzy values, is calculated as follows

$$\forall y \in [0,1] : U_i'(y) = \min\{h_i, U_i(y)\}. \quad (8)$$

The final fuzzy evaluation of the alternative is given as the union of all the fuzzy evaluations that were calculated for the particular rules in the previous step, i.e.,

$$U' = \bigcup_{i=1}^{n} U_i'. \quad (9)$$

Generally, the result obtained by the Mamdani inference algorithm need not be a fuzzy number. So, for further calculations within the fuzzy model, it must be approximated by a fuzzy number.

The advantage of the generalized Sugeno inference algorithm (see [7]) is that the result is always a fuzzy number. In its first step, the degrees of correspondence h_i, $i = 1, \ldots, n$, are calculated in the same way as in the Mamdani fuzzy inference algorithm.

The resulting fuzzy evaluation U is then computed as a weighted average of the fuzzy evaluations U_i, $i = 1, 2, \ldots, n$, which model the mathematical meanings of linguistic evaluations on the right-hand sides of the rules, with the weights h_i. This is done by the following formula

$$U = \frac{\sum_{i=1}^{n} h_i . U_i}{\sum_{i=1}^{n} h_i}. \quad (10)$$

3.4 Overall fuzzy evaluations, the optimum alternative

The final result of the consecutive aggregation of the partial fuzzy evaluations is an overall fuzzy evaluation of the given alternative. The obtained overall fuzzy evaluations are fuzzy numbers on $[0,1]$. They express uncertain degrees of fulfillment of the main goal by the particular alternatives.

The FuzzME software compares alternatives according to the centers of gravity of their overall fuzzy evaluations. A center of gravity of a fuzzy number U on $[0,1]$ that is not a real number, is defined as follows

$$t_U = \frac{\int_0^1 U(x).x\ dx}{\int_0^1 U(x)\ dx}. \quad (11)$$

If $U = u$ and $u \in \Re$, then $t_U = u$. In the FuzzME software, the optimum alternative is the one whose overall fuzzy evaluation has the largest center of gravity.

At present, the FuzzME software is aimed above all at solving multiple-criteria evaluation problems. To ensure high performance in choosing the optimum alternative, it will be necessary to include in the software other methods of ordering of the fuzzy evaluations in the future. Some approaches are proposed in [7] and further research in this area is planned.

4 Example of a practical application of the FuzzME software

The FuzzME software was tested e.g. on a soft-fact-rating problem of one of the Austrian banks. The problem was solved in co-operation with the Technical University in Vienna (see [14]). The fuzzy model of evaluation represents a part of the creditability evaluation of companies carried out by the bank - the evaluation according to soft (qualitative) data, which complements the evaluation according to hard (quantitative) data. The previous practical experience of the bank

ISBN: 978-989-95079-6-8

showed that it is not good to restrict the evaluation to hard data only.

In total, 62 companies were evaluated by the fuzzy model. The goals tree of the model contained 27 qualitative criteria.

During the testing, two approaches were compared - the original soft-fact-rating model used by the bank and the fuzzy models created in the FuzzME software.

The original evaluation model used simple discrete numeric scales with intuitively set linguistic descriptors for the evaluation according to the particular qualitative criteria. The aggregation of partial evaluation was done by the standard weighted average.

In testing by the FuzzME software, the applied linguistically described numeric scales were analyzed. It was found that in some cases the correspondence between the linguistic and numerical values was not perfect. Two new fuzzy models were formed. The first one used uniform fuzzy scales representing a simple fuzzification of the original numeric scales. The other worked with fuzzy values which tried to model, as closely as possible, the linguistic descriptors used in the original evaluation model. The results of the two models were quite different. At the same time, the normalized crisp weights were replaced by normalized fuzzy weights which correspond better to the expert's knowledge about the importance of criteria.

The subsequent discussion on results of the soft-fact-rating showed that there exist criteria values and combinations of criteria values which signalize a substantial danger that the company will go bankrupt or at least will have problems acquitting the debt. That is why, besides the evaluation of companies based on fuzzy weighted average ("average rating"), a fuzzy expert system was applied to calculate another evaluation ("a risk rate of the company"). The particular rules of the base identified the dangerous combinations of criteria values and assigned to them the corresponding risk rates. The solely use of the original fuzzy model without the fuzzy expert system would have lead to a rating score, which may have underestimated the risk inherent to this company. The use of the fuzzy expert systems offers the possibility to visualize and calculate such additional risk combinations.

Finally, both evaluations were aggregated with the fuzzy MINIMAX method. This method is a special case of a fuzzy OWA operator.The resulting evaluation is the infimum of the fuzzy numbers representing the partial evaluations.

The obtained results showed that the solid theoretical basis of the evaluation fuzzy models formed in the FuzzME software improves the quality of evaluations. Positive experiences with such fuzzy models of evaluation could win over the present-day opponents to the soft-fact-rating in the future.

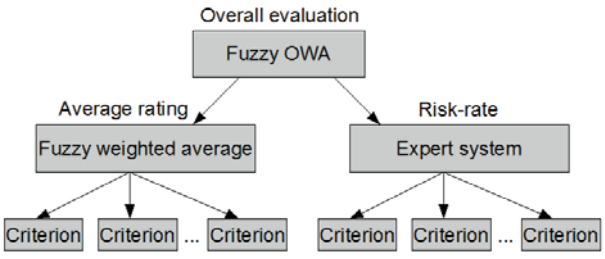

Figure 2: The simplified structure of the used goals tree

5 Conclusion

The software product FuzzME is a result of many years of research in the area of the theory and methods of multiple-criteria fuzzy evaluation. The type of evaluation consistently used in the software corresponds well to the fuzzy sets theory paradigm; the evaluations of alternatives express the fuzzy degrees of fulfillment of given goals. In the FuzzME software, several new methods, algorithms and tools of fuzzy modeling were implemented, e.g.: a structure of normalized fuzzy weights, fuzzy weighted average and ordered fuzzy weighted average operations and algorithms for their calculation, linguistic scales and linguistic variables derived from them. Well-elaborated theoretical basis of the FuzzME software provides a clear interpretation of all steps of the evaluation process and brings understanding of methodology to the user. The FuzzME software is user-friendly. The positive features of the software product proved themselves by solving the mentioned soft-fact-rating problem.

A Computing with Words path from fuzzy logic to natural language *

Claudio Moraga Enric Trillas

European Centre for Soft Computing, 33600 Mieres, Asturias, Spain
{claudio.moraga, enric.trillas}(at) softcomputing.es

Abstract *– Linguistic variables are reviewed and some aspects of the original definition revisited, showing that they provide a first formal frame to do computing with words in a "narrow sense". A two-levels hierarchy of languages is discussed in order to move to simple cases of computing with words in natural language, supported by linguistic variables.*

Keywords – Computing with words, linguistic variables, meaning modifiers

1 Introduction

In the late 90's, L.A. Zadeh introduced the idea of *computing with words* [1]. Much efforts have been done ever since to face the challenge and to develop the required proper concepts, models and methods to turn the bright initial idea into a sound area of research. Fuzzy logic seems predestined to be an appropriate formal frame to support the above efforts. Among other things, because fuzzy if-then rule bases may be understood as a specification of (the model of) a system in a language close to natural language and each rule, as the specification of a computation based on words, even though at the moment of doing real computations, this is done at the level of numbers. At this time, fuzzy if-then rule bases may be considered as a metaphor of what we would like to achieve by *really* computing with words. In this sense, what is currently known as fuzzy logic may be considered as a particular case of computing with words.

This paper shows, that in the context of fuzzy linguistic variables there are already processes that are representative of computing with words, albeit possibly in a "narrow sense". Furthermore it will be shown that it is possible to build a hierarchical relationship between words based on linguistic variables at the level of fuzzy logic and "words" – (actually short sentences)- at the level of natural language; to move from linguistic variables to "linguistic expressions" and from linguistic modifiers to "meaning modifiers". In analogy to the fact that linguistic modifiers, when applied to linguistic variables constitute possibly the simplest case of computing with words, it will be shown that "meaning modifiers", when applied to "linguistic expressions" may lead to non-trivial linguistic results of non-negligible complexity, in what may be thought of, as computing with "words".

The rest of the paper provides first a set of needed definitions to continue with a discussion about computing with words in fuzzy logic. An extension to computing with "words" in natural language is analyzed in the closing section.

2 Definitions

Definition 1 [1]:
Computing with words and perceptions, or CWP for short, is a mode of computing in which the objects of computation are words, propositions and perceptions described in a natural language.

Definition 2:
Let Ω be a set of (non-ambiguous) words that are used in a given context. The elements of Ω are considered to be pairs (representation, meaning). Representations may be taken from different syntactic domains, but meanings, from a single semantic domain. Moreover, let Γ be a finite set of functions $\{\gamma_1, \gamma_2, \ldots, \gamma_k\}$, with

$$\gamma_i : \Omega^n \rightarrow \Omega$$

The functions $\{\gamma_1, \gamma_2, \ldots, \gamma_k\}$ must be *designed* in such a way, that applied to words of Ω will produce reasonable words of Ω for the given context.

Definition 3:
In this paper when speaking of computing with words, the *objects* of computation are specified in definition 1. The *agents* of computation are functions taken from Γ, as stated in definition 2.

Examples: Let Ω be a subset of English.
If γ_1 is an appropriate "association" function. Then
γ_1(parent, children) = family
If γ_2 is a synonym function. Then
γ_2(pretty) = beautiful
If γ_3 is an antonym function. Then
γ_3(near) = far

These examples show that since the functions in Γ represent some "linguistic transformation", their interpretation should be taken take in account in the line of language precisiation (*à la* Zadeh).

At this stage, it should be mentioned that not under the scope of "computing with words", but simply with the goal of designing good fuzzy if-then rules, work has been done to select or build the most convenient operations connecting premises and the conclusion [2], [3]. In the context of this paper, the given references correspond to a basic contribution in the design of the most convenient functions for the corresponding Γ.

3 Computing with words in fuzzy logic

One of the key concepts in the development of fuzzy logic is that of a *linguistic variable*, introduced by L.A. Zadeh in 1975 [4]. The value set of a linguistic variable is a set of words –"linguistic terms"– denoting predicates or linguistic labels, and the syntactic domain of those words is constituted by appropriate convex fuzzy sets. "*… in general, a linguistic variable is associated with two rules: (1) a syntactic rule, which may have the form of a grammar for generating the names of the values of the variable; and (2) a semantic rule which defines an algorithmic procedure for computing the meaning of each value"* (See section 2 of Part II of [4])

In what follows, this idea is extended to include a formal grammar and a data base. The grammar will control possible transformations on the fuzzy sets representing the linguistic terms of a linguistic variable. The effect of linguistic modifiers (originally called "hedges of type I" [5]) as well as the generation of antonyms of linguistic terms (which was studied much later [6], [7], [8]) may, for instance, be formalized in terms of productions of a grammar. The data base, on the other hand, is meant to contain the meanings associated to the linguistic terms and their considered possible modifications through the grammar.

It is easy to see that the grammar and the data base have a functionality which is subsumed by that of the functions presented in Definition 2.

For the representation of linguistic terms as fuzzy sets, if no further information is available, a trapezoidal shape is appropriate since an agreement among users about the subset of the universe where the predicate is indeed valid, defines the core of the fuzzy set and the agreement about the subset of the universe where the predicate is not at all valid, defines its co-support. Our human experience with predicates indicates that the transitions between co-support and core are continuous and monotone. Therefore, if no further information is available, linear transitions leading to a piecewise linear convex normalized fuzzy set is an appropriate first choice. If the core contains only one point, then the trapezium reduces to a triangle. Notice that the above analysis does not require the trapezium (triangle) to be symmetric.

Trapezoidal fuzzy sets are simple to represent as an ordered quadruple of the ordinates of their four corners (t_1, t_2, t_3, t_4). The interval between the first and the fourth corner represents the support of the fuzzy set. (If non-normalized trapezoidal fuzzy sets are considered, then a preceding scaling factor is needed.)

Another basic assumption, normally associated to linguistic variables, is that all linguistic terms of the variable constitute a partition of unity, *i.e.*, at every point of the universe of discourse, the membership degrees of the linguistic terms add up to 1.

Definition 4:

A linguistic modifier is a unary function in the set of fuzzy sets representing linguistic terms. A linguistic modifier LM is *compressing* if for any fuzzy set A representing a linguistic term, $LM(A) \subset A$, and is *expanding* if $A \subset LM(A)$. There are however linguistic modifiers that are neither compressing nor expanding.

In what follows, to keep the notation as simple as possible, the label of a linguistic term will also be used to denote the membership function of the fuzzy set representing it.

Let $T := (t_1, t_2, t_3, t_4)$

$LM(T) := ((t_1+t_2)/2, t_2, t_3, (t_3+t_4)/2)$ is a compressing modifier and in what follows will be given the meaning *more_strictly*(T).

$LM(T) := (t_1, (t_1+t_2)/2, (t_3+t_4)/2, t_4)$ is an expanding modifier and in what follows will be given the meaning *roughly*(T).

Lemma 1:

Let $T := (t_1, t_2, t_3, t_4)$

Define $T_{left} := ½(t_1, (t_1+ t_2)/2, (t_1+ t_2)/2, t_2)$

$T_{right} := ½(t_3, (t_3+ t_4)/2, (t_3+ t_4)/2, t_4)$

Then:

$T = T_{left} + more\_strictly(T) + T_{right}$

Proof: By adding point-to-point the piecewise linear segments.

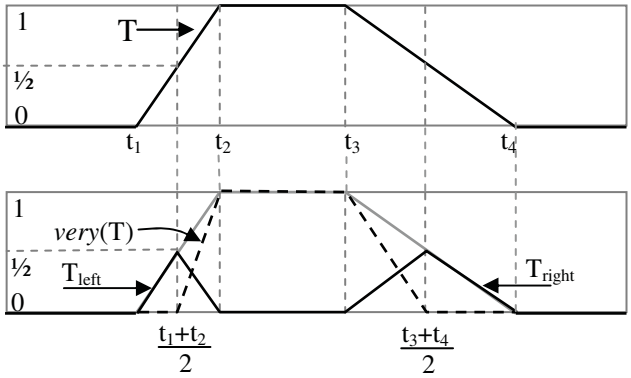

Figure 1**:** The relationship among the fuzzy sets T, *more_strictly*(T), T_{left} and T_{right}

It is easy to see that for all $x < t_3$, T_{right} takes the value 0. Moreover, since $(t_1 + t_2)/2$ is equidistant of t_1 and t_2, then at this point, T takes the value ½. (See Figure 1). Moreover between t_2 and t_3, both T_{left} and T_{right} have membership degree 0, meanwhile T and *more_strictly*(T) have membership degree 1, therefore in this interval the claim trivially holds. Table 1 summarizes the relevant membership values at t_1, $(t_1 + t_2)/2$ and t_2.

Table 1: relevant membership values

	t_1	$(t_1 + t_2)/2$	t_2
T	0	½	1
more_strictly(T)	0	0	1
T_{left}	0	½	0
more_strictly(T) + T_{left}	0	½	1

In the interval $[t_1, t_2]$, both *more_strictly*(T) and T_{left} are piecewise linear; therefore their sum will also be piecewise linear. In the subinterval $[t_1, (t_1+t_2)/2]$, since the membership value of *more_strictly*(T) is 0, the sum will be given by T_{left}, which has a representation as a straight line segment with slope $1/(t_2-t_1)$. In the subinterval $[(t_1+t_2)/2, t_2]$, both *more_strictly*(T) and T_{left} have a representation as straight line segments, therefore also their sum. It is simple to see

ISBN: 978-989-95079-6-8

from Figure 1, that the sum segment runs from the point $\langle(t_1+t_2)/2, 1/2\rangle$ to the point $\langle t_2, 1\rangle$, with slope $1/(t_2-t_1)$. Since both sum segments share a common point and have the same slope, they constitute a single straight line segment with slope $1/(t_2-t_1)$ in the whole interval $[t_1, t_2]$. This corresponds with the left part of T. A similar analysis will prove that in $[t_3, t_4]$ the sum of *more_strictly*(T) plus T_{right} returns the corresponding part of T. For reasons that will become clear below, no attempt will be done here to associate a meaning to T_{right} and T_{left}.

Corollary 1.1:
Assume that T is a rectangular trapezium. Without loss of generality let T := (t_1, t_2, t_3, t_3). Then :

$T = T_{left} + more\_strictly(T)$

since T_{right} has zero-support.

Example 1:
Consider a linguistic variable with three linguistic terms building a partition of unity, as shown in Figure 2(a). Furthermore, let it be assumed that some experiments done using this representation –(model)- of the variable, made advisable a refinement of the middle linguistic term, and that this is done by applying Lemma 1 (with $t_2 = t_3$). This is shown in Figure 2(b). Solving the superposition of the small triangles with the respective trapeziums leads to a new model of the linguistic variable, as shown in Figure 2(c).

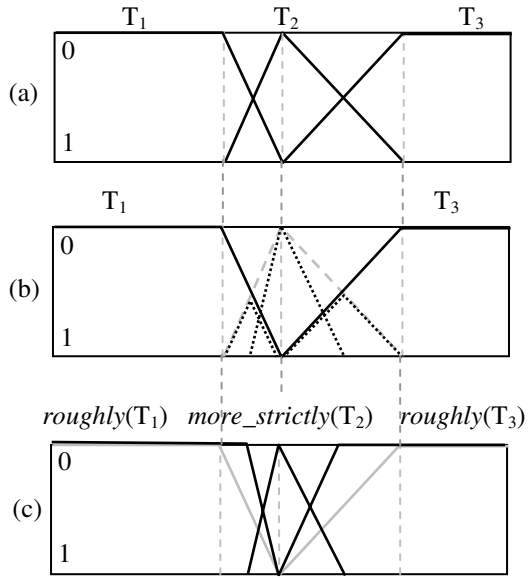

Figure 2**:** (a) Initial model of the linguistic variable
(b) Effect of applying Lemma 1 to T_2
(c) The resulting new model for the linguistic variable

An analysis of the process shows that T_2 changed into *more_strictly*(T_2). Furthermore, the core of T_1 was expanded by one half of the support corresponding to the right wing of the trapezoidal representation. From Definition 4 follows that it represents *roughly*(T_1). Similarly, T_3 turns into *roughly*(T_3). In summary, a new representation of the linguistic variable, which preserves the partition of unity, was obtained through a refinement process by using appropriate linguistic modifiers. This represents (possibly the simplest) elementary operations in the context of computing with words.

Case study 1:
In the context of linguistic variables with structure of a partition of unity, *two* consecutive linguistic terms T_j and T_{j+1} will be considered, which will be refined under Lemma 1.

Let T_j := (t_1, t_2, t_3, t_4)
and T_{j+1} := (t_3, t_4, t_5, t_6)
Lemma 1 generates:

$more\_strictly(T_j)$:= $((t_1+ t_2)/2, t_2, t_3, (t_3+ t_4)/2)$
$(T_j)_{right}$:= $½(t_3, (t_3+ t_4)/2, (t_3+ t_4)/2, t_4)$
$more\_strictly(T_{j+1})$:= $((t_3+ t_4)/2, t_4, t_5, (t_5+ t_6)/2)$
$(T_{j+1})_{left}$:= $½(t_3, (t_3+ t_4)/2, (t_3+ t_4)/2, t_4)$

(Lemma 1 also generates $(T_j)_{left}$ and $(T_{j+1})_{right}$, which are however not in the focus of this case study).
Notice that $(T_j)_{right} = (T_{j+1})_{left}$ therefore
if $T' = (T_j)_{right} + (T_{j+1})_{left}$ then
T' := $(t_3, (t_3+ t_4)/2, (t_3+ t_4)/2, t_4)$
It is easy to see that T' is an isosceles triangle. To T' the following *specification of meaning* can be associated:

$T' = between(more\_strictly(T_j), more\_strictly(T_{j+1}))$

and, the other way around, the operation *between* is defined as the structure of T'. See Figures 3(a) and 3(b).

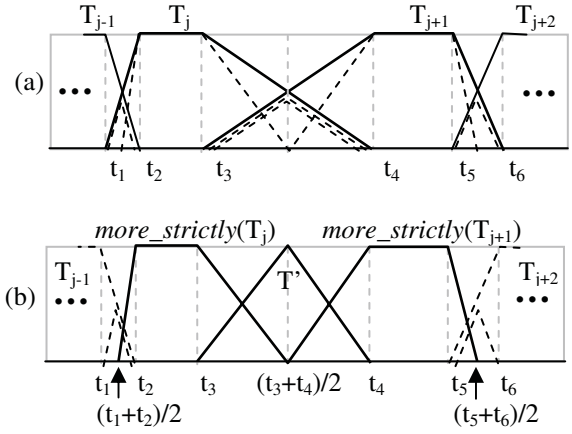

Figure 3**:** (a) Two neighbor linguistic terms and their refinement with Lemma 1 (dotted).
(b) Effect of the superposition of the overlapping side triangles generated by the refinement.

From $T' = between(more\_strictly(T_j), more\_strictly\ (T_{j+1}))$ it may be concluded that there exists a $\gamma \in \Gamma$ such that

$\gamma = between \circ (more\_strictly \times more\_strictly)$

and $T' = \gamma(T_j, T_{j+1})$

Notice that if all linguistic terms of a linguistic variable are refined with Lemma 1, then all "new" linguistic terms may be obtained with the composition of *between* and the Cartesian product *more_strictly* × *more_strictly*. A refinement of all linguistic terms after Lemma 1, may be related to wavelets [9], but almost duplicates the number of linguistic terms. Partial refinements, however, were studied in [10] under the scope of a metasemantics.

ISBN: 978-989-95079-6-8

Before studying a next case, two elementary operations will be introduced.

Definition 5:
Let $T_j := (t_1, t_2, t_3, t_4)$
Then, the operation *less than or equal to*, abbreviated "LE" is defined for all x in the universe of discourse, as:

$$(LE(T_j))(x) = \begin{cases} 1 & \text{if } x \le t_3 \\ T_j & \text{if } x > t_3 \end{cases}$$

Similarly, the operation *more than or equal to*, abbreviated "ME" is defined as:

$$(ME(T_j))(x) = \begin{cases} 1 & \text{if } x \ge t_2 \\ T_j & \text{if } x < t_2 \end{cases}$$

Case study 2:
Consider a linguistic variable with more than 3 linguistic terms and refine some linguistic term in the middle. What will be the effect upon its non-refined neighbors?

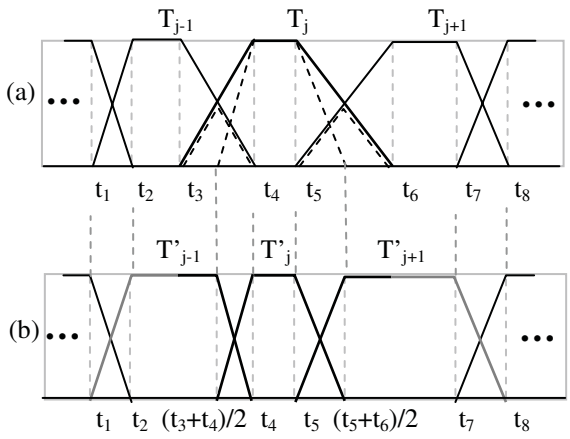

Figure 4 **:** (a) A linguistic variable with the prepared refinement of the j-th linguistic term.
(b) Effect of refining T_j upon its neighbors.

Figure 4 shows the linguistic terms before and after refining the j-th term. From Lemma 1 follows that:

$$T'_j = more\_strictly(T_j)$$

An interpretation of T'_{j+1} is not straight forward. Fig. 4(b) shows however that at the left hand side, the core of T'_{j+1} increased by one half of the support of the left wing, *i.e.*, by $\frac{1}{2}(t_6-t_5)$, with respect to the original core of T_{j+1}. Notice that this is the same (partial) effect caused by the operation $roughly(T_{j+1})$; however, the right hand side of T'_{j+1} does not change as compared to T_{j+1}. This may be given a formal expression as follows, for all x in the universe of discourse:

$$(T'_{j+1})(x) = minimum(roughly(T_{j+1}), LE(T_{j+1}))$$

or "in words",

$$T_{j+1} = roughly(T_{j+1})\ and\ LE(T_{j+1})$$

where *and* is realized with the operation *minimum*.

Similarly,

$$(T'_{j-1})(x) = minimum(roughly(T_{j-1}), ME(T_{j-1}))$$

or "in words",

$$T_{j-1} = roughly(T_{j-1})\ and\ ME(T_{j-1})$$

Example 1 and the two above cases show that at the lowest level, that of terms of linguistic variables, transformations may be formalized, which represent the possibly simplest cases of computing with words in narrow sense.

4 First steps towards natural language

When working with formal languages, "words" are build with "symbols" of an alphabet. Quotations are being used, since the "symbols" may be words of a reference language and, consequently the "words" will (normally) be (meaningful) sentences of the reference language. This model of a hierarchy of languages will be used in an attempt to transfer or imitate the elementary operations discussed above to short statements in natural language. These "words" will be written in square brackets. Furthermore the notation "linguistic statement" instead of linguistic variable, and "meaning modifier" instead of linguistic modifier will be used. Finally it becomes apparent that "words" will no longer be just pairs (representation, meaning), but at least triples (representation, structure, meaning). Representation is concerned with the rules of writing, meanwhile the structure refers to the grammatical ordering of the reference words to support a meaning.

Example 3:
Consider the "word" [*The weather is improving*], where the linguistic statement has the value set {hardly a bit, slightly, steadily, strongly}. How could the meaning of this "word" be emphasized?

i) *Use* the "word" consistently within the value subset {steadily, strongly}

ii) Design a meaning modifier MM_1 which integrates explicitly in the "word" the desired predicate from the value set, preserving the structure:
MM_1 (***steadily***, [*The weather is improving*]) =
[*The weather is* ***steadily*** *improving*]

It may be observed that this modifier changes the representation of the "word", preserves the grammar of the "word" and emphasizes its meaning.

iii) Design a meaning modifier MM_2 which integrates an additional reference word, taken from a pre-defined "subset of emphasizers" of the corresponding natural language, preserving the structure, to produce an enhancement:

MM_2 (***indeed***, [*The weather is improving*]) =
[*The weather is* ***indeed*** *improving*]

Notice that it is only claimed that both [*The weather is* ***steadily*** *improving*] and [*The weather is* ***indeed*** *improving*]

ISBN: 978-989-95079-6-8

emphasize the meaning of [*The weather is improving*], but not that they are synonyms.

Example 4:
Consider the "word" [*Yesterday it rained*]. A value set for the linguistic statement may be thought of as $D_1 \times D_2 \times D_3$, where D_1 = {in the morning, at midday, in the afternoon, in the evening, at night}, D_2 = {a couple of minutes, several hours, the whole day} and D_3 = {a few drops, moderately, cats-and-dogs}. Notice that D_1 and D_2 may be associated both to *yesterday* and to *rain*, meanwhile D_3 is clearly related only to *rain*.

i) It is requested that [*Yesterday it rained*] be emphasized. The *rained*-component may be emphasized in a way similar to that discussed in example 3. Can *yesterday* be emphasized? At the level of natural language, it is possible to design a 2-place meaning modifier MM_1 giving:

MM_1([*December the 1st*], [*Yesterday it rained*]) =
[*Yesterday December the 1st it rained*],

which may be considered as a possible way of emphasizing *yesterday*.

ii) In the context of [*Yesterday it rained*] D_1, D_2 and D_3 may be seen as value sets of the linguistic variables "when", "how_long" and "how_much" (at the reference level), respectively. As linguistic variables, they have grammars that, among other things, may change number, shape and distribution of the fuzzy sets representing the corresponding linguistic terms, as well as a database keeping track of their meanings. Assume that the corresponding grammars are G_1, G_2 and G_3. Let $r_{2,i}$ and $r_{3,j}$ represent the i-th and j-th rules of G_2 and G_3, respectively, such that:

$r_{2,i}(D_2)$ = {a couple of minutes, *half an hour*, several hours, the whole day}

$r_{3,j}(D_3)$ = {a few drops, moderately, *a lot*, cats-and-dogs}

Some elements of the new domains may have the same labels as in the original domains, but will possibly be different since at least some of them are shifted and compressed, because in both cases, a new linguistic term was introduced. (Notice here the importance of the data base with meanings).
Then it is possible to use linguistic modifiers at the low level to build meaning modifiers MM (at the upper level) to generate new, richer "words" as, for instance,

MM[*Yesterday it rained*] =
[*Yesterday it rained quite a lot about half an hour almost at midday*]

It may be observed that the meaning modifier reordered the domains as $r_{3,j}(D_3) \times r_{2,i}(D_2) \times D_1$, made use of the new generated linguistic terms "half an hour" and "a lot", applied the linguistic modifiers "quite" (to "a lot") "about" (to "half an hour") and "almost" (to "at midday"). Fuzzy logic offers sound methods to perform all these reference level operations, which put together, formally specify the meaning modifier.

Analysis of the meaning modification
[*quite a lot about half an hour almost at midday*]:

Recall that the value set for [*Yesterday in rained*] was specified as the Cartesian product of three domains. Therefore, its "value" is a triple, whose components are possibly modified linguistic terms within the prevailing versions of the corresponding domains. Therefore, each one of the linguistic terms may be analyzed separatedly and the required linguistic modifiers, *designed* to satisfy the requirements of the use of the language.

i) Design of *quite*, to produce the modified linguistic term *quite a lot*.
It should be noticed that *quite* is a rather complicated linguistic modifier, since it is very context dependent: in American English it seems to be used mostly to emphasize, in a way similar to *more_strictly*, meanwhile in British English it may also be ironically used to mean exactly the contrary. Furthermore, *quite* is also used as an idiom, like in "*quite* a few", possibly meaning the same as "*quite* a lot". In the case under analysis however, it seems that *quite* is intended to be used to suggest rather more precisely, what is expressed by "a lot" alone. If this is the case, then a compressing linguistic modifier should be used, but with possibly a smaller amount of compression than in the case of *more_strictly*.
A general analysis leading to a proposal for a prototype of *quite* is shown in Figure 5.

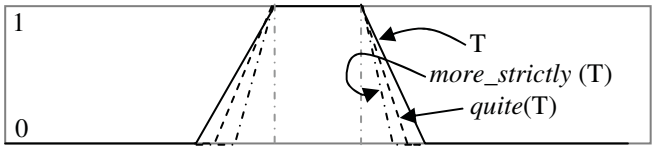

Figure 5**:** A possible prototype for *quite* as a linguistic modifier, which is less compressing than *more_strictly*

Observations on the *use* of *quite* in the context where it will be applied and in similar contexts will be needed to properly tune this modifier. Notice that it may well be the case that the contexts at the reference level and at the natural language level pose different constraints for the design of the modifier.

ii) Design of *about*, to produce the modified linguistic term *about half an hour*.
In the use of the language, *about* half an hour, appears to have a meaning close to that of *around* half an hour or *roughly* half an hour. Experiences with numerical approximation with fuzzy numbers indicate that *around* is an expanding modifier that preserves the core –(which in this case contains only one point, since the fuzzy set is triangular)– and increases the support. It seems reasonable to extend this modifier to trapezoidal fuzzy sets in the same way. On the other hand, *roughly*, as defined earlier, expands the core and preserves the support. If the meaning of *about* half an hour is indeed close to that of *around* half an hour and *roughly* half an hour, then the corresponding modified fuzzy sets should exhibit a high degree of "family resemblance" [11] and this can be used as an additional guiding constraint to design *about*.
A proposal for a prototype of *about* is illustrated in Figure 8 with respect to some abstract T (to more clearly show the effect of the (known) linguistic modifiers and of the proposed prototype).

ISBN: 978-989-95079-6-8

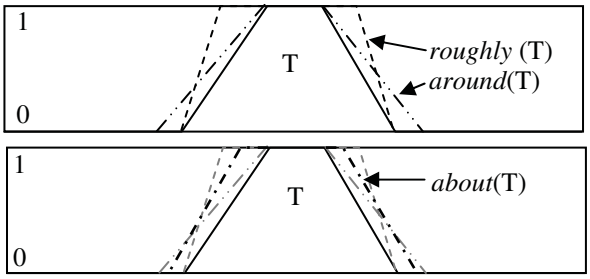

Figure 6: A possible prototype for *about*, for some abstract T, as related to *roughly* and *around*

As in the former case, observations on the *use* of the modifier in the target context will be needed to properly tune it.

iii) Design of *almost*, to produce the modified linguistic term *almost at midday*.
The use of the language, *e.g.* "the glass is *almost* empty" or "Peter was *almost* crazy with so many problems", indicates that this is a one-sided shifting and possibly expanding modifier, which applied to a fuzzy set representation of a linguistic term, displaces and possibly expands the fuzzy set towards the "less than" side. (See Figure 7). It is simple to see that *almost at midday* and *around midday* will have some "family resemblance", but to a clear weaker degree than the one discussed in the former paragraph.

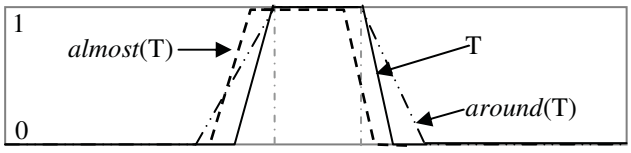

Figure 7: A possible prototype for *almost*, as compared to *around*, applied to some abstract T

Observations on the *use* of all above modifiers in the actual target context, including experimentation at the level of the language, will be needed to ensure their empirical correctness. See, for instance [12], [13], [14].

5 Conclusions

Within the formalism of linguistic variables in fuzzy logic, linguistic modifiers represent a very simple case of computing with words. Some new elementary operations have been defined, that allow new non trivial instances of low level computing with words. The paper shows that it is possible to extend these ideas to "linguistic statements" (short sentences) and "meaning modifiers" in natural language. The "linguistic statements" become the new "words" (as is the case of programming languages when considered as context free formal languages). This is done however keeping a solid base on linguistic terms and linguistic modifiers. The hierarchy of languages suggests that the more about computing with words is learnt in fuzzy logic, the more can be projected to natural languages to do computing with "words".

Acknowledgement

The authors thank the reviewers for their constructive criticism and the suggestions for the improvement of the paper.

Approximation properties of inverse fuzzy transforms over a residuated lattice

Martina Daňková Martin Štěpnička
Institute for Research and Applications of Fuzzy Modeling, University of Ostrava
Ostrava, Czech republic
Email: {martina.dankova,martin.stepnicka}@osu.cz

Abstract— *This contribution focuses on inverse fuzzy transforms (shortly inverse F-transforms) over residuated lattices introduced by I. Perfilieva and their approximation properties. We will try to reduce some requirements used in the original work to prove Approximation theorem. Moreover, we show in which sense F-transforms are the best approximations.*

Keywords— Fuzzy transform, Approximation, Extensional relation.

1 Introduction

In [1], F-transforms were introduced basically in three forms: the first (ordinary) was constructed over the ordinary algebra of reals[1], while the other two were constructed over the residuated lattice. Note that up to now, most of the applications of F-transforms, e.g. ordinary/partial differential equations [2]/[3], image compression/fusion (see [4]/[5, 6]), data analysis [7] etc., employ only the ordinary one. The main reason follows from the character of the inverse F-transforms, where the ordinary F-transform average the function values. Whereas the other two approximate them from above and from below, respectively. And since these F-transforms (over the residuated lattice) can be viewed as formalizations of a collection of *graded fuzzy rules* [8], they are primarily suitable for applications, which use fuzzy "IF-THEN" rules.

In this contribution, we will focus on the inverse F-transforms over the residuated lattice and show their approximation properties. Moreover, we will provide a simpler way to get the approximation theorem than the one in [1] (Theorem 10 and 11). Thus, we would like to brush up this topic and make it more attractive for a broader community.

Note that we present mainly an excerpt of a larger manuscript [9] that has been submitted for publication. For background information and proof details, readers are referred to this upcoming article.

2 Basic definitions and overview of the known results.

2.1 Basic definitions

Definition 1 *A residuated lattice on L is an algebra*

$$\mathcal{L} = \langle L, \vee, \wedge, *, \to, \mathbf{0}, \mathbf{1} \rangle \tag{1}$$

with four binary operations and two constants such that

- $\mathcal{L} = \langle L, \vee, \wedge, \mathbf{0}, \mathbf{1} \rangle$ *is a lattice with the largest element* $\mathbf{1}$ *and the least element* $\mathbf{0}$ *w.r.t. the lattice ordering* $\leq$,
- $\mathcal{L} = \langle L, *, \mathbf{1} \rangle$ *is a commutative semigroup with the unit element* $\mathbf{1}$*, i.e.* $*$ *is commutative, associative, and* $\mathbf{1} * x = x$ *for all* $x \in L$,
- $*$ *and* $\to$ *form an adjoint pair, i.e.*

$$z \leq (x \to y) \quad \textit{iff} \quad x * z \leq y \quad \textit{for all } x, y, z \in L.$$

In the sequel, let us assume $\mathcal{L}$ be a residuated lattice of the form (1). Moreover, we define the biresidual operation (biresiduum)

$$x \leftrightarrow y = (x \to y) \wedge (y \to x).$$

Throughout the whole text, we will deal with fuzzy relations whose membership functions take values from the support of $\mathcal{L}$ and we denote this fact by $\subseteq$. Let $M_1, \ldots, M_n$ be some nonempty sets of objects, $\mathcal{R}_I = \{R_i \subseteq M_i^2\}_{i \in I}$ be a system of binary fuzzy relations ordered by $I = \{1, \ldots, n\}$, $f \subseteq M_1 \times \ldots \times M_n$ be an n-ary fuzzy relation.

Convention 2 *For the sake of brevity, we will denote* $M_1 \times \cdots \times M_n$ *by* $M^{(n)}$*. Moreover, we will write* $R(\bar{x}, \bar{y}) = R_1(x_1, y_1) * \cdots * R_n(x_n, y_n)$.

Definition 3 *We say that f is extensional w.r.t. $\mathcal{R}_I$ if*

$$R(\bar{x}, \bar{y}) * f(\bar{x}) \leq f(\bar{y}),$$

for each $\bar{x}, \bar{y} \in M^{(n)}$.

Let us recall that a fuzzy $*$-equivalence (also known as similarity or indistinguishability) $R \subseteq M^2$ (M be some nonempty set of objects) is reflexive, symmetric and transitive w.r.t. $*$. Observe that $\leftrightarrow$ is $*$-equivalence on L. In the following we will omit specification $*$ whenever it will be clear from the context.

Additionally, we recall notions used in the original approximation theorems in [1].

Definition 4 *A system of fuzzy sets* $\{A_1, \ldots, A_k\}$ *on a nonempty set M establishes a semi-partition if*

$$\bigvee_{x \in M} A_i(x) * A_j(x) \leq \bigwedge_{x \in M} A_i(x) \leftrightarrow A_j(x),$$

for each $i, j \in \{1, \ldots, k\}$.

[1] Due to a nature of the used operations, it can be reinterpreted over ŁΠ-algebra.

ISBN: 978-989-95079-6-8

2.2 $F^{\uparrow(\downarrow)}$-transforms

Let us recall inverse F-transforms from [1] generalized for the n-dimensional case[2]:

$$\begin{aligned}
&\text{Assume } f \subsetsim M^{(n)}, C \subseteq M^{(n)}, A_{j_i} \subsetsim M_i,\\
&\qquad \forall j \in J = \{1,\dots,k\}, \forall i \in I = \{1,\dots,n\},\\
&\qquad \text{and } \mathbf{j} \text{ be abbreviation for } [j_1,\dots,j_n],\\
&f^{\downarrow}_{F,k}(\bar{x}) = \bigvee_{\mathbf{j}\in J^n} A_{\mathbf{j}}(\bar{x}) * [\bigwedge_{\bar{c}\in C} A_{\mathbf{j}}(\bar{c}) \to f(\bar{c})],\\
&f^{\uparrow}_{F,k}(\bar{x}) = \bigwedge_{\mathbf{j}\in J^n} A_{\mathbf{j}}(\bar{x}) \to [\bigvee_{\bar{c}\in C} A_{\mathbf{j}}(\bar{c}) * f(\bar{c})], \text{ where}\\
&A_{\mathbf{j}}(\bar{x}) = A_{j_1}(x_1) * \ldots * A_{j_n}(x_n), \forall \mathbf{j} \in J^n.
\end{aligned}$$

In [1], $f^{\downarrow}_{F,k}$ is called inverse F$^{\downarrow}$-transform and $f^{\uparrow}_{F,k}$ inverse F$^{\uparrow}$-transform. Moreover, the expression in the square brackets above is denoted by $F^{\uparrow(\downarrow)}_{\mathbf{j}}$ in the case of $f^{\uparrow(\downarrow)}_{F,k}$ and known as $\mathbf{j}$-th component of F$^{\uparrow(\downarrow)}$-transform.

Below, we overview known results from [1] that are in the center of our interest:

1. From the inequality $a * (a \to b) \le b \le a \to (a * b)$, it follows that for an arbitrary f:
$$f^{\downarrow}_{F,k}(\bar{x}) \le f(\bar{x}) \le f^{\uparrow}_{F,k}(\bar{x}),\ \forall \bar{x} \in C. \tag{2}$$
2. The $\mathbf{j}$-th components of F$^{\uparrow}$-transform and F$^{\downarrow}$-transform are the least elements of the following respective sets:
$$S_{\mathbf{j}} = \{a \in M^{(n)} |\ A_{\mathbf{j}}(\bar{x}) \le f(\bar{x}) \to a,\ \forall \bar{x} \in C\}, \tag{3}$$
$$T_{\mathbf{j}} = \{a \in M^{(n)} |\ A_{\mathbf{j}}(\bar{x}) \le a \to f(\bar{x}),\ \forall \bar{x} \in C\}. \tag{4}$$
3. A core of the approximation theorems inheres in the following inequality:
$$\bigvee_{\mathbf{j}\in J^n} A_{\mathbf{j}}(\bar{x}) * A_{\mathbf{j}}(\bar{x}) \le f^{\uparrow(\downarrow)}_{F,k}(\bar{x}) \leftrightarrow f(\bar{x}),\ \forall \bar{x} \in C. \tag{5}$$
Remark that a closeness of elements is expressed using $\leftrightarrow$, which is the dual concept to pseudo-metric as shown in [10], and naturally, the estimation goes there from below.

Below, we summarize the requirements that were used in [1] to prove (5), i.e., the estimation of the equivalence of $f^{\downarrow(\uparrow)}_{F,k}$ to the original function f:

	Requirements in [1] (Theorems 10 and 11)
1.	$\mathcal{L}$ be a BL-algebra,
2.	each $A \in \{A_{j_i}\}_{j\in J, i\in I}$ be normal,
3.	$\{A_{1_i},\dots,A_{k_i}\}$ forms a semi-partition $\forall i \in I$,
4.	f be extensional w.r.t. $\mathcal{P}_I = \{P_i\}_{i\in I}$ defined by $P_i(x,y) = \bigwedge_{j\in J} A_{j_i}(x) \leftrightarrow A_{j_i}(y)$, for all $i \in I$,
5.	$E = \{\bar{e}_j \in M^{(n)} |\ P_i(x, e_{j_i}) = A_{j_i}(x), i \in I, j \in J\}$ be subset of C (see p. 1013 in [1]).

[2] Note that in the original work, f was a mapping from a finite subset of L into L (support of the fixed residuated lattice $\mathcal{L}$), where $L = [0,1]$. Since we measure a precision of the approximation using values of L and we do not use specific properties of $[0,1]$, this determination is not needed in our work.

3 Approximation properties

3.0.1 Formulation of the problem and basic properties

Let $\mathcal{L}$ and $\mathcal{R}_I = \{R_i \subsetsim M_i^2\}_{i\in I}$ be as specified in Subsection 2.1, and $\varepsilon \in L$. Moreover, we assume to have only a partial information about $f \subsetsim M^{(n)}$ in the form of a set of samples $\{f(\bar{c}) |\ \bar{c} \in C \subseteq M^{(n)}\}$. The problem (ApproxF) that we are going to solve is formulated as follows:

$$\begin{aligned}
&\text{Find } D \subseteq M^{(n)} \text{ and } \tilde{f} \in \mathbb{M}^D_{\vee(\wedge)} \text{ such that}\\
&\qquad \varepsilon \le f(\bar{x}) \leftrightarrow \tilde{f}(\bar{x}),\ \forall \bar{x} \in C,
\end{aligned}$$

where

$$\mathbb{M}^D_{\vee} = \Big\{ \bigvee_{\bar{d}\in D} (R(\bar{d},\bar{x}) * g(\bar{d})) |\ g \subsetsim M^{(n)} \Big\} \quad \text{and}$$
$$\mathbb{M}^D_{\wedge} = \Big\{ \bigwedge_{\bar{d}\in D} (R(\bar{x},\bar{d}) \to g(\bar{d})) |\ g \subsetsim M^{(n)} \Big\}.$$

Due to terminology introduced in [11], we approach this problem from the view point of fuzzy relations of a special structure, the so-called *normal forms*:

$$\mathrm{DNF}^P_h(\bar{x}) = \bigvee_{\bar{p}\in P} (R(\bar{p},\bar{x}) * h(\bar{p})) \quad \text{and} \tag{6}$$
$$\mathrm{CNF}^P_h(\bar{x}) = \bigwedge_{\bar{p}\in P} (R(\bar{x},\bar{p}) \to h(\bar{p})), \tag{7}$$
$$\text{where } h \subsetsim M^{(n)}, P \subseteq M^{(n)}, \bar{x} \in M^{(n)}, \tag{8}$$

are called the disjunctive and conjunctive normal forms for h w.r.t. P, respectively. Hence,

$$\mathbb{M}^D_{\vee} = \Big\{ \mathrm{DNF}^D_g |\ g \subsetsim M^{(n)} \Big\} \quad \text{and}$$
$$\mathbb{M}^D_{\wedge} = \Big\{ \mathrm{CNF}^D_g |\ g \subsetsim M^{(n)} \Big\}.$$

It is possible to rewrite inverse F-transforms using normal forms if we take $\{R_i\}_I$ and D:

- Assume $M^{(n)}$ contains sufficiently many elements to define set D.
- Take $D = \{\bar{d}_j \in M^{(n)} |\ d_{j_i} \ne d_{j'_i},\ \forall j,j' \in J, \forall i \in I\}$.
- Define $R(\bar{x},\bar{d}_j) = R(\bar{d}_j,\bar{x}) = A_{\mathbf{j}}(\bar{x}), \forall j \in J, \mathbf{j} \in J^n$ and $R(\bar{x},\bar{y}) = \mathbf{0},\ \forall \bar{y} \in M^{(n)} \setminus D$.

In the case of lacking elements to construct set D, which can hypothetically arise because there is no restriction to the number of sets A_{j_i}, we can artificially extend $M^{(n)}$ to reach the required cardinality. Then we obtain that $\mathrm{DNF}^D_{\mathrm{CNF}^C_f}$ corresponds to an inverse $F^{\downarrow}$-transform $f^{\downarrow}_{F,k}$ and $\mathrm{CNF}^D_{\mathrm{DNF}^C_f}$ to an inverse $F^{\uparrow}$-transform $f^{\uparrow}_{F,k}$.

For an arbitrary $f \subsetsim M^{(n)}$, we can certainly show[3]

$$\bigvee_{\bar{d}\in D} (R(\bar{d},\bar{x}) * f(\bar{x})) \le f(\bar{x}) \le \bigwedge_{\bar{d}\in D} (R(\bar{x},\bar{d}) \to f(\bar{x})), \forall \bar{x} \in C.$$

[3] Considering $\bigvee_{\bar{d}\in D} R(\bar{d},\bar{x}) = \bigvee_{\bar{d}\in D} R(\bar{x},\bar{d}) = \mathbf{1}$ gives the following equality $f(\bar{x}) = \bigvee_{\bar{d}\in D} (R(\bar{d},\bar{x}) * f(\bar{x})) = \bigwedge_{\bar{d}\in D} (R(\bar{x},\bar{d}) \to f(\bar{x}))$, for all $\bar{x} \in C$, because in an arbitrary residuated lattice $\mathbf{1} * a = \mathbf{1} \to a = a$, for all $a \in L$. Hence, it is reasonable to apply this requirement for the partitioning of the domain of f in the practise.

ISBN: 978-989-95079-6-8

The task stands in the replacement of $f(\bar{x})$ by suitable values so that the approximation is the best possible w.r.t. the available knowledge. In the following proposition, we are going to show that the combinations of $\{\mathrm{DNF}_f^D, \mathrm{CNF}_f^C\}$ and $\{\mathrm{CNF}_f^D, \mathrm{DNF}_f^C\}$ have this property.

Theorem 5 – DNF_f^C *is the least element of the following set:*

$$S = \{g \subsetsim M^{(n)} |\ f(\bar{x}) \leq \bigwedge_{d\in D} (R(\bar{x},\bar{d}) \to g(\bar{d})),\ \forall \bar{x} \in C\}. \tag{9}$$

– CNF_f^C *is the greatest element of the following set:*

$$S' = \{g \subsetsim M^{(n)} |\ \bigvee_{d\in D} (R(\bar{d},\bar{x}) * g(\bar{d})) \leq f(\bar{x}),\ \forall \bar{x} \in C\}. \tag{10}$$

As it has been shown above, there cannot be better lower approximation of f from the set $\mathbb{M}_\vee^D$ than $\mathrm{DNF}^D_{\mathrm{CNF}_f^C} \in \mathbb{M}_\vee^D$. And analogously, $\mathrm{CNF}^D_{\mathrm{DNF}_f^C} \in \mathbb{M}_\wedge^D$ is the best upper approximation of f. In other words, the best choice for coefficients in the inverse formula of $\mathrm{F}^{\uparrow(\downarrow)}$-transform is to take just the coefficients of the direct $\mathrm{F}^{\uparrow(\downarrow)}$-transform. Both results do not consider any boundary for an $\varepsilon-$precision of the approximations. It is dependent on the suitable choice of $\mathcal{R}_I$ and the set of nodes D arising from the following estimation in terms of a $*$-equivalence:

Theorem 6 *Let $f \subsetsim M^{(n)}$ be extensional w.r.t. $\mathcal{S}_I = \{S_i \subsetsim M_i^2\}_{i\in I}$ as follows:*

$$S_i(x,y) = \bigvee_{\bar{d}\in D} R_i(x,d_i) * R_i(d_i,y). \tag{11}$$

Then we can prove

$$\bigvee_{\bar{d}\in D} R(\bar{x},\bar{d}) * R(\bar{d},\bar{x}) \leq \begin{array}{l}\mathrm{DNF}^D_{\mathrm{CNF}_f^C}(\bar{x}) \leftrightarrow f(\bar{x}),\\ \mathrm{CNF}^D_{\mathrm{DNF}_f^C}(\bar{x}) \leftrightarrow f(\bar{x}),\end{array} \quad \forall \bar{x} \in C. \tag{12}$$

Corollary 7 *Let $\overline{\mathcal{R}}_I = \{\bar{R}_i\}_{i\in I}$ be defined by*

$$\bar{R}_i(x,y) = \bigvee_{j\in J} A_{j_i}(x) * A_{j_i}(y), \tag{13}$$

for all $i \in I$. If $f \subsetsim M^{(n)}$ is extensional w.r.t. $\overline{\mathcal{R}}_I$ then (5) is valid.

Here, we provide an alternative proof of this assertion independent of the above theorem.

Proof: Due to extensionality, we have

$$A_{\mathbf{j}}(\bar{x}) * A_{\mathbf{j}}(\bar{y}) \leq R(\bar{x},\bar{y}) = \bigvee_{\mathbf{j}\in J^n} A_{\mathbf{j}}(\bar{x}) * A_{\mathbf{j}}(\bar{y}) \leq$$
$$\leq f(\bar{x}) \leftrightarrow f(\bar{y}), \text{ and hence}$$
$$A_{\mathbf{j}}(\bar{x}) * A_{\mathbf{j}}(\bar{x}) * f(\bar{x}) \leq A_{\mathbf{j}}(\bar{x}) * (A_{\mathbf{j}}(\bar{y}) \to f(\bar{y})),$$
$$A_{\mathbf{j}}(\bar{x}) * A_{\mathbf{j}}(\bar{x}) * f(\bar{x}) \leq A_{\mathbf{j}}(\bar{x}) * \bigwedge_{\bar{y}\in C} (A_{\mathbf{j}}(\bar{y}) \to f(\bar{y})),$$
$$f(\bar{x}) * \bigvee_{\mathbf{j}\in J^n} A_{\mathbf{j}}(\bar{x}) * A_{\mathbf{j}}(\bar{x}) \leq$$
$$\leq \bigvee_{\mathbf{j}\in J^n} (A_{\mathbf{j}}(\bar{x}) * \bigwedge_{\bar{y}\in C} (A_{\mathbf{j}}(\bar{y}) \to f(\bar{y}))) = f^{\downarrow}_{F,k}(\bar{x}),$$

for all $\bar{x} \in M^{(n)}$. Adding the left side of inequality (2), we receive the first required estimation (5). Analogously we proceed to prove the inequality for $f^{\downarrow}_{F,k}$. QED

Hence, to obtain the desired ε-approximation[4], it only remains to choose D w.r.t. $\mathcal{R}_I$ so that

$$(\forall \bar{x} \in C)(\varepsilon \leq \bigvee_{\bar{d}\in D} R(\bar{x},\bar{d}) * R(\bar{d},\bar{x})),$$

which completes the task.

Corollary 8 *Let $\varepsilon \in L, D \subseteq M^{(n)}$ and $f \subsetsim M^{(n)}$ be extensional w.r.t. $\mathcal{S}_I$ defined by (11). If for each $\bar{x} \in C$ there exists $d \in D:\ \varepsilon \leq R(\bar{x},d) * R(d,\bar{x})$ then*

$$\varepsilon \leq \begin{array}{l}\mathrm{DNF}^D_{\mathrm{CNF}_f^C}(\bar{x}) \leftrightarrow f(\bar{x}),\\ \mathrm{CNF}^D_{\mathrm{DNF}_f^C}(\bar{x}) \leftrightarrow f(\bar{x}),\end{array} \quad \forall \bar{x} \in C. \tag{14}$$

Corollary 9 *Let $\varepsilon \in L$ and $f \subsetsim M^{(n)}$ be extensional w.r.t. $\bar{\mathcal{R}}_I$ defined by (13). If for each $\bar{x} \in C$ there exists $\mathbf{j} \in J^n$: $\varepsilon \leq A_{\mathbf{j}}(x) * A_{\mathbf{j}}(x)$ then*

$$\varepsilon \leq f^{\downarrow(\uparrow)}_{F,k}(\bar{x}) \leftrightarrow f(\bar{x}),\ \forall \bar{x} \in C. \tag{15}$$

Corollary 10 *Let $L = [0,1]$, $*$ be a continuous t-norm, $\varepsilon \in L$, M be a pre-compact (totally bounded) subset over a standard metric space, $R \subsetsim M$ be reflexive and uniformly continuous. If $f \subsetsim M$ is extensional w.r.t. R then for every $\varepsilon < 1$ there exists a finite $D \subseteq M$ such that (14) is valid.*

Whenever we assume each $R \in \mathcal{R}$ to be a $*$-equivalence, we obtain an estimation by means of the following pseudometrics:

$$d_n(\bar{x},\bar{y}) = \varphi^{-1}R_1(x_1,y_1) \oplus_\varphi \ldots \oplus_\varphi \varphi^{-1}R_n(x_n,y_n)$$
$$= \bigoplus_{i\in I} \varphi^{-1}R_i(x_i,y_i),\ \forall \bar{x},\bar{y} \in M^{(n)},$$
$$d(x,y) = \varphi^{-1}(x \leftrightarrow y),\ \forall x,y \in L$$

where φ is an order-reversing bijection on L, $\oplus_\varphi$ is an operation defined by $x \oplus_\varphi y = \varphi^{-1}(\varphi(x) * \varphi(y))$.

Corollary 11 *Let each $R \in \mathcal{R}_I$ be a $*$-equivalence and $d_n : M^{(n)} \times M^{(n)} \to L, d : L \times L \to L$ be defined as above. If $f \subsetsim M^{(n)}$ is extensional w.r.t. $\mathcal{S}_I$ defined by (11) then f is 1-Lipschitz continuous w.r.t. (d,d_n), i.e.,*

$$d(f(\bar{x}),f(\bar{y})) \leq d_n(\bar{x},\bar{y}),\ \textit{for all } \bar{x},\bar{y} \in M^{(n)},$$

and

$$\begin{array}{l} d(\mathrm{DNF}^D_{\mathrm{CNF}_f^C}(\bar{x}), f(\bar{x}))\\ d(\mathrm{CNF}^D_{\mathrm{DNF}_f^C}(\bar{x}), f(\bar{x}))\end{array} \leq \bigwedge_{\bar{d}\in D} 2d_n(\bar{x},\bar{d})$$
$$= \bigwedge_{\bar{d}\in D} d_n(\bar{x},\bar{d}) \oplus d_n(\bar{d},\bar{x}),\ \forall \bar{x} \in C. \tag{16}$$

[4]Notice that the choice of $\mathcal{R}_I$ is the limitation for ε as well as for D, e.g. D might become very huge if ε is close to $\mathbf{1}$.

ISBN: 978-989-95079-6-8

Let us consider a simple problem to illustrate the way of approximation by F-transforms.

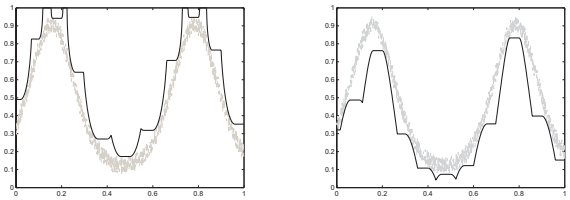
Example 12 *Let us take the following function*

$$f(x) = \frac{1}{3} \cdot e^{\sin(10x)} + Rand(x),\ \forall x \in M = [0,1],$$

where $Rand(x)$ is some additive random noise. Moreover, assume $*$ to be the t-norm generated by $g(x) = (1-x)^2$ and $\mathcal{L}$ be the associated residuated lattice. Take

$$R(x,y) = 1 \wedge (0 \vee (1.2 - 10 \cdot |x-y|)),$$

and create the approximation using 11 and 21 nodes and equidistant discretization $C = \{k \cdot 0.001 |\ k = 1, \ldots, 999\}$. The resulting approximations are depicted on Fig. 1, where f is represented by grey line and inverse $F^{\uparrow(\downarrow)}$-transforms by black lines, set D contains 11 nodes and set D' contains 21.



(a) $\mathrm{CNF}^{D}_{\mathrm{DNF}^{C}_{f}}$ (b) $\mathrm{DNF}^{D}_{\mathrm{CNF}^{C}_{f}}$

(c) $\mathrm{CNF}^{D'}_{\mathrm{DNF}^{C}_{f}}$ (d) $\mathrm{DNF}^{D'}_{\mathrm{CNF}^{C}_{f}}$

Figure 1: Approximation of f (grey line) from Example 12 using F-transforms (black line) with 11 (set D) and 21 (set D') nodes.

4 Conclusions

We have shown that the only one requirement is needed to show (5):

New requirements
$\mathcal{L}$ be a residuated lattice
f be extensional w.r.t. $\{\bar{R}_i\}_{i \in I}$

While in [1], we were limited to the stronger algebraic structure, a special type of partition, $E \subseteq C$, additionally requiring normality, and extensionality of f (see Subsection 2.2). Notice that all the additional requirements follow from the procedure of replacement of fuzzy sets A_{i_i} by P_i based on the special set E (such relations can be found in [12]). We have found a way how to get around this construction and to reach such simplification.

Moreover, our approach enabled to express direct and inverse $F^{\uparrow(\downarrow)}$-transforms using combinations of normal forms. This allowed us to show an optimality of choice of all coefficients of the direct $F^{\uparrow(\downarrow)}$-transform in the inverse formula at once (see Theorem 5). Additionally, we gave some interesting corollaries that contributes only to the theory of normal forms and they cannot be translated into the theory of $F^{\uparrow(\downarrow)}$-transforms, which shows that even though both theories have a lot in common, it is also important to study them separately.

An Interval Type-2 Fuzzy Distribution Network

Simon M. Miller, Viara Popova, Robert John, Mario Gongora

Centre for Computational Intelligence, De Montfort University, Leicester, UK.
Email: {smiller,vpopova,rij,mgongora}@dmu.ac.uk

Abstract— *Planning resources for a supply chain is a major factor determining its success or failure. In this paper we introduce an* ***Interval Type-2 Fuzzy Logic model*** *of a distribution network. It is believed that the additional degree of uncertainty provided by Interval Type-2 Fuzzy Logic will allow for better representation of the uncertainty and vagueness present in resource planning models. First, the subject of* ***Supply Chain Management*** *is introduced, then some background is given on related work using Type-1 Fuzzy Logic. A description of the Interval Type-2 Fuzzy model is given, and a test scenario detailed. A* ***Genetic Algorithm*** *uses the model to search for a near-optimal plan for the scenario. A discussion of the results follows, along with conclusions and details of intended further work.*

Keywords— Distribution model, Evolutionary Computing, Interval Type-2 Fuzzy Logic, Resource Planning, Supply Chain Management

1 Introduction

There are a number of definitions of Supply Chain Management (SCM), each having minor variances but describing the same core idea. SCM is the management of material flow in and between facilities including vendors, manufacturing/assembly plants and distribution centres [1]. Planning the allocation of resources within a Supply Chain (SC) has been critical to the success of manufacturers, warehouses and retailers for many years. Mastering the flow of materials from their creation to the point of sale offers considerable advantages to those within a well managed SC. Poorly managed resources result in two main problems: stock outs and surplus stock.

The consequence of stock outs is lost sales, and potentially lost customers. Surplus stock causes additional holding cost and the possibility of stock losing value as it becomes obsolete. Holding some surplus stock is advantageous however; safety stock can be used in the event of an unexpected increase in demand or to cover lost productivity.

The problem has been addressed numerous times in the literature using different approaches. An overview of traditional and Computational Intelligence approaches to supply-chain resource planning can be found in [2]. Here a novel approach using Type-2 Fuzzy Logic (T2FL) [3] is reported together with optimisation by means of a Genetic Algorithm (GA)[4].

This research is part of a project on demand forecasting and resource planning (Data Storage, Management, Retrieval and Analysis: Improving Customer Demand and Cost Forecasting Methods funded by the Technology Strategy Board in the UK). The project aims to: (1) improve the forecasting of demand by using a variety of disparate sources and statistical and Machine Learning (ML) methods for analysis; (2) improve the allocation of resources in which the generated forecast is used as an input and the output is a (long- or short-term) plan of raw materials and resources within the supply chain in order to meet such demand. Various degrees of uncertainty are present in the different data sources used that are amplified in the generated forecast by applying methods of analysis with (again) varying degrees of inherent uncertainty. Furthermore, other data that is often used in resource planning such as transportation and other costs, customer satisfaction information, etc. is also uncertain. Therefore, FL and especially T2FL are particularly appropriate for this problem. While Type-1 FL (T1FL) has successfully been used many times for modelling SC operation (see Section 2), T2FL has been shown to offer a better representation of uncertainty on a number of problems (e.g., [5] and [6]). However, to date T2FL has not been applied to SCM in the literature. This paper presents a T2FL model of a SC problem which is optimised by a GA to find a near-optimal configuration.

The paper is organised as follows. Section 2 discusses Fuzzy Logic and its application to SCM. Section 3 introduces the model and the test case used for evaluation. The results from the experiments on the test case are presented in Section 4. Section 5 concludes the paper with a summary and future research directions.

2 Fuzzy Logic for Supply Chain Management

FL and GAs have been successfully used for supply chain modelling [2] and are particularly appropriate for this problem due to their capacity to tackle the inherent vagueness, uncertainty and incompleteness of the data used. A GA [4] is a heuristics search technique inspired by evolutionary biology. Selection, crossover and mutation are applied to a population of individuals representing solutions in order to find a near-optimal solution. FL is based on fuzzy set theory and provides methods for modelling and reasoning under uncertainty, a characteristic present in many problems, which makes FL a valuable approach. It allows data to be represented in intuitive linguistic categories instead of using precise (crisp) numbers which might not be known, necessary or in general may be too restrictive. For example, statements such as *'the cost is about n'*, *'the speed is high'* and *'the book is very old'* can be described. These categories are represented by means of a membership function which defines the degree to which a crisp number belongs to the category. In this research the aim is to allow linguistic terms to be used by Supply Chain Managers when describing their operation. For example, instead of asking for crisp numbers to describe the current stock level of a product, we may allow them to make statements like 'Warehouse 1 has *About 500* of product 1' or even more abstract 'Warehouse 1's stock level of product 1 is *low*'. By removing the need for exact information it is possible to produce a system that is much more usable when the information available is vague, uncertain or incomplete.

ISBN: 978-989-95079-6-8

T1FL has been applied to SC modelling numerous times with good results. Some of the research that is considered most relevant for this paper is discussed in the following paragraphs.

Petrovic et al. [7] use fuzzy sets to model vagueness and imprecision in customer demand, external supplier reliability and supply within a SC. The system demonstrates the effect of differing conditions and strategies on fill rate and holding costs of a SC. The results of the evaluation show that there is a slight improvement in the performance of the SC when the inventories are partially co-ordinated. In [8] Petrovic et al. employ two-level fuzzy optimisation to find ideal order-up-to quantities in a one warehouse-multiple retailer SC. The problem is decomposed for individual control of the warehouse and retailers; a co-ordination mechanism provides overall control of the SC. Customer demand, inventory levels, holding cost, and shortage cost are represented by fuzzy sets. A measure of satisfaction is derived from the cost incurred at each element. The solution produced by the system is the best compromise between members, though not necessarily the cheapest.

In [9] a fuzzy system is used with a GA to model a SC. The model uses a global policy of management with emphasis on integrating the production and distribution models. The GA searches for a near-optimal configuration; fuzzy sets are used to describe costs, returns, production capacities, storage capacities and forecasts. The proposed fuzzy method, a crisp method and a non-integrated method are compared. The crisp system is unable to produce a feasible configuration if actual demand is lower than the forecast. In contrast, the fuzzy model presented is robust and able to cope with fluctuation in demand and production capacity with little impact on profitability. The non-integrated model performed significantly worse than the fuzzy integrated model.

A similar approach is presented by Wang and Shu [10]. FL is used to represent customer demand, processing time and delivery reliability; a GA finds order-up-to levels. The system attempts to find the configuration that incurs the minimum cost. An optimism-pessimism index is set by the user and passed to the system. When optimistic, the model assumes the best case scenario for material response time. A pessimistic attitude produces the opposite effect. The results show that more pessimistic strategies increase the fill rate, reducing the sales lost through stock outs, and incur higher inventory cost as more stock is kept. More optimistic strategies result in a drop in fill rate and an increase in sales loss, though inventory cost is also reduced.

T2FL [3] provides the means to model an additional dimension of uncertainty as the membership functions are themselves modelled as fuzzy numbers, thus providing the means for a more accurate representation of uncertainty in a complex system and the potential for better performance. On a number of problems, T2FL has been shown to outperform T1FL (e.g., [5] and [6]), however it has not yet been applied to SC modelling in the literature. In this paper, Interval Type-2 FL (IT2FL) [11] is used which is computationally cheaper as it restricts the additional dimension, referred to as secondary membership function, to only take the values 0 or 1. We believe that the extra degree of freedom will allow a better representation of the uncertain and vague nature of data used in SCM. Section 3 describes the created model in detail as well as the test case used for evaluation.

3 Model

The model presented here describes a distribution network consisting of a set of manufacturing warehouses and customers. Each warehouse holds one or more products; when demand of an item is forecast for a customer, a warehouse is selected to satisfy the demand. Before the model is used it is configured to model the required network. This is done by telling the model how many warehouses, customers and products there are, the distances between the warehouses and customers, the costs associated with network operation and how many periods the model is to run for. As input, the model takes a forecast of demand over a given period and a suggested resource plan for the warehouses detailing how much of each item to hold at each warehouse in each period.

The purpose of the model is to calculate the cost of a given resource plan. This is calculated based on a number of factors:

Production Cost - Each product is assigned an individual production cost. The total production cost for each batch is calculated by multiplying the number of items by their production cost.

Holding Cost - A holding cost is charged if a product is kept in a warehouse for more than one period. The cost is calculated by taking a specified percentage of the purchase price of the goods held, for items carried over from one period to the next. The purpose of the charge is to represent the costs of storing items, depreciating value of stock and the losses incurred by tying up capital in unsold stock.

Transport Cost - The cost of transporting goods is produced using a matrix of distances between warehouses and customers, and a list of transport costs per mile for each product. The product of the relevant cost and mileage gives the overall transport cost for a batch of product.

Stock out cost - Stock out is the shortfall of a product in a particular period. In this model we make the assumption that the customer is always provided with an item. If it is not in the warehouse, it is purchased at full retail price from a competing producer. The stock out cost is the sum of the value of items that had to be purchased in this period. Cost of purchase is not the only penalty incurred when stock out occurs. The customer may cancel their order if they discover that it is not in stock, and will be ordered elsewhere. To represent this a multiplier is applied to the stock out cost, taking into account the cost of lost orders.

Batch cost - The cost of setting up an order is called the batch cost. This represents the cost of administration and setting up any machines that are required, and picking the items for dispatch. There is a flat fee for each batch which is charged once at each warehouse for the production of a particular item for a particular customer.

Using these costs a total cost is produced, allowing comparison of competing solutions.

3.1 Interval Type 2 Fuzzy Logic

For the experimental model IT2FL has been used to represent some of the values within the model. Previous examples (as

ISBN: 978-989-95079-6-8

discussed in Section 2) of research in this area have focused on the use of T1FL; we believe there exists an opportunity to exploit the extra degree of uncertainty provided by IT2FL in a model of this type.

As the model operates on fuzzy numbers, fuzzy arithmetic is used to calculate costs. This involves taking fuzzy sets, discretising them, performing the arithmetic operation, and then reconstructing the fuzzy set. In this model, fuzzy sets are represented using a series of α-cuts. Each set is an array of pairs of intervals. Each pair shows the area of values covered at a particular value of μ, the first interval is the left hand side of the set, and the second the right. Storing the sets in this way removes the need to discretise before fuzzy arithmetic is performed, and then reconstruct the result. Operations on fuzzy sets are performed at interval level, corresponding intervals (at the same μ) are taken from two sets, the operation performed and the result stored in a third fuzzy set.

The following values are represented by IT2 fuzzy numbers: forecast demand, inventory level, transportation distances, transportation cost, stock out level, stock out cost, carry over and holding cost. For each of these values we can use the linguistic term *'about n'*, e.g., forecast demand of product 1 for customer 1 in period 1 may be *'about 200'*. When the fuzzy total cost for a solution has been calculated, it is defuzzified to produce a crisp cost value. Fig. 1 shows how the set *'about 200'* may look with the α-cut representation used, where x is the scale of values being represented. The set is described using a collection of pairs of intervals. Each pairing represents the left and right hand intervals of the set for a given value of μ. As stated before, representing the set in this way considerably simplifies the arithmetic operators that are applied as simple interval arithmetic is used throughout, without discretisation or reconstruction.

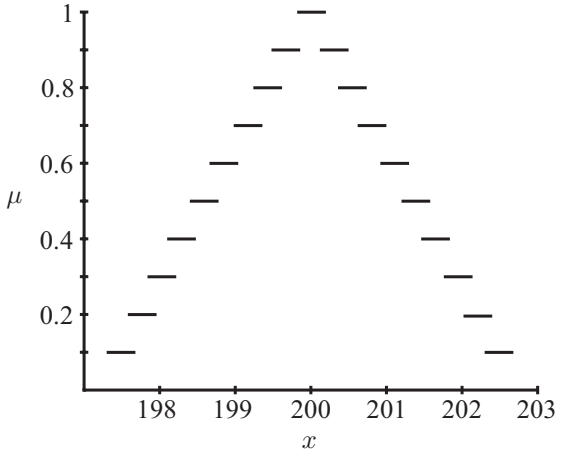

Figure 1: Interval representation of IT2 fuzzy set *'about 200'*

3.2 Defuzzification

The defuzzification process used is described in (1) where n is equal to the number of α-cuts, and l and r denote the left and right hand intervals respectively. To reference the left and right endpoints of the intervals $_1$ and $_2$ are used; so l_1 refers to the left bound of l and l_2 the right bound. M denotes the mid-point of an interval, in the case of M_i^x this means the centres of the intervals in x described by the i^{th} pair of intervals. For M^{α_i} we take the mid-point between the current and subsequent α-cut's μ values. The mid-point values are used along with the height (H) and length (L) to calculate the weighted area of each pair of intervals, giving more weight the those with higher μ values.

$$\frac{\sum_{i=0}^{n-1} M_i^x H_i L_i M^{\alpha_i}}{\sum_{i=0}^{n-1} H_i L_i M^{\alpha_i}} \tag{1}$$

where:

$$M_i^x = \begin{cases} \frac{x_{l_2}^{\alpha_i} + x_{l_1}^{\alpha_i}}{2} & \text{for left interval} \\ \frac{x_{r_2}^{\alpha_i} + x_{r_1}^{\alpha_i}}{2} & \text{for right interval} \end{cases} \tag{2}$$

$$H_i = \alpha_{i+1} - \alpha_i \tag{3}$$

$$L_i = \begin{cases} x_{l_2}^{\alpha_i} - x_{l_1}^{\alpha_i} & \text{for left interval} \\ x_{r_2}^{\alpha_i} - x_{r_1}^{\alpha_i} & \text{for right interval} \end{cases} \tag{4}$$

$$M^{\alpha_i} = \frac{\alpha_i + \alpha_{i+1}}{2} \tag{5}$$

In the test scenario, μ is discretised in a uniform manner. This removes the need to calculate the height of intervals as they are all the same, and therefore cancel out. The process used in the actual code is given in (6).

$$\frac{\sum_{i=0}^{n-1} M_i^x L_i M^{\alpha_i}}{\sum_{i=0}^{n-1} L_i M^{\alpha_i}} \tag{6}$$

It should be pointed out that while this method works well for the convex fuzzy numbers used in this system, it cannot be applied to non-convex fuzzy sets as the interval representation employed will cease to accurately represent the set. In this model, the fuzzy numbers will always be convex. In addition to this the method of representation being used ensures that the intervals are already present, no further discretisation is required. Using a method that requires re-discretisation would incur unnecessary computation. A consideration for future work is the possibility of using another approach such as the one proposed by Karnik and Mendel [12], however this method would involve rediscretising on the x axis, at present the model is discretised on the μ axis.

3.3 Optimisation

The focus of the experiment described here is the validation of an IT2FL model that has been constructed. This is to be achieved by using the model to find a good resource plan for a

ISBN: 978-989-95079-6-8

given forecast, confirming that the model can be used to evaluate potential solutions. A GA has been chosen for this purpose. GAs have been used successfully in previous work (e.g., [13] and [14]) to find good solutions with T1FL models. GAs are useful when a search area is too large to allow evaluation of every solution. In this case the GA is used to search for a resource plan that incurs the minimum cost. The GA has a population of 250 and is executed for 500 generations, in all 125000 solutions are evaluated. Even in this relatively small problem the GA only covers approximately $\frac{1}{10^{62}}$ of the total search space. New generations consist of: 1% individuals produced with elitism, 20% copied individuals, 20% individuals created with single point crossover and 59% of individuals created using mutation. A description of the chromosome, operators and processes employed follows.

Chromosome - The chromosome used to describe potential solutions is a 3-D matrix of inventory levels. Columns represent customers, and rows represent a product at a warehouse. If there are 3 warehouses and 5 products this will result in 15 rows. The first 5 rows will be products 1 to 5 for warehouse 1, and second 5 for warehouse 2 and so on. The third dimension represents the period, in each period there is a complete inventory plan for all warehouses and customers.

Initial population - The initial population is randomly generated. Each element of the resource plan matrix can be a number between 0 and 500 in steps of 100. This has been done to reflect the fact that in industry, products are usually manufactured in round quantities. If the model suggests that a warehouse should make 102 of product 1, this could lead to difficulties and extra expense. Limiting the valid inventory numbers also has the side effect of reducing the search space.

Fitness evaluation - Fitness is evaluated using the IT2FL model described. Candidate solutions are given to the model which evaluates them, and returns the cost. The cheaper a solution is, the fitter it is judged to be. In reality, cost may not be the only factor in deciding how much of a product to stock at each warehouse. Other criteria such as customer service level can also be used to prevent the system from choosing solutions that do not meet service requirements. Customer service level could be calculated by looking at the percentage of orders fulfilled completely, or orders fulfilled on time.

Selection - Selection is performed using a fitness ranking proportionate method similar to *roulette wheel selection*. First all solutions in the population are ranked by fitness. They are then given a number of elements of an array in proportion to their fitness ranking. For example, if we have a population of 250 the fittest individual would be allocated 250 elements in the array, the second fittest 249 and so on. An element of the array is then selected at random, and the identification number of the individual it contains is used to retrieve a parent. This tombola style approach ensures that it is possible for any individual to be selected, while weighting in favour of those with greater fitness.

Crossover - Crossover is achieved with a single point crossover. Two parents are selected using the method of selection described. Then, a new individual is created with the first half of the first parent and the second half of the second parent. Division is done by rows, if we have 5 nodes with 4 products we would have 20 rows; in this case the first 10 rows of the first parent and the final 10 of the second parent would be used to create a new individual. If the example were to span 6 periods, we would take the first 10 rows for all 6 periods of the first parent, and the final 10 rows for all 6 periods from the second to create our new individual.

Mutation - To create a mutated individual, a parent is selected, then one of the elements of its resource plan is randomly replaced with another valid value to create a new child.

3.4 Test Scenario

The test scenario is as follows:

The distribution network consists of 3 manufacturing warehouses located in Bristol (W1), Manchester (W2) and Edinburgh (W3) and 6 customers in Plymouth (C1), Cardiff (C2), Derby (C3), Liverpool (C4), Newcastle (C5) and Aberdeen (C6). Each manufacturing warehouse holds the same 5 products, and may supply any customer. The model will be executed over one period and holding costs are 10% of the purchase price of an item per period. Stock outs will be charged at 5 times the cost of purchasing an item, per item short. Each batch of product produced will incur a batch cost of £100. Table 1 details the costs associated with each product.

Table 1: Product costs (£s)

Product	1	2	3	4	5
Purchase price (per item)	3	4	2	3	3
Production cost (per item)	2	3	1	2	2
Transport cost (per item/per mile)	1	2	1	3	1

The forecast being used states that each customer would like 200 of each product. The location of the manufacturing warehouses and customers have been arranged so that a good solution is easily identifiable. Each warehouse has 2 customers that are best served by it. Table 2 shows how an ideal plan should look. In this case the problem is intentionally kept relatively simple, making it easy to evaluate the found solution and see if it is near the optimal solution. Clearly, simple problems do not require such a system in order to solve them. The work shown here is an initial experiment, future work will build upon this so that it can be applied to larger non-trivial problems where the benefit from the system will be greater.

The next section presents and interprets the results from the experiments with the GA.

4 Results

As stated previously, in each test the GA was applied to the model using 250 individuals over 500 generations. The test was repeated 10 times with differing random seeds, the best solution found in each test was recorded. Table 3 shows the costs incurred by the best solution found in each test. For reference, the cost of the ideal solution presented is £19178.26.

Using the IT2FL model the GA is able to find solutions that are close to the optimum. The best solution found is just £264.76 (1.38%) from the ideal solution, and the mean difference between solutions found and the ideal solution is £1344.79 (7.01%). Table 4 shows the best solution found (with random seed 1). Comparing this solution with the ideal

solution we can see that not only are the plans found cost-effective, but also represent a sensible allocation of resources. The found solution is very close to the ideal solution, and where there are differences the found model is producing the correct amount of product, but a different warehouse has been chosen. This would not be the case if the model was inadequate for the problem and did not provide a clear distinction between good and bad solutions. All customers will receive their order, the only negative point is that some of customer 4 and 5's orders could be supplied by a closer warehouse.

When the program begins, the best individual in the first generation tends to cost around £70000. Fig. 2 shows a typical run, in this case for the test with a random seed of 1. Evolution can clearly be seen to be heading toward the ideal solution, we also know what the perfect solution looks like, and that the solutions found are close to it. This suggests that the model is working correctly. If the model were not correct, evolution may occur, but possibly in an unexpected direction. This could result in cheap solutions that are not sensible, or in an inability to find cost-effective solutions at all.

Out of interest, an extra test was run to see whether the GA would find a better solution if it were left to run over more generations. The best seed from the previous tests (random seed 1) was used as a starting point, and the GA was allowed to run for 2500 generations. In generation 2141 the ideal solution was found, proving that using only feedback from the model, the GA is able to find the ideal solution.

5 Conclusion

In this paper we have presented an IT2FL model that can be used to model a distribution network. The advantage of this model is that IT2FL accounts for the uncertain nature of the real world, allowing inputs to the model to be vague. IT2FL has been chosen as it is believed that the extra level of uncertainty over T1FL offered will benefit a model of this type, while avoiding the computational complexity of a Generalised Type-2 FL model.

Using the model, it was shown that a GA was able to find good resource plans that were both cost-effective and sensible. Over a longer duration, the GA was able to find the ideal solution. As a GA is solely guided by fitness and essentially 'blind' to the practicality of the solutions it finds, this was taken as indication of the model's validity.

There is much further work to be done with this model in order to make it useful in real world applications. Initially, the model will be extended for use in cases where an ideal result has been calculated by other means (e.g., a statistical model) so that performance comparison is possible. In these cases we would be looking for both accuracy of costings provided,

ISBN: 978-989-95079-6-8

and the ability of an optimisation algorithm to find good solutions. As well as being larger problems, these case studies may also call for more than just cost as a measure of fitness. As discussed in the paper, this will mean adding in a measure of customer satisfaction such as fill rate to ensure that good plans are those that are not only cost-effective, but also help to retain customers.

The current model does not take into account the temporal nature of manufacture and supply. Another dimension that is to be considered is how *lead times* affect the operation of the network. Lead times are another attribute that could benefit from an IT2FL representation, as we can never be certain when a product will arrive, or exactly how long it will take to produce. Part of this will include representing capacity, as at present only inventory is accounted for by the model. This will allow the optimising algorithm to suggest not only stock levels, but also capacity levels within a factory. Capacities can then be used to provide some indication of how long we should expect to wait for a given batch of product to be manufactured.

1 Introduction

The spaces $\mathcal{K}$, of all closed and bounded intervals of $\mathbb{R}$ is not linear spaces since it do not contain inverse elements for the addition and therefore subtraction is not well defined. As a consequence, alternative formulations for subtraction have been suggested. One of those alternatives are the H-diference [3, 13] and by embedding the space $\mathcal{K}$ in a linear space [22].

The Radström's embedding theorem [22] tell us that there is a real normed linear space $\mathcal{B}$ and an isometric mapping $\pi : \mathcal{K} \to \mathcal{B}$. Then, taking advantage of this embedding theorem, a set-valued mappings F is π-differentiable at t_0 if $\pi \circ F$ is differentiable at t_0. In [3], we can find various properties of this derivative and its connection with other definitions of derivatives for set-valued mappings. On the other hand, in [20] each element of $\mathcal{B}$ can be represented in the form (x, δ). Thus, the π-derivative of $\pi \circ F$ is associated with the derivative of an ordered pair. In [9] the authors obtained a set $F'_{\pi}(t) \in \mathcal{K}$, which is said π-derivative of F at t. Some properties and the conection with generalized derivative are studied.

The aim of this paper is introduce the π-derivative for fuzzy interval valued functions based in the generalization of π-derivative for set-valued mappings given in [9]. Consequently, using the π-derivative for fuzzy functions, we study fuzzy differential equations. In particular, we build a solution for a fuzzy differential equation with the help of a system of ordinary differential equations which is generates of the π-derivative.

2 Preliminaries

Let $\mathbb{R}$ be the 1-dimensional Euclidian space. We denote by $\mathcal{K}$ the family of all bounded intervals

$$\mathcal{K} = \{A = [a, b] \subset \mathbb{R} \mid A \neq \emptyset \text{ is bounded } \}$$

The Hausdorff metric H is defined by

$$H(A, B) = \max \{|a - c|, |b - d|\}.$$

where $A = [a, b]$ and $B = [c, d]$.

Also, by using the Minkowski sum between two sets, we defined the following operations on $\mathcal{K}$

$$A + B = \{a + b \mid a \in A,\ b \in B\} \text{ and } \lambda A = \{\lambda a \mid a \in A\}. \tag{1}$$

The spaces $\mathcal{K}$ is not linear spaces since it do not contain inverse elements and therefore subtraction is not well defined [1, 2].

We have, from (1), that $A - B = A + (-1)B$. Also, if $A = B + C$, then the Hukuhara difference of A and B is denoted by $A -_H B$ and it is equal to C. The Hukuhara difference of A and B is also called the geometrical difference between the sets A and B [27].

In [3] the authors introduce subtraction in $\mathcal{K}$ by using the Radström's embedding theorem [22] which tell us that there is a real normed linear space $\mathcal{B}$ and an isometry $\pi : \mathcal{K} \to \mathcal{B}$ such that $\pi(\mathcal{K})$ is a convex cone in $\mathcal{B}$.

To construct $\mathcal{B}$, we consider the following equivalence relation in the space $\mathcal{K} \times \mathcal{K}$

$$(A, B) \sim (C, D) \quad \text{if and only if } \ A + D = B + C.$$

If $\langle A, B\rangle$ is the equivalence class of the pair (A, B), then $\mathcal{B}$ is the quotient space $\mathcal{K} \times \mathcal{K}/\sim$. Now, in $\mathcal{B}$ we introduce the operations of addition and scalar multiplication by means

$$\langle A, B\rangle + \langle C, D\rangle = \langle A + C, B + D\rangle,$$

$$\lambda \langle A, B\rangle = \begin{cases} \langle \lambda A, \lambda B\rangle & \lambda \geq 0, \\ \langle |\lambda| B, |\lambda| A\rangle & \lambda < 0 \end{cases}$$

Then $\mathcal{B}$ is a linear space.

One defines the embedding $\pi : \mathcal{K} \to \mathcal{B}$ as follows

$$\pi(A) = \langle A, 0\rangle, \ \ A \in \mathcal{K},$$

so that $\langle A, 0\rangle$ is the equivalence class
$\{(A + D, D) \mid A, D \in \mathcal{K}\}$.

The metric and the norm in $\mathcal{B}$ are defined by

$$\rho(\langle A, B\rangle \ , \ \langle C, D\rangle) = H(A + D \ , \ C + B)$$

$$\|\langle A, B\rangle\| = \rho(\langle A, B\rangle \ , \ \langle 0, 0\rangle)$$

If $A, B \in \mathcal{K}$, then the difference of the sets A and B is an alement of $\mathcal{B}$ equal to $\langle A, B\rangle$. Since $\mathcal{B}$ is a linear space, difference has all the properties of difference in linear spaces.

ISBN: 978-989-95079-6-8

In general, the difference of two sets in $\mathcal{K}$ is not necessarily an element of $\mathcal{K}$. On the other hand if the Hukuhara diference is well defined for two sets A, B in $\mathcal{K}$, then

$$\langle A, B\rangle = \langle A -_H B, 0\rangle .$$

3 π-derivative for set-valued mappings

In this Section we present the π-derivative for set-valued mappings. This concept has been studied by the authors in [9].

Elements of the space $\mathcal{K}$ are bounded and closed intervals, therefore each equivalence class can be represented in the form

$$\langle [x, x+\delta]\ ,\ 0\rangle\ ,\ \delta \geq 0 \quad \text{or} \quad \langle 0\ , [-x, -x-\delta]\rangle\ ,\ \delta < 0.$$

We will call this the canocical representation [20].

In fact, an arbitrary element $([a,b]\ ,\ [c,d])$ belongs to a class of the first kind if $b-a \geq d-c$ (then $x = a-c,\ \delta = (b-a)-(d-c)$) and to a class of the second kind if $b-a < d-c$ (then $x = a-c,\ \delta = (b-a)-(d-c)$).

For the canonical representation of an equivalence class we will use the notation (x, δ), which implies that

$$(x,\delta) = \begin{cases} \langle [x,\ x+\delta]\ ,\ 0\rangle & \text{if} \quad \delta \geq 0 \\ \langle 0,\ [-x,\ -x-\delta]\rangle & \text{if} \quad \delta < 0. \end{cases} \tag{2}$$

Given $A = [a,b] \in \mathcal{K}$ we have

$$\pi(A) = \pi([a,b]) = \langle [a,\ b]\ ,\ 0\rangle = \langle [x, x+\delta], 0\rangle ,$$

where $x = a$ and $\delta = b-a$.

Theorem 1 *([20]) The following results hold*

(a) $(x,\delta) = (y,\beta) \Longleftrightarrow x = y,\ \delta = \beta$;

(b) $(x,\delta) + (y,\beta) = (x+y, \delta+\beta)$;

(c) $a(x,\delta) = (ax, a\delta)$ *for each* $a \in \mathbb{R}$.

Theorem 2 *([20]) The equality*

$$D_\pi(x(t), \delta(t)) = (x^{'}(t), \delta^{'}(t))$$

holds, where $D_\pi(x(t),\delta(t))$ *is the* π*-derivative ([3]) of the pair* $(x(t),\delta(t))$ *and* $x^{'}$ *is the derivative of the real-valued function* $x(t)$.

Let $F : T \to \mathcal{K}$ be a set-valued mapping. If we denote by $F(t) = [f(t), g(t)]$, then

$$\pi(F(t)) = \langle [x(t), x(t)+\delta(t)], 0\rangle ,$$

where $x(t) = f(t)$ and $\delta(t) = g(t) - f(t)$.

From Theorem 2 $D_\pi(x(t),\delta(t)) = (x^{'}(t), \delta^{'}(t))$ and from canonical representation (2) we obtain the set $F_\pi^{'}(t) \in \mathcal{K}$ such that

$$F_\pi^{'}(t) = \begin{cases} \left[x^{'}(t), x^{'}(t) + \delta^{'}(t)\right] & \text{if} \quad \delta^{'}(t) \geq 0 \\ \left[x^{'}(t) + \delta^{'}(t), x^{'}(t)\right] & \text{if} \quad \delta^{'}(t) < 0. \end{cases} \tag{3}$$

We will say that $F_\pi^{'}(t_0)$ is the π-derivative of the set-valued mapping F at t_0.

Corollary 1 *([9]) Let* $F : T \to \mathcal{K}$ *be a set-valued mapping and we denote* $F(t) = [f(t), g(t)]$. *Then* F *is* π*-differentiable at* t_0 *if and only if* f *and* g *are differentiable functions at* t_0.

Example 1 *([9]) Consider the set-valued mapping* $F : (-1,1) \to \mathcal{K}$ *defined by* $F(t) = \left[-t^2, e^{-t}\right]$. *If* $f(t) = -t^2$ *and* $g(t) = e^{-t}$, *we have that* f *and* g *are differentiable functions and* $f^{'}(t) = -2t$ *and* $g^{'}(t) = -e^{-t}$. *In this case* $x^{'}(t) = -t^2$ *and* $\delta^{'}(t) = -e^{-t} + 2t$. *Therefore, from (3) we have*

$$F_\pi^{'}(t) = \begin{cases} [-e^{-t}\ ,\ -2t] & \text{if} \quad t \in (-1, 0.35173] \\ [-2t\ ,\ -e^{-t}] & \text{if} \quad t \in (0.35173, 1). \end{cases}$$

Note that the π-derivative (3) is coincident with the generalized derivative introduced in [26].

4 π-derivative for fuzzy functions

Let $\mathcal{F}$ be the set of all fuzzy intervals with bounded α-level intervals. This means that if $u \in \mathcal{F}$ then the α-level set is a closed bounded interval which we denote by $[u]^\alpha$, for all $\alpha \in [0,1]$.

Let T be a real interval. A mapping $X : T \to \mathcal{F}$ is called a fuzzy function. We denote

$$[X(t)]^\alpha = X_\alpha(t) = [f_\alpha(t), g_\alpha(t)],\ \ t \in T,\ \ 0 \leq \alpha \leq 1.$$

Note that X_α is a set-valued mapping for each $\alpha \in [0,1]$. The π-derivative $X_\pi^{'}(t)$ of a fuzzy function X is defined by

$$[X_\pi^{'}(t)]^\alpha = X_{\alpha\pi}^{'}(t),\ \ 0 \leq \alpha \leq 1, \tag{4}$$

provided that is equation defines a fuzzy interval $X_\pi^{'}(t) \in \mathcal{F}$. Note that, if the family $\{X_{\alpha\pi}^{'}(t)\}$ satisfies the conditions of the Representation Theorem [10], then there exists the π-derivative $X_\pi(t)^{'}$ of the fuzzy function X.

Example 2 *Consider the fuzzy function* $X : (0, +\infty) \to \mathcal{F}_C$ *defined by*

$$X(t)(s) = \begin{cases} \frac{s}{t} + 1 & \text{if} \quad -t \leq s \leq 0 \\ -\frac{s}{t^2} + 1 & \text{if} \quad 0 \leq s \leq t^2 \\ 0 & \text{if} \quad s \notin [-t, t^2]. \end{cases}$$

Then, for all $\alpha \in [0,1]$ *we have*

$$[X(t)]^\alpha = [f_\alpha(t), g_\alpha(t)] = [(\alpha-1)t, (1-\alpha)t^2],$$

and from (3)

$$X_{\alpha\pi}^{'}(t) = [(\alpha-1), 2(1-\alpha)t].$$

Now, the family $\{X_{\alpha\pi}^{'}(t)\}_{\alpha\in[0,1]}$ *satisfies the conditions from Representation Theorem [10] for each* $t > 0$. *Therefore, there exists the* π*-derivative* $X_\pi^{'}(t)$ *of the fuzzy function* X *for each* $t > 0$ *and*

$$\left[X_\pi^{'}(t)\right]^\alpha = [(\alpha-1), 2(1-\alpha)t].$$

5 Fuzzy differential equation with π-derivative

We consider the initial value problem

$$X^{'}(t) = F(t, X(t)), \quad X(0) = X_0, \tag{5}$$

where $F : [0, T] \times \mathcal{F} \to \mathcal{F}$ is a continuous function and X_0 is a fuzzy interval.

Note that there are different interpretations for the problem (5). For example, in the problem (5), we can consider the H-derivative [15, 16, 17, 19, 23, 24, 25]; the Generalized derivative [4, 5, 6, 7, 8]. Also, the problem (5) can be rewrite as a family of differential inclusions [11, 12, 14]. In this section we will consider the π-derivative in the problem (5), i.e. we will study the following problem

$$X^{'}_{\pi}(t) = F(t, X(t)), \quad X(0) = X_0, \tag{6}$$

where $F : [0, T] \times \mathcal{F} \to \mathcal{F}$ is a continuous function and X_0 is a fuzzy interval. A solution of (6) is a continuous fuzzy function $X : T \to \mathcal{F}$ which verifies the equation (6) for each $t \in T$.

Taking in account the Theorem 1 and Theorem 2, we obtain a useful procedure to solve the fuzzy differential equation (6).

In fact, denote

$$[X(t)]^{\alpha} = [f_{\alpha}(t), g_{\alpha}(t)] \ , \quad [X_0]^{\alpha} = [u^0_{\alpha}, v^0_{\alpha}]$$

and

$$[F(t, X(t))]^{\alpha} = [U_{\alpha}(t, f_{\alpha}(t), g_{\alpha}(t)) \ , \ V_{\alpha}(t, f_{\alpha}(t), g_{\alpha}(t))].$$

Then, using the canocical representation (Section 3), we obtain

$$\pi\left([X(t)]^{\alpha}\right) = (x_{\alpha}(t) \ , \ \delta_{\alpha}(t)) \ , \ \pi\left([X_0]^{\alpha}\right) = \left(x^0_{\alpha} \ , \ \delta^0_{\alpha}\right)$$

where $x_{\alpha}(t) = f_{\alpha}(t)$, $\delta_{\alpha}(t) = g_{\alpha}(t) - f_{\alpha}(t)$, $x^0_{\alpha} = u^0_{\alpha}$ and $\delta^0_{\alpha} = v^0_{\alpha} - u^0_{\alpha}$. Also

$$\pi\left([F(t, X(t))]^{\alpha}\right) = \left(U^1_{\alpha}(t, x_{\alpha}(t), \delta_{\alpha}(t)), V^1_{\alpha}(t, x_{\alpha}(t), \delta_{\alpha}(t))\right)$$

Thus, we consider the following family of equations corresponding to the problem (6)

$$\begin{array}{l} D_{\pi}(x_{\alpha}(t), \delta_{\alpha}(t)) = \left(U^1_{\alpha}(t, x_{\alpha}(t), \delta_{\alpha}(t)), V^1_{\alpha}(t, x_{\alpha}(t), \delta_{\alpha}(t))\right) \\ (x_{\alpha}(0), \delta_{\alpha}(0)) = (x^0_{\alpha}, \delta^0_{\alpha}) \end{array} \tag{7}$$

with $\alpha \in [0, 1]$.

Now, using the Theorem 1 and 2 and the problem (7), we obtain a solution from problem (6). For this, we proceed as follows:

(i) Solve the differential system

$$\left\{ \begin{array}{ll} x^{'}_{\alpha}(t) = U^1_{\alpha}(t, x_{\alpha}(t), \delta_{\alpha}(t)), & x_{\alpha}(0) = x^0_{\alpha} \\ \delta^{'}_{\alpha}(t) = V^1_{\alpha}(t, x_{\alpha}(t), \delta_{\alpha}(t)), & \delta_{\alpha}(0) = \delta^0_{\alpha} \end{array} \right.$$

for x_{α} and δ_{α};

(ii) from class $(x_{\alpha}(t), \delta_{\alpha}(t))$ we obtain the interval

$$X_{\alpha}(t) = \left\{ \begin{array}{ll} [x_{\alpha}(t), x_{\alpha}(t) + \delta_{\alpha}(t)] & \text{if} \quad \delta_{\alpha}(t) \geq 0 \\ [x_{\alpha}(t) + \delta_{\alpha}(t), x_{\alpha}(t)] & \text{if} \quad \delta_{\alpha}(t) < 0 \end{array} \right.$$

(iii) By using the Representation Theorem [10], we build a fuzzy solution $X(t)$ such that $[X(t)]^{\alpha} = X_{\alpha}(t)$, for all $\alpha \in [0, 1]$.

Example 3 *Let us consider the fuzzy malthusian problem*

$$\left\{ \begin{array}{l} X'_{\pi}(t) = -\lambda X(t) \\ X(0) = \ X_0, \end{array} \right. \tag{8}$$

where $\lambda > 0$ and, as in [12], the initial condition X_0 is a symmetric triangular fuzzy number with support $[-a, a]$. That is,

$$[X_0]^{\alpha} = [-a(1 - \alpha), a(1 - \alpha)].$$

For obtain a solution of (8), we have solve the following differential system

$$\left\{ \begin{array}{ll} x^{'}_{\alpha}(t) = -\lambda x_{\alpha}(t), & x_{\alpha}(0) = -a(1 - \alpha) \\ \delta^{'}_{\alpha}(t) = -\lambda \delta_{\alpha}(t), & \delta_{\alpha}(0) = 2a(1 - \alpha). \end{array} \right.$$

The solutions of this system are

$$x_{\alpha}(t) = -a(1 - \alpha)e^{-\lambda t} \quad \textit{and} \quad \delta_{\alpha}(t) = 2a(1 - \alpha)e^{-\lambda t},$$

where $\delta_{\alpha}(t) \geq 0$ for all $t > 0$. Thus there exists a fuzzy solution from (8) $X(t)$ for all $t > 0$, such that

$$\begin{array}{rcl} [X(t)]^{\alpha} & = & [x_{\alpha}(t), x_{\alpha}(t) + \delta_{\alpha}(t)] \\ & = & [-a(1 - \alpha)e^{-\lambda t}, a(1 - \alpha)e^{-\lambda t}]. \end{array}$$

6 Conclusions

In this paper we present the concept of π-derivative for fuzzy function using the canonical representation of a class equivalence of two intervals. Those classes of equivalence are obtained by embedding the space of closed and bounded intervals in a Banach space using the embedding theorem [22].

In a forthcoming paper we will study the properties of the π-derivative fuzzy and the connection between this approach and the π-derifferentiabiliy in the fuzzy context introduced in [21]. Also, we will study the connection with others concept of fuzzy derivatives. For example, the connection with the G-differentiability introduced in [4]. Note that this concept of π-derivative is equivalent to generalized derivative in the case of set-valued function [9].

In Section 5 we study fuzzy differential equations considering π-derivative. In particular we present a form for obtain a fuzzy solution from FDEs. This approach have some advantages in relation to others interpretation, for example, an advantage that have the fuzzy solutions obtained considering π-derivative seem to be more intuitive than other solution using H-derivative (Example 3). It is worthy to stress also that the interpretation using extension principle [7, 18] and fuzzy differential inclusion [11, 12, 14] has a disadvantage because we cannot speak about the fuzzy derivative. In this issue, in a forthcoming paper, we will study the existence of solution of a fuzzy differential equation considering π-derivative.

Abstract— *The indicator of groundwater contamination developed and used in agriculture is calculated from data available in the field or data estimated by an expert. The modeling of this indicator generally requires a large number of parameters whose measure is imprecise. Several information sources provide information about the same imprecise quantities which have to be combined for defining what is called an "indicator of groundwater contamination" (I_{gro}). This indicator estimates the impact of cultivation practices on the groundwater contamination.*

In this paper, we explore a possibilistic information fusion method by using the notion of maximal coherent subsets to represent the imprecisions of multisource variables of the indicator. We also calculate the bounds of this indicator, and we propagate imprecision by using an interval analysis. Finally, we present the indicator's results for pesticides applied on different crops.

Keywords— Possibility theory, fuzzy set, fusion, maximal coherent subset, interval analysis, indicator

1 Introduction

Data used in application domains are often imperfect: imprecise, uncertain, incoherent... Some data come from information sources (database, expert) and others are approximative measurements. When multiple sources –such as a database, an expert, a website, a book– deliver information about some unknown quantity, aggregating this information can be a tedious task, especially when information are incoherent. Actually, there are many approaches to specify the impact of input parameter imprecision of a model, such as statistical sampling methods, the Monte-Carlo method [1], and bayesian method. These methods require either a significant number of data and a lot of computation time, or an exact definition of the statistical properties of the input parameters. There exists also alternative approaches based on fuzzy set and possibility theory [2, 3] to express, in a non-probabilistic sense, imprecision of parameters. Each approach represents parameters imprecision in a specific way. When, we need to aggregate data from multiple sources, fuzzy approaches show more flexibility in the treatment of incoherent information. Recently, Destercke et al [4] explored a possibilistic information fusion using the notion of maximal coherent subsets to synthesize information from several incoherent data. In this paper, we will use this method to synthesize an information from several information sources to calculate variables used in indicator assessment.

An indicator measures a certain aspect of the agrosystem. It is proposed to help farmers to improve the environmental sustainability of their agricultural practices and to reduce the pollution of environment such as indicator of groundwater contamination I_{gro}. It estimates the possibility for a pesticide to reach groundwater through leaching. The modeling and the assessment of an indicator generally require a large number of parameters whose measure is imprecise such as the variable "soil depth", that indicates how thick the soil cover is. Multiple sources provide information about the imprecise quantities which compose the indicator I_{gro}, for example, pesticide characteristics such as pesticide half-life $DT50$. The calculation of I_{gro} is based on a system of decision rules using fuzzy sets [5]. Authors in [5] do not take into account the imprecision in parameters of the indicator.

In this paper, we present an original work that, at our knowledge, has not been carried out until now. We propose here an analysis of imprecision of the indicator, especially variables used and their nature. We are interested in imprecision of parameters provided by several sources. Then, we use imprecision for evaluating the amplitude and the effect of imprecision on the value of the indicator I_{gro}. Firstly, we change the input values of variables in the process of calculation. Then, we use intervals of values in place of single values of input variables in the calculation process of the indicator I_{gro}. We also explore a fusion method, using the notion of maximal coherent subset, for summarizing information about the quantity given by several sources [4]. Finally, we calculate a variation interval for the indicator I_{gro} given by the input intervals of the variables.

The paper is divided as follows: the first section presents the indicator of groundwater contamination I_{gro}, its definition, structure and data used. Theoretical preliminaries are introduced in the third section. Then, the fourth section describes the fusion method used and the way how maximal coherent subsets can be used to obtain intervals of the imprecise variables; we also explore a way to compute the lower and upper bounds of the indicator. Then, the fifth section presents the indicator of groundwater contamination, its definition and its structure. Finally, the sixth section shows the results of the indicator for four pesticides applied in different crops.

2 Application description

In this section, we define the indicator I_{gro}, its structure and data used in the process of calculation.

ISBN: 978-989-95079-6-8

2.1 The risk of groundwater contamination I_{gro}

2.1.1 Definition and data used

The indicator module I_{gro} reflects the potential of a pesticide to reach groundwater through leaching and to affect its potential use as a source of drinking water. I_{gro} as proposed by Van der Werf and Zimmer [5] depends on four input variables : (1) pesticide leaching potential (GUS); (2) position ; (3) leaching risk, and (4) toxicity of the pesticide for humans (based on Acceptable Daily Intake). Table 1 shows variables used to calculate I_{gro}.

Table 1: All variables for the I_{gro} and their description.

Variables	Description
Pesticide characteristics (quantitative variables)	
GUS	pesticide leaching potential
DT50	pesticide half-life
koc	organic-carbon partition
ADI	Acceptable Daily Intake
Environmental characteristics (qualitative variables)	
Leaching risk	Quantity leaching
Application characteristics (quantitative variables)	
Position	Position of application

Variable "pesticide leaching potential" (GUS) provides an estimation of the risk of leaching of the compound. This potentiel is calculated by the formula:

$$GUS = \log(DT50) * (4 - \log(koc)) \quad (1)$$

where variable DT50 is the pesticide half-life and "koc" is the organic-carbone partition coefficient.
Variable DT50 is the time required for the pesticide concentration under defined conditions to decrease to 50% of the amount in application. Variable "koc" is the organic-carbon constant that describes the tendency of a pesticide to bind to soil particles. Variable "position" is the position of application of the pesticide (on the crop, on the soil, in the soil). This position is the interception rate of active ingredient per leaf area of studied culture. It is obtained from variable "soil cover". Variable "soil cover" is a value thats depends on the leaf surface of the culture. The variation of "soil cover" over time is fixed. Then, the position depends on the date of application by the farmer. The variable "leaching risk" depends on characteristics of the soil. In I_{gro}, the estimation of soil "leaching risk" is given by experts on a scale between 0 (minor leaching risk) and 1 (major leaching risk). The "position" and "leaching risk" take values between 0 and 1. The variable "Acceptable Daily Intake" (ADI) reflects chronic toxicity from humans. The pesticide properties (DT50, koc, and ADI) are given by several heterogeneous information sources such as Agritox (database, France), RIVM (database, Netherlands), Pesticide Manual (book, england), Dabene (expert, France), etc .... For each pesticide, these infomation sources give fuzzy intervals for each characteristic. Let us consider the following example: Three sources (Pesticide manuel: a book, Agritox: a database, Dabene: an expert) provide information, about the variable "DT50" (pesticide half-life) of "I_{gro}", in term of two intervals Int_1 and Int_2. The information is summarized in Table 2 and represented on Figure 1. The interval Int_2 represents the most plausible values for the variable DT50.

Table 2: Example information from sources

Source	Int_1	Int_2
Dabene	[10,42]	[20,35]
Agritox	[46,53]	50
Pesticide Manual	[21,56]	[35,40]

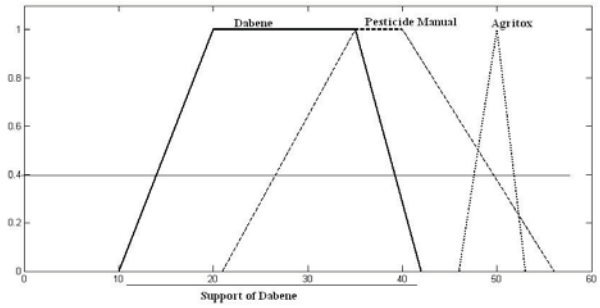

Figure 1: An example of values of DT50 given by sources, α-cut with $\alpha = 0.4$ and the support of data given by Dabene

2.1.2 The structure of the indicator of groundwater contamination I_{gro}

The indicator of groundwater contamination I_{gro} is calculated on a scale between 0 (maximal risk) and 10 (minimal risk). These values are calculated according to fuzzy if-then rules and to the degree of membership of the input variables to fuzzy subsets. The mechanism is explained below.

To calculate the indicator I_{gro}, we need to aggregate expertise knowledge and variables heterogeneous (qualitatives and quantitatives), authors in [5] are used fuzzy control [6] for achieving this two goals. For all input variables, two fuzzy subsets F (Favourable, i.e. the sets of values giving rise to acceptable environmental effect) and U (Unfavourable, i.e. the set of values giving rise to unacceptable environmental effect) are defined. Table 3 shows favourable and unfavourable limits for input variables of I_{gro}, which are extracted from literature or based on human expert knowledge.

Table 3: Favourable and unfavourable limits of input variables

Variable	Favourable limit	Unfavourable limit
DT50	1	30
GUS	1.8	2.8
ADI	1	10^{-4}
Position	1	0
Leaching risk	0	1

For each class (favourable, unfavourable, and transition interval which corresponds to values between favourable and unfavourable limits), we have defined a membership function on knowledge of experts.
The membership of values of input variables takes any value in the interval [0,1]. The value 0 represents complete non-membership and the value 1 represents complete membership. Values between 0 and 1 are used to represent partial membership. The membership function is defined in such a way that the value of an input variable either belongs fully to one of the

ISBN: 978-989-95079-6-8

two fuzzy subsets (favourable, unfavourable), or partially to both. In the latter case, the value is within a transition interval. We used membership functions that are sinus shaped in the transition interval, as they provide smoother variations of the output values than membership functions that are linear in the transition interval [5].
For example, experts classify the leaching potential GUS into three classes. They affect pesticides classified as "leacher" (i.e. GUS $>$ 2.8 or called unfavourable subset) a membership value of 1 for the fuzzy subset U and membership value of 0 for the fuzzy subset F. Pesticides classified as "no-leacher" (GUS $<$ 1.8 or called favourable subset) are given a membership value of 0 for the subset U and a membership value of 1 for the fuzzy subset F. The class of borderline compounds (1.8 $<$ GUS $<$ 2.8) falls within a transition interval where the membership value for F decreases from 1 (GUS = 1.8) to 0 (GUS= 2.8), and the membership value of U increases from 0 to 1 (see Fig. 2). The favourable (respectively unfavourable) membership function "F-Function" (respectively "U-Function") of GUS is the degree for GUS to be in the favourable subset (respectively unfavourable subset). We have also "U-Function" = 1 - "F-Function". The function of subset favourable of GUS is $0.5 + 0.5\cos(\pi(\text{GUS} - 1.8))$. If variable GUS has a value of 2.5, then "F-Function" = 0.16 and "U-Function" = 0.84.

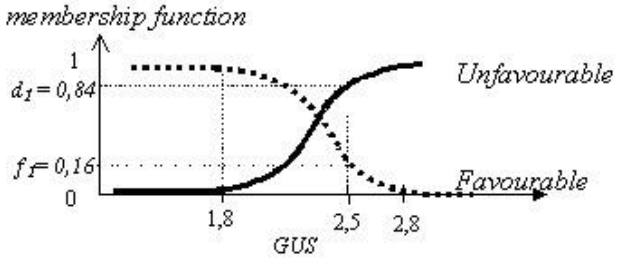

Figure 2: F-Function and U-Function function of variable GUS

The calculations are carried out according to a set of if-then rules. The experts attribute values between 0 and 10 for each rule.They consider firstly –what determines the leaching– the properties of organic matter (molecule), so they use variable GUS. If the variable GUS is favourable (GUS $<$ 1.8), then there is no problem. The molecule does not present the characteristics of leaching. If variable GUS is unfavourable (GUS $>$ 2.8), the experts are interested in the other variables of indicator. When a molecule is able to leach, it is able to reach the soil. Then, the experts use variable "position" of application. If the variable "position" is favourable, experts set a value to 9 for indicating the risk of leaching, but it is not too important. Then the environment is taken into account through the variable "leaching risk" (is the molecule leaching or not?, is the soil sensitive to the leaching?) and, finally they set on the variable "ADI".
Fig. 3 shows the if-then rules of I_{gro}. For example, if all input variables of I_{gro} are F then conclusion is 10. If all input variables of I_{gro} are U then conclusion is 0.

For each rule, we obtain the truth value by applying the minimum operator on the set of membership of the rule. For the first rule, if all input variables are F, the memberships of

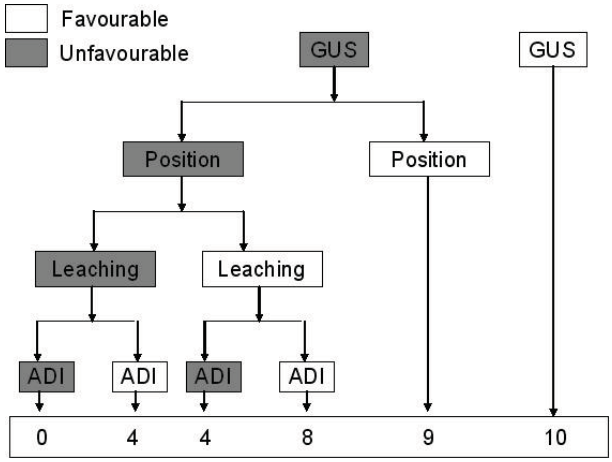

Figure 3: If-then rules of the indicator I_{gro} (I_{gro} has $2^4 = 16$ rules)

four input variables are f_i for each variable, then the truth value is $\omega_1 = \min_{i=1,\ldots,4}(f_i)$. The final score of the indicator is the average of rule conclusions weighted by their values of truth

$$I_{gro} = \frac{\sum_{i=1}^{16} \omega_i s_i}{\sum_{i=1}^{16} \omega_i}$$

3 Preliminaries

3.1 Problem statement

In this paper, we consider the indicator of groundwater contamination I_{gro}, which depends on parameters: GUS, DT50, "koc", ADI, "leaching risk" and "position". It is calculated by Van der Werf and others in [5] as $I_{gro} = \frac{\sum_{i=1}^{16} \omega_i s_i}{\sum_{i=1}^{16} \omega_i}$, where ω_i depends of variables of I_{gro}, and $s_i \in [0, 10]$.
We are interested here in multisource variable DT50, koc, ADI. Assume that the set of n information sources provide n fuzzy intervals about these variables (see Table 2). We have to search the most plausible values to calculate the indicator. We use here the support of fuzzy interval (α-cut with $\alpha = 0$ i.e. the interval Int_1 in Table 2). We use the notion of maximal coherent subset into a possibilistic fusion to synthesize a final result for multisource variables. These results combined with values of others variables will be used to compute the bounds (lower and upper) of the indicator I_{gro}.
In this paper, $\forall x \in \mathbb{R}$, x^- and x^+ represent the lower and upper bounds of interval where x can vary.

3.2 Possibility theory, fuzzy sets

In this section, we briefly summarize basic concepts of possibility theory, which are needed for understanding this paper. Fuzzy sets were firstly introduced by Zadeh [2] as a possible way to handle uncertainty in processing incertain or imprecise data, and to control expert knowledge. This theory allows the notion of graduation to express whether an element belongs to a set (For more details, see[2, 3, 7]).

3.2.1 Possibility theory

Possibility theory was introduced in 1978, in connection with fuzzy set theory, to allow reasoning to be carried out on imprecise or vague knowledge, making it possible to deal with uncertainties on knowledge [3, 8]. The basic tool of possibility

ISBN: 978-989-95079-6-8

theory is possibility distribution. A possibility distribution is equivalent to the definition of a normalized fuzzy membership function. We are interested in this theory, in this paper, because we need to synthesize information of a variables which come from various sources. When we want to synthetize the value of a variable (i.e. approximate the value of the variable depending a set of a different sources (This process is called "information fusion" (see here after). In such a situation, possibility theory can be used to handle this kind of problems. This theory presents many choices of fusion operators in different contexts.

3.3 Information fusion

Definition 1 *Information fusion consists of merging, or exploiting conjointly, several sources of information for answering questions of interest and make proper decisions.*

A large set of information fusion operators has been designed in the possibility theory framework [3]. They can be split into three subsets, according to the behavior of operators:

- Conjunctive type operators: it is the equivalent of a set intersection. It makes the assumption that all sources are reliable (i.e. all sources give information with high confidence), and usually results in very precise information. If there is an incoherence between variable values (i.e. detected by domain expert), then the result of the conjunction becomes poorly reliable, or even empty.
- Disjunctive type operators: it is the equivalent to a set union. It makes the assumption that at least one source is reliable. The result of a disjunctive operator can be considered as very reliable.
- Trade-off type operators: they are compromise operators between conjunctive and disjunctive operators. They are typically used when sources are partially conflicting (i.e. in contradiction). As its name indicates, such an operator tries to make a trade-off between disjunction and conjunction for achieving a good balance between informativeness and reliability.

4 Methodology

4.1 Fusion based on maximal coherent subsets to assess imprecision of multi-source variables

Information sources which supply the information about imprecise variables (DT50, koc, ADI) are heterogeneous (book, expert, database). They come from different places (France, USA, Netherlands), then the type of soil, weather and laboratory conditions are not similar. Furthermore, we ignore the reliability of sources (they do not supply a degree of confidence with the value). They provide data in term of a fuzzy interval (or fuzzy number). Also, no information about conflict and relations between sources is available. Then, we can not use a conjunctive rule (respectively disjunctive and compromise rule). We need a fusion method which take into account all information given by sources (i.e. without discarding any source). The notion of maximal coherent subset is a natural way for achieving this goal. The fusion method using the notion of maximal coherent subset consists firstly inn applying a conjunctive operator into each non-conflicting subset of sources, then a disjunctive operator between those partial results. With such a method, as much precision as possible is gained when we do not ignore any sources [9, 10]. We will explain in details how this approach applies to support of fuzzy intervals of variables of I_{gro} (see the section 4.3).

4.2 Computing maximal coherent subsets of intervals

In this section, we describe how we can obtain values of multisource variable using the fusion method based on maximal coherent subset of intervals, which are give by information sources. Let us consider n intervals, $I_i = [a_i, b_i], (i = 1, \ldots, n)$. This method allows to find every maximal subsets of sources. A maximal subset is obtained when $\bigcap_{i\in[n]} I_i \neq \emptyset$, where $[n]$ represents the set of 2^n subsets of the set $\{1, \ldots, n\}$. Then, we apply the union of these partial results (i.e. $\bigcup_j \bigcap_{i\in[n]} I_i$).

Algorithm 1: Maximal coherent subset of intervals

Input: n intervals
Output: List of m maximal coherent subsets I_j
List=$\emptyset$;$j = 1$;$I_j = \emptyset$;
Order in an increasing order
$\{a_i, i = 1, \ldots, n\} \cup \{b_i, i = 1, \ldots, n\}$;
Rename them $\{c_i, i = 1, \ldots, 2n\}$with $type(i) = a$
if $c_i = a_k$ and $type(i) = b$ if $c_i = b_k$;
for $i = 1$ to $2n - 1$ **do**
  if $type(i) = a$ **then**
    Add source k to I_j t.q. $c_i = a_k$;
    if $type(i + 1) = b$**then**
      Add k to List (I_j);
      $j = j + 1$;
  else
    Remove source k from I_j such as $c_i = b_k$;

Algorithm 1, that finds maximal coherent subsets, was introduced by Dubois and others in [11]. The algorithm 1 is linear in the number of intervals, and thus computationally efficient. The algorithm is based on an increasing sorting of the interval end-points into a sequence $(c_i)_{i=1,\ldots,2n}$. Each time and only then, an element c_i of type upper bound which is an upper bound of an interval, followed by an element c_{i+1} of type lower bound wich is a lower bound of an interval meet, a maximally coherent set is obtained.

4.3 Example of application

We consider the variable DT50 (pesticide half-life) provided by three information sources (see Table 2): a French expert (Dabene), a French database (Agritox), and an England book (Pesticide Manual).
Using algorithm 1 on the level $\alpha = 0$ (i.e. the support Int_1 of fuzzy intervals in Table 2), we find two maximal coherent subsets $K_1 = \{\text{Dabene, Pesticide Manual}\}$ and $K_2 = \{\text{Agritox, Pesticide Manual}\}$. After applying the maximal coherent subset method, the result of the variable DT50 is: (Dabene $\cap$ Pesticide Manual) $\cup$ (Agritox $\cap$ Pesticide Manual) = [21,42] $\cup$ [46,53].

4.4 Computation method to the fuzzy weighted average

The objective of this section is to compute the bounds of the indicator I_{gro}. The function $f(s_1, s_2, \ldots, s_n, \omega_1, \ldots, \omega_n) = \frac{\sum_{i=1}^{n} \omega_i s_i}{\sum_{i=1}^{n} \omega_i}$, where ω_i is a fuzzy interval and $s_i \in \mathbb{R}$, is called

ISBN: 978-989-95079-6-8

fuzzy weighted average by Dong and Wong [12]. Authors in [12] proposed an algorithm to compute the fuzzy weighted average. Their algorithm is based on the α-cut representation of fuzzy sets and combinatorial interval analysis. Subsequently, Liou and Wang [13] suggested an improved fuzzy weighted average algorithm to simplify the computational process. Afterwards, Lee and Park [14] have proposed an even more efficient algorithm for fuzzy weighted average by reducing the number of arithmetic operations to $O(n \log n)$. The main idea of Lee and Park in [14] is to sort the s_i variables such as for all $i < j$, we have $s_i \leq s_j$. In this order, we can find a rank k with $1 < k < n$ such as for all $i \leq k$, the function f is decreasing with respect to ω_i, and for all $i > k$, the function f is increasing with respect to ω_i. Then, we can compute the lower and the upper bounds of the fuzzy weighted average in accordance with [15],which are bounds of I_{gro}, as:

$$f_k^- = \frac{\sum_{j=1}^{k}(\omega_j)^+.s_j + \sum_{j=k+1}^{n}(\omega_j)^-.s_j}{\sum_{j=1}^{k}(\omega_j)^+ + \sum_{j=k+1}^{n}(\omega_j)^-} \quad (2)$$

$$f_k^+ = \frac{\sum_{j=1}^{k}(\omega_j)^-.s_j + \sum_{j=k+1}^{n}(\omega_j)^+.s_j}{\sum_{j=1}^{k}(\omega_j)^- + \sum_{j=i+1}^{n}(\omega_k)^+} \quad (3)$$

Where ω_i^- and ω_i^+ are respectively the lower and upper bounds of ω_i. The equation (2) (respectively (3)) represent the lower (upper) bound of the level k and $k = 1, \ldots, n$. Then, we determinate the fuzzy interval of indicator such as introduced by Fortin and others in [15]:

$$[\min_{k=1,\ldots,n}(f_k^-), \max_{k=1,\ldots,n}(f_k^+)] \quad (4)$$

5 Results

In this application when computing I_{gro}, about fifteen information sources are used such as ARS (USA), Agritox (France), Pesticide manual (England)... These sources provide information based on a fuzzy interval or on a fuzzy number. In this paper, we use the support of fuzzy intervals given by the sources. The decision rules do not change. For each variable, we replace the input value by an input interval. We propagate the imprecision into computation indicator to calculate a fuzzy interval of indicator. For a pesticide application, an indicator of groundwater contamination score is calculated.
The application considers the indicator of groundwater contamination I_{gro} in several sites with different crops. The positions of application of pesticides is shown in Table 4. Its value is calculated as: "position $= \frac{\text{soil coverd by the crop}}{100}$". The "soil covered" by the crop is estimated by the user of the systems [16]. The variable "leaching risk" set the value of 0.9 [16].

Table 4: Values of the variables of application condition

Pesticide name	Position	soil covered
Chloridazone	0.9	90
Glyphosate	0.75	75
Nicosulfuron	0.1	10
Isoproturon	0.1	10

Pesticide properties (DT50, koc, and ADI) given by several information source are calculated by fusion based on maximal coherent subsets. Table 5 shows the results of pesticide characteristics. The values shown in Table 5 are convexified to simplify the calculation. By using the interval analysis [17] and the equation 1, we compute the fuzzy interval of variable GUS, such as:

$$\text{GUS}^- = \log(\text{DT50}^-) \times (4 - \log(\text{koc}^+)) \quad (5)$$

$$\text{GUS}^+ = \log(\text{DT50}^+) \times (4 - \log(\text{koc}^-)) \quad (6)$$

where ([DT50$^-$,DT50$^+$]) and ([koc$^-$,koc$^+$]) are fuzzy intervals of variables DT50 and Koc.

Table 5: Results of pesticide characteristics

Pesticide name	GUS	DT50	koc	ADI
Chloridazone	[2.53,3.19]	[21,46]	120	0.025
Glyphosate	[0.73,2.97]	[18,47]	[167,2640]	0.3
Nicosulfuron	[2.78,5.39]	[15,43]	[5,43]	0.4
Isoproturon	[2.68,3.03]	[22,28]	[80,99.99]	0.4

Afterwards, we compute the membership intervals of input variables of indicator. For each input variable that varies in $[a, b]$ and has a membership function f, we compute the membership interval by using the function:

$$f([a,b]) = \begin{cases} [f(a), f(b)] & \text{if } f \text{ is increasing} \\ [f(b), f(a)] & \text{if } f \text{ is decreasing} \end{cases} \quad (7)$$

Then, we calculate the truth intervals of the sixteen decision rules of I_{gro}. These truth intervals can be computed by minimum extension applied on intervals such as $\min([a, b], [c, d]) = [\min(a, c), \min(b, d)]$. Then, we use the equations (2) and (3) to compute respectively the lower and upper bounds of indicator for the sixteen α-cuts established by the fuzzy input membership intervals. Finally, we obtain the final interval of indicator by the equation (4).
The Table 6 shows the results of I_{gro} for different pesticides. The fuzzy interval in Table 6 represent the exact interval when the indicator is varying. It represents also the support, of the fuzzy interval of the indicator I_{gro}, that can obtain from all fuzzy intervals of input variables.

Table 6: Results of indicator

Pesticide name	Interval of I_{gro}
Chloridazone	[4.3,9.82]
Glyphosate	[0,10]
Nicosulfuron	[4.42, 4.45]
Isoproturon	[4.42,5.27]

The results presented in Table 6 show a lot of imprecision in some cases. We take example of the organic matter "glyphosate": the indicator obtained by application of glyphosate on the soil varies between 0 and 10. This imprecision is due to the variable GUS –which varies in [0.73,2.97]– that reach limits fixed by experts in Table 3 (i.e (lower limit) $<$ (favourable limit), and (upper limit) $>$ (unfavourable limit)). We note that the indicator varies in [0,10], when we have one of the input variables has a lower (respectively upper) limit exceeds favourable (respectively unfavourable) limit. In the

ISBN: 978-989-95079-6-8

calculation of only one value of indicator I_{gro} [5], the role of the variable GUS is more important than the role of others variables. In this paper, all variables have the same influence in the final result.

6 Discussion and conclusions

In this paper, we introduced the calculus of the indicator of groundwater contamination I_{gro}. We try to control the imprecisions of input variables by using a possibilistic fusion method based on the maximal coherent subsets. Then, we use the notion of interval analysis to propagate the imprecision in the process of calculus of indicator. A fusion method for merging fuzzy subsets, based on the notion of maximal coherent subsets, is proposed to represent the imprecision of input parameters of the indicator of groundwater contamination. This notion appears as a very natural way to conciliate two objectives, gaining information and considering all the conflicts between sources. The method of fusion is simple: it can be applied without any additional information, and its computational complexity remains affordable. The way is summarizes information is conceptually attractive: maximal coherent subsets are the best we can do in the presence of conflict.
We have also described a way to calculate the bounds of indicator. The method of fuzzy interval arithmetic used in this paper is also simple. The support of the fuzzy number of intervals is calculated. Also, we can calculate the membership function of indicators by computing several values of α-cut of input variables. This method allows to obtain exact fuzzy profiles of indicator with reducing time complexity as in the sampling case. It still remains to validate the fusion method using the notion of maximal coherent subset in contrast with other fusion rules. We have to calculate the fuzzy interval for all α-cut to obtain the distribution of I_{gro}. We plane to use the methodology described in this paper (representing by fuzzy intervals the imprecision and propagating this imprecision by interval analysis) to calculate other indicators such as indicator of pesticide in environment which has a process of calculation similar to process of I_{gro}.

***Abstract*— *Any MV-algebra M can be embedded as a lattice in the Boolean algebra $B(M)$ that is R-generated by M. We relate the study of states on an MV-algebra M to the study of finitely additive probabilities on $B(M)$. In particular, we show that each state on M can be uniquely extended to a finitely additive probability on $B(M)$. In case that M is a PMV-algebra, the conditional state $s(a|b)$ defined for $a, b \in M$ with $s(b) \neq 0$ is extended to the classical conditional probability $p(a \cdot b|b)$ on $B(M)$ of the a-proportion of the event b, given the event b.*

***Keywords*—** MV-algebra, R-generated Boolean algebra, state, probability, conditional probability

1 Introduction

States on MV-algebras were investigated by Mundici in [1] as $[0, 1]$-valued additive functionals on (equivalence classes of) formulas in Łukasiewicz propositional logic with the intention to capture the notion of "average" truth degree of a formula. In [2] a probability theory on MV-algebras is systematically developed. The study of states is frequently enhanced by looking directly at certain probabilities induced by the states: there is a one-to-one correspondence between the states on an MV-algebra and the Borel probability measures on the maximal spectrum of the MV-algebra [3, 4], where the bijection is the Lebesgue integral of a continuous function on the maximal spectrum with respect to a uniquely determined Borel probability measure. In this paper we introduce another way of representing a state within a Boolean probability theory. By Jenča's result [5], each MV-algebra M is embedded as a lattice in a uniquely determined Boolean algebra $B(M)$ that is said to be R-generated by M (see [6], [5]). We will show how to relate the study of states over M to the study of certain finitely additive probabilities on $B(M)$. In particular, our approach sheds a new light on the definition of conditional state appearing in [7].

In Section 2 we repeat the basic notion concerning MV-algebras and R-generated Boolean algebras. Section 3 contains the main results: Proposition 3, in which we show that there is only one probability on $B(M)$ extending a state on M, and Proposition 4, which gives a geometrical and topological description of such extensions in case M is a semisimple MV-algebra. In Section 4 we relate conditional states on M to conditional probabilities on $B(M)$ (Proposition 5).

2 Preliminary Notions

2.1 MV-algebras

MV-algebras [8] were introduced by Chang in 1958 as the algebraic counterpart of propositional Łukasiewicz logic.

Definition 1. An MV-algebra is a structure $\langle A, \oplus, \neg, 0\rangle$ with a binary operation $\oplus$, a unary operation $\neg$ and a constant 0 such that $\langle A, \oplus, 0\rangle$ is an abelian monoid and the following equations hold for every $x, y \in A$:

$$\neg\neg x = x$$
$$x \oplus \neg 0 = \neg 0$$
$$\neg\left(\neg x \oplus y\right) \oplus y = \neg\left(\neg y \oplus x\right) \oplus x$$

The most important example of an MV-algebra is the real unit interval $[0, 1]$ equipped with operations $x \oplus y = \min(1, x + y)$ and $\neg x = 1 - x$. Indeed, the class of MV-algebras form a variety that is generated by $[0, 1]$.
On each MV-algebra A we define $1 = \neg 0$, $x \odot y = \neg\left(\neg x \oplus \neg y\right)$, $x \ominus y = x \odot \neg y$. Note that in the MV-algebra $[0, 1]$ we have $x \odot y = \max\left(0, x + y - 1\right)$ and $x \ominus y = \max(0, x - y)$.

Let A be an MV-algebra. For any two elements x and y of A we write $x \leq y$ if and only if $\neg x \oplus y = 1$. It follows that $\leq$ is a partial order that in the case of the algebra $[0, 1]$ coincides with the natural order. Further, defined connectives

$$x \vee y = \neg\left(\neg x \oplus y\right) \oplus y \quad (1)$$
$$x \wedge y = \neg\left(\neg x \vee \neg y\right) \quad (2)$$

are such that the structure $\langle A, \wedge, \vee, 0, 1\rangle$ is a distributive lattice with bottom element 0 and top element 1. An *MV-chain* is an MV-algebra in which the order relation $\leq$ is total.

For any MV-algebra M, the set $\{x \in M \mid x \oplus x = x\}$ is the largest Boolean algebra contained in M.

Given an MV-algebra A and a set X, the set A^X of all functions $f : X \to A$ becomes an MV-algebra if the operations $\oplus$ and $\neg$ and the element 0 are defined pointwise. MV-algebras of functions taking values in $[0, 1]$ can be characterized by means of their ideals.

An *ideal* of an MV-algebra A is a subset I of A such that $0 \in I$, if $x, y \in I$ then $x \oplus y \in I$, and if $x \in I$, $y \in A$ and $y \leq x$ then $y \in I$. An ideal is *maximal* if it is not contained in any proper ideal. An MV-algebra A is said to be *semisimple* if

ISBN: 978-989-95079-6-8

and only if A is non trivial and the intersection of all maximal ideals of A is $\{0\}$. By the *maximal spectrum* we mean the (nonempty) set of all maximal ideals of A. This set can be made into a compact Hausdorff space.

It can be shown that an MV-algebra A is semisimple if and only if A is isomorphic to a separating MV-algebra of $[0,1]$-valued continuous functions on some nonempty compact Hausdorff space (actually the maximal spectrum of A), with pointwise operations. For other notions related to MV-algebras we refer the reader to [9].

A *product MV-algebra* (or PMV-algebra, for short, see [10], [11]) is a structure $\langle A, \oplus, \neg, \cdot, 0\rangle$, where $\langle A, \oplus, \neg, 0\rangle$ is an MV-algebra and $\cdot$ is a binary associative and commutative operation on A such that for any $x, y, z \in A$, $x \cdot 1 = x$ and $x \cdot (y \ominus z) = (x \cdot y) \ominus (x \cdot z)$.

Note that $[0,1]$ is a PMV-algebra where the operation $\cdot$ is the usual multiplication of real numbers. Further, a semisimple MV-algebra A is a PMV-algebra if and only if A is closed with respect to the pointwise real product of functions and, in this case, the unique product on A is the pointwise real product of functions.

2.2 Boolean algebra R-generated by an MV-algebra

Let M be an MV-algebra. There exists a unique (up to a Boolean isomorphism) Boolean algebra $B(M)$ such that the lattice reduct of M

(i) is a sublattice of $B(M)$ containing both the elements 0 and 1 of M,

(ii) generates $B(M)$ as a Boolean algebra.

The Boolean algebra $B(M)$ is called an *R-generated Boolean algebra*. See [6, Chapter II.4] for details. For every $a \in B(M)$ there exists $n \in \mathbb{N}$ and a finite chain $a_1 \le \cdots \le a_{2n}$ in M such that

$$a = \bigvee_{i=1}^{n} (a_{2i} \setminus a_{2i-1}) \tag{3}$$

holds true in $B(M)$ and $(a_{2i} \setminus a_{2i-1}) \wedge (a_{2j} \setminus a_{2j-1}) = 0$ for each $i, j \in \{1, \ldots, n\}$ with $i \neq j$, where $\setminus$ denote the symmetric difference in the Boolean algebra $B(M)$.

Theorem 1 (Jenča [5], Theorem 2)**.** *Let M be an MV-algebra. Then there exists a surjective mapping $\varphi_M : B(M) \to M$ such that*

$$\varphi_M(a) = \bigoplus_{i=1}^{n} (a_{2i} \ominus a_{2i-1}), \quad a \in B(M), \tag{4}$$

where $a_1, \ldots, a_{2n} \in M$ are as in (3) *and the value of $\varphi_M(a)$ is independent on the choice of the representation* (3)*. Moreover, the mapping φ_M satisfies*

(i) $\varphi_M(1) = 1$,

(ii) $\varphi(a) = a$, *for every* $a \in M$,

(iii) if $a, b \in B(M)$ *are such that* $a \wedge b = 0$, *then* $\varphi_M(a) \odot \varphi_M(b) = 0$ *and* $\varphi_M(a \vee b) = \varphi(a) \oplus \varphi(b)$.

The following two examples appear in [5].

Example 1. Let M be an MV-chain. Given two elements $a, b \in M$, put $[a, b) = \{x \in M \mid a \le x < b\}$. By [6], $B(M)$ is isomorphic to the Boolean algebra of all subsets of M having the form

$$[a_1, b_1) \cup \cdots \cup [a_n, b_n)$$

where $a_i, b_i \in M$ and $[a_i, b_i) \cap [a_j, b_j) = \emptyset$, for every $i, j \in \{1, \ldots, n\}$ with $i \neq j$. Note that each $a \in M$ can be identified with $[0, a) \in B(M)$. Then

$$\varphi_M([a_1, b_1) \cup \cdots \cup [a_n, b_n)) = (b_1 \ominus a_1) \oplus \cdots \oplus (b_n \ominus a_n).$$

Example 2. Suppose now M is a semisimple MV-algebra, then M can be viewed as an MV-algebra of continuous functions from the maximal spectrum X of M to the unit interval $[0,1]$. Let $\mathcal{B} = B([0,1])$ be the Boolean algebra of all subsets of $[0,1]$ of the form $[a_1, b_1) \cup \cdots \cup [a_n, b_n)$ for some $n \in \mathbb{N}$, where $[a_i, b_i) \cap [a_j, b_j) = \emptyset$ with $i, j \in \{1, \ldots, n\}$ and $i \neq j$. Just as in Example 1, each element a of the MV-algebra $[0,1]$ can be identified with the interval $[0, a)$ of $\mathcal{B}$.

Since lattice operations in $[0,1]^X$ (and hence in M) are componentwise, then $B(M)$ is a Boolean subalgebra of $\mathcal{B}^X$. Each element $f \in M \subseteq [0,1]^X$ can be identified with the function $f^* \in B(M)$ such that $f^* : x \in X \mapsto [0, f(x)) \in \mathcal{B}$. Then, according to (3), for every $g \in B(M)$ there is $n \in \mathbb{N}$ and $a_1 \le b_1 \le \ldots \le a_n \le b_n \in M$ such that

$$g = \bigvee_{i=1}^{n} b_i^* \setminus a_i^*. \tag{5}$$

The mapping φ_M is defined as follows. For every $g \in B(M)$ and any $x \in X$, we have, by (5):

$$g(x) = \bigvee_{i=1}^{n} [0, b_i(x)) \setminus [0, a_i(x)).$$

It suffices to let $\varphi_M(g) : x \in X \mapsto (b_1(x) \ominus a_1(x)) \oplus \cdots \oplus (b_n(x) \ominus a_n(x)) \in [0,1]$.

Observe that the length n of the chain representing g does not depend on the coordinate (maximal ideal) x.

3 States and Probabilities

A *state* on an MV-algebra M is a mapping $s : M \to [0,1]$ such that $s(1) = 1$ and $s(a \oplus b) = s(a) + s(b)$, for every $a, b \in M$ with $a \odot b = 0$. In case that M is a Boolean algebra, then we denote a state on it by p and call p a *(finitely additive) probability.* Let $\mathscr{S}(M)$ be the *state space* of M, that is, the (nonempty) set of all states on M. Analogously, by $\mathscr{S}(B(M))$ we denote the set of all probabilities on the R-generated Boolean algebra $B(M)$. In the sequel we will introduce and study the relation between the two state spaces.

Proposition 1. *If s is a state on an MV-algebra M, then there is a probability p on $B(M)$ such that $p(a) = s(a)$ for every $a \in M$.*

Proof. Put

$$p(a) = s(\varphi_M(a)), \quad a \in B(M), \tag{6}$$

where φ_M is the mapping from Theorem 1, and observe that this definition is correct since, by the same Theorem 1, it does not depend on the representation of a given in (3). Then $p(1) = s(\varphi_M(1)) = s(1) = 1$. Let $a, b \in B(M)$ be such that $a \wedge b = 0$. Then Theorem 1(iii) yields

$$\begin{aligned} p(a \vee b) &= s(\varphi_M(a \vee b)) = s(\varphi_M(a) \oplus \varphi_M(b)) \\ &= s(\varphi_M(a)) + s(\varphi_M(b)) = p(a) + p(b). \end{aligned}$$

Since every $a \in M$ is a fixed point of φ_M due to Theorem 1(ii), we get that p coincides with s over M. □

ISBN: 978-989-95079-6-8

The next proposition shows that every probability on $B(M)$ is uniquely determined already on the embedded MV-algebra M.

Proposition 2. *If p and p' are two probabilities on $B(M)$ and $p(b) = p'(b)$ for every $b \in M$, then $p = p'$.*

Proof. Let $a \in B(M)$. By equation (3), there exists a finite chain $a_1 \leq \cdots \leq a_{2n}$ in M such that

$$a = \bigvee_{i=1}^{n} (a_{2i} \setminus a_{2i-1}) \tag{7}$$

in $B(M)$ and $(a_{2i} \setminus a_{2i-1}) \wedge (a_{2j} \setminus a_{2j-1}) = 0$, for each $i, j \in \{1, \ldots, n\}$ with $i \neq j$. Hence

$$\begin{aligned} p(a) &= p\Big(\bigvee_{i=1}^{n} (a_{2i} \setminus a_{2i-1})\Big) = \sum_{i=1}^{n} p(a_{2i} \setminus a_{2i-1}) \\ &= \sum_{i=1}^{n} (p(a_{2i}) - p(a_{2i-1})) = \sum_{i=1}^{n} (p'(a_{2i}) - p'(a_{2i-1})) \\ &= \sum_{i=1}^{n} p'(a_{2i} \setminus a_{2i-1}) = p'\Big(\bigvee_{i=1}^{n} (a_{2i} \setminus a_{2i-1})\Big) \\ &= p'(a). \end{aligned}$$

□

Putting together Proposition 1 with (6) and Proposition 2, we get the following uniqueness result.

Proposition 3. *If s is a state on an MV-algebra M, then the probability $p = s \circ \varphi_M$ on $B(M)$ is the unique probability on $B(M)$ such that $p(a) = s(a)$ for every $a \in M$.*

The above introduced correspondence between the states in $\mathscr{S}(M)$ and the probabilities in $\mathscr{S}(B(M))$ works in general only in one direction. Define a mapping $\Phi : \mathscr{S}(M) \to \mathscr{S}(B(M))$ by

$$\Phi(s)(a) = s(\varphi_M(a)), \tag{8}$$

for every $s \in \mathscr{S}(M)$ and every $a \in B(M)$. Since every MV-algebra M is embedded into $B(M)$, it is natural to expect that the state space of the Boolean algebra $B(M)$ is much larger than that of M. Indeed, already in case that M is the standard MV-algebra $[0, 1]$, the set $\mathscr{S}([0, 1])$ contains only one element (the state s defined by $s(x) = x$, for every $x \in [0, 1]$). So the image of $\Phi(\mathscr{S}([0, 1]))$ is a singleton, but $\mathscr{S}(B([0, 1]))$ contains infinitely-many probabilities: for every $x \in [0, 1]$, the mapping

$$a \in B([0, 1]) \mapsto \begin{cases} 1, & x \in a, \\ 0, & \text{otherwise}, \end{cases}$$

is a two-valued probability and hence it belongs to $\mathscr{S}(B([0, 1]))$.

Properties of the operator Φ are summarized below. In particular, we will show that Φ preserves the geometrical-topological structure of $\mathscr{S}(M)$. In order to show this, the convex sets $\mathscr{S}(M)$ and $\mathscr{S}(B(M))$ are endowed with the subspace topology of the product spaces $[0, 1]^M$ and $[0, 1]^{B(M)}$, respectively, so that both $\mathscr{S}(M)$ and $\mathscr{S}(B(M))$ became compact spaces (see [1]).

Proposition 4. *Let M be a semisimple MV-algebra. Then:*

(i) $\Phi(s)(a) = s(a)$, for every $s \in \mathscr{S}(M)$ and every $a \in M$;

(ii) the mapping Φ is an affine homeomorphism of $\mathscr{S}(M)$ onto the compact convex set $\Phi(\mathscr{S}(M))$;

(iii) the set $\Phi(\mathscr{S}(M))$ is affinely homeomorphic to the set of all Borel probability measures on the maximal spectrum X of M;

(iv) if M is not a Boolean algebra, then $\Phi(\mathscr{S}(M)) \subsetneq \mathscr{S}(B(M))$.

Proof. (i) This follows directly from the definition (8) and Proposition 3.

(ii) First, we will show that the mapping Φ is *affine,* that is, for every $s, s' \in \mathscr{S}(M)$ and $\alpha \in [0, 1]$, we have

$$\Phi(\alpha s + (1 - \alpha)s') = \alpha\Phi(s) + (1 - \alpha)\Phi(s').$$

For every $a \in B(M)$, the definition (8) yields:

$$\begin{aligned} \Phi(\alpha s + (1 - \alpha)s')(a) &= (\alpha s + (1 - \alpha)s')(\varphi_M(a)) \\ &= \alpha s(\varphi_M(a)) + (1 - \alpha)s'(\varphi_M(a)) \\ &= \alpha\Phi(s)(a) + (1 - \alpha)\Phi(s')(a). \end{aligned}$$

The mapping Φ is injective. Given $s, s' \in \mathscr{S}(M)$ with $s \neq s'$, find $a \in M$ such that $s(a) \neq s'(a)$. Hence it follows from (i) that $\Phi(s) \neq \Phi(s')$. The mapping Φ is continuous: take a net s_γ of elements of $\mathscr{S}(M)$ such that $s_\gamma \to s$ for some $s \in \mathscr{S}(M)$. This means that $s_\gamma(b) \to s(b)$ for every $b \in M$. Thus for every $a \in B(M)$, we get

$$\Phi(s_\gamma)(a) = s_\gamma(\varphi_M(a)) \to s(\varphi_M(a)) = \Phi(s)(a).$$

The set $\Phi(\mathscr{S}(M))$ is compact convex as an affine continuous image of $\mathscr{S}(M)$. Since Φ is a continuous bijection $\mathscr{S}(M) \to \Phi(\mathscr{S}(M))$, it is actually a homeomorphism by compactness.

(iii) The set $\mathscr{B}(X)$ of all Borel (σ-additive) probability measures on the maximal spectrum X of M is compact and convex [12, Proposition 5.22]. In the topology of $\mathscr{B}(X)$ a net μ_γ converges to μ in $\mathscr{B}(X)$ if for every continuous function $f : X \to \mathbb{R}$ we have $\int f \, \mathrm{d}\mu_\gamma \to \int f \, \mathrm{d}\mu$. By Corollary 29 in [3] or [4, Proposition 1.1], there exists a unique mapping $\Psi : \mathscr{S}(M) \to \mathscr{B}(X)$ such that

$$s(a) = \int_X \hat{a} \, \mathrm{d}\Psi(s) \tag{9}$$

for every $s \in \mathscr{S}(M)$ and every $a \in M$, where $\hat{a}$ is the image of a via the isomorphism identifying the elements of M with the separating MV-algebra of continuous functions $X \to [0, 1]$. We claim that the mapping Ψ is an affine homeomorphism. It is onto since every integral (9) with respect to some Borel probability measure from $\mathscr{B}(X)$ determines a state. It is also injective as every two states $s, s' \in \mathscr{S}(M)$ coincide whenever $\Psi(s) = \Psi(s')$ by the representation (9). The mapping Ψ is affine since the functional $\mu \in \mathscr{B}(X) \mapsto \int_X f \, \mathrm{d}\mu$ is linear for every continuous function $f : X \to [0, 1]$. Finally, we will show that Ψ^{-1} is continuous. Take a net μ_γ and μ with $\mu_\gamma \to \mu$ in $\mathscr{B}(X)$. It results directly from the definition of convergence in $\mathscr{B}(X)$ and in $\mathscr{S}(M)$ that $\Psi^{-1}(\mu_\gamma) \to \Psi^{-1}(\mu)$ in $\mathscr{S}(M)$, so Ψ^{-1} is continuous. Since $\mathscr{S}(M)$ is compact, the mapping Ψ is a homeomorphism. As an inverse of an affine homeomorphism is an

ISBN: 978-989-95079-6-8

affine homeomorphism and a composition of affine homeomorphisms is again an affine homeomorphism, take the mapping $\Psi \circ \Phi^{-1} : \Phi(\mathscr{S}(M)) \to \mathscr{B}(X)$ to finish the proof.
(iv) The MV-algebra M is not a Boolean algebra, so there exists an element $f \in M$ and $x \in X$ with $0 < f(x) < 1$. Put $\beta = \frac{\min(f(x),1-f(x))}{2}$ and define a mapping $p : B(M) \to [0,1]$ by

$$p(g) = \begin{cases} 1, & \beta \in g(x), \\ 0, & \text{otherwise}, \end{cases} \qquad g \in B(M).$$

A routine check shows that p is a probability on $B(M)$. We will show that there is no state $s \in \mathscr{S}(M)$ such that $\Phi(s) = p$. By way of contradiction, assume that such a state s exists. Then Proposition 3 together with (8) imply that $s(g) = p(g)$ for every $g \in M$. Since $s(f) = p(f) = 1$ and $s(\neg f) = p(\neg f) = 1$, we get

$$s(f \oplus \neg f) = s(1) = 1 \neq 2 = s(f) + s(\neg f),$$

which is a contradiction and thus $p \in \mathscr{S}(B(M)) \setminus \Phi(\mathscr{S}(M))$. □

On the one hand, every state on a semisimple MV-algebra can be viewed as the integral (9) with respect to a uniquely determined Borel probability measure that is defined on the maximal spectrum X of M. On the other hand, the operator Φ maps a state to a finitely additive probability on a Boolean subalgebra of the direct sum $\mathcal{B}^X$ (see Example 2). While the transformation Φ enables only to embed $\mathscr{S}(M)$ into a (huge) state space $\mathscr{S}(B(M))$, we will show below that and how probabilities on direct sums of Boolean algebras appear naturally already in classical Kolmogorov model of probability.

Let $B_1, \dots, B_k$ be Boolean algebras. Let p_i be a probability on B_i for $i = 1, \dots, k$. By B we denote a Boolean algebra that is the direct sum of $B_1, \dots, B_k$ (see [13, §16]). Every element of $b \in B$ can be identified with an n-tuple $(b_1, \dots, b_k)$ such that $b_i \in B_i$ for each $i = 1, \dots, k$. The elements b of B are random events whose meaning is "precisely one of all the events $b_1, \dots, b_k$ occurs". These classes of random events capture *two-stage random experiments*, such as the random selection of a ball from a randomly selected box. In this interpretation, each number $i = 1, \dots, k$ denotes a box and the corresponding Boolean algebra B_i models all outcomes of a random selection of a ball from the box i. Precisely, for some nonnegative $\alpha_1, \dots, \alpha_k$ with $\sum_{i=1}^k \alpha_i = 1$, the procedure can be described as follows:

(i) select B_i with a probability α_i;
(ii) if B_j was selected in the previous stage, then perform the random experiment with outcomes in B_j and probabilities described by p_j.

A probability p on B should then express the above introduced meaning of the two-stage experiment. This means that for every $b \in B$, we get

$$p(b) = \sum_{i=1}^{k} \alpha_i p(b_i). \tag{10}$$

The interrelationship between states on MV-algebras and probabilities on direct sums as defined above is made possible by the mappings Φ and φ_M.

Example 3. Let M be the direct product of two standard MV-algebras, that is, $M = [0,1]^2$. According to (9) every state s on M is of the form

$$s(a) = s((a_1, a_2)) = \alpha a_1 + (1-\alpha)a_2, \quad a = (a_1, a_2) \in M, \tag{11}$$

for some $\alpha \in [0,1]$. The Boolean algebra $B(M)$ is precisely the direct sum of the two Boolean algebras $\mathcal{B}$, where $\mathcal{B}$ is as in Example 2. The MV-algebra M embeds into $B(M)$ by sending each $a = (a_1, a_2) \in M$ to the function $a^*(i) = [0, a_i)$, $i = 1, 2$. Let λ denotes the restriction of Lebesgue measure to $\mathcal{B}$. Then it follows from (11) that

$$\Phi(s)(g) = \alpha\lambda(g(1)) + (1-\alpha)\lambda(g(2)), \quad g \in B(M). \tag{12}$$

Indeed, as in Example 2, for every $g \in B(M)$ and $i = 1, 2$ find the representation $a_1^i, b_1^i, \dots, a_n^i, b_n^i \in [0,1]$ such that $g(i) = [a_1^i, b_1^i) \cup \dots \cup [a_n^i, b_n^i)$ with all the intervals disjoint. Then

$$\varphi_M(g)(i) = (b_1^i \ominus a_1^i) \oplus \dots \oplus (b_n^i \ominus a_n^i)$$

and $(\varphi_M(g)(1), \varphi_M(g)(2)) \in M$. As a consequence,

$$\begin{aligned} \Phi(s)(g) &= s(\varphi_M(g)) = \alpha\varphi_M(g)(1) + (1-\alpha)\varphi_M(g)(2) \\ &= \alpha(b_1^1 \ominus a_1^1) \oplus \dots \oplus (b_n^1 \ominus a_n^1) \\ &\quad + (1-\alpha)(b_1^2 \ominus a_1^2) \oplus \dots \oplus (b_n^2 \ominus a_n^2) \\ &= \alpha\lambda(g(1)) + (1-\alpha)\lambda(g(2)), \end{aligned}$$

which proves (12).

The model from Example 3 can be given a straightforward probabilistic interpretation. Suppose that some underground platform is accessible from a street either via a stairway or via an escalator. Mr. Smiley chooses the stairway with a probability $\alpha \in [0,1]$ and the escalator with a probability $1-\alpha$. Train arrivals are uniformly distributed over the interval $[0,1]$. What is a probability that Mr. Smiley's waiting time for the train will be smaller or equal to $a_1 \in [0,1]$ (in case he uses the stairway) or smaller or equal to $a_2 \in [0,1]$ (in case he uses the escalator)? The investigated event $a = ([0, a_1), [0, a_2))$ belongs to $B(M)$, while the many-valued event $a = (a_1, a_2)$ is an element of M. If $p(a)$ denotes the probability of a, then (10) together with uniformity of the waiting times yield

$$\begin{aligned} p(a) &= \alpha\lambda([0, a_1]) + (1-\alpha)\lambda([0, a_2]) = \alpha a_1 + (1-\alpha)a_2 \\ &= s(a). \end{aligned}$$

4 Conditional Probability

In this section we use the probabilistic operator Φ to study conditioning in the framework of MV-algebras and states. Conditional probability on MV-algebras was studied from a variety of perspectives. In [7] the conditional probability on MV-algebras is defined in a way that mimicks the classical (Boolean) approach of conditioning "an event by an event" or "an event by a subalgebra". This approach makes use of an additional operation (product) on an MV-algebra and it was employed by Montagna in order to prove de Finetti-style coherence theorem for conditional bets in many-valued logic [14]. A completely different definition of conditional probability (so-called "conditional") was proposed by Mundici in [15].

ISBN: 978-989-95079-6-8

The following approach to conditioning is taken from [7, Definition 5]. Let s be a state on a PMV-algebra M. Given a many-valued event $b \in M$ with $s(b) > 0$, put

$$s(a|b) = \frac{s(a \cdot b)}{s(b)}, \quad a \in M. \tag{13}$$

The number $s(a|b)$ is called a *conditional state of a given b*. If $s(b)$ vanishes, then we leave $s(a|b)$ undetermined. This makes the function $a \in M \mapsto s(a|b)$ defined for "almost all" $b \in M$. Since $(a_1 \oplus a_2) \cdot b = (a_1 \cdot b) \oplus (a_2 \cdot b)$ for every $a_1, a_2 \in M$ such that $a_1 \odot a_2 = 0$, it can be easily verified that the mapping $s(.|b) : M \to [0,1]$ is a state (so-called *conditional state*) on M whenever $b \in M$ is such that $s(b)$ is nonzero. If p is a probability on a Boolean algebra B, then a product operation $\cdot$ on B becomes $\wedge$ and the formula (13) for $p(b) > 0$ reduces to

$$p(a|b) = \frac{p(a \wedge b)}{p(b)}, \quad a \in B. \tag{14}$$

Analogously, the function $p(.|b) : B \to [0,1]$ is a probability on B whenever $p(b) > 0$. In this case we call $p(.|b)$ a *conditional probability*. The major difference between (13) and (14) is the consequence of non-idempotence of the product operation on M. For every $b \in M$ with $s(b) \neq 0$, we have in general only

$$s(b|b) \leq 1 \quad \text{and} \quad s(\neg b|b) \geq 0. \tag{15}$$

In contrast to this, in classical probability $p(b|b) = 1$ and $p(\neg b|b) = 0$ holds true for any $b \in B$ with $p(b) \neq 0$. Surprisingly, this concept of conditioning found a natural application in Montagna's framework [14]: conditional bets are updated in proportion to the truth value of the event in the condition. In that follows we make an effort to justify the definition (13) with the probabilistic interpretation of states via Φ and $B(M)$.

Proposition 5. *Let M be an MV-algebra with product and $s(.|b)$ be a conditional state on it for $b \in M$ with $s(b) \neq 0$. Then there exists a probability p on $B(M)$ such that*

$$\Phi(s(.|b))(a) = p(a \cdot b|b), \quad a \in M. \tag{16}$$

Proof. Put $p = \Phi(s)$. For every $a \in M$, we obtain

$$\begin{aligned} \Phi(s(.|b))(a) = s(a|b) &= \frac{s(a \cdot b)}{s(b)} = \frac{\Phi(s)(a \cdot b)}{\Phi(s)(b)} \\ &= \frac{p(a \cdot b)}{p(b)} = \frac{p((a \cdot b) \wedge b)}{p(b)} \\ &= p(a \cdot b|b), \end{aligned}$$

since $(a \cdot b) \wedge b = a \cdot b$. □

It is worth emphasizing that the probability $\Phi(s(.|b))$ is not a conditional probability on M since $\Phi(s(.|b))(b) = p(b \cdot b|b)$ fails to be equal to 1 in general. So the operator Φ does not map conditional states to conditional probabilities. The formula (16) nevertheless connects the values of conditional states of a given b on M to the values of the classical conditional probability of $a \cdot b$ given b on $B(M)$. Conditioning a by a many-valued event b means in terms of classical conditional probability this: given b, what is a probability $p(a \cdot b|b)$ that an observation of the a-proportion of the many-valued event b will be made? Thus the conditional state defined by the formula (13) leads in accordance with (16) to the conditional probability of $a \cdot b$ given b on the Boolean algebra $B(M)$, which focuses only on the event which is included in b. The use of product in place of infimum makes the difference: the equality $p(a \wedge b|b) = p(a|b)$ holds true in contrast to $p(a \cdot b|b) \neq p(a|b)$. Taking into account the proposed interpretation, the inequalities in (15) look no longer unnatural. The "probabilistic" meaning of $s(b|b)$ is the value of $p(b \cdot b|b)$ that corresponds to the occurrence of the event $b \cdot b$ (given b) rather than b alone as the notation $s(b|b)$ suggests.

Example 4. Consider the situation from Example 3. Assume now that we know the actual waiting time does not exceed $b = (b_1, b_2) \in M = [0,1]^2$. Then the value $s(a|b)$ is according to Proposition 5 the same as $p(a \cdot b|b)$. This probability is precisely the conditional probability that the waiting time will be at most the a-proportion of b given our knowledge that it is at most b.

Contributions to Dynamic Multicriteria Decision Making Models

Tiago C. Pais[1] Rita A. Ribeiro[1]

Caparica 2829-516, Portugal
Email: {tpp, rar}@uninova.pt

Abstract— *In this work we start by presenting a possible architecture for MultiCriteria Dynamic Decision Making (MCDDM) problems. Then we focus on contributions for the rating process because it involves two important aspects of any dynamic spatial-temporal decision problem: how to deal with uncertainty in dynamically changing input data and how consider different criteria importance, depending on criteria satisfaction and respective phase (or iteration) of the decision process. To explain and clarify the contributions we use an illustrative example of site selection for spacecraft landing on planets.*

Keywords— multicriteria dynamic decision making, imprecision on input data, dynamic criteria weighting.

1 Introduction

The main objective of this work is to present some contributions for building general multicriteria dynamic decision making (MCDMM) models. We will focus on two important aspects of any dynamic spatial-temporal decision problem: a) how to deal with uncertainty in dynamically changing input data; b) and how to consider different criteria importance, depending on criteria satisfaction and on the decision process phase (iteration). These two aspects belong to the classical process of evaluating alternatives of MCDM [1] [2] [3].

In general, the aim of Multicriteria or Multi-attribute decision making problems is to find the best compromise solution from all feasible alternatives assessed by pre-defined criteria (or attributes). This type of problems is widespread in real life situations [2], [4]. There are many methods and approaches proposed in the literature to deal with this static decision process, from utility methods to scoring and ranking ones [2] [3]. However, when facing multicriteria dynamic decisions making problems (MCDDM), where feedback from step to step is required, there are few contributions in the literature (see for example [5] [6]) .

To better explain our proposed contributions to deal with uncertainty in dynamically changing input data and criteria weights changes, during the temporal decision process, we use an simplified illustrative case study of a site selection problem for spacecraft landing on planets [7] [8].

2 MultiCriteria dynamic decision making (MCDDM)

Usually, a multicriteria decision model [1] includes 2 main tasks, rating the alternatives by aggregating their classifications for each criterion and then ranking them. In this work we discuss a dynamic multicriteria decision model because we are addressing decision paradigms with several iterations, which need to take into account past/historic information, to reach a decision (or consensus).

According to Richardson and Pugh [9] system dynamics problems have two main features: "they are dynamic: they involve quantities which change over time"; "involves the notion of feedback." This is exactly the perspective in this work: dynamically changing data and feedback from historical data.

A general multicriteria dynamic decision making (MCDDM) architecture is depicted in Fig. 1 (adapted from [7] and using concepts from [9]).

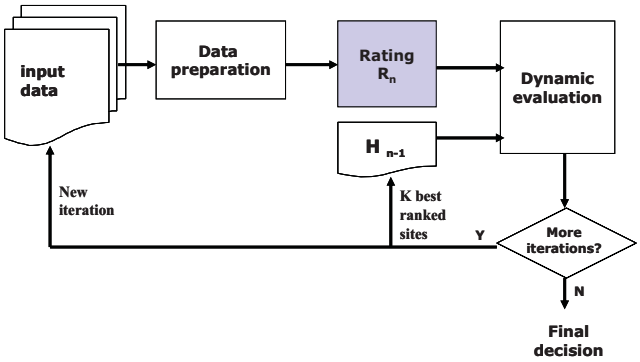

Figure 1: MCDDM architecture.

R_n represents the set of alternatives rating values from iteration n and H_{n-1} represents the historic set of rated alternatives from the previous iteration. The feedback is the set of ranked alternatives of iteration n (updated historic set of each iteration).

In summary, the main characteristics of processes/components, included in a MCDDM are:

a) Data preparation – this process deals with transformation of inputs for the decision model. It includes three main tasks: a.1) cleaning & filtering the data to extract the required criteria and the set of alternatives to be assessed (per iteration); a.2) normalization and representation of criteria for the decision model; a.3) Definition of weighting functions to express the relative importance for each criterion, within a phase or per iteration.

b) Rating process – This process refers to the classification of each alternative regarding all criteria, weighted with their relative importance. I.e. it refers to the aggregation of criteria values weighted with relative importance of criteria. Several methods exist in the literature [1] [2] [3], in our case

ISBN: 978-989-95079-6-8

we used an improved WSM method, as explained in section 3.2..

c) Dynamic evaluation process – This process refers to the aggregation of historical information about alternatives with their current rating to obtain the set of ranked alternatives [7] for the current iteration (n). When there are no more iterations the decision process stops and the best alternative is the one with the highest rate. For this evaluation we propose to use full-reinforcement operators as described in [7]

d) Historical process – This process determines a subset of good alternatives, from the ranked alternatives, to be considered as feedback information from iteration to iteration. Since this process takes places after ranking, it means historical information for a specific site "remembers" its past behaviour plus the actual rating. There are different sizes (K) for this set of historical information, depending on different phases of the decision process. For our case study we consider three phases according to expert advice.

The topic addressed in detail, in this work, will be the rating process (b), which is highlighted in grey in Figure 1.

3 Case Study: Site selection for spacecraft landing on planets

The case study used for discussing the rating process of multicriteria dynamic decision making (MCDDM) models is based on a real project [7], which objective was to determine the best target site for landing on planets for spacecrafts. The case study MCDDM model was developed for the final descent of the spacecraft (around 2 Km from surface), when hazard maps can be obtained. Some values used in the description are just indicative due to reasons of confidentiality.

3.1 Background

In this case study the criteria are hazard maps corresponding to images taken by the Spacecraft during the final descent (around 1000 m from surface) [8] [7]. We consider 7 input criteria, which correspond to the hazard maps obtained during the descent process: slope, texture, fuel, reachability, distance, shadow and scientific interest. The alternatives are the pixels of the combined search space (derived from merging 7 matrices of 512x512, corresponding to the input images/hazard maps), resulting from a data preparation process (not discussed in this work). The resulting set of alternatives is about 260.000 possible sites for each iteration (512*512= 262,144). The number of iterations is about 40 and for each one there is a evaluation process (called ranking process) including a combination of the *k* best alternatives from iteration *n-1* (historic set) with the current rated ones at the *n* iteration (for details about this process see [7]). We only consider the last iteration as historical information for two reasons: a) time constrains- we have less than 1 minute to perform 40 iterations hence an efficient process is required; b) the historic set implicitly includes all past ratings because we aggregate previous information with current one, i.e we update the alternative evaluation at each iteration and pass this information to the next iteration.

As mentioned in the abstract, in this work we focus on the rating process of MCDMM because it involves two important aspects of any dynamic spatial-temporal problem: how to deal with uncertainty in the input data of each iteration and how to consider different importance for each criteria, depending on the criteria satisfaction as well as on the phase of the decision process (iteration).

Before discussing the rating process we should explain that we assume 3 phases for this case study as follows. Phase 1 is executed until 1000 m of altitude and considers a historic of 250 set of sites, the rationale is that at higher attitudes there is a need for considering more alternatives (pixels) because the Spacecraft is still too far away from the surface and the information about the sites is still quite imprecise. Phase 2 is executed between the 1000 m and 300 m of altitude (parameters can be changed) and uses a historic set of 10 sites; since we are getting closer to the surface what we need is a small historic set (pixels) of "good" alternatives, ensuring sufficient distance between them (radius) to cover a reasonable search space. Phase 3 starts being executed at 300 m of altitude when the Spacecraft is quite close to the surface and the historic set considered was 5 sites.

Although it is out of scope to discuss the data preparation process for this case study we should mention that the results of this process are fuzzified variables (for references dealing with fuzzification see for example [4]), corresponding to each hazard map, adapted (i.e. re-calculated) at each iteration. Hence, a variable input includes a value and its corresponding membership value in the fuzzified variable.

3.2 Rating process

The rating process deals with aggregation of all classifications obtained by each alternative in each criterion. During the three phases considered, we compute these values for each alternative (per iteration). The general formulation for the weighted sum method (WSM), used as rating process in our dynamic decision process (MCDDM) is:

$$r_i = \oplus (W(ac_{i1}) \otimes ac_{i1}, ..., W(ac_{in}) \otimes ac_{in}) \quad (1)$$

Where,

$\oplus$ is the sum operator;

$\otimes$ is the product operator;

ac_{ij} is the accuracy & confidence membership value of j^{th} criterion for site *i*. (section 3.3)., and $W(ac_{ij}) = \dfrac{L(ac_{ij})}{\sum_{k=1}^{n} L(ac_{ik})}$, represents the normalized relative weight, considering a weighting function, $L(ac_{ij})$ as described in section 3.4.,

The basic principle of the aggregation method WSM (weighted sum method) is that "The overall score of an alternative is computed as the weighted sum of the attribute values" [8]. In our case study we tested other methods of aggregation besides this one (e.g. WPM, Compromise ratio [2]), however WSM combined with the proposed weighting functions, showed the best trade-of between computational efficiency versus correctness of results.

ISBN: 978-989-95079-6-8

3.3 Accuracy & confidence in input values

The accuracy and confidence parameters (a_{ij} and wc_j, respectively) will be taken into account in the decision model using the following expression:

$$ac_{ij} = wc_j * (1 - \max_{x \in [a;b]} \{ | \mu(x) - \mu(x_{ij}) | \}) * \mu(x_{ij}) \quad (2)$$

where:

wc_j is the confidence associated to criterion j;

x_{ij} is the value of jth criterion for site i;

$\mu(.)$ is the membership degree in a fuzzy set;

The interval [a,b] for x is defined by (a_{ij} is the accuracy associated to criterion j for site i):

$$a = \begin{cases} \min(D), & if\ x_{ij} - a_{ij} < \min(D) \\ x_{ij} - a_{ij}, & if\ x_{ij} - a_{ij} \geq \min(D) \end{cases}$$

$$b = \begin{cases} x_{ij} + a_{ij}, & if\ x_{ij} + a_{ij} < \max(D) \\ \max(D), & if\ x_{ij} - a_{ij} \geq \max(D) \end{cases} \quad (3)$$

D is the variable domain.

The accuracy is given as a percentage of criterion value and confidence belongs to the unit interval. For example, an accuracy of 90% for slope means that each slope value belongs to the interval $[a,b]$ where $a_{ij} = 0.9 \times x_{ij}$. On the other hand, a 0.9 confidence value means that we have a confidence on the $[a,b]$ interval of 0.9.

As can be observed, this formulation enables dealing with imprecision in the collected input hazard maps. Moreover, it allows dealing with two types of imprecision: lack of accuracy in the data and lack of confidence in the data. We believe this is a simple and easy way to tackle the problematic of how to handle imprecision in data in dynamic decision models. It is one of the contributions proposed in this work.

3.4 . Weighting functions

The second contribution is the proposal is to compute the weights using the following linear weighting function [10], [11]:

$$L(ac_{ij}) = \alpha \frac{1 + \beta ac_{ij}}{1 + \beta}, where\ 0 \leq \alpha \leq 1\ and\ 0 \leq \beta \leq 1 \quad (4)$$

Where: ac_{ij} is the accuracy and confidence membership value of j^{th} criterion for site *i*.

The logic of these weighting functions is that the satisfaction value of a criterion should influence its assigned relative importance. For example, if we are buying a car and the price is a "very important" criterion, if the car is quite expensive the final decision result should be less than the simple multiplication of weight*satisfaction value. We will not use quadratic weighting functions because it penalizes values near 1, contrarily to the linear function that presents a more smooth behaviour, which better fits our model [10], [11].

We consider the relative importance of criteria has different morphologies for each criterion, depending on each of the three phases defined. The definition of these weighting functions morphologies is given by parameters α and β. The α parameter provides the semantics for the weighting functions as follows:

- Very Important (VI =1);
- Important (I=0.8);
- Average importance (A=0.6);
- Low importance (L=0.4);
- Very Low importance (VL=0.2).

The β parameter provides the slope for the weighting functions, which will depend on the criterion at hand, with the logic that higher β means higher slope. For our case study this parameter has the following values:

- High (H =1);
- Medium (M=0.6667);
- Low (L=0.3333);
- Null (N=0);

As mentioned above the relative importance of criteria changes according to the altitude of the spacecraft, i.e. depends on the closeness to planet surface. We defined different weights for each sub-phase we are in, as described in the next two sub-sections, but these importances's can be modified by the decision maker anytime.

3.4.1 Discussion of Criteria Weighting in case study

Phase 1 (altitude: > 1000m, <2000; historic set size 250)

This phase refers to altitudes between 1000m to 2000m and a historic size of 250 candidate alternatives. In Table 1 we show the proposed values for α and β parameters for this phase, in Figure 2 we depict their respective plots, where Y-axis represents the weights and X-axis shows criteria satisfaction values within interval [0-1].

Table 1: α & β parameters (Phase 1).

	Fuel	Reach	Slope	Dist	Shad	Text	ScIn
α	1	1	1	0.6	0.4	0.8	0.2
β	0.25	0.667	0.111	0.333	0	0.333	0

For example, the rationale for "very important" is that although fuel, reachability and slope are all "very important" criteria for this phase, a lower satisfaction for criteria reachability should be quite penalized (e.g. X=0.25 corresponds to W=0.7, hence W(x)= 0.25*0.7=> 0.175). Further,, fuel and slope also consider high penalties for lower satisfaction values, visible on their plot (Figure 2).

ISBN: 978-989-95079-6-8

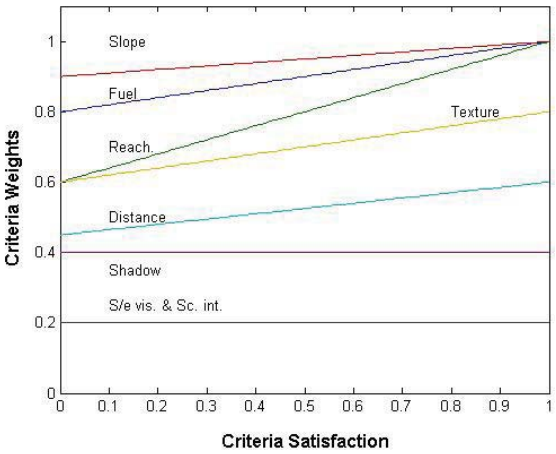

Figure 2: Weighting functions Phase I.

Phase I1 (altitude: ≤ 1000m, >300m; historic set size 10)
In Table 2 we depict the proposed values for α and β parameters for this phase, in Figure 3 their respective plots.

Table 2: α & β parameters (Phase II).

	Fuel	Reach	Slope	Dist	Shad	Text	ScIn
α	0.6	1	1	0.6	0.4	0.8	0.2
β	0.5	0.667	0.111	0.333	0	0.333	0

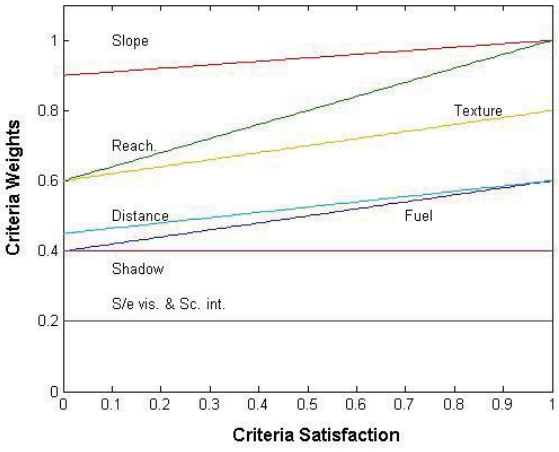

Figure 3: Weighting functions Phase II.

For example, in this phase the same rationale as in phase 1 applies for the two "very important" criteria, slope and reachability, althought slope is less penalized for lower satisfaction of criteria (e.g.0.8 weight for satisfaction 0.5 and weight 1 for satisfaction 1).

Phase III (altitude: ≤ 300m; historic set size 5)
In Table 3 we depict the proposed values for α and β parameters for this phase, in Figure 4 their respective plots.

Table 3: α & β parameters (Phase III).

	Fuel	Reach	Slope	Dist	Shad	Text	ScIn
α	0.2	1	1	0.2	0.4	0.8	0.2
β	0	0.667	0.111	0	0	0.333	0

For example, in this phase scientific interest and shadow do not play an important role because the alternatives are focused on a small area. Further, it almost does not require fuel due to the surface proximity. Hence their weights are small and constant, 0.2 for fuel & scientific interest, and 0.4 for shadow (all flat functions not dependent on satisfaction of criterion).

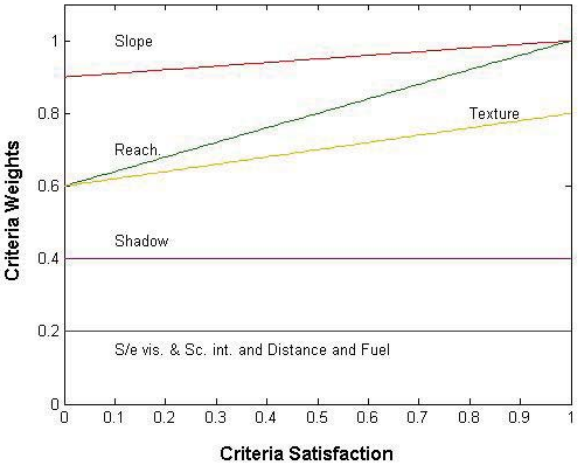

Figure 4: Weighting functions Phase III.

In summary, the relative importance proposed for each criterion followed the semantic rational:

- Slope relative importance (weight) in all phases is considered to be "very important";
- Reachability relative importance (weight) in all phases is considered to be "very important";
- Texture relative importance (weight) in all phases is considered to be "important";
- Shadow relative importance (weight) in all phases is considered to be "low";
- Distance relative importance (weight) in the first 2 phases is considered to be "average" and then it will change to "low" and "very low";
- Scientific interest (Sc int.) relative importance (weight) in all phases is considered to be "very low";
- Sun/Earth visibility (S/e vis.) relative importance (weight) in all phases is considered to be "very low";
- Fuel relative importance (weight) in phase 1 is considered to be "very important";
- Fuel relative importance (weight) in phase 2 is considered to be "medium";
- Fuel weight in phase 3 is considered to be "very low".

The rational above is expressed by the α parameter, while the β parameter provides more or less penalties for lower satisfaction values in the criteria, as depicted in the figures for each phase. A simplification of the weighting functions could be to define "a priori" a slope for each importance i.e. avoids having to define different β parameters for each weighting functions. This option simplifies the weight assignment process but it is less accurate.

ISBN: 978-989-95079-6-8

An important point to highlight is that the parameter values proposed for the phases (or iterations) can be tuned for any other dynamic decision application.
This section concludes the second proposed contribution of this work, i.e. contributions to deal with different criteria weights for steps of the dynamic decision process.

4 Discussion

In Table 4 are depicted the best three alternatives on the last iteration of each phase using default weights (described in previous section). For instance, the best alternative on the end of the 2nd phase (iteration 25) has 3D coordinates: (86 , -27 , 12) and rating value of 0.7807.

We can observe that from 16th to the 25th iteration the best site is completely different. However, the 2nd and 3rd best sites seem to be on the same region on both iterations (50 meters south). Furthermore, the best and 2nd best sites from iteration 25 changed positions with each other on the 40th iteration.

Table 4 – Rating values and 3D coordinates of the best sites on the last iteration of each phase (default weights).

Iter.	3D coord (meters)	R_n
16 (1st Phase)	(51 , 29 , 35)	0.7833
	(65 , -0.4 , 33)	0.7801
	(94 , 26 , 35)	0.7798
25 (2nd Phase)	(86 , -27 , 12)	0.7807
	(66 , -50 , 10)	0.7783
	(95 , -26 , 12)	0.7772
40 (3rd Phase)	(79 , -53 , -6)	0.9955
	(86 , -53 , -6)	0.5119
	-	-

In table 5 we present the results regarding the best sites on the last iteration of the 2nd and 3rd phase, only this time changing the Distance criterion weight to Very High on both phases. For illustrative purposes we considered the distance towards the centre of image for computing the Distance Criterion.
Comparing the results of Table 5 with Table 4, we can observe that at iteration 25th the first result is exactly the same and the 2nd and 3rd too, but on a different order. The best site maintained is position very close to the centre of the image and the distance criterion is now considered to be very high. By the same reason, site (95 , -26 , 12) went to the 2nd position because it is must closer to the image centre than site (66 , -50 , 10)..

On the other hand, the 2 best sites on the 40th iteration are completely different on both Tables. The sites on Table 4 are not close to the centre of the image and when the Distance criterion is set to very high the model tends to rate higher sites closer to the centre of the image. Hence, the best sites on Table 5 are closer to centre of the image (see Figure 5).
It should be noted that the experiences discussed here were adaptations of tests done within a research project [7] [8]. Furthermore, here we do not discuss the results rating values, because we are not addressing the aggregation methods used to evaluate the alternatives.

Table 5 – Rating and 3D coordinates of 3 best sites on last iterations of 2nd and 3rd phases (weight for Distance Criterion =Very high).

Iter.	3D coord (meters)	R_n
25 (2nd Phase)	(86 , -27 , 12)	0.7991
	(95 , -26 , 12)	0.7938
	(66 , -50 , 10)	0.7932
40 (3rd Phase)	(88 , -31 , -3)	0.9979
	(78 , -30 , -3)	0.9977
	-	-

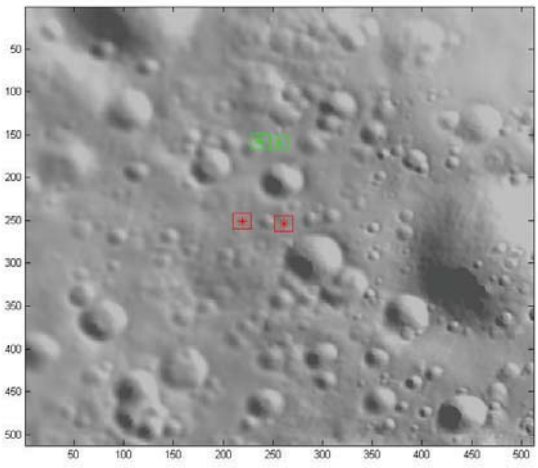

Figure 5 – Image of the surface on iteration 40. Green stars best sites from Table 4 and red stars from Table 5.

In Figure 5 we show the results, just discussed for the last iteration (40). It is quite notorious the influence of changing criterion weights for Distance, from average to very-high, on the last phase. Raising the importance of that criterion "forces" the final decision choice to be closer (shortest distance) to the initial target (center of image), even though the surface is more "bumpy" than the choices from Phase II.

5 Conclusions

In this work we presented a general architecture to cope with dynamic multi-attribute decision problems. We focused our attention on two spatial-temporal aspects of the rating process, .specifically proposing contributions for dealing with uncertainty in dynamically changing input data and also for dealing with dynamic changes in criteria importance.
Potential applications of this work could be on medical diagnose decision support and/ or fault, detection and isolation (FDI) problems.

A Fuzzy Set Approach to Ecological Knowledge Discovery

Arkadiusz Salski

Institute of Computer Science, University of Kiel
Kiel, Germany
E-mail: asa@email.uni-kiel.de

Abstract— *Besides the problem of searching for effective methods for extracting knowledge from large databases (KDD) there are some additional problems with handling ecological data, namely heterogeneity and uncertainty of these data. A fuzzy set approach can be used to handle these problems at some stages of the knowledge discovery process. Ecological data can be defined as fuzzy sets without sharp boundaries, which reflect better the continuous nature of ecological parameters. The paper focuses on one of the important methods of data reduction, namely clustering, and on the data transformation and construction of a combining operator. Two support systems developed at the University of Kiel and their applications are presented, namely the Fuzzy Clustering System ECOFUCS and the Fuzzy Evaluation and Kriging System FUZZEKS.*

Keywords— ecological data, fuzzy clustering, fuzzy data transformation, uncertainty of ecological data.

1 Some properties of ecological data

Dealing with a very large data basis (long time series, spatial data with high resolution, etc.) is a typical problem in data mining and knowledge discovery, but there are some additional problems with handling the environmental data. The first one is the heterogeneity of ecological data sources (e.g. sources of quantitative and qualitative information). The next problem in ecological data mining is the large inherent uncertainty of these data that results not only from the presence of random variables but also from the difficult comparability of these data, approximate estimations, and imprecision and the subjectivity of the information obtained from an expert [12, 13]. This paper deals with processing both "subjective" data derived from experts and "objective" measurement data. Statistical or stochastic aspects of the uncertainty problem are not taken into account.

Some requirements for methods of searching for ecological knowledge arise from the properties of ecological data mentioned above. Special methods of data analysis should be used to handle the uncertainty and heterogeneity of these data. The fuzzy approach, as a possible way to handle uncertainty, is particularly useful for processing imprecise or uncertain data. Ecological data can be defined as fuzzy sets or fuzzy clusters without sharp boundaries. That reflects better the continuous nature of environmental parameters.

Knowledge discovery is a very complex process, which includes data cleaning, data integration, data reduction, data transformation, data mining, pattern evaluation and knowledge presentation [9]. Collaboration with an expert in the data domain can be very useful at some stages of this process. The fuzzy approach enables us to integrate the expert knowledge in the knowledge discovery process. The paper focuses on the applications of fuzzy sets and fuzzy operators at some stages of this process, namely data reduction (section 2) and constructing a combining attribute (section 3).

2 Data reduction: a fuzzy clustering approach

Clustering belongs to the most popular methods of numerosity reduction of data sets, i.e. "replacing" the data set by smaller representations such as clusters in order to reduce the size of the data set. The clustering methods are based on the principle of maximizing the intraclass similarity of objects and minimizing the interclass similarity of these objects, i.e. objects within a cluster have a high similarity, but are very dissimilar to objects in other clusters. Conventional clustering methods based on Boolean logic ignore the continuous nature of ecological parameters and the uncertainty of data. That can result in misclassification.

Fuzzy clustering methods provide additional information, namely the distribution of the membership values which can be interpreted as a similarity measure. The common fuzzy clustering methods, like the fuzzy c-means method, work only with crisp data, that means they provide the fuzzy partition only for crisp data (e.g. exact measurement data). In ecology we have often to deal with data with a semblance of accuracy. In such cases it may only be possible to obtain estimates of data scatter which can be treated in the context of fuzzy sets and used for defining fuzzy data in the form of fuzzy vectors in a high dimension, the so-called conical fuzzy vectors [5]. They are defined by the apex and the so-called panderance matrix which describes the accuracy of the data. This matrix contains spreads of data in each dimension on its diagonal. Yang [15] defined the distance between two conical fuzzy vectors, $\tilde{A}$ and $\tilde{B}$ in (1), as follows:

$$d^2(\tilde{A},\tilde{B}) = \left\|\bar{a}-\bar{b}\right\|^2 + tr\left((A-B)^T(A-B)\right) \qquad (1)$$

where:

A and B are the so-called panderance matrices of $\tilde{A}$ and $\tilde{B}$,
$\left\|\bar{a}-\bar{b}\right\|$ is the distance norm (metric) between the apexes $\bar{a}$ and $\bar{b}$, and the trace
$tr\left((A-B)^T(A-B)\right)$ is the diagonal sum of $\left((A-B)^T(A-B)\right)$.

Yang proved that $d^2(\tilde{A},\tilde{B})$ defined above is a complete metric, which is an assumption for the convergence of the

ISBN: 978-989-95079-6-8

fuzzy c-means clustering procedure by Bezdek [3]. That means, we can define the well known objective function of the fuzzy c-means procedure for conical fuzzy vectors by

$$F_{(c)} = \sum_{i=1}^{n} \sum_{j=1}^{c} \left(\mu_{ij}\right)^m d_c^2\left(\tilde{A}_i, \tilde{B}_j\right) \qquad (2)$$

where:

$\tilde{A}_i$ is the *i*th object and $\tilde{B}_i$ is the *j*th cluster, both defined as conical fuzzy vectors,

n is the number of objects, and

c is the number of clusters.

The clustering algorithm for conical vectors proposed by Yang has been extended for the diagonal norm using the so-called z-transformation of the Euclidian norm and implemented for the Fuzzy Clustering System EcoFucs v.5.1 developed at the University of Kiel [8]. The diagonal norm is a highly recommendable distance measure in the case of heterogeneous ecological data with different domain scales. In such cases we can transform data in a uniform manner before we start the fuzzy c-means procedure for conical vectors:

$$z - trans\left(\tilde{A}_i\right) = \frac{\tilde{A}_i - \tilde{V}}{\tilde{S}} \qquad (3)$$

where:

$\tilde{V} = \frac{1}{n}\sum_{j=1}^{n} \tilde{A}_j$ is the mean vector of all fuzzy conical vectors of the input data set, and

$\tilde{S}$ is the vector of spreads from the panderance matrix.

To obtain back the coordinates of the cluster centers in the real scale we have to apply the inverse transformation of the results of the fuzzy c-means procedure. EcoFucs works also with crisp data and offers four different distance norms as a measure of similarity between an object and a respective cluster (the Euclidean-, the Diagonal-, the Mahalonobis- and L1-norms) and a set of methods for calculating the start partition (WARD, conventional c-means, maximum-distance-algorithm, sharp or fuzzy random partitions). The choice of the distance norm depends on the data set. The partition efficiency indicators (entropy, partition coefficient, payoff and non-fuzziness index) available in EcoFucs can be very helpful in searching for the optimal partition and finding the objects which can serve as the representatives of each cluster (see the example below) [10].

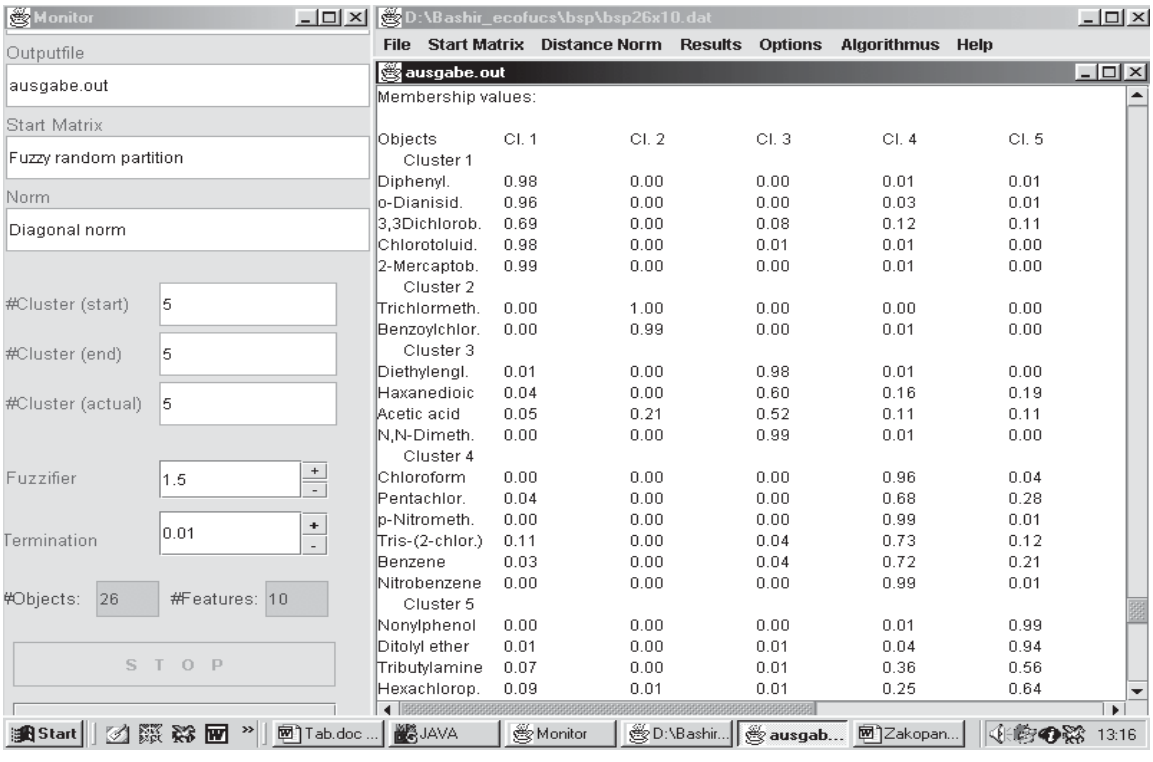

Figure 1: The main window of EcoFucs [8] with a small part of the results of the clustering of ecotoxicological data into 5 clusters.

The fuzzy clustering of chemicals according to their ecotoxicological properties [7] can be mentioned here as an example of data reduction. Both the large number of existing chemicals and the costs of ecotoxicological testing procedures make it necessary to select representative chemicals which faithfully reflect the relevant properties of possibly a major group of compounds. So the main tasks of this application were to find distinguishable clusters with characteristic properties and to find chemicals representative for each cluster. These representatives can be used for further data mining and other steps of the knowledge discovery process instead of all chemicals which belong to the cluster. Compared to conventional clustering methods a fuzzy clustering technique is more appropriate to handle the uncertainty of ecotoxicological data. The degree of uncertainty of these data is very high and can arise, for

ISBN: 978-989-95079-6-8

example, from a mixture of quantitative and qualitative data or from the difficult comparability of these data because of different measurement or test conditions (e.g. test results for different animals). The distribution of the membership values provides information from which the degree of similarity between the properties of a particular chemical and the properties characterising particular clusters can be deduced. This is particularly important since there are many chemicals with more or less overlapping properties. That would not be recognised by conventional clustering methods.

The analysis of the membership values helps us to find the representatives of each cluster. Their membership values are close (or equal) to 1. Figure 1 presents a small example of the results of the clustering of chemicals into 5 clusters for 10 ecotoxicological features (toxicity indicators and the potentials for biodegradability and hydrolysis). Trichlormethylbenzene and 2-Mercaptobenzothiazole, for example, can be taken as the representatives of clusters 2 and 1, respectively. We can also see some chemicals (e.g. Tributylamine and Hexachloropentadiene in cluster 5) with membership values strongly divided between different clusters. These values can be interpreted as the degree of similarity to the respective clusters.

3 Data transformation and the construction of a combining operator

One of the important stages of the knowledge discovery process is the data transformation needed to combine the data. In the case of heterogeneous data we have to normalise these data in a uniform manner before we construct the combining operator [4]. In order to do this we can scale data so that they fall within the same range. We can use the membership functions of fuzzy sets to transform the data into the interval 0.0 to 1.0. The definition of the membership functions of these fuzzy sets should express the evaluation criterion formulated by an expert.

We can consider an analysis of hydrogeological spatial data as an example. Figure 2 presents the membership function of the feature “large water table depth” used for the data normalization in the analysis of the suitability of a specified land unit as a waste disposal site [2, 14]. The shape of the defined membership function corresponds to the evaluation criterion. The values of the water table depth lower than 2 m are not suitable (the membership values equal 0); the values bigger than 5 m are very suitable for a waste disposal site (the membership values equal 1).

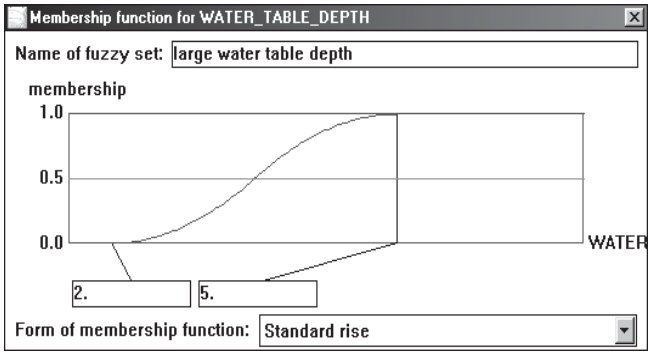

Figure 2: The membership function of the fuzzy set “large water table depth” used for the data transformation (the membership function window of FUZZEKS [2]).

Four land characteristics, namely water table depth, hydrologic conductivity, clay content and Cl concentration, are taken into account in this example. The values of these four features were transformed into a common scale 0.0 to 1.0 using suitable membership functions, like “large water table depth” or “high Cl concentration”. Now, we can combine these data by constructing a new combining attribute (Fig. 3), namely the joint degree of land suitability for a specified utilization (in this case, as a waste disposal site). Different logical and arithmetical operators can be used for the construction of such a combining attribute. Arithmetical operators (like the sum operator) can be weighted and that makes them particularly useful to express the degree of importance of a particular parameter. The distribution of weights is subjectively determined by a domain expert. In our example we combined the four land characteristics by means of a weighted sum operator and the “and”- operator using the Fuzzy Evaluation and Kriging System FUZZEKS developed at the University of Kiel (Fig. 3) [2].

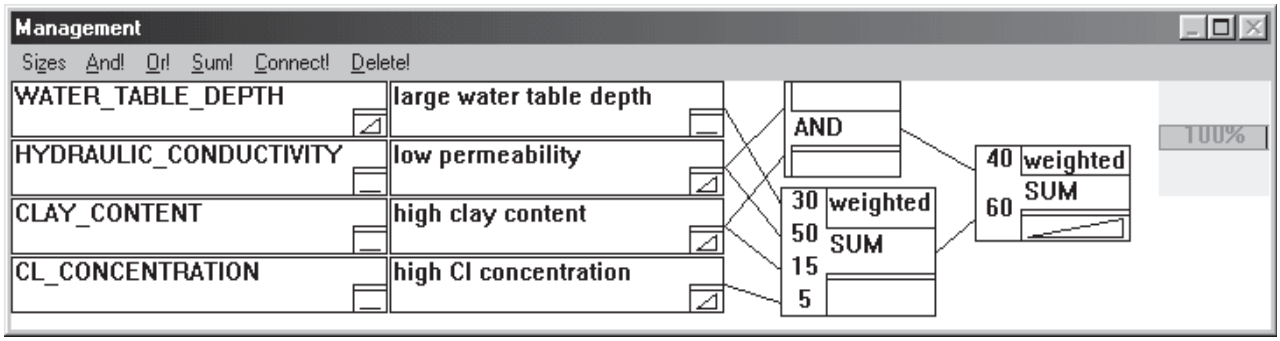

Figure 3: Constructing a combining operator (the management window of FUZZEKS [2]).

The calculated values of the joint attribute can be presented in the form of isolines using the fuzzy interpolation procedure, the so-called fuzzy kriging (Fig. 4). Fuzzy kriging is an extension of the conventional kriging procedure [1,6]. The application of the conventional methods of spatial interpolation is often restricted owing to insufficient amounts

ISBN: 978-989-95079-6-8

of data [11]. If the gathering of new data is too expensive or impossible, we can consider the use of additional imprecise data subjectively estimated by an expert. The fuzzy kriging procedure utilizes exact (crisp) measurement data as well as imprecise estimates obtained from an expert. These imprecise data can be defined as fuzzy numbers and taken as additional input data for the kriging procedure implemented in FUZZEKS. To simplify the preparation of the input data file a special ASCII-file format was implemented, combining both exact (crisp) and fuzzy data (fuzzy numbers) in one unified form [2]. Fuzzeks supports a user in the preparation of the so-called experimental variogram and in the interactive fitting of the crisp theoretical variogram, which is a basis for the interpolation procedure, to the fuzzy experimental variogram (see the small window left in Fig. 4).

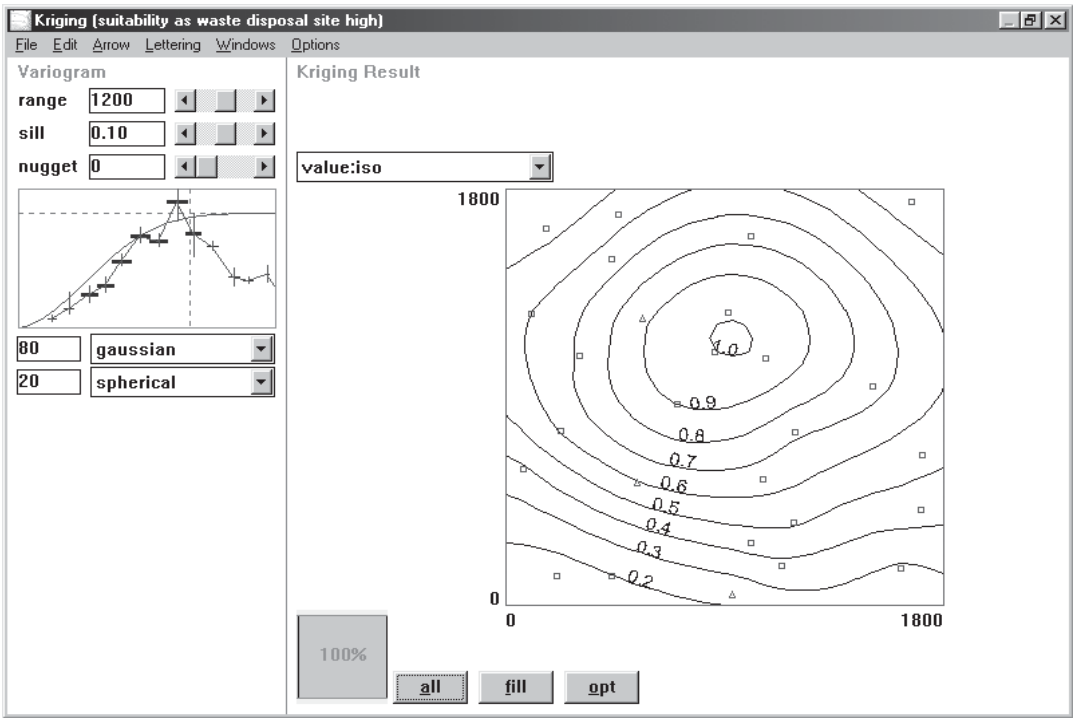

Figure 4: The presentation of the interpolated values of the joint attribute in the form of isolines (on the right in the main window of FUZZEKS,); interactive fitting of a theoretical variogram to an experimental variogram (small window left).

The logical structure of this fuzzy kriging procedure is shown in Fig. 5. The zigzag lines mark the stages with fuzzy data input in the form of fuzzy numbers. At two stages fuzziness is introduced into the calculation. First, fuzziness in the input values causes fuzziness in the experimental variogram. An expert takes the experimental variogram and its fuzziness into account when fitting the crisp theoretical variogram. Second, the fuzzy input values are used at the final step of kriging. Therefore, the kriging results are also fuzzy.

The main fuzzy kriging estimation is a linear combination of the input values and can be calculated using the extension principle and the α -cut-representation of fuzzy sets:

$$Z^*(x)_\alpha = \sum_{i=1}^{n} \delta_i(x) Z(x_i)_\alpha \qquad (4)$$

where:

$Z^*(x)_\alpha$ is is the α -cut of the interpolated value $Z^*(x)$ at the position *x*,

$Z(x_i)_\alpha$ are the α -cuts of the input values $Z(x_i)$, and

$\delta_i(x)$ are the crisp minimizing parameters.

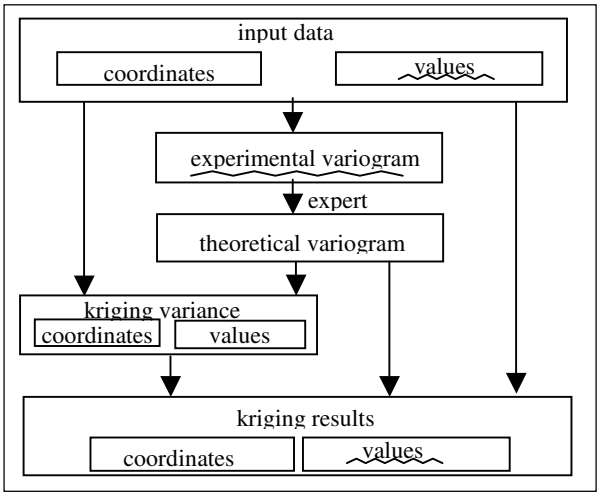

Fig. 5. Logical structure of fuzzy kriging (zigzag lines indicate the fuzziness of data).

ISBN: 978-989-95079-6-8

The kriging estimation (4) formulated by α-cut-representation of fuzzy sets has been used for the implementation of the fuzzy kriging procedure for the Fuzzy Kriging and Evaluation System FUZZEKS.

4 Final remarks

The fuzzy approach can support users in discovering interesting knowledge in uncertain ecological data at different stages of this process. The searching for representatives of groups of ecological objects by means of clustering methods can be very useful not only in numerosity reduction but also in dimensionality reduction of the data set. Fuzzy clusters of objects without sharp boundaries reflect better the continuous nature of ecological features. That enables a better interpretation of the data structure.

Heterogeneous and imprecise ecological data and vague expert knowledge can be integrated more effectively using a fuzzy approach. The data transformation by means of fuzzy sets can be used for this integration. The membership functions of fuzzy sets can describe the evaluation criteria (e.g. "high clay content") defined by an expert. The construction of a combining attribute in the next step reduces the dimensionality and the size of the data set.

And finally, the intention of the author was to draw the reader's attention to a large field for applications, namely ecology. The paper illustrates it briefly using some short application examples. The development of the easy to use tools (like EcoFucs and FUZZEKS developed at the University of Kiel) can be very helpful for the promotion of fuzzy methods in ecological applications.

Numerical Solution of Interval Differential Equations with generalized Hukuhara differentiability

Barnabas Bede, Luciano Stefanini
Department of Mathematics, University of Texas-Pan American, USA. email: bedeb@utpa.edu.
Department of Economics and Quantitative Methods, University of Urbino "Carlo Bo", Italy. email: lucste@uniurb.it

Abstract— *In the present paper we propose novel numerical methods for interval differential equations with generalized Hukuhara differentiability. The algorithms proposed here are based on characterization theorems of interval differential equations with ODEs. Usng the characterizations we can translate an interval problem into two ODE systems. We observe that an interval problem may have several solutions under the interpretation considered. Several examples are presented and discussed.*

Keywords— Generalized Hukuhara Differentiability, Interval Differential Equations, Interval Analysis.

1 Introduction

Interval Analysis was introduced as an attempt to handle interval (nonstatistical) uncertainty that appears in our mathematical or computer models of some deterministic real-world phenomena. The first monograph dealing with interval analysis is the book of R. Moore, [10]. Since then, Reliable Computing, Validated Numerics and Interval problems with Differential Equations are discussed in several monographs and research papers ([11], [2]).

Another major approach to a set of similar problems is that of differential inclusions and multivalued analysis ([1], [5]). This approach is also able to deal with discontinuous dynamical systems which do not fully fit into the Interval Analysis topic.

Hukuhara derivative of a set-valued mapping was first introduced by Hukuhara and it has been studied in several works. The paper of Hukuhara was the starting point for the topic of Set Differential Equations and later also for Fuzzy Differential Equations [8], [12], [6]. Recently, several works as e.g.[9], have brought back into the attention of the nonlinear analysis community, the topics of set differential equations and the Hukuhara derivative.

Recently a generalization of the Hukuhara difference for compact convex sets (gH-difference) was presented in [13] and the strongly and weakly generalized (Hukuhara) differentiability concepts have been proposed in [3]. Then, in [14] a combination (gH-derivative) was proposed and it was shown to be a useful concept in the interval setting. Our approach to interval differential equations is different from the approaches based on differential inclusions or interval analysis, however we can see that there is some connection among these approaches and the presented one, some connections with differential inclusions we discuss here.

After recalling some results of [14], we propose a numerical solution method for IDEs. Also, a numerical method for differential inclusions is discussed and several examples are proposed.

2 Generalized Hukuhara difference

Consider the space $\mathbb{I}$ of real intervals. Given two elements $A, B \in \mathbb{I}$ and $k \in \mathbb{R}$, the usual interval arithmetic operations, i.e. Minkowski addition and scalar multiplication, are defined by $A+B = \{a+b | a \in A, b \in B\}$ and $kA = \{ka | a \in A\}$. It is well known that addition is associative and commutative and with neutral element $\{0\}$. If $k = -1$, scalar multiplication gives the opposite $-A = (-1)A = \{-a | a \in A\}$ but, in general, $A + (-A) \neq \{0\}$, i.e. the opposite of A is not the inverse of A in Minkowski addition (unless $A = \{a\}$ is a singleton). A first implication of this fact is that, in general, additive simplification is not valid, i.e. $(A + C = B + C) \nRightarrow A = B$ or $(A + B) - B \neq A$ (the Minkowski difference is $A - B = A + (-1)B$).

To partially overcome this situation, the Hukuhara H-difference has been introduced as a set C for which $A \ominus B = C \iff A = B + C$ and an important property of $\ominus$ is that $A \ominus A = \{0\}\, \forall A \in \mathcal{K}_C^n$ and $(A+B) \ominus B = A, \forall A, B \in \mathcal{K}_C^n$.

The H-difference is unique, but it does not always exist (a necessary condition for $A \ominus B$ to exist is that A contains a translate $\{c\} + B$ of B).

A generalization of the Hukuhara difference proposed in [13] aims to overcome this situation.

Definition 1 *([13]) The generalized Hukuhara difference of two sets $A, B \in \mathbb{I}$ (gH-difference for short) is defined as follows*

$$A \ominus_g B = C \iff \begin{cases} (a) & A = B + C \\ \textit{or} \quad (b) & B = A + (-1)C \end{cases} \tag{1}$$

The following property ensures the existence of gH-differences.

Proposition 1 *([13]) The gH-difference $C = A \ominus_g B$ of two intervals $A = [a^-, a^+]$ and $B = [b^-, b^+]$ always exists and*

$$[a^-, a^+] \ominus_g [b^-, b^+] = [c^-, c^+] \tag{2}$$

with

$$c^- = \min\{a^- - b^-, a^+ - b^+\}$$
$$c^+ = \max\{a^- - b^-, a^+ - b^+\}.$$

Conditions (a) and (b) in (1) are satisfied simultaneously if and only if the two intervals have the same length and $c^- = c^+$.

3 Differentiation of interval valued functions

There exist several alternative definitions for the derivative of an interval-valued function. The first concept is a partic-

ISBN: 978-989-95079-6-8

ularization of the fuzzy concepts presented in [3] to the interval case, based on the generalized fuzzy differentiability concept, more general than one-sided derivatives, using the usual Hukuhara difference $\ominus$.

Definition 2 *([3]) Let $f :]a,b[\to \mathbb{I}$ and $x_0 \in]a,b[$. We say that f is strongly generalized (Hukuhara) differentiable at x_0, if there exists an element $f'(x_0) \in \mathbb{I}$, such that, for all $h > 0$ sufficiently small,*

(i) $\exists f(x_0+h) \ominus f(x_0)$, $f(x_0) \ominus f(x_0-h)$ and

$$\lim_{h \searrow 0} \frac{f(x_0+h) \ominus f(x_0)}{h} = \lim_{h \searrow 0} \frac{f(x_0) \ominus f(x_0-h)}{h} = f'(x_0),$$

or (ii) $\exists f(x_0) \ominus f(x_0+h)$, $f(x_0-h) \ominus f(x_0)$ and

$$\lim_{h \searrow 0} \frac{f(x_0) \ominus f(x_0+h)}{(-h)} = \lim_{h \searrow 0} \frac{f(x_0-h) \ominus f(x_0)}{(-h)} = f'(x_0),$$

or (iii) $\exists f(x_0+h) \ominus f(x_0)$, $f(x_0-h) \ominus f(x_0)$ and

$$\lim_{h \searrow 0} \frac{f(x_0+h) \ominus f(x_0)}{h} = \lim_{h \searrow 0} \frac{f(x_0-h) \ominus f(x_0)}{(-h)} = f'(x_0),$$

or (iv) $\exists f(x_0) \ominus f(x_0+h)$, $f(x_0) \ominus f(x_0-h)$ and

$$\lim_{h \searrow 0} \frac{f(x_0) \ominus f(x_0+h)}{(-h)} = \lim_{h \searrow 0} \frac{f(x_0) \ominus f(x_0-h)}{h} = f'(x_0).$$

Based on the gH-difference in [14] the following definition was proposed.

Definition 3 *Let $x_0 \in]a,b[$ and h be such that $x_0 + h \in]a,b[$, then the gH-derivative of a function $f :]a,b[\to \mathbb{I}$ at x_0 is defined as*

$$f'(x_0) = \lim_{h \to 0} \frac{1}{h}[f(x_0+h) \ominus_g f(x_0)]. \quad (3)$$

If $f'(x_0) \in \mathbb{I}$ satisfying (3) exists, we say that f is generalized Hukuhara differentiable (gH-differentiable for short) at x_0.

The next result is a characterization of the derivative concept proposed in (3) and it was proved in [14].

Theorem 2 *Let $f : [a,b] \longrightarrow \mathbb{I}$ be such that $f(x) = [f^-(x), f^+(x)]$. The function $f(x)$ is gH-differentiable if and only if $f^-(x)$ and $f^+(x)$ are differentiable real-valued functions and*

$$f'(x) = [\min\{(f^-)'(x), (f^+)'(x)\}, \quad (4)$$
$$\max\{(f^-)'(x), (f^+)'(x)\}]. \quad (5)$$

The following definition will be helpful in the discussion of the numerical methods for IDEs.

Definition 4 *Let $f : [a,b] \longrightarrow \mathbb{I}$ be gH-differentiable at $x_0 \in]a,b[$. We say that f is (i)-gH-differentiable at x_0 if*

$$\textit{(i.)} \qquad f'(x_0) = [(f^-)'(x_0), (f^+)'(x_0)] \quad (6)$$

and that f is (ii)-gH-differentiable at x_0 if

$$\textit{(ii.)} \qquad f'(x_0) = [(f^+)'(x_0), (f^-)'(x_0)]. \quad (7)$$

It is an interesting problem to see how the switch between the two cases (i.) and (ii.) in Definition 4 can occur.

Definition 5 *We say that a point $x_0 \in]a,b[$ is an l-critical point of f if it is a critical point for the length function $len(f(x)) = f^+(x) - f^-(x)$.*

Definition 6 *We say that a point $x_0 \in]a,b[$ is a switching point for the differentiability of f, if in any neighborhood V of x_0 there exist points $x_1 < x_0 < x_2$ such that*

type I) at x_1 (6) holds while (7) does not hold and at x_2 (7) holds and (6) does not hold, or

type II) at x_1 (7) holds while (6) does not hold and at x_2 (6) holds and (7) does not hold.

First, let us observe that any switching point is also an *l-critical* point. Indeed, if x_0 is a switching point then $[(f^-)'(x_0), (f^+)'(x_0)] = [(f^+)'(x_0), (f^-)'(x_0)]$ and so $(f^+)'(x_0) = (f^-)'(x_0)$ and $len(f(x_0))' = 0$. Clearly, not all *l-critical* points are also switching points.

The relation which exists between the two differentiability concepts was given in [14].

Theorem 3 *Let $f :]a,b[\to \mathbb{I}$ be a function $f(x) = [f^-(x), f^+(x)]$. The following affirmations are equivalent:*

(1) f is GH-differentiable

(2) f is gH-differentiable and the set of switching points is finite.

If the number of l-critical points is finite then the number of switching points is also finite. So, from now on we will use the GH-differentiability concept or equivalently the gH-differentiability with a finite number of switching points.

4 Interval differential equations

In this section we consider an interval valued differential equation

$$y' = f(x,y)\ , y(x_0) = y_0 \quad (8)$$
where
$$f : [a,b] \times \mathbb{I} \longrightarrow \mathbb{I}$$
with $f(x,y) = [f^-(x,y), f^+(x,y)]$ for $y \in \mathbb{I}$
$$y = [y^-, y^+],\ y_0 = [y_0^-, y_0^+].$$

We consider only GH-differentiable solutions, i.e. such that there exists $\delta > 0$ such that there are no switching points in $[x_0, x_0 + \delta]$.

An existence result for the solutions of an IDE was obtained in [14]. Let us consider $\overline{B}(y_0, q) \subset \mathbb{I}$ be a closed ball with center y_0 and radius q.

ISBN: 978-989-95079-6-8

Theorem 4 *Let $R_0 = [x_0, x_0 + p] \times \overline{B}(y_0, q)$, $y_0 \in \mathbb{I}$ nontrivial and $f : R_0 \to \mathbb{I}$ be continuous, nontrivial (i.e., y nontrivial interval gives $f(x, y)$ a nontrivial interval). If f satisfies the Lipschitz condition $D(f(x, y), f(x, z)) \leq L \cdot D(y, z)$, $\forall (x, y), (x, z) \in R_0$ then the interval problem*

$$\begin{cases} y' = f(x, y) \\ y(x_0) = y_0 \end{cases}$$

has two unique solutions $y^i, y^{ii} : [x_0, x_0 + r] \to \overline{B}(y_0, q)$ and the successive iterations in

$$y_0(x) = y_0$$

$$y_{n+1}(x) \ominus_g y_0 = \int_{x_0}^{x} f(t, y_n(t))dt,$$

or more precisely,

$$y^i_{n+1}(x) = y_0 + \int_{x_0}^{x} f(t, y^i_n(t))dt \qquad \textit{i.e.}$$

$$(a) \begin{cases} y^{i-}_{n+1}(x) = y_0^- + \int_{x_0}^{x} f^-(t, y^i_n(t))dt \\ y^{i+}_{n+1}(x) = y_0^+ + \int_{x_0}^{x} f^+(t, y^i_n(t))dt \end{cases}$$

and

$$y_0 = y^{ii}_{n+1}(x) - \int_{x_0}^{x} f(t, y^{ii}_n(t))dt \qquad \textit{i.e.}$$

$$(b) \begin{cases} y^{ii-}_{n+1}(x) = y_0^- + \int_{x_0}^{x} f^+(t, y^{ii}_n(t))dt \\ y^{ii+}_{n+1}(x) = y_0^+ + \int_{x_0}^{x} f^-(t, y^{ii}_n(t))dt \end{cases}$$

converge to these two solutions y^i and y^{ii} respectively.

Considering the interval problem

$$\begin{cases} y' = f(x, y) \\ y(x_0) = y_0 \end{cases} \tag{9}$$

we set

$$\begin{cases} \varphi^-(x, y^-, y^+) = f^-(x, y) \\ \varphi^+(x, y^-, y^+) = f^+(x, y) \end{cases} \tag{10}$$

with $\varphi^- \leq \varphi^+$ defined on a subset of $\mathbb{R}^3$.

Finally, we obtain two situations:

ODE(a): $y'^-(x) \leq y'^+(x)$; the differential equations are

$$\begin{cases} y'^-(x) = \varphi^-(x, y^-(x), y^+(x)) \\ y'^+(x) = \varphi^+(x, y^-(x), y^+(x)) \\ \text{s.t.} \\ y^-(x_0) = y_0^- \\ y^+(x_0) = y_0^+ \end{cases} \tag{11}$$

and if φ^- depends only on y^- and φ^+ depends only on y^+, the two equations are independent.

ODE(b): $y'^-(x) \geq y'^+(x)$; the differential equations are

$$\begin{cases} y'^-(x) = \varphi^+(x, y^-(x), y^+(x)) \\ y'^+(x) = \varphi^-(x, y^-(x), y^+(x)) \\ \text{s.t.} \\ y^-(x_0) = y_0^- \\ y^+(x_0) = y_0^+ \end{cases} \tag{12}$$

and if φ^+ depends only on y^- and φ^- depends only on y^+, the two equations are independent.

Now we present a characterization result obtained in [14]:

Theorem 5 *Let $R_0 = [x_0, x_0 + p] \times \overline{B}(y_0, q)$, $y_0 \in \mathbb{I}$ nontrivial and $f : R_0 \to \mathbb{I}$ be nontrivial and continuous. If f satisfies the Lipschitz condition $D(f(x, y), f(x, z)) \leq L \cdot D(y, z)$, $\forall (x, y), (x, z) \in R_0$ then the interval problem*

$$\begin{cases} y' = f(x, y) \\ y(x_0) = y_0 \end{cases} \tag{13}$$

is equivalent to the union of the ODEs (11) and (12) on some interval $[x_0, x_0 + q]$. Here, by equivalent, we understand that $y = [y^-, y^+] : [x_0, x_0 + q] \to \mathbb{I}$ is a solution of 13 if and only if $(y^-, y^+) : [x_0, x_0 + q] \to \mathbb{R}^2$ is a solution of one of the problems (11) or (12).

Remark 1 *We can write the IDE (13) in terms of the midpoint representations of y, y' and $f(x, y)$. Let $y = \langle \widehat{y}, \overline{y} \rangle$, $y_0 = \langle \widehat{y}_0, \overline{y}_0 \rangle$, $f(x, y) = \left\langle \widehat{f}(x, y), \overline{f}(x, y) \right\rangle$; then $y' = \langle \widehat{y}', |\overline{y}'| \rangle$ and (13) becomes*

$$\begin{cases} \widehat{y}' = \widehat{f}(x, y) \\ |\overline{y}'| = \overline{f}(x, y) \\ \widehat{y}(x_0) = \widehat{y}_0 \\ \overline{y}(x_0) = \overline{y}_0; \end{cases} \tag{14}$$

they represent a system of differential algebraic equations (DAEs) and can be investigated by the help of the corresponding theory.

All the preceding results hold for general interval-valued functions so possibly they depend on interval parameters, i.e. interval extensions of real-valued functions of the form $f(x, y, p_1, ..., p_n)$ with $p_i \in P_i \in \mathbb{I}$.

Let us analyze the case when $f(x, y)$ is the interval extension of a real valued function $f(x, p)$, i.e.

$$f(x, y) = [\inf_{p \in y} f(x, p), \sup_{p \in y} f(x, p)]. \tag{15}$$

Let us suppose further that f is monotonic with respect to p.

1) if $f(x, p)$ is increasing with respect to p,

$$case(a) : y'^-(x) \leq y'^+(x)$$
$$\begin{cases} y'^-(x) = f(x, y^-(x)) \\ y'^+(x) = f(x, y^+(x)), \\ \text{s.t. } y^-(x_0) = y_0^-, \\ y^+(x_0) = y_0^+ \end{cases} \tag{16}$$

$$case(b) : y'^-(x) \geq y'^+(x)$$
$$\begin{cases} y'^+(x) = f(x, y^-(x)) \\ y'^-(x) = f(x, y^+(x)), \\ \text{s.t. } y^-(x_0) = y_0^-, \\ y^+(x_0) = y_0^+ \end{cases} \tag{17}$$

2) if $f(x, p)$ is decreasing with respect to p

$$case(a) : y'^-(x) \leq y'^+(x)$$
$$\begin{cases} y'^-(x) = f(x, y^+(x)) \\ y'^+(x) = f(x, y^-(x)), \\ \text{s.t. } y^-(x_0) = y_0^-, \\ y^+(x_0) = y_0^+ \end{cases} \tag{18}$$

$$case(b) : y'^-(x) \geq y'^+(x)$$
$$\begin{cases} y'^+(x) = f(x, y^+(x)) \\ y'^-(x) = f(x, y^-(x)), \\ \text{s.t. } y^-(x_0) = y_0^-, \\ y^+(x_0) = y_0^+ \end{cases} \tag{19}$$

ISBN: 978-989-95079-6-8

Also, in this case, a very interesting result from [4] connects these cases to differential inclusions. In the followings we formulate a particularization of the result of Chalco-Cano and Roman-Flores. Namely we have:

Theorem 6 *[4] Let $f(x,p)$ be a monotonic function with respect to $p \in \mathbb{R}$ and let $y_0 \in \mathbb{I}$ nontrivial interval.*

a) If $f(x,y)$ is the interval extension of f and f is an increasing function, then the solution in case (a) of (16) and the attainable set of the differential inclusion $y' = f(x,y)$, $y(x_0) \in y_0$ coincide on some interval $[x_0, x_0+q]$.

b) If $f(x,y)$ is the interval extension of f and f is a decreasing function, then the solution in case (b) of (18) and the attainable set of the differential inclusion $y' = f(x,y)$, $y(x_0) \in y_0$ coincide on some interval $[x_0, x_0+q]$.

5 Solution methods for interval differential equations

From the results and discussion of previous sections, the interval differential equation concept presented in this paper does not coincide with the concept of a differential inclusion. It is a different, new approach to model interval uncertainty in dynamical systems. It is related (as it is seen from the above theorems) to differential inclusions but we do have in our case more than one solution. The existence of several solutions can be an advantage when we search for solutions with specific properties like e.g., periodic, almost periodic, asymptotically stable, etc. Also, it can be very useful when we have unknown correlations between the parameters. In those situations, the uncertainty about the correlation introduces supplementary uncertainty in our system, so the existence of several solutions appears to be natural in this case.

The above characterization theorems, together with the existence results, lead easily to a numerical algorithm to solve interval differential equations.

5.1 General description of the solution methods

First, let us remark that a switch between the cases (i) and (ii) of gH-differentiability is possible if and only if $y'(x)$ is a singleton as in fact possible switch-points are l-critical points, i.e., critical points of the length of $y(x)$. Let us remark that if at a point $y(x_0)$ is a singleton for some x_0, then this point is enforcing a switch to the case (i), because, according to the existence result in Theorem 4, the second solution does not exist in this case. All other l-critical points make possible a switch from (i) to (ii) case or vice versa, but they do not enforce a switch, so at each l-critical point x_0 with $y(x_0)$ nontrivial interval, two new local solutions arise. One is (i)-differentiable, the other is (ii)-differentiable.

These remarks, together with the characterization Theorem 5, lead to the following general approach to numerically solve interval differential equations. We solve basically ODEs (11) and (12) on subintervals of the time domain having the initial value y_0 updated at all the possible critical points. In this way on a bounded time interval we obtain a finite number of solutions. For the solution of (11) and (12) by the characterization theorem above, any efficient numerical method for ODEs can be used. This is an advantage of the method presented here, as we do not need to reinvent numerical methods for interval differential equations. Instead we can use the classical ones on the ODE translations of the interval differential equations.

This algorithm generates a tree structure for the solutions of the IDE. All the nodes of the tree will be critical points except the terminal nodes. All the branches represent local solutions of (i) or (ii) kind between two nodes. This is illustrated in Figure 1. Each node represents an l-critical point with a switching and each branch corresponds to one of the cases (i) or (ii) of differentiability.

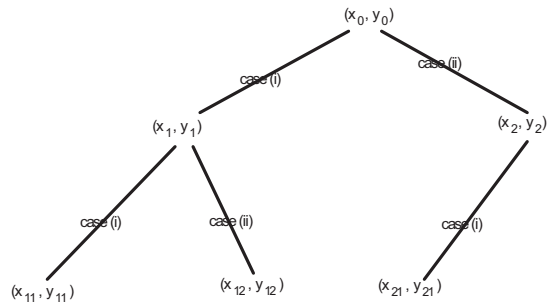

Figure 1. The structure of the tree of local solutions.

Our algorithm which generates all the solutions on a bounded interval is as follows.

Algorithm 1. (Find solutions of an interval differential equation - IDE)

Let us consider y_0 be any interval.

- Step 1. If y_0 is a singleton then we solve (11) and we obtain solution y_1.
- Step 2. Else we solve both (11) and (12) and we obtain solutions y_1, y_2.
- Step 3. Let $x_1 = \inf\{x > x_0 : y_1'(x) \in \mathbb{R}\}$ and $x_2 = \inf\{x > x_0 : y_2'(x) \in \mathbb{R}$ or $y_2(x) \in \mathbb{R}\}$ be the nearest l-critical point. (Let us remark here that since the algorithm applies to general interval-valued functions, it is possible that $y_2(x) \in \mathbb{R}$ however $y_2'(x) \notin \mathbb{R}$)
- Step 4. We insert the solutions which are found in a tree structure: y_1 in the left branch and y_2 in the right branch (the root will be simply (x_0, y_0)).
- Step 5. If $x_1 < X$ (a preset maximum value for x) then let $x_0 = x_1$ and $y_0 = y_1(x_1)$ and go to step 1.
- Step 6. If $x_2 < X$ then let $x_0 = x_2$ and $y_0 = y_2(x_2)$ and go to step 1.
- Step 7. Else Return.
- Step 8. Using a standard backtracking algorithm we generate all the solutions from the tree structure generated above.

The presented algorithm will generate a finite number of solutions on the interval $[x_0, X]$ provided that there are a finite number of critical points. Later we can extract those solutions which are closely reflecting the phenomenon which we have to model.

An approach to interval and fuzzy differential equations has been suggested in [7], based on differential inclusions.

ISBN: 978-989-95079-6-8

When $f(x,y)$ is the interval extension of a continuous function $f(x,p)$, $p \in \mathbb{R}$ and if we are interested in finding the *attainable set* for the differential inclusions $y' = f(x,y)$, $y(x_0) \in y_0$, $x \in [x_0, X]$, then we have a simpler algorithm based on the characterization Theorem 5 and the results shown in Theorem 6.

Let us consider y_0 be any interval. Let $f(x,y)$ be the interval extension of a real function $f(x,p)$. We use the same notation for both functions, and from the context we can identify them.

Algorithm 2. (Find the *attainable set* of a differential inclusion)

- Step 1. We find the points where the real function f changes its monotonicity w.r.t. p (if f is differentiable then we solve $\frac{\partial f}{\partial p} = 0$ and we find the critical points where monotonicity w.r.t. the second variable is changed). Let (x_1, y_1) be a critical point such that in $]x_0, x_1[$ there are no other critical points.
- Step 2. If f is increasing w.r.t. p on $[x_0, x_1] \times [y_0, y_1]$ we solve (11)
- Step 3. Else if f is decreasing w.r.t. p on $[x_0, x_1] \times [y_0, y_1]$ we solve (12)
- Step 4. If $x_1 < X$ then let $x_0 = x_1$ and $y_0 = y(x_1)$ and go to step 2.
- Else Stop.

This algorithm leads to the unique solution (*attainable set*) of the differential inclusion $y' = f(x,y)$, $y(0) \in y_0$.

It is easy to see that the proposed methods are very efficient from the numerical point of view, since for the local solutions we can use any standard algorithm.

5.2 Examples

The above algorithms were implemented in MATLAB. We have used MATLAB's standard ODE solver *ode45*, which is based on a Runge-Kutta (4,5) formula. Surely, any other solver could be used. Let us remark here that the critical points were in all the cases *a priori* determined. The critical points cannot be easily found on the run. The problem is that if we detect a critical point, due to the machine precision the algorithm finds further points which are close to the correct critical point as critical ones. Also, if we have a solution in the case (ii) with length decreasing asymptotically to zero, due to the machine precision the program detects them as critical points.

We will start with a simple example, which is easy to be solved analytically and we can compare the analytical solution to the numerical solution.

5.2.1 Example 1

Let us consider the interval differential equation

$$\begin{cases} y' = -y + [1,2]x \\ y(0) = [0,1] \end{cases} \quad x \in [0,4]. \tag{20}$$

We denote $y = [u, v]$, where u, v are real-valued functions. The systems (11) and (12) are respectively

$$\begin{cases} u' = -v + x \\ v' = -u + 2x \\ u(0) = 0 \\ v(0) = 1 \end{cases} \text{ and } \begin{cases} u' = -u + 2x \\ v' = -v + x \\ u(0) = 0 \\ v(0) = 1 \end{cases} \tag{21}$$

This equation (20) has exactly two solutions. One of them starts with the case (i) of differentiability

$$y_1(x) = [2x - e^x + 2e^{-x} - 1, x + e^x + 2e^{-x} - 2]$$

and there are no critical points in the trajectory.

If we start with case (ii) then we have a critical point of type II at $x = 1$ (i.e., $y(1)$ is a singleton). In this case we have to switch to case (i) of differentiability since the (ii)-differentiable solution does not exist. We obtain

$$u(x) = \begin{cases} 2x + 2e^{-x} - 2 & \text{if} \quad 0 \le x \le 1 \\ 2x - e^{x-1} + 2e^{-x} - 1 & \text{if} \quad 1 \le x \end{cases}$$

$$v(x) = \begin{cases} x + 2e^{-x} - 1 & \text{if} \quad 0 \le x \le 1 \\ x + e^{x-1} + 2e^{-x} - 2 & \text{if} \quad 1 \le x \end{cases}$$

The analytic solution and the numerical solutions obtained by the proposed algorithms are shown in Figs 2. and 3. respectively. We can see that the proposed method is very accurate. The error is controlled by the precision of *ode45* algorithm in MATLAB, and it is less than 10^{-6}.

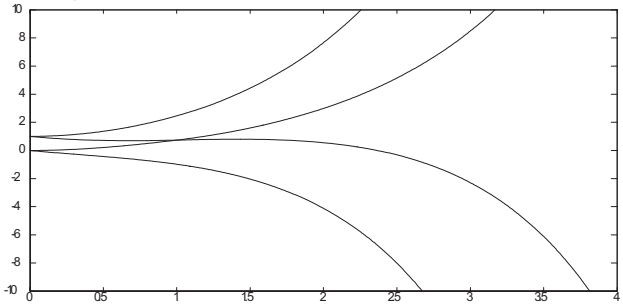

Figure 2. Analytic (exact) solutions of the IDE (20)

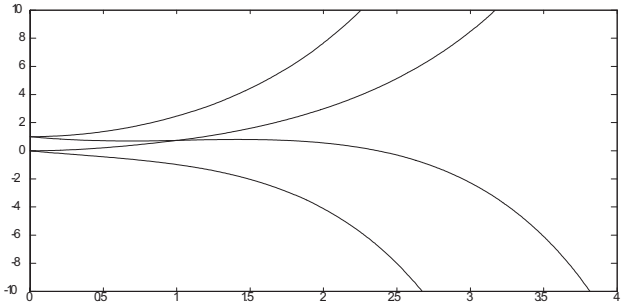

Figure 3. Numerical solutions of (20) by the proposed *Algorithm 1*.

5.2.2 Example 2

The structure of solution of an interval DE can be well illustrated on the problem

$$\begin{cases} y' = y \sin x + 2x, \\ y(0) = [1,3] \end{cases} \tag{22}$$

According to the characterization theorems it can be written as

$$\begin{cases} u'(x) = u(x)\sin(x) + 2x \\ v'(x) = v(x)\sin(x) + 2x \end{cases}$$

ISBN: 978-989-95079-6-8

or

$$\begin{cases} u'(x) = v(x)\sin(x) + 2x \\ v'(x) = u(x)\sin(x) + 2x \end{cases}.$$

The *l-critical points* are at $x = k\pi$, $k \in \mathbb{Z}$. If we solve the problem in the interval $[0, X]$ with $X < 2\pi$ we have only one *l-critical point* in the interval. Then we may have *four* solutions, as illustrated in Figure 4.

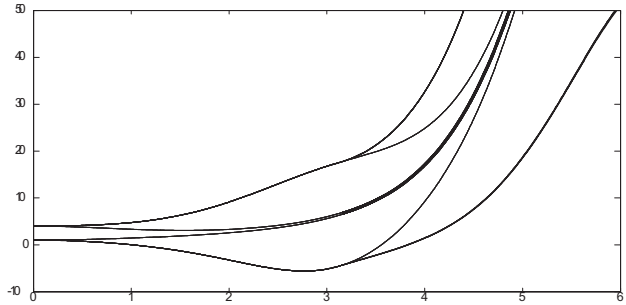

Figure 4. The four solutions of IDE (22) on the interval $[0, 6]$

If we consider time intervals containing more critical points, we may have more solutions. In Figure 5. we illustrate the solutions found by *Algorithm 1* to IDE (22) for $x \in [0, 11]$.

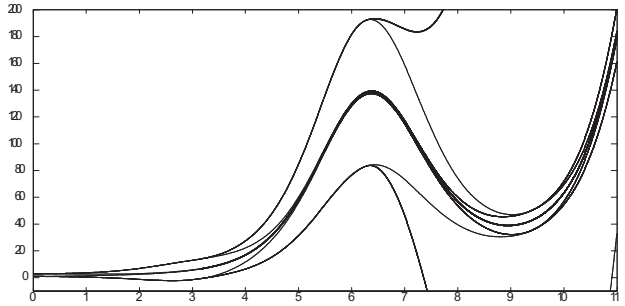

Figure 5. Existence of several solutions for IDE (22) on $[0, 11]$

5.2.3 Example 3

Regarding the second algorithm for solving differential inclusions when the function $f(x, y)$ is the interval extension of a crisp function we present the following problem

$$\begin{cases} y' = y\sin x + 2x, x \in [0, 6] \\ y(0) \in [1, 2]. \end{cases} \quad (23)$$

We observe that the function $y \sin x$ changes monotonicity at the points $k\pi$, $k \in \mathbb{Z}$. Also, we observe that in the interval $[0, \pi]$ it is increasing w.r.t. y. Using the *Algorithm 2* proposed for differential inclusions we obtain the solution presented in Figure 6.

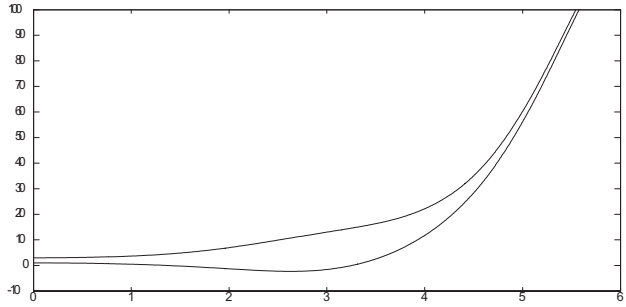

Figure 6. Solution of differential inclusion (23) using the proposed *Algorithm 2*

Remark: It is interesting to remark that the solution (attainable set) of the differential inclusion (23) is obtained by solving one of the ordinary differential equations (11) or (12) in steps 2. and 3. derived from the use of the generalized Hukuhara derivative.

***Abstract*—*This paper aims at applying a fuzzy arithmetic of intervals calculus and fuzzy quantities to automatic control. This one called φ–calculus fuzzy arithmetic is more practical than the extension principle one and α-cut based methods. It comes from a different representation of fuzzy numbers. The present paper follows up work in introducing. The present paper is interested in its use for a fuzzy internal model control scheme based.*

Keywords— Fuzzy arithmetic, fuzzy model inversion, fuzzy number, weighted fuzzy fusion, model based control.

1 Introduction

The fuzzy set theory elaborated by L.A. Zadeh [1] has been shown to be used in the characterization of fuzziness and/or uncertainty using a coherent mathematical model. Various applications came at hand, in particular in the fuzzy control area [2, 3]. The uncertain calculus was undergoing quite a boom these last years. Several works exhibit interesting results, often referring to intervals theory [4, 5] or arithmetic based on fuzzy numbers such as Triangular or Trapezoidal Fuzzy Numbers [6, 7]. In the fuzzy arithmetic case, the different approaches are generally based either on Zadeh's extension principle [1, 6], either on fuzzy relation [8], or finally use the α-cuts [9]. However, no general approach allowing common arithmetic operations to be used on fuzzy numbers is available. This work proposes the use of a so-called φ–calculus fuzzy arithmetic based on a "different" modeling of fuzzy numbers [10, 11]. For this algebra, the modeling of fuzzy numbers is considered through the distribution function instead of the classical membership function. The first part presents some generalities on this φ–calculus arithmetic.

One of the main interests of this algebra is to provide some nice properties for what is called "exact calculus" with fuzzy numbers. These properties can be used in order to invert a fuzzy model. Therefore, the second part presents a possible application in control to fuzzy internal model control scheme.

2 Fuzzy arithmetic: φ-calculus

In the literature, many modeling approaches of imprecision, which is involved in many applications and domains, use fuzzy numbers and fuzzy arithmetic. In many works, the methods have led to the development of various membership functions for representing fuzzy numbers. Fuzzy numbers are often represented in applications by LR fuzzy sets and in particular, triangular and trapezoidal fuzzy sets. There exist two approaches for fuzzy arithmetic, on one hand the Zadeh's extension principle, on the other hand, the alpha-cuts and intervals arithmetic. Our works concern the first case, using a new modeling for fuzzy numbers [11], and it allows including a large part of the results existing in the domain of arithmetic [4, 6, 8, 12].

2.1 Fuzzy numbers modeling

Usually, a fuzzy number is modeled by its membership function $\mu_{\tilde{a}}$ not null on a bounded set $Supp(\tilde{a}) \subset \mathbb{R}$. For example, a triangular fuzzy number (TFN) $\tilde{a}$ can be represented by the shorthand symbol (b, m, c) with $\mu_{\tilde{a}}(x)=1$ for $x=m$ (mode) and the kernel defined by the interval $[m-b, m+c]$.

Herein, instead of the classical membership function, the modeling used for the representation of fuzzy numbers is based on the distribution function $\varphi_{\tilde{a}}$ defined by the following expression:

$$\varphi_{\tilde{a}}(x)=\frac{\int_{-\infty}^{x}\mu_a(t)\cdot dt}{\int_{-\infty}^{+\infty}\mu_a(t)\cdot dt} \qquad (1)$$

Convergence of $\int_{-\infty}^{+\infty}\mu_a(t)\cdot dt$ (finite cardinality of $\tilde{a}$) is assumed by considering only membership functions on a compact support $I \subset \mathbb{R}$. Thus, the major interest is that the distribution function for all fuzzy number $\tilde{a}$ is always an increasing monotone function, from $Supp(\tilde{a})$ to $[0,1]$. Thus, an inverse function $\varphi_{\tilde{a}}^{-1}$ from $[0,1]$ to $Supp(\tilde{a})=[\underline{a},\overline{a}]$ can always be defined and its definition is very important for the operations. The set of fuzzy numbers represented by a distribution function is noted Φ.

It should be noticed that the distribution function for a singleton is also a singleton and the one for an interval is a line between its bounds.

ISBN: 978-989-95079-6-8

2.2 Fuzzy realization and extension

Similarly to defuzzification and fuzzification concepts, it is necessary to define a relation between a crisp value and a fuzzy number. Therefore, an application from Φ to $\mathbb{R}$, which associates a crisp number to a fuzzy number, is called *fuzzy realization*. Conversely, an application from $\mathbb{R}$ to Φ is called *fuzzy extension*.

The choice of a realization depends obviously on the application. The most frequently encountered are:

- The median realisation noted $R_{med}(\tilde{a})$, it associates to a distribution function $\varphi_{\tilde{a}}$ the number a_0 such as $\varphi_{\tilde{a}}(a_0)=0.5$. Through this median realization, the following equivalence relation $\Re$ in Φ can be defined: the set of the functions $\varphi_{\tilde{a}}$ such as $\varphi_{\tilde{a}}(a_0)=0.5$ defines the class of equivalence of $a_0 \in \mathbb{R}$. Every element of this class will be called "fuzzy a_0", and denoted $\tilde{a}_0$.
- The modal realisation noted $R_{\mathrm{mod}}(\tilde{a})$ is defined as: $a_0 = R_{\mathrm{mod}}(\tilde{a}) \Leftrightarrow \varphi_{\tilde{a}}(a_0) = \underset{x\in\tilde{a}}{Max}\left[\mu_{\tilde{a}}(x)\right]=1$.
- The mean realization noted $R_{mean}(\tilde{a})$ is defined as: $a_0 = R_{mean}(\tilde{a}) = \int_0^1 \varphi_{\tilde{a}}^{-1}(y).dy$.

2.3 arithmetic operations

Consider two fuzzy numbers $\tilde{a}$ and $\tilde{b}$ using their distribution $\varphi_{\tilde{a}}$ and $\varphi_{\tilde{b}}$. For a fuzzy number $\tilde{a}$ whose support includes 0 let us also define its "negative" $\varphi_{\underline{\tilde{a}}}$ and "positive" $\varphi_{\overline{\tilde{a}}}$ parts as $\varphi_{\tilde{a}} = \varphi_{\underline{\tilde{a}}} + \varphi_{\overline{\tilde{a}}}$ with:

$$\varphi_{\underline{\tilde{a}}}(x)=\begin{cases}0 & \text{if } x<\underline{a}\\ \varphi_{\tilde{a}}(x) & \text{if } x\in[\underline{a},0]\\ 1 & \text{if } x>0\end{cases}, \qquad (2)$$

$$\varphi_{\overline{\tilde{a}}}(x)=\begin{cases}0 & \text{if } x<0\\ \varphi_{\tilde{a}}(x) & \text{if } x\in[0,\overline{a}]\\ 1 & \text{if } x>\overline{a}\end{cases} \qquad (3)$$

The classical arithmetic operations on fuzzy numbers (addition $\tilde{a}+\tilde{b}$, pseudo-opposite $-\tilde{a}$, subtraction $\tilde{a}-\tilde{b}$, multiplication $\tilde{a}\times\tilde{b}$, pseudo-inverse only for a non mixed-type fuzzy number $\tilde{b}^{-1}=1/\tilde{b}$ and division $\tilde{a}/\tilde{b}$) are defined hereinafter [9].

$$\begin{aligned}
&\varphi^{-1}_{\tilde{a}+\tilde{b}}(x)=\varphi^{-1}_{\tilde{a}}(x)+\varphi^{-1}_{\tilde{b}}(x)\\
&\varphi_{-\tilde{a}}(x)=1-\varphi_{\tilde{a}}(-x)\ \forall x\in\mathbb{R}\\
&\varphi^{-1}_{\tilde{a}-\tilde{b}}(x)=\varphi^{-1}_{\tilde{a}}(x)+\varphi^{-1}_{-\tilde{b}}(x)\\
&\varphi^{-1}_{\tilde{a}\times\tilde{b}}(x)=\varphi^{-1}_{\underline{\tilde{a}}\times\underline{\tilde{b}}}(x)+\varphi^{-1}_{\overline{\tilde{a}}\times\overline{\tilde{b}}}(x)\\
&\varphi_{\tilde{a}^{-1}}(x)=1-\varphi_{\tilde{a}}(1/x)\ \forall x\in\mathbb{R}^*\\
&\varphi^{-1}_{\tilde{a}/\tilde{b}}(x)=\varphi^{-1}_{\tilde{a}\times\tilde{b}^{-1}}(x)
\end{aligned} \qquad (4)$$

with $\varphi^{-1}_{\underline{\tilde{a}}\times\underline{\tilde{b}}}=\min\left[\varphi^{-1}_{\underline{\tilde{a}}}\times\varphi^{-1}_{\underline{\tilde{b}}},\varphi^{-1}_{\overline{\tilde{a}}}\times\varphi^{-1}_{\overline{\tilde{b}}}\right]$ and $\varphi^{-1}_{\overline{\tilde{a}}\times\overline{\tilde{b}}}=\max\left[\varphi^{-1}_{\underline{\tilde{a}}}\times\varphi^{-1}_{\underline{\tilde{b}}},\varphi^{-1}_{\overline{\tilde{a}}}\times\varphi^{-1}_{\overline{\tilde{b}}}\right]$.

Let us notice that these four classical operations are compatible with the Moore's interval operations.

2.4 Weighted fuzzy fusion operator

This part deals with a fusion operator introduced within the framework of this Φ-calculus algebra. This operator is called the weighted fuzzy fusion (WFF) [13] and is useful for the next sections.

Consider two fuzzy numbers $\tilde{a},\tilde{b}\in\Phi$ and their distribution $\varphi_{\tilde{a}},\varphi_{\tilde{b}}: x\in\mathbb{R}\rightarrow y\in[0,1]$. The weighted fuzzy fusion (WFF) of the two fuzzy numbers is defined as:

$$\varphi_{WFF}(x)=\frac{p_{\tilde{a}}\cdot\varphi_{\tilde{a}}(x)+p_{\tilde{b}}\cdot\varphi_{\tilde{b}}(x)}{p_{\tilde{a}}+p_{\tilde{b}}},\quad \forall x\in\mathbb{R} \qquad (5)$$

with $p_{\tilde{a}},p_{\tilde{b}}\in\mathbb{R}$ and $p_{\tilde{a}}+p_{\tilde{b}}=1$.

3 Internal model control

3.1 Principle of the structure

As with any open-loop control scheme, the internal model control (IMC) structure applies only on stable systems with a minimum phase behavior, according to Fig. 1.

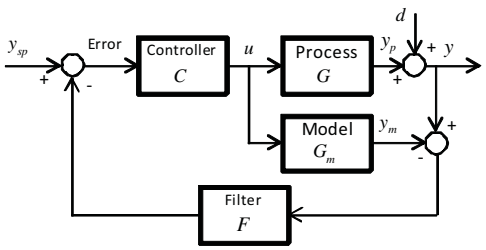

Figure 1: Internal model control scheme.

The filter F is introduced in order to filter out the measurement noise and to introduce some robustness in the loop. Its static gain is 1. Classically for linear models, it can be shown that the output equation y_k (Fig. 1) is given by:

$$y_k = F_{FB}(q^{-1})\cdot y_{sp_k} + S_{yd}(q^{-1})\cdot d_k \qquad (6)$$

with:

$$F_{FB}(q^{-1})=\frac{G(q^{-1})C(q^{-1})}{1+C(q^{-1})F(q^{-1})\left[G(q^{-1})-G_m(q^{-1})\right]}$$

$$S_{yd}(q^{-1})=\frac{1-G_m(q^{-1})C(q^{-1})F(q^{-1})}{1+C(q^{-1})F(q^{-1})\left[G(q^{-1})-G_m(q^{-1})\right]}$$

and the control law equation is given by:

ISBN: 978-989-95079-6-8

$$u_k = \frac{C\left(q^{-1}\right)}{1-C\left(q^{-1}\right)F\left(q^{-1}\right)G_m\left(q^{-1}\right)}\left(y_{c_k} - F\left(q^{-1}\right)y_k\right) \quad (7)$$

The minimum purpose of the internal model structure is to guarantee closed-loop stability and disturbance rejection, i.e. $F_{FB}(1)=1$ and $S_{yd}(1)=0$.

Recall also that the internal model control performs a kind of model simplification. Therefore its extension to fuzzy internal control needs the definition of an inverse model. The next part treats this issue.

3.2 Model inversion

Let us consider a stable time-invariant controllable SISO linear process model whose mathematical description is given in the form of recurrent equation:

$$y_k = -\sum_{i=1}^{N}\left(a_i \cdot y_{k-i} + b_i \cdot u_{k-i}\right) \quad (8)$$

where y_k and u_k correspond to the process output and input at sample k, $a_i, b_i, i \in \{1,\ldots,N\}$, denote the model parameters.

Suppose now that these parameters are fuzzy numbers, $\tilde{a}_i, \tilde{b}_i, i \in \{1,\ldots,N\}$ leading to:

$$y_k = -\sum_{i=1}^{N}\left(\tilde{a}_i \cdot y_{k-i} + \tilde{b}_i \cdot u_{k-i}\right) \quad (9)$$

For model inversion, the following question arises [14]:

knowing the description of uncertainties for the model, is it possible to synthesize a controller, based on the inverse model, able to maintain the model output within a tolerance envelope around the exact trajectory y_{sp} ?

Which means:

$$\text{Model output} \in \left[y_{sp} - \Delta,\ y_{sp} + \Delta\right] \quad (10)$$

where Δ is the accepted tolerance around the nominal trajectory.

To answer to this question, this work will use an approach developed in [14]. Notice that the "fuzzy" part of the uncertainties is not really taken into account, i.e. this problem could be solved using interval techniques, for example [15, 16, 17]. Nevertheless, the arithmetic provided therein gives an "easy" way to solve non exact calculus by means of probability distribution.

To compute the control law u_k at sample k, the terms defined at previous samples $\{y_{k-1}, i=1,\ldots,N\}$ and $\{u_{k-1}, i=1,\ldots,N\}$ are known. As $b_1 \neq 0$, equation (6) can be rewritten as:

$$u_k = \frac{1}{b_1}\left(y_{k+1} + \sum_{i=1}^{N}\left(a_i \cdot y_{k-i+1}\right) - \sum_{i=2}^{N}\left(b_i \cdot u_{k-i+1}\right)\right) \quad (11)$$

Or, considering the unknown term at sample k, y_{k+1}, expression (9) can be rewritten as follow:

$$u_k = \frac{1}{b_1}\left(y_{k+1} + \psi\left(z(k)\right)\right) \quad (12)$$

with

$$\psi\left(z(k)\right) = \sum_{i=1}^{N} a_i \cdot y_{k-i+1} - \sum_{i=2}^{N} b_i \cdot u_{k-i+1} \text{ and}$$

$$z(k) = \left[y_k \ \ \ldots \ \ y_{k-N+1} \ \ u_{k-1} \ \ \ldots \ \ u_{k-N+1}\right]^T \in \mathbb{R}^{2N-1}.$$

For a linear model without time delay, if y_{k+1} is replaced with the desired reference trajectory the ideal result is: $y_{k+1} = y_{sp_k}$. Therefore, with a perfect compensation, the model output follows the desired trajectory with a pure time delay corresponding to one sample.

Going back to the question (cf. (10)), we want to guarantee that $y_{k+1} \in \left[\underline{y}_{k+1}, \overline{y}_{k+1}\right]$. With equations (11) and (12), for a fuzzy model (9), we have straightforwardly:

$$\tilde{u}_k = \frac{1}{\tilde{b}_1}\left(\tilde{y}_{k+1} + \tilde{\psi}\left(\tilde{z}(k)\right)\right) \quad (13)$$

$$\tilde{\psi}\left(\tilde{z}(k)\right) = \sum_{i=1}^{N} \tilde{a}_i \cdot \tilde{y}_{k-i+1} - \sum_{i=2}^{N} \tilde{b}_i \cdot \tilde{u}_{k-i+1} \text{ and}$$

$$\tilde{z}(k) = \left[\tilde{y}_k \ \ \ldots \ \ \tilde{y}_{k-N+1} \ \ \tilde{u}_{k-1} \ \ \ldots \ \ \tilde{u}_{k-N+1}\right]^T \in \mathbb{R}^{2N-1}.$$

Equation (13) gives a model inversion description using fuzzy numbers. The term $\tilde{y}_{k+1}$ is replaced with a desired trajectory defined by a fuzzy number $\tilde{y}_{sp_k}$ to obtain a causal control law. For example, if $\tilde{y}_{sp_k}$ is a triangular fuzzy number (TFN) written as:

$$\tilde{y}_{sp_k} = triple\left(y_{sp} - \Delta,\ y_{sp},\ y_{sp} + \Delta\right) \quad (14)$$

the control law is:

$$\tilde{u}_k = \frac{1}{\tilde{b}_1}\left(\tilde{y}_{sp_k} + \tilde{\psi}\left(\tilde{z}(k)\right)\right) \quad (15)$$

$$\tilde{\psi}\left(\tilde{z}(k)\right) = \sum_{i=1}^{N} \tilde{a}_i \cdot \tilde{y}_{sp_k-i+1} - \sum_{i=2}^{N} \tilde{b}_i \cdot \tilde{u}_{k-i+1} \text{ and}$$

$$\tilde{z}(k) = \left[\tilde{y}_{sp_k} \ \ \ldots \ \ \tilde{y}_{sp_k-N+1} \ \ \tilde{u}_{k-1} \ \ \ldots \ \ \tilde{u}_{k-N+1}\right]^T \in \mathbb{R}^{2N-1}.$$

Of course, the vector $\tilde{z}(k)$ depends on the control part meaning that all $\tilde{y}_i$ are replaced with desired set point $\tilde{y}_{sp_i}$ which corresponds to the schematic diagram of Fig. 2.

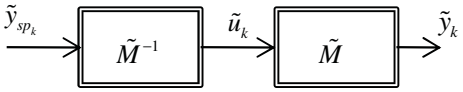

Figure 2: Fuzzy model inversion.

Naturally, perfect cancellation, i.e. $\tilde{y}_{k+1} = \tilde{y}_{sp_k}$ is not possible. Moreover using arithmetic of fuzzy numbers, or intervals or φ–calculus will introduce over-estimations. To illustrate this important point, an example issued from [14] is discussed hereinafter.

Let us consider the second-order:

$$\tilde{y}_k = -\tilde{a}_1 \cdot \tilde{y}_{k-1} - \tilde{a}_2 \cdot \tilde{y}_{k-2} + \tilde{b}_1 \cdot \tilde{u}_{k-1} + \tilde{b}_2 \cdot \tilde{u}_{k-2} \quad (16)$$

where $\tilde{a}_1$, $\tilde{a}_2$, $\tilde{b}_1$ and $\tilde{b}_2$ are fuzzy numbers defined as:

ISBN: 978-989-95079-6-8

$$\begin{aligned}\tilde{a}_1 &= triple(-0.6, -0.55, -0.5)\\ \tilde{a}_2 &= triple(0.05, 0.1, 0.15)\\ \tilde{b}_1 &= triple(0.6, 0.625, 0.65)\\ \tilde{b}_2 &= triple(0.15, 0.2, 0.25)\end{aligned} \quad (17)$$

The desired trajectory is:

$$y_{sp_k} = 0.5 \cdot \left(\sin\left(\frac{2\pi k}{50}\right) + \sin\left(\frac{2\pi k}{75}\right)\right) \quad (18)$$

and $\tilde{y}_{sp_k}$ is chosen as

$$\tilde{y}_{sp_k} = triple\left(y_{sp_k} - 1,\ y_{sp_k},\ y_{sp_k} + 1\right) \quad (19)$$

Using (15), the evolutions of the set point $\tilde{y}_{sp_k}$ envelopes (minimum $\underline{y}_{sp_k}$ and maximum $\overline{y}_{sp_k}$ of $Supp\left(\tilde{y}_{sp_k}\right)$) and the output model $\tilde{y}_k$ envelopes are illustrated in Fig. 3. Obviously, like interval calculus or α-cut fuzzy arithmetic, it clearly appears that the φ–calculus arithmetic generates overestimated results.

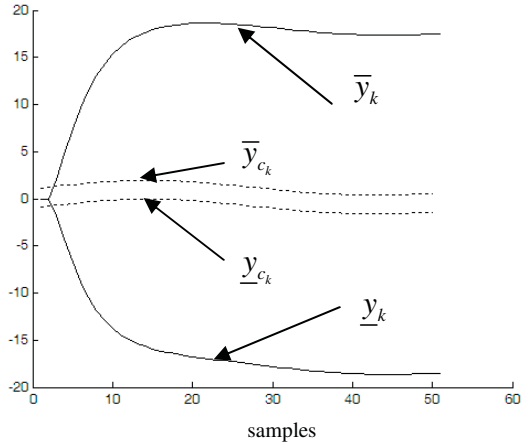

Figure 3: Set point $\tilde{y}_{sp_k}$ and output model $\tilde{y}_k$ envelopes.

We claim that this overestimation is not justified in such cases. Therefore, we need to introduce some extra constraints in order to take into account some knowledge and to reduce the pessimism of the results.

3.3 "Exact" inverse computation

Equation (15) corresponds to resolution of a fuzzy affine equation:

$$\tilde{b} \times \tilde{x} + \tilde{a} = \tilde{y} \quad (20)$$

The idea developed in [15] is to exactly solve this equation according to the two following steps.

Step1: Solve (20) with respect to $\tilde{d} = \tilde{b} \times \tilde{x}$.

The objective is to compute an "acceptable" solution $\tilde{d}$ of the equation $\tilde{d} + \tilde{a} = \tilde{y}$; i.e. the solution being exact when possible and approximated otherwise.

Notice that the exact solution can always be computed according to the arithmetic used:

$$\varphi_{\tilde{d}}^{-1}(u) = \varphi_{\tilde{y}}^{-1}(u) - \varphi_{\tilde{a}}^{-1}(u) \quad (21)$$

The problem arises when the result $\varphi_{\tilde{d}}^{-1}(u)$ is not an increasing function, resulting to $\tilde{d} \notin \Phi$. Nevertheless we can provide an approximate solution to the problem $\tilde{d}_{app} \in \Phi$. The fact of proposing an alternative to exact calculus is the key idea. Contrary to what generally authors accept, i.e. no solution for interval arithmetic or α-cut fuzzy arithmetic cases [14], we provide an approximate solution based on the initial $\varphi_{\tilde{d}}^{-1}(u)$.

For that purpose, we propose to use the weighted fuzzy fusion (WFF) operator on the set of pairs $\left(\varphi_{\tilde{d}}^{-1}(u_i), u_i\right)$, $i \in \{1, \ldots, N\}$. It results in a re-ordering of the pairs that constructs an increasing function $\tilde{d}_{app}$, thus $\tilde{d}_{app} \in \Phi$ is a feasible solution to the problem.

Step2: Finding a solution to equation $\tilde{d} = \tilde{b} \times \tilde{x}$ with $0 \notin Supp\left(\tilde{b}\right)$. If $\tilde{b} > 0$ and $\tilde{d} > 0$, the exact calculus uses a point by point division:

$$\varphi_{\tilde{x}}^{-1}(u) = \varphi_{\tilde{d}}^{-1}(u) \big/ \varphi_{\tilde{b}}^{-1}(u) \quad (22)$$

In the general case, we use a "positive-negative" decomposition (see section 2.3) for $\tilde{d}$ and $\tilde{x}$. We define:

$$\begin{cases}\varphi_{\tilde{d}}^{-1}(u) = \varphi_{\tilde{d}_-}^{-1}(u) + \varphi_{\tilde{d}_+}^{-1}(u)\\ \varphi_{\tilde{x}}^{-1}(u) = \varphi_{\tilde{x}_-}^{-1}(u) + \varphi_{\tilde{x}_+}^{-1}(u)\end{cases} \quad (23)$$

with $\varphi_{\tilde{d}_-}^{-1}(u)$, $\varphi_{\tilde{d}_+}^{-1}(u)$, $\varphi_{\tilde{x}_-}^{-1}(u)$ and $\varphi_{\tilde{x}_+}^{-1}(u)$ defined equations (3) and (4). At last, the exact solution is given by:

$$\begin{cases} if\ \tilde{b} > 0, \begin{cases}\tilde{x}_+ = \tilde{d}_+ \big/ \tilde{b},\ \tilde{x}_- = -\left(\left(-\tilde{d}_-\right) \big/ \tilde{b}\right),\\ \tilde{x} = \tilde{x}_+ + \tilde{x}_-\end{cases}\\ if\ \tilde{b} < 0, \begin{cases}\tilde{x}_+ = \tilde{d}_+ \big/ \left(-\tilde{b}\right),\ \tilde{x}_- = -\left(\left(-\tilde{d}_-\right) \big/ \left(-\tilde{b}\right)\right),\\ \tilde{x} = -\left(\tilde{x}_+ + \tilde{x}_-\right)\end{cases}\end{cases} \quad (24)$$

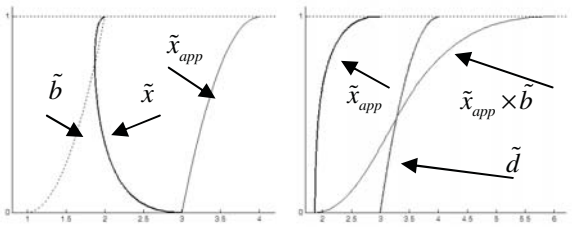
Once again the problem arises when the result $\varphi_{\tilde{x}}^{-1}(u)$ is not an increasing function, resulting to $\tilde{x} \notin \Phi$. Therefore approximate solution to the problem $\tilde{x}_{app} \in \Phi$ is generated in the same way using the WFF operator on the set of pairs $\left(\varphi_{\tilde{x}}^{-1}(u_i), u_i\right)$, $i \in \{1, \ldots, N\}$.

Consider an example to illustrate this second step with the fuzzy numbers $\tilde{b} = triple(1, 2, 2)$ and $\tilde{d} = triple(3, 3, 4)$. As shown Fig. 4(a), the exact solution $\tilde{x} \notin \Phi$, i.e. $\varphi_{\tilde{x}}^{-1}$ is not a monotone increasing function. Using the weighted fuzzy fusion (WFF) operator, an approximate solution $\tilde{x}_{app}$ is generated by re-ordering $\varphi_{\tilde{x}}^{-1}$. Fig. 4(b) shows the comparison between $\tilde{d}$ and $\tilde{b} \times \tilde{x}_{app}$. In a sense, the difference between these two fuzzy numbers exhibits the pessimism induced by the method when no exact solution in Φ is available. This pessimism can be shown comparing the supports of the numbers:

$$Supp\left(\tilde{d}\right) = [3, 4] \subset Supp\left(\tilde{b} \times \tilde{x}_{app}\right) = [1.87, 6].$$

ISBN: 978-989-95079-6-8

The next example demonstrates very clearly the interest of the complete algorithm used to find solutions to the problem $\tilde{b}\times\tilde{x}+\tilde{a}=\tilde{y}$. Consider again the inverse model of section 3.2 with the fuzzy numbers (17) and the desired trajectory (18), (19). Fig. 5 shows the same trial as for Fig. 3. For this test, we obtain the result considering, i.e. $\tilde{y}_{k+1}=\tilde{y}_{sp_k}$. This result indicates that an "exact solution" has been found at each time k.



a) « Exact » result b) φ–calculus result

Figure 4: Results with the numbers $\tilde{b}$ and $\tilde{d}$.

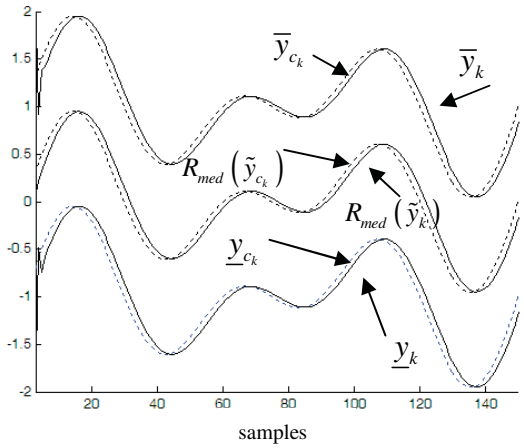


Figure 5: Set point $\tilde{y}_{sp_k}$ and output model $\tilde{y}_k$ envelopes.

In order to show the interest of the method, we will change the constraints level. To do so, the values of model uncertainties (17) are increased in order to deal with cases where an exact inversion is not always possible. New bounds for the fuzzy numbers (17) are defined. They correspond to the greatest possible values with pole-zero assignment located inside the unit circle – for evident stability purpose. Moreover, the fuzzy numbers are not more symmetric and correspond to:

$$\begin{aligned}\tilde{a}_1 &= triple(-0.825,-0.4,0.3)\\ \tilde{a}_2 &= triple(-0.175,0.25,0.95)\\ \tilde{b}_1 &= triple(0.415,0.625,0.835)\\ \tilde{b}_2 &= triple(-0.01,0.2,0.41)\end{aligned} \qquad (25)$$

Fig. 6 repeats the same trial with the desired trajectory (18), (19). The figure exhibits that an exact simplification, i.e. $\tilde{y}_{k+1}\neq\tilde{y}_{sp_k}$ is not always possible. Contrary to have no solution in such cases, the proposed approximate solutions seem perfectly adapted.

With the help of this inverse model control strategy based on constraints, justified in the control framework, it is now possible to consider a fuzzy internal model control.

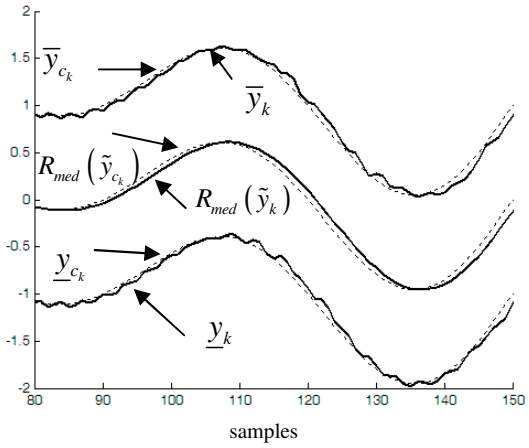

Figure 6: Set point $\tilde{y}_{sp_k}$ and output model $\tilde{y}_k$ envelopes.

3.4 Fuzzy internal model control

From Fig. 6 showing IMC scheme and different equations (6) and (7), it is possible to define several solutions.

First solution: Let $G_m(q^{-1})=q^{-r}G_m^+(q^{-1})$, $G_m^+(q^{-1})$ corresponds to function with an inverse (exactly proper and stable). We chose $C(q^{-1})=\dfrac{1}{G_m^+(q^{-1})}$ and propose the equivalent model given Fig. 7.

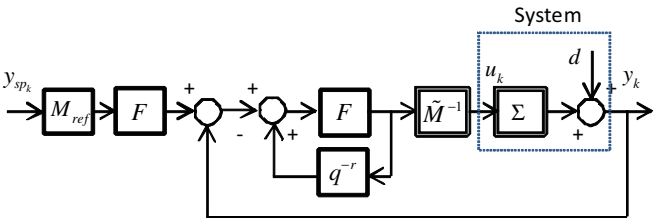

Figure 7: IMC1, equivalent scheme.

Indeed, equation (7) can be rewritten as follow:

$$u_k=\frac{1}{G_m^+(q^{-1})\left(1-q^{-r}\cdot F(q^{-1})\right)}\left(y_{c_k}-F(q^{-1})\,y_k\right) \qquad (26)$$

By analogy, we have the fuzzy inverse model $\left[\tilde{G}_m^+(q^{-1})\right]^{-1}$ multiplied by linear transfer function $\dfrac{F(q^{-1})}{1-q^{-r}\cdot F(q^{-1})}$.

For every case, it is possible to add a model reference control M_{ref} in order to attenuate the control signal.

ISBN: 978-989-95079-6-8

3.5 Example

Consider a nominal second-order transfer function:

$$\frac{y\left(q^{-1}\right)}{u\left(q^{-1}\right)}=\frac{B\left(q^{-1}\right)}{A\left(q^{-1}\right)}=\frac{0.0233\cdot q^{-1}+0.0197\cdot q^{-2}}{1-1.5729\cdot q^{-1}+0.6037\cdot q^{-2}} \quad (27)$$

and the following definition for the fuzzy numbers:

$$\begin{aligned}\tilde{a}_1 &= triple\left(-1.574,-1.573,-1.497\right)\\ \tilde{a}_2 &= triple\left(0.602,0.603,0.652\right)\\ \tilde{b}_1 &= triple\left(0.013,0.023,0.033\right)\\ \tilde{b}_2 &= triple\left(0.01,0.02,0.03\right)\end{aligned} \quad (28)$$

The control structure used is the IMC1 Fig. 7 with a reference model defined as:

$$\frac{B_m\left(q^{-1}\right)}{A_m\left(q^{-1}\right)}=\frac{0{,}1784\cdot q^{-1}+0{,}1071\cdot q^{-2}}{1-0{,}9315\cdot q^{-1}+0{,}2169\cdot q^{-2}} \quad (29)$$

Fig. 8 shows the results for different set points. The first set-point leads to results around the nominal model (27) (represented by the value 2). Secondly, two successive variations are made (set-point value of 3 and set-point value of 4), lastly a return to nominal position.

During both successive changes the model is changed in order to reach the bounds on $\tilde{a}_1$ and $\tilde{b}_2$. Two disturbances have been also added at samples 900 and 2300. The responses show a good robustness according to the parametric variations of the model.

This work presents a first possible track to use fuzzy arithmetic for control purpose. Next steps would be to prove stability and evaluate the robustness of these approaches. We can think to several possibilities including Lyapunov approach that are insightfully used for Takagi-Sugeno models [18] or Kharitonov polynomials [19].

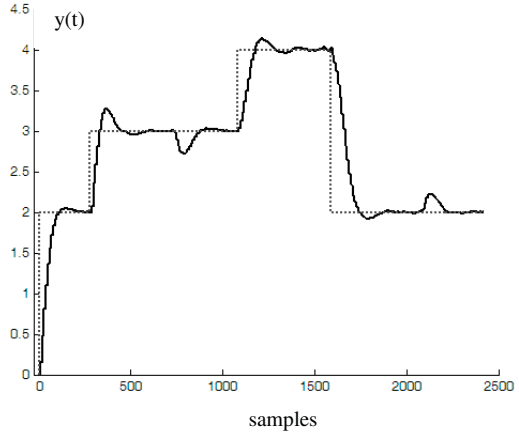

Figure 8: IMC1 results.

4 Conclusions

This paper attempts to show possible applications of the φ–calculus arithmetic for automatic control. As a first step, a new characterization of fuzzy numbers by the distribution function instead of the classical membership function has been presented. For this algebra, it is possible to use a set of arithmetic operators (addition, opposite and subtraction, multiplication, inverse and quotient) compatible with the classical algebra by using the median realization, or the Moore's calculus by using the fuzzy number support. A procedure allowing an "exact" calculus of an inverse model was proposed on the basis of φ–calculus. This approach was successfully implemented on internal model control structures.

Thus, the application of φ–calculus arithmetic to the stability of system seems to open some new prospects for other basic concepts (observation, stabilization…).

Abstract *— The definitions of the number of fuzzy sets and their proper distribution on their domains are fundamental issues for fuzzy systems since these basic parameters deeply affect the quality of the systems results, both in terms of performance rates and interpretability. Several methods have been proposed in the literature to define these parameters, although it is common to find works in which the number of fuzzy sets is defined empirically, distributing them equally in the domains. This paper presents a fast and easy method to estimate the number of fuzzy sets for each attribute and compares three methods for the distribution of fuzzy sets. Two of them are non-supervised methods, using same width and same frequency, the third one is an adaptation of the 1-R supervised method to discretize attributes. Experiments with 10 datasets for classification problems, 10-fold cross validation, using the Wang & Mendel method, and the classic and general fuzzy reasoning methods are presented and discussed.*

Keywords— Fuzzy systems, granulation of attributes, Wang & Mendel method, fuzzy data base generation.

1 Introduction

Fuzzy set theory and fuzzy logic [1] proposed by professor Loft A. Zadeh are the base for the fuzzy systems. Fuzzy set theory is used to represent and process information. The main characteristic of fuzzy sets, contrasting with crisp sets, is the progressive transition from one set to another. This natural characteristic of the fuzzy sets provides automatic mechanisms to deal with imprecision and uncertainty, which are inherent to real world knowledge. Moreover, the fuzzy logic theory prevents the creation of unnatural frontiers in the partitioning of attributes domains [2].

A fundamental issue, due to its direct impact on fuzzy systems, is the definition of the fuzzy sets that model the linguistic variables of a given domain, both in terms of shape (triangular, trapezoidal, S-function, etc) and partitioning of the attributes domains (number of fuzzy sets and their distribution). Unfortunately, there are no general rules or guidelines for these tasks that suit every domain [3]. In fact, many methods may have to be tested in order to find the appropriate definitions for a given application.

It is also common to find studies in which the definition of the membership functions is done empirically. In fact, the Gaussian, trapezoidal and triangular shapes are the most used in the literature, probably because they produce comparable results to other shapes and are easily interpretable [4]. Regarding the definition of the number of fuzzy sets and their distribution on the partitions, most of the papers in the literature use from 2 to 10 fuzzy sets for each attribute, equally distributed in their domains, *i.e.*, all fuzzy sets have same width.

Another aspect to be considered when defining fuzzy sets is personal interpretations, which make this task non trivial. For instance, let us consider a linguistic variable *temperature*; the interpretation of the linguist term *low temperature* is closely related to the region where one lives (consider a continental country such as Brazil, for example). Thus, personal interpretations may generate strong variations for the same concept: since each person may have different and personal interpretations on the meaning of a concept, it is natural that different membership functions may be created to define the same concept. This flexibility on the subjective selection of membership functions and, as previously stated, in the distribution of the fuzzy sets in their partitions shows the robustness of the fuzzy logic, which is closely related to the inherent characteristics of fuzzy sets [5].

Although this flexibility exists, the task of defining membership functions is largely ignored. The choice of the method, in fact, depends on the particular application and domain [6]. While the shape of the fuzzy sets may not present expressive differences in the results of fuzzy systems, the number of fuzzy sets and their distribution are relevant parameters that affect the system in terms of performance and in terms of interpretability. Thus, this paper presents a fast and easy method to estimate the number of fuzzy sets, in order to use this estimated number with more costly approaches, such as genetic algorithms. This paper also presents experiments carried out using three distinct methods for the definition of the distribution of fuzzy sets, in an attempt to provide further insight on the task, focusing specifically on classification problems. One of these methods uses same width distribution for the fuzzy sets, the second uses same frequency distribution, and the third takes the classes into consideration in the process.

This paper is organized as follows: Section 2 reviews methods for the automatic definition of fuzzy membership functions; Section 3 describes the three methods used in the experiments for the definition of fuzzy sets. Section 4 describes the heuristic method for the definition of the number of fuzzy sets proposed here. Section 5 presents the experiments and results, followed by the conclusions in Section 6.

2 Methods for the Automatic Definition of Fuzzy Sets

There is a wide variety of methods applied for the definition of fuzzy sets, ranging from heuristic methods, genetic algorithms, artificial neural networks, clustering algorithms, the use of indexes, to the adaptation of classic machine learning methods, such as the K-NN algorithm. Next, we present some of these methods. More details on these and on other related methods can be found in [7] and on the provided references.

Several methods explore the use of special parameters for the distribution of fuzzy sets. In [2], for example, the authors use the concept of 2-tuple to define linguistic terms. The 2-tuple strategy is used to define both, the center of a fuzzy set (support), and a value for a symbolic translation, which enables the fuzzy sets to be moved sideways, always keeping the same base width. This symbolic translation of a linguistic term is a number within the interval $[-0.5, 0.5)$. A genetic algorithm is then used to define the best position for the fuzzy sets. The experiments used a fixed number of triangular shaped sets.

In [6] and [8] the authors use the Fuzzy C-Means algorithm for the definition of fuzzy membership functions. In the first method [6], a modified version of the Xie-Beni index [9] is used to define the number of clusters and, therefore, the number of fuzzy sets, for the Fuzzy C-Means algorithm. Once the number of fuzzy sets is defined, the centers of the sets are initialized based on two methods, the equalized universe method, which divides the partition equally by the number of sets, and the subtractive clustering method, which classifies the points present in the training data by their number of neighboring points (thus, a data point will have a high potential value if it has many neighboring points). After the initialization of the centers, the Fuzzy C-Means algorithm is employed to search for the best positions for centers. A hybrid learning algorithm for refining the system parameters based on the ANFIS method [10] is then presented. The second method [8] proposes the use of a Fuzzy C-Means variant for the generation of fuzzy term sets with ½ overlap. This method uses the mean squared error criterion to determine the number of fuzzy sets and the optimal shape of the membership functions associated with each term.

Genetic algorithms are used to tune the parameters of fuzzy sets in [11]. The genetic algorithm is used to find membership functions suitable for mining problems and then uses the final best set of membership functions to mine fuzzy association rules. The fitness of each chromosome is evaluated by the number of large 1-itemsets generated and by the suitability of the membership functions.

The use of artificial neural networks has also been explored for the definition of fuzzy membership functions. The authors in [12] and [13] present an overview of several neuro-fuzzy methods for the definition of fuzzy sets. These methods, although some present good results, have the problem of tunning parameters for the neural networks, and, in some cases, might need further tests.

There are also works focusing on the use of special indexes to generate membership functions. For instance, the concept of entropy is used in [14] and in [15] to determine membership functions. In [16] the authors propose a method for the definition of fuzzy sets based on two indexes, the fuzzy entropy and the fuzziness index, adopting the S shaped fuzzy set. These papers focus on image recognition applications. The Kappa measure was also used. In [17] the authors use the Kappa measure to calculate the *fuzzy Kappa* index in order to define a suitable segmentation of partitions.

Several other approaches can be found in the literature, such as heuristic methods [18], histograms [3], and even a fuzzy version of the classic machine learning K- nearest neighbor algorithm [19].

Although such a variety of methods exist, it is important to emphasize the fact that many studies define the number of fuzzy sets empirically, and employ the equalized universe method [6] to define the distribution of the fuzzy sets, which simply distributes the sets evenly in the partitions. Regarding the number of fuzzy sets, most researchers define this variable empirically using a range usually varying from 2 to 10 fuzzy sets per attribute. The main reasons why researchers decide to define such important variables without the aid of any formal method may include:

- The complexity of the methods available, which may require more time and effort to be implemented than the actual application in focus;
- The flexibility of the fuzzy logic for the definition of fuzzy variables and fuzzy terms, which allows the users to define their own fuzzy data base, since it will be the base for the generation of the fuzzy rules, which in turn will be adjusted to provide a suitable performance;
- The lack of consensus and/or guidelines on which of the available methods is the best for a given application;

The next section presents the methods used in the experiments conducted for this paper.

3 Evaluated Methods for Fuzzy Sets Distribution

The three methods tested and compared in this paper are the equalized universe method, same frequency method, and an adaptation of the 1-R method for attribute discretization. These methods are described next.

3.1 Equalized Universe Method

This method uses the same width for each fuzzy set [6]. Figure 1 presents an attribute described by five triangular fuzzy sets using the equalized universe method. Notice that, usually, the fuzzy sets at the extremes have half the width of the other fuzzy sets in the middle of the domain.

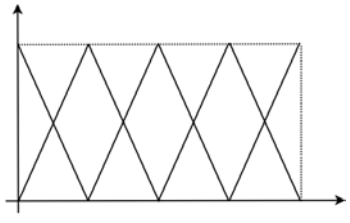

Figure 1: Attribute defined by 5 fuzzy sets using the equalized universe method.

This method is the most widely found in the literature. Some of the reasons for that may include the fact that it is

ISBN: 978-989-95079-6-8

a simple and easy method to use, and that it generates isosceles triangles, with ½ overlap, so no area of the domain will have a membership degree inferior to 0.5 [20]. Besides, they are easy to interpret.

3.2 Same Frequency Method

This method divides the domains of the attributes according to the frequency distribution of the examples. For our implementation, percentiles [21] were used to find the correct distribution for the sets. This way, if an attribute is described by 5 triangular fuzzy sets, the maximum membership degree for the first fuzzy set will be on the 16.7th percentile, on the 33.3th percentile for the second fuzzy set, on the 50.0th percentile for the third one, on the 66.7th percentile for the fourth one, and on the 83.3th percentile for the last fuzzy set. The triangles will not have the same base width, on the contrary, depending on the distribution of the examples, they are likely to be different. Notice that in the case of many examples with the same value, two or more fuzzy sets might be defined with exactly the same middle point. In order to avoid this problem, if the same example is chosen by two or more different percentile values, the neighboring examples of the left and right are chosen to replace the original value.

Figure 2 shows an attribute represented by 5 fuzzy sets distributed using the same frequency method, having 20 examples in the interval $[0, 10]$ (0, 0, 0, 1, 1, 2, 2, 2, 3, 5, 5, 6, 7, 7, 7, 9, 9, 9, 9, 9).

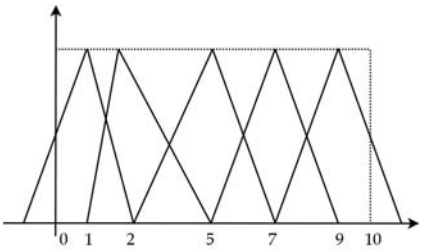

Figure 2: Attribute defined by 5 fuzzy sets using the same frequency method.

Notice that the fuzzy sets of the laterals are defined beyond the actual domain values. This strategy was used to avoid leaving any spaces of the domain with maximum membership degrees close to zero. The space between the actual beginning and end of the domain and the vertices of the triangles is calculated as the same space between the middle vertex of the triangle and the adjacent extremity of the domain.

3.3 1-R Supervised Method

The 1-R method is used for discretization of attributes. It basically divides the domain of an attribute in n intervals, in relation to the frequency of the examples, calculates the optimum class for each interval, and tries to find the best split point using the class. The original algorithm can be found in [22]. Algorithm 1 presents the adapted version of the 1-R algorithm used in the experiments.

Input: n = number of examples;
m = number of attributes;
i = number of fuzzy sets describing the attribute;
for a = *1* **to** m **do**
  Sort the examples by attribute a;
  Divide the examples in i intervals;
  for b = *1* **to** $i - 1$ **do**
    Calculate the optimal(majority) class for the interval;
    for c = *1* **to** *interval* $i - 2$ **do**
      for d = *index of first example of interval* $c + 1$ **to** *index of last example of interval* $c + 1$ **do**
        if *first example of interval* $c + 1$ *belongs to optimal class of interval* c **then** ;
        Adjust intervals so that the first example of interval $c + 1$ is transfered to interval c;
        else d = index of last example of interval $c + 1$;
        if d = *index of last example of interval* $c + 1$ **then** Split the examples of interval c between intervals c and $c + 1$;
      end
    end
  end
  For each interval, create a fuzzy set with core in the middle of the interval and laterals in the cores of the neighboring intervals;
end

Algorithm 1: 1-R adapted algoritghm.

The same strategy used for the same frequency method, to avoid leaving any spaces of the domain with maximum membership degrees close to zero, was used similarly for the 1-R adapted method.

Figure 3 shows an attribute represented by 5 fuzzy sets distributed by the same frequency method, having the following 20 examples (attribute value, class) in the interval $[0, 10]$: 0, 3; 0, 3; 0, 1; 1, 3; 1, 3; 2, 3; 2, 2; 2, 2; 3, 2; 5, 2; 5, 1; 6, 1; 7, 1; 7, 3; 7, 3; 9, 2; 9, 3; 9, 1; 9, 2; 9, 3.

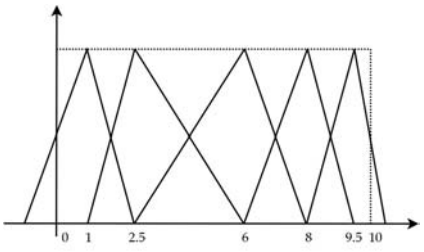

Figure 3: Attribute defined by 5 fuzzy sets using the 1-R adapted method.

4 Heuristic Method to Define the Number of Fuzzy Sets

The approaches used by the recently proposed methods to generate fuzzy rules usually demand a great computational effort, such as the genetic algorithms, that can take from minutes to days to converge to good solutions. Since the definition of the number of fuzzy sets is an open area of research, it is common to see researchers using a few different numbers of fuzzy sets for each attribute in order to validate their methods, usually ranging from 2 to 10, thus, repeating the complete round of experiments several times, according to the range of number of fuzzy sets used. If it were possible to establish an approximate optimal number of fuzzy sets, the total number of experiments would be greatly reduced. Thus, we propose a heuris-

ISBN: 978-989-95079-6-8

tic strategy to define this number using the Wang & Mendel method [23], which is able to generate fuzzy rule bases from data examples.

The Wang & Mendel method has been widely used due to its low complexity ($O(m \times n)$, m attributes, n examples) and the fact that it produces relatively small rule bases with good classification rates and no conflicting or redundant rules. However, nowadays it is possible to generate more precise fuzzy rule bases with even lower number of rules using other approaches, such as the genetic fuzzy systems or neural networks. The heuristic of the proposed method is based on the assumption that the Wang & Mendel method can be used as an indicator of the quality of the results that can be achieved by other methods, when using the same data base, *i.e.*, the same number, distribution, and shape of fuzzy sets.

Experiments shown in Section 5 were carried out using from 2 to 10 triangular shaped fuzzy sets defining each attribute of the domains. The idea is to run the experiments with the Wang & Mendel method before running the experiments with more time consuming approaches, and select the number of fuzzy sets that produced the best accuracy rates, or, in case of ties, the smaller number, due to interpretability reasons. Notice that a tolerance interval may be defined to allow the user to select the smaller number of fuzzy sets when a small difference between the accuracy rates is not significant, but the difference in the number of fuzzy sets is.

5 Experiments and Results

The experiments were conducted using 10-fold cross validation on 10 datasets. Table 1 shows a summary of the characteristics of the datasets used in the experiments, presenting the number of examples in each dataset (# Examples), number of attributes (# Attribs), number of classes (# Classes), and the majority class error (MCE).

Table 1: Characteristics of the datasets.

Two fuzzy reasoning methods, frequently employed in the fuzzy classification domain, were used, the classic and the general fuzzy reasoning methods. The classic fuzzy reasoning method uses the class of the rule with highest compatibility with an input pattern to classify it. The general fuzzy reasoning method, on the other hand, calculates the sum of compatibility degrees for each class and uses the class with highest sum to classify an input pattern. The accuracy was measured in terms of correct classification rates.

Table 2 presents the results for the experiments that were carried out using the classic fuzzy reasoning method. **Sets** describes the number of fuzzy sets used for each attribute in the experiments; **EU** represents the equalized universe method, which uses the same width for each fuzzy set, **F** represents the method that uses same frequency, and **1-R** represents the 1-R adapted method, which takes the classes into consideration when distributing the fuzzy sets.

Table 3 presents the results for the experiments that were carried out using the general fuzzy reasoning method. **Sets** describes the number of fuzzy sets used for each attribute; **EU** represents the equalized universe method, **F** represents the method that uses same frequency, and **1-R** represents the 1-R adapted method.

Table 4 shows the best estimated number of fuzzy sets, according to the proposed method, for the classic and general fuzzy reasoning methods, using the equalized universe method (**EU**), frequency method (**F**) and 1-R adapted method (**1-R**). The suffixes **C** and **G** were used to describe the classic and general fuzzy reasoning methods, respectively. A tolerance interval of 0.02 was used. Notice that the best classification rates used to define these values are light-gray shaded in Tables 2 and 3. The proposed method was able to estimate a small number of fuzzy sets for most of the datasets.

Figures 4 and 5 present the classification rates (vertical axis) for the classic and general fuzzy reasoning methods, respectively, for each of the 10 datasets, using from 2 to 10 fuzzy sets (horizontal axis) to define each of the attributes.

To test whether there is a significant difference among the methods, the Friedman test [24] was used with the null-hypothesis that the performance of the three methods, assessed in terms of the error rate, are comparable. As the null-hypothesis was rejected with a 95% confidence level, the Bonferroni-Dunn post-hoc test (to detect whether the differences among the methods are significant) was used [24]. Results showed that the equalized universe method is signifi-

Classic	1.694	2.411	1.894
General	1.350	2.711	1.939

One of the reasons for the good performance of the equalized universe method may be the fact that it generates fuzzy sets with the same distance amongst them, promoting the creation of rules that will cover equal areas of the attributes partitions, rather than promoting the creation of fuzzy sets in areas with a concentration of examples but with less differences regarding the classes, which could have a deeper effect on the classification rates. The 1-R method, since it uses the classes to adjust the fuzzy sets defining each attribute, should perform

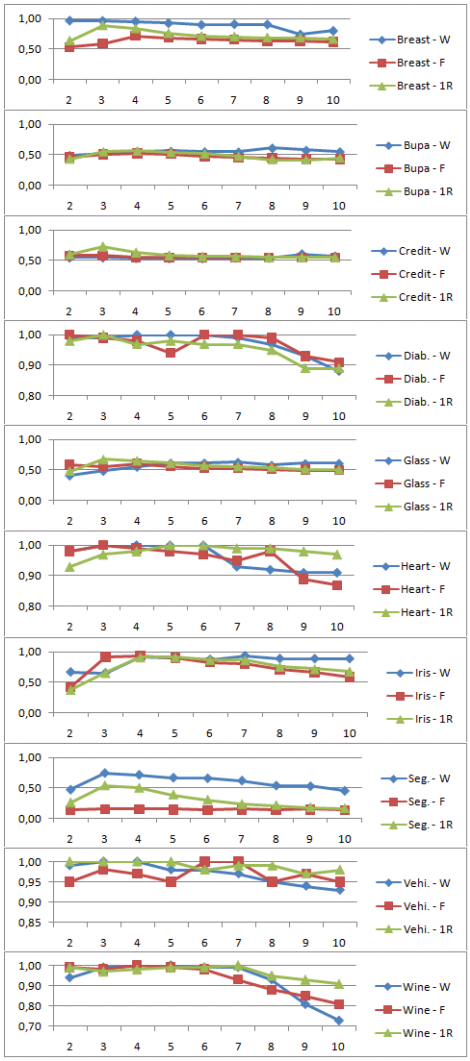

Figure 4: Results for the classic fuzzy reasoning method.

better than the frequency method.

6 Conclusions

In this paper we have tested and compared three different methods for the definition of fuzzy sets, the equalized universe method, the frequency method, and an adaptation of the 1-R supervised method. We have also proposed a heuristic method to estimate the number of fuzzy sets for each attribute using the Wang & Mendel method, to be used by other more costly approaches, able of finding smaller sets of rules with better accuracy. The experiments were carried out with 10 datasets for classification problems using 10-fold cross validation and the classic and general fuzzy reasoning methods. Each attribute of each dataset was defined using from 2 to 10 fuzzy triangular shaped sets. Statistical methods were carried out in order to find significant differences among the methods. The results show that the equalized universe method performed significantly better than the frequency and 1-R methods. The results also showed that the 1-R method performed better than the frequency method. Regarding the estimation of the number of fuzzy sets for the attributes, the proposed method provides support for the researcher to select small intervals of numbers of fuzzy sets that would be worthwhile using in more costly

Abstract—*The pattern recognition literature is replete with the use of principal component analysis in the interpretation and analysis of data. However, in the specific case of classification, especially of biomedical patterns, this pre-processing method, which transforms possibly correlated features into a new set of uncorrelated variables, must be used with caution since a principal component, which may account for significant variance in the data, is not necessarily discriminatory. To compensate for this deficiency, we present a novel classification method using an adaptive network of fuzzy logic connectives to select the most discriminatory principal components. We empirically demonstrate the effectiveness of this method using a benchmark combination of a conventional classifier and principal component analysis.*

Keywords— fuzzy logic network; principal component analysis; biomedical data; pattern classification.

1 Introduction

Today's biomedical instrumentation provides the acquisition of complex data rich in information content; however, its analysis and interpretation is often difficult and requires the latest pattern analysis methodologies [1,2,3]. This is particularly true for the domain of biomedical pattern classification, the prediction by a classifier of the class (for example, normal or abnormal) to which a pattern (for instance, an infrared spectrum of a biofluid) belongs. This prediction is validated against a gold standard, an external reference test such as a pathologist's expert assessment of the same biofluid. Although many classifier methods exist [4,5,6], the most successful approaches combine them with well designed pre-processing techniques, which simplify, in some sense, the feature space prior to presentation to a classifier, and a sound validation protocol to ensure realistic and clinically useful results.

A standard approach to biomedical pattern classification is to use simple linear classifiers coupled with pre-processing transformations that create new features (coordinates, parameters) ordered by the cumulative variance of the original features. A common pairing is linear discriminant analysis coupled with principal component analysis. The ordering allows for the reduction of the feature space by using only the first few components that account for the bulk of the data variance. While this combination is often successful when used in the classification of patterns, its success lies more in the feature reduction aspect rather than the exploitation of the data variance. This is because the feature variance is not concomitant with the discriminatory power of individual features.

We present a new classification method that uses an adaptive network of fuzzy logic connectives that operate on the entire set of principal components. This method exploits the discriminatory power of any principal component regardless of the amount of variance for which it accounts. We empirically demonstrate that this method produces superior classification performance compared to a benchmark using the conventional approach of linear discriminant analysis operating on the first few principal components of the original feature space. Section 2 presents a general discussion on classification including classifier validation, principal component analysis, linear discriminant analysis, and a recent fuzzy adaptive logic network on which the current method is based. Details of our novel approach are presented in Section 3. The synthetic and biomedical datasets, experiment design, and results are discussed in Section 4 followed by some concluding remarks and areas of future investigations.

2 Pattern classification

2.1 Classifier Validation

We begin by defining formal pattern classification notation: N is the number of patterns (samples, vectors, individuals, or cases); n is the number of features (dimensions, attributes, coordinates, or measurements); c is the number of classes (groups); and $\boldsymbol{X}=\{(\boldsymbol{x}_k,\omega_k),\ k=1,2,\ldots,N\}$ is a set of N labeled patterns where $\boldsymbol{x}_k\in\Re^n$ and $\omega_k\in\Omega=\{1,2,\ldots,c\}$. A classifier is a system that determines a mapping $f:\boldsymbol{X}\rightarrow\Omega$. If a classifier predicts that the class label for pattern $\boldsymbol{x}_i$ is ω_p then: a correct classification occurs if $\omega_p=\omega_i$; otherwise it is considered a misclassification.

Many investigations involving data classification are biased as they use the entire dataset to determine the mapping. This approach leads to unrealistic classification results that do not take into account the possibility of overfitting, wherein the

ISBN: 978-989-95079-6-8

mapping becomes a simple table lookup, between the patterns and class labels (that is, it possesses no generalized predictive power for new patterns). To compensate for this bias, it is essential to perform some type of validation. For instance, patterns in $\boldsymbol{X}$ may be randomly allocated to a design subset, $\boldsymbol{X}^D$ containing N^D patterns, or a validation subset, $\boldsymbol{X}^V$ containing N^V patterns ($N^D+N^V=N$). Now, a mapping is determined using only design patterns, $f':\boldsymbol{X}^D\rightarrow\Omega$, but the classification performance is measured using f' with the validation patterns.

Performance of a classification system is measured using the $c\times c$ confusion matrix, $\boldsymbol{C}$, of the desired class labels (as determined by an external reference test or "gold standard") versus the predicted class labels (as generated by the classifier). If the class prediction for $\boldsymbol{x}_i$ is ω_p then element $[\omega_p,\omega_i]$ of $\boldsymbol{C}$ is incremented by one. The conventional performance measure is the ratio of correctly classified patterns to the total number of patterns, $P_O=(\sum_i n_{ii})/N^V$ (i=1, 2,…, c), where n_{ij} is the number of class i validation patterns that are predicted to belong to class j.

A significant problem with P_O occurs when there is a large disparity between class sizes. For instance, if a validation set has many more patterns in one class than another, the classification accuracy relating to the former will outweigh any effects from the latter. For instance, a high value for P_O may occur due to few misclassifications with the larger class even though many misclassifications occur with the smaller class. This is especially problematic for biomedical patterns where it is relatively easy to acquire patterns from "normal" samples (tissues, biofluids, and so on) but clinically difficult to obtain "abnormal" samples. As a result, it is often better to forgo the use of P_O for these types of datasets and use the class-wise average accuracy, P_A

$$P_A = c^{-1}\sum_i^N \frac{n_{ii}}{\sum_j^N n_{ij}} (i,j=1,\ldots,c) \qquad (1)$$

2.2 Principal Component Analysis

The motivation behind principal component analysis, first described by Pearson [7] (with a practical computing method described by Hotelling [8]), is to find a set of directions (coordinates) that explain as much of the variability of the original data as possible. In other words, the principal components are a new set of orthogonal linear coordinates such that the variances of the original features with respect to these derived coordinates are in decreasing orders of magnitude [9]. As a result, each principal component is uncorrelated with all other principal components (in a normal distribution, they are statistically independent). Moreover, it can be shown [10] that no other set of m coordinates can account for more of the variability in the original data than the first m principal components.

The first principal component, $\boldsymbol{Y}_1$, of the original features x_1, x_2, …, x_n, is the linear combination

$$\boldsymbol{Y}_1 = \sum_i^n a_{1i}x_i, \sum_i^n a_{1i}^2 = 1 \qquad (2)$$

The constraint on the coefficients is necessary; otherwise the variance of $\boldsymbol{Y}_1$ can be increased simply by increasing the value of any coefficient. The second principal component, $\boldsymbol{Y}_2$, would be computed in a similar fashion to (1). Fig. 1 is a plot of some bivariate data and their two principal components. It is clear from this figure that an additional constraint, orthogonality to the first principal component, is required to compute the second principal component, otherwise it would simply be driven to the first principal component. Orthogonality is ensured by restricting the variables of the second principal component to those that are uncorrelated with the first principal component. As a result of this orthogonality constraint, if there are n features then there can be up to n principal components [11]. In fact, if the original features are completely uncorrelated, then all n principal components must be used to take into account the variance in the original features. In this case, principal component analysis serves little purpose, with respect to pattern classification, since the motivation behind the technique is to reduce the dimensionality of the original input (feature) space. However, in "real-world" high-dimensional biomedical patterns, the converse is usually true; features are highly correlated and hence only $1\leq m<<n$ principal components are required to account for all (or nearly all) of the variation.

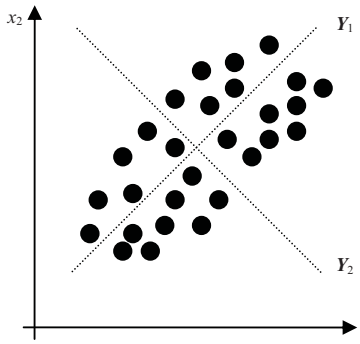

Figure 1: Principal components, $\boldsymbol{Y}_1$ and $\boldsymbol{Y}_2$, for some bivariate data.

Determining the principal components is a straightforward process involving the computation of the eigensystem of the original data's covariance matrix, $\boldsymbol{V}$, whose element v_{lm} is the sample covariance between features x_l and x_m

$$v_{lm} = \frac{1}{N-1}\sum\nolimits_N \left(x_{il}-\mu_l\right)\left(x_{im}-\mu_m\right) \qquad (3)$$

where μ_j is the mean for feature x_j (cf. [12] for a derivation of the proof). The variances of the principal components are the eigenvalues of $\boldsymbol{V}$, $\lambda_1\geq\lambda_2\geq\ldots\geq\lambda_n\geq 0$ (the covariance matrix is quadratic and hence admits no negative eigenvalues). The variance of a principal component, $\boldsymbol{Y}_i$, is λ_i and its constants a_{i1}, a_{i2}, …, a_{in} are the elements of the corresponding eigenvector.

A standard strategy employed in biomedical pattern classification is to take the first m principal components whose cumulative variance exceeds some pre-defined threshold. This reduction is often significant ($m<<n$): for instance in some high-dimensional infrared spectra more than 80% of the cumulative variance may be accounted for by only the first one or two principal components [13].

ISBN: 978-989-95079-6-8

While this pre-processing strategy may be effective, it must be noted that the components are ordered by maximal variance. Unfortunately, this does not necessarily translate into maximal discriminatory power [14]. For instance, if the method used to acquire values for a particular feature is extremely prone to measurement error, then this feature will have a high variance. Now, assuming this variance is greater than other features, the first principal component will be approximately equal to this suspect feature, and hence, this principal component will be useless in discriminating between classes. Conversely, a highly discriminatory feature may have an extremely small variance and hence will not contribute to the first few principal components. In summary, maximal discriminatory power is not equivalent to maximal variance.

2.3 Linear Discriminant Analysis

Linear discriminant analysis (LDA) [15] is a standard pattern classification strategy that determines linear boundaries between c classes while taking into account between-class and within-class variances. If the error distributions for the classes are the same (identical covariance matrices), LDA constructs the optimal linear boundary between the classes. In real-world situations, this optimality is seldom achieved since different classes typically give rise to different distributions.

LDA assigns a pattern, $\boldsymbol{x}$, to class i for which the probability distribution, $p_i(\boldsymbol{x})$, is greatest. That is, $\boldsymbol{x}$ is allocated to class i, if $q_i p_i(\boldsymbol{x}) \geq q_j p_j(\boldsymbol{x})$ $(\forall j=1,2,\ldots,c\ [j\neq i])$, where q_i is the class' prior (or proportional) probability. The discriminant function for class i is

$$D_i(\boldsymbol{x}) = \log q_i + \boldsymbol{\mu}_i^{\mathrm{T}} \boldsymbol{W}^{-1} \left(\boldsymbol{x} - \tfrac{1}{2} \boldsymbol{\mu}_i \right) \qquad (4)$$

where $\boldsymbol{\mu}_i$ is the mean for class i and $\boldsymbol{W}$ is the covariance matrix of the patterns in $\boldsymbol{X}$. The feature space hyperplane separating class i from j is defined by $F_{ij}(\boldsymbol{x})=D_i(\boldsymbol{x})-D_j(\boldsymbol{x})=0$. As a classification system, LDA is often used with the first m principal components of a dataset rather than the original features. This combination will serve as the classification benchmark against which our novel pattern classification method will be evaluated.

2.4 Fuzzy Adaptive Logic Network

Our novel approach is partly based upon a modification to the fuzzy adaptive logic network (cf. [16] for a thorough description). This network, which can be used for pattern classification, combines two different subsystems within a general architecture. A neurocomputing subsystem uses a set of perceptrons to construct class boundaries. Through a set of weights and respective inputs, a perceptron is defined as $P(\boldsymbol{x},\boldsymbol{w})=f(\sum_i w_i x_i + w_0)$ (f is a sigmoidal transfer function) describing an n-dimensional hyperplane. This geometric information is presented to the logic processing subsystem composed of a layer of fuzzy conjunctions ("and" elements) and disjunctions ("or" elements). The intent is to use these fuzzy logic connectives to combine the hyperplanes from the neurocomputing subsystem to form convex hull-like topologies. For instance, a convex region delineated by p perceptrons may be represented by the compound logic predicate, $Q = P_1(\boldsymbol{x},\boldsymbol{w}_1)$ *and* $P_2(\boldsymbol{x},\boldsymbol{w}_2)$ *and* … *and* $P_p(\boldsymbol{x},\boldsymbol{w}_p)$, which produces values close to one (in other words, approaching the crisp notion of *true*) when all contributing predicates are *true* (that is, the respective perceptrons produce high outputs).

To capture the geometric notion of disjoint regions one may take a union (in the fuzzy set theoretic sense) of the individual regions described by the Q's, $R = Q_1$ *or* Q_2 *or* … *or* Q_q. To implement these fuzzy predicates, one uses t-norms to model the *and* logic connectives and s-norms to model the *or* logic connectives. A t-norm, $\wedge$, is a function $[0,1]^2 \rightarrow [0,1]$ that is commutative, symmetric, monotonic, and satisfies the boundary conditions $x\mathrm{t}0=0$ and $x\mathrm{t}1=x$, while the boundary conditions for the s-norm, $\vee$, are $x\mathrm{s}0=x$ and $x\mathrm{s}1=1$. The fuzzy *or* and *and* connectives may now be defined as

$$\begin{aligned} OR(\boldsymbol{x};\boldsymbol{w}) &= \wedge_i \left(w_i \vee x_i \right) \\ AND(\boldsymbol{x};\boldsymbol{w}) &= \vee_i \left(w_i \wedge x_i \right) \end{aligned} \qquad (5)$$

where $\boldsymbol{x}$ are the inputs and $\boldsymbol{w}$ are the corresponding adjustable weights (connections) confined to the unit interval. In the case of $OR(\boldsymbol{x};\boldsymbol{w})$, the greater the weight value the more relevant the respective input (if all weights are 1, it becomes a standard *or* gate). In the case of $AND(\boldsymbol{x};\boldsymbol{w})$, the greater the weight value the less relevant the respective input (if all weights are 0, it becomes a standard *and* gate). If we restrict ourselves to differentiable t- and s-norms, a gradient descent strategy can be used to train a fuzzy adaptive logic network (cf. [16] for details).

3 Fuzzy logic classification network using principal components

Building upon the concepts described in Section 2, we now describe a novel pattern classification algorithm, COAP (Classification using a fuzzy Or/And network with Principal components), a component of which extends the fuzzy logic network architecture developed by the authors [17]. There are three major steps to the COAP algorithm: (i) apply principal component analysis on the original features to find all n principal components; (ii) Use a genetic algorithm to determine the optimal weights for the fuzzy logic network given the principal component values found in (i); (iii) use the patterns from the validation subset to assess the classification performance using the selected feature regions and principal component values. Fig. 2 illustrates the architecture of the COAP system.

Let us now look at each algorithmic step in more detail. After applying principal component analysis to the feature space, we replace pattern, $\boldsymbol{x}_i=[x_1,x_2,\ldots,x_n]$, with its respective principal component values, $\boldsymbol{y}_i=[\boldsymbol{Y}_1(\boldsymbol{x}_i),\boldsymbol{Y}_2(\boldsymbol{x}_i),\ldots,\boldsymbol{Y}_n(\boldsymbol{x}_i)]$. These principal component values for all design set patterns are subsequently presented to the fuzzy logic network component.

COAP's fuzzy logic network uses the product $(x_1 \times x_2)$ and probabilistic sum $(x_1+x_2-x_1 \times x_2)$ for the t- and s-norms, respectively, with p (user selected) *AND* connectives and c *OR* connectives. There are two issues with this network that

ISBN: 978-989-95079-6-8

do not exist with the fuzzy adaptive logic network described in Section 2.4. First, while output from a perceptron maps onto the unit interval (due to the sigmoidal nature of its transfer function), which is necessary for input into a fuzzy logic *AND* connective, principal component values map onto $\Re$. This can be dealt with by rescaling the principal component values prior to presentation to the fuzzy logic network ((*x*–*min*)÷(*max*–*min*), where *min* and *max* are the respective minimum and maximum for all principal component values).

The second, more serious, issue is that a gradient descent strategy cannot be used to minimize the fuzzy logic network error (optimize the weights) since the weight adjustments are now based on sets of principal components rather than differentiable perceptron output. We deal with this issue by using a straightforward implementation of a genetic algorithm [18,19,20] to perform the structural optimization of the network. While much slower than gradient descent, this solution still provides adequate computational performance. In this study, we implemented a conventional genetic algorithm as described in [21], but other more sophisticated genetic algorithm variants could certainly be explored.

As mentioned in Section 2.1, $\Omega=\{1,2,\ldots,c\}$; however, it is often beneficial [13] to use 1-of-*c* encoding for the class labels for iterative classifiers such as artificial neural networks or fuzzy logic networks, namely, $\Omega=\{\gamma_1,\gamma_2,\ldots,\gamma_c\}$ where, for $\boldsymbol{x}_i$, $\gamma_{\omega_i}=1$ and $\gamma_{\omega_j}=0$ $(\forall\omega_i\neq\omega_j)$. Instead of using one output element to represent all *c* classes, we use *c* output elements.

Finally, all performance results using P_A are based on the class predictions of COAP using the biomedical patterns from the validation subset. That is, the principal component values are obtained for the validation patterns and presented to the fuzzy logic network component. Subsequently, the predictions are compared against the desired class labels (if the output element with the maximum value corresponds to the desired label's non-zero component then we have a successful classification, otherwise it is a misclassification).

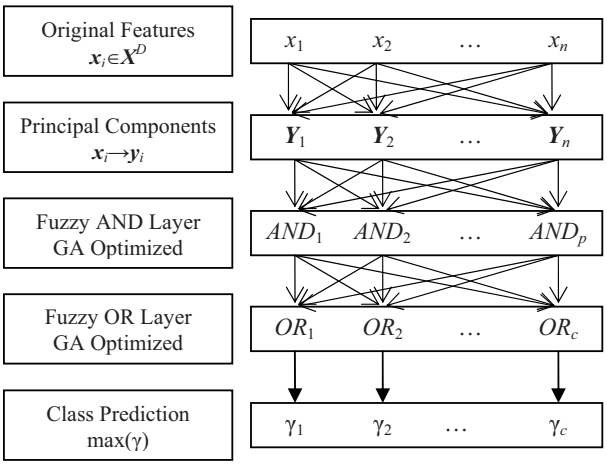

Figure 2: General architecture of COAP with the GA (genetic algorithm) optimized fuzzy logic network.

4 Experiments and discussion

4.1 Synthetic Datasets

We begin our experiments with the "exclusive or" dataset (*n*=2, *c*=2, *N*=4): patterns {{0,0},{1,1}} and {{0,1},{1,0}}; and respective principal component values of {{0,0},{1,–1}} and {{1,0},{0,–1}}. Intuitively, one expects that LDA would perform poorly in this case as no hyperplane can act as a class boundary to perfectly separate the patterns. Using LDA with the principal components, this is actually the case with P_A=0.5 (one misclassification for each class). [As this is a strictly pedagogical experiment, we skip validation.] Setting the initial genetic algorithm population to 50, the number of iterations to 5, and the number of *AND* connectives to 2, we now get perfect accuracy, P_A=1.0. The weights for the two *AND* connectives are {0.95,0.05} and {0.0,1.0}. The weights for the two *OR* connectives are {0.53,0.05} and {0.07,0.35}.

This next dataset is a variant of the exclusive or dataset described above (*n*=10, *c*=2, *N*=400, $\boldsymbol{x}\in[0,1]^n$). A pattern belongs to the first class, if all of its features are identical; otherwise it belongs to the second class. Fig. 3 is a plot of the first two features of this dataset. The initial genetic algorithm population is 100, the number of iterations is 5, and the number of *AND* connectives is 10. In this case, LDA with principal components also performed poorly, P_A=0.5, while COAP produced a higher classification accuracy, P_A=0.81.

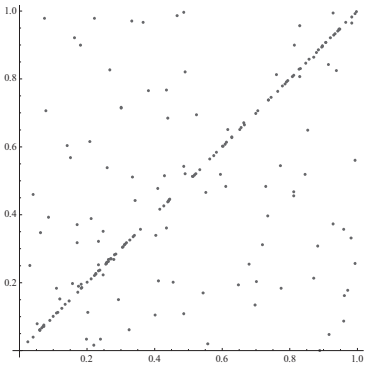

Figure 3: Plot of, x_1 and x_2, for the second synthetic dataset.

4.2 Biomedical Dataset

We used a biomedical dataset from the Machine Learning Repository at the University of California, Irvine [22]. This archive is used to evaluate machine learning algorithms. This dataset [23,24] comprises voice measurements acquired from two classes of subjects: those with Parkinson's disease (abnormal); and those without (normal). There are *N*=195 patterns from one of two classes: N_a=48 abnormal patterns; N_n=147 normal patterns. The *n*=22 features include: the maximum, minimum, and average fundamental vocal frequency (3 features); several measures of variation in fundamental frequency (5 features); several measures of variation in amplitude (6 features); measures of the ratio of noise to tonal components in the voice (2 features); nonlinear dynamical complexity measures (2 features); a

ISBN: 978-989-95079-6-8

signal fractal scaling exponent (1 feature); and nonlinear measures of fundamental frequency variation (3 features).

For this dataset, the following COAP parameters were used: p=7 (the number of *AND* connectives); crossover rate, 0.07; mutation rate, 0.005; size of genetic algorithm population, 200; and 20 iterations of the genetic algorithm. The patterns were randomly assigned to either a design subset (N^D=64 with 32 normal patterns and 32 abnormal patterns) or a validation subset (N^V=131 with 115 normal patterns and 16 abnormal patterns). Finally, given the class size disparity between the abnormal and normal patterns within the validation set, P_A was used to assess classification accuracy.

Table 1 lists the confusion matrices for COAP for the design patterns and validation patterns. For the design patterns, P_A=0.91, while P_A=0.85 for the validation patterns. While only 70% of the normal validation patterns were correctly classified, all abnormal validation patterns were correctly classified. Table 2 lists the confusion matrices for LDA using all n principal components. In the case of this benchmark, P_A=0.94 for the design patterns and P_A=0.70 for the validation patterns. The disparity between the design and validation results is a classic sign of potential overfitting. While 75% of the abnormal validation patterns were correctly classified, only 65% of the normal patterns were correctly classified.

Table 1: COAP confusion matrices for $\boldsymbol{X}^D$ and $\boldsymbol{X}^V$.

Desired vs	Design Set (P_A=0.91)		Validation Set (P_A=0.85)	
Predicted	Abnormal	Normal	Abnormal	Normal
Abnormal	29	3	16	0
Normal	3	29	35	80

Table 2: Benchmark confusion matrices for $\boldsymbol{X}^D$ and $\boldsymbol{X}^V$.

Desired vs	Design Set (P_A=0.94)		Validation Set (P_A=0.70)	
Predicted	Abnormal	Normal	Abnormal	Normal
Abnormal	31	1	12	4
Normal	3	29	40	75

Table 3 lists the confusion matrices (desired versus predicted class labels) using successive combinations of principal component in turn (ordered by variance) for both the design and validation sets. Note that: P_A is listed for the design set followed by the validation set; $\sum^{\alpha}\lambda_i$ refers to the cumulative variance of the first α principal components used to produce the corresponding results; and the last entry is the same as that described in Table 2. The best result, P_A=0.781, occurred when using the first 13 principal components. It is clear with this dataset that feature variance is not well correlated with discriminatory features (for example, the first three principal components, which account for 0.998 of the cumulative variance, produce a low accuracy score, P_A=0.60).

Fig. 3 summarizes these results by plotting the COAP validation result against the validation results using all successive combinations of principal components. It should also be noted that the last few entries in Table 3 clearly demonstrate a problem with overfitting with a disparity of approximately 0.24 between the design and validation results.

Table 3: Results using successive principal components.

ISBN: 978-989-95079-6-8

Finally, after examination of the weights of the fuzzy logic network, six principal components tended to significantly contribute to the COAP training, $\boldsymbol{Y}_1$, $\boldsymbol{Y}_4$, $\boldsymbol{Y}_5$, $\boldsymbol{Y}_{10}$, $\boldsymbol{Y}_{12}$, and $\boldsymbol{Y}_{16}$. This is further evidence that care must be taken when using principal component analysis as one may overlook discriminatory components simply because they account for little feature variance (for example, the variance for $\boldsymbol{Y}_{10}$, $\boldsymbol{Y}_{12}$, and $\boldsymbol{Y}_{16}$ is zero).

5 Conclusions

We have empirically demonstrated the effectiveness of a novel classification method that uses an adaptive network of fuzzy logic connectives to combine new features generated using principal component analysis. Using a "real world" biomedical dataset, COAP correctly classified significantly more patterns from a validation set compared to the benchmark.

While this novel classification method has demonstrated the utility of merging fuzzy logic connectives with multivariate statistical discrimination, the investigation has also led to the identification of future areas of research to potentially improve its overall effectiveness and computational performance. First, rather than setting the number of fuzzy *and* connectives by the user *a priori*, it would be worthwhile to investigate a cascade approach to determining an optimal number of *and* connections that would be completely data-driven. Second, alternative structural optimizations to the fuzzy logic network need to be examined beginning with more sophisticated evolutionary computational approaches or exploiting recent advances in stochastic optimization techniques. A final area of investigation is using more sophisticated component analysis methods for feature pre-processing (non-linear and local principal component methods, other kernel based approaches, and fuzzy set based feature selection/extraction approaches).

Acknowledgment

We are grateful to Max Little of the University of Oxford who, in collaboration with the National Centre for Voice and Speech, Denver, Colorado, recorded the speech signals for the contribution of the biomedical dataset within the publicly available machine learning repository. We thank Drs. Asuncion and Newman of the University of California, Irvine who maintain the highly useful and publicly available data repository.

Conrad Wiebe and Aleksander Demko are gratefully acknowledged for the implementation and testing of some of the software framework components used in the implementation of this pattern classification method and validation protocol.

This investigation was supported in part by the Natural Sciences and Engineering Research Council of Canada (NSERC).

Abstract— *In this paper we propose a generalization of Atanassov's operators and we prove that these generalized operators and OWA operators of dimension* 2 *provide the same numerical results. We apply Atanassov's operators to image compression and use different families of OWA operators in order to calculate the coefficient* α *of the Atanassov's operator.*

Keywords— Image compressing, OWA operators, Atanassov's operator, Interval-valued fuzzy set.

1 Introduction

Image compression consists of reducing the resolution of an image in order to display it, print it, or even speed up some other computations (see [10, 11, 18]). The target of image reduction algorithms is to reduce the size of the image with the smallest possible quality loss.

Atanassov's operator was given in 1983 ([1, 2]) allowing to associate a fuzzy set to each Atanassov's intuitionistic fuzzy set or interval-valued fuzzy set ([9, 12, 14]). Later, in 1988, Yager presented the Ordered Weighted Averaging (OWA) operators ([16])). Our paper is based on the idea that, under certain conditions, the numerical results of both operators are the same. For this reason, we define an operator generalizing Atanassov's operators, being an OWA operator of dimension 2([3, 4, 5]).

We apply this operator in image compression. In this way, we divide the image in blocks. We associate each block with an interval, getting an interval-valued fuzzy set associated with the image. We use the Atanassov's operator to obtain a single point from each interval. The result is a new (fuzzy) set representing the reduced image.

In order to calculate the α parameter of the Atanassov's operator, we focus on several families of OWA operators of dimension 2. We calculate the α coefficient according to the type of OWA operator, with the aim of getting different reductions from a single image.

This paper is organized in the following way. First, we start recalling some concepts related to interval-valued fuzzy sets and Atanassov's operator. In Section 3, we see the relation between OWA operators of dimension 2 and generalized Atannasov's operators. In Section 4 we present different methods to calculate α, based on different families of OWA operators. In Section 5 we propose an algorithm to compress images and in Section 6 we see different experimental results. We finish with some conclusions and references .

2 Preliminary definitions

We denote by L([0,1]) the set of all closed subintervals of the unit interval [0,1], that is,

$$L([0,1]) = \{\mathbf{x} = [\underline{x}, \overline{x}] | (\underline{x}, \overline{x}) \in [0,1]^2 \text{ and } \underline{x} \leq \overline{x}\}.$$

L([0,1]) is a partially ordered set with respect to the order relationship $\leq_L$ defined in the following way: given **x**,**y** $\in$ L([0,1])

$$\mathbf{x} \leq_L \mathbf{y} \text{ if and only if } \underline{x} \leq \underline{y} \text{ and } \overline{x} \leq \overline{y}.$$

With this order relationship, (L([0,1]),$\leq_L$) is a complete lattice ([7, 8, 3, 4]), where the smallest element is $0_L = [0,0]$ and the largest is $1_L = [1,1]$.

Definition 1. *An interval-valued fuzzy set (IVFS) A on the universe* $U \neq \emptyset$ *is a mapping* $A : U \to L([0,1])$.

M_A(u)=[$\underline{A}$(u),$\overline{A}$(u)] $\in$ L([0,1]) is the membership degree of u $\in$ U, with $\underline{A}$(u), $\overline{A}$(u) $\in$ [0,1] denoting the lower bound and the upper bound respectively of the membership associated to u.

In 1983, Atanassov proposed an operator to associate a fuzzy set with each interval-valued fuzzy set (see [1, 2]). This operator associates each interval with a point.

Definition 2. *Let* $\alpha \in [0,1]$. *The Atanassov's operator* K_α *is a mapping* $K_\alpha : L([0,1]) \to [0,1]$ *defined by*

1. $K_0(x) = \underline{x}$ *for all* $x \in L([0,1])$,
2. $K_1(x) = \overline{x}$ *for all* $x \in L([0,1])$,
3. $K_\alpha(x) = K_\alpha([K_0(x), K_1(x)]) = K_0(x) + \alpha(K_1(x) - K_0(x)) = \underline{x} + \alpha(\overline{x} - \underline{x})$ *for all* $x \in L([0,1])$.

To generalize this operator, the following definition was proposed in [4]:

Definition 3. *Let* $\alpha \in$ *[0,1]. An operator* D_α *is a mapping* $D_\alpha : L([0,1]) \to [0,1]$ *such that it satisfies the following conditions:*

1. *If* $\underline{x} = \overline{x}$, *then* $D_\alpha(\boldsymbol{x}) = \underline{x}$,
2. $D_0(\boldsymbol{x}) = \underline{x}$, $D_1(\boldsymbol{x}) = \overline{x}$ *for all* $\boldsymbol{x} \in L([0,1])$,
3. *If* $\boldsymbol{x} \leq_L \boldsymbol{y}$ *with* $\boldsymbol{x}, \boldsymbol{y} \in L([0,1])$, *then* $D_\alpha(\boldsymbol{x}) \leq D_\alpha(\boldsymbol{y})$,
4. $D_\alpha([0,1]) = \alpha$ *for any* $\alpha \in [0,1]$.

Example 1.

$$D_\alpha([\underline{x}, \overline{x}]) = \begin{cases} \overline{x} & \text{if } \overline{x} \leq \alpha \\ \underline{x} & \text{if } \underline{x} \geq \alpha \\ \alpha & otherwise \end{cases}$$

Proposition 1. *For any* $\alpha \in [0,1]$, K_α *is a* D_α *operator.*

Next, we propose a theorem to construct D_α operators using one-variable real functions.

ISBN: 978-989-95079-6-8

Theorem 1. *Let $\alpha \in [0,1]$ and let $f : [0,1] \to [0,1]$ be a continuous and strictly increasing function. Then the operator*

$$D_\alpha : L([0,1]) \to [0,1] \text{ given by}$$
$$D_\alpha(\boldsymbol{x}) = f^{-1}\Big(pf(\underline{x}) + (1-p)f(\overline{x})\Big)$$

with $p = \frac{f(1)-f(\alpha)}{f(1)-f(0)}$, is a D_α operator in the sense of Definition 3.

Proof:

1. If $\underline{x} = \overline{x}$, then $D_\alpha(\mathbf{x}) = f^{-1}(pf(\underline{x}) + (1-p)f(\underline{x})) = = f^{-1}(f(\underline{x})) = \underline{x}$.
2. If $\alpha = 0$, then $p = 1$. In these conditions $D_0([\underline{x}, \overline{x}]) = = f^{-1}(f(\underline{x})) = \underline{x}$.
   If $\alpha = 1$, then $p = 0$ and therefore $D_1([\underline{x}, \overline{x}]) = \overline{x}$.
3. If $[\underline{x}, \overline{x}] \leq_L [\underline{y}, \overline{y}]$, as f is continuous and strict, we have that $D_\alpha([\underline{x}, \overline{x}]) = f^{-1}(pf(\underline{x}) + (1-p)f(\overline{x})) \leq f^{-1}(pf(\underline{y}) + (1-p)f(\overline{y})) = D_\alpha([\underline{y}, \overline{y}])$.
4. If $\mathbf{x} = [0,1]$, then $D_\alpha([0,1]) = f^{-1}(p(f(0) + (1-p)f(1)) = f^{-1}(\frac{f(0)(f(1)-f(\alpha))-f(1)(f(1)-f(\alpha))+f(1)(f(1)-f(0))}{f(1)-f(0)}) = f^{-1}(\frac{f(\alpha)(f(1)-f(0))}{f(1)-f(0)}) = \alpha$.

Remark: In this paper, we take $f(x) = x$. Under this condition, by Theorem 1, we have that

$$D_\alpha([\underline{x}, \overline{x}]) = \underline{x} + \alpha(\overline{x} - \underline{x}) = K_\alpha([\underline{x}, \overline{x}])$$

3 K_α and OWA operators

In [16], Yager introduced the Ordered Weighted Aggregation Operator (OWA operator) in the following way:

Definition 4. *A mapping $F : [0,1]^n \to [0,1]$ is called an OWA operator of dimension n if there exists a weighting vector W,$W = (w_1, w_2, \ldots, w_n) \in [0,1]^n$ with $\sum_i w_i = 1$ and such that*

$$F(a_1, a_2, \ldots, a_n) = \sum_{j=1}^{n} w_j b_j$$

with b_j the j-th largest of the a_i.

In the original definition, Yager considered the OWA operators as a mapping from the whole euclidean space $\mathbb{R}^n$ to $\mathbb{R}$. However, for us it is better to reduce the domain only to $[0,1]^2$.

There exist three important special cases of OWA operators that coincide with well known aggregation functions, as we can see in [17].

1. F^*: The weighting vector, denoted as W^*, is defined as $w_1 = 1$ and $w_j = 0$ for all $j \neq 1$.
   $F^*(a_1, \ldots, a_n) = max\{a_1, \ldots, a_n\}$
2. F_*: The weighting vector, denoted as W_*, is defined as $w_n = 1$ and $w_j = 0$ for all $j \neq n$.
   $F_*(a_1, \ldots, a_n) = min\{a_1, \ldots, a_n\}$.
3. F_A: The weighting vector, denoted as W_A, is defined as $w_j = 1/n$ for all $j \in 1, \ldots, n$.
   $F_A(a_1, \ldots, a_n) = \frac{1}{n}\sum_{i=1}^{n} a_i$.

If we focus on two-dimensional OWA operators using as weighting vector $W = (\alpha, 1-\alpha)$, we can think of applying it to the bounds of an interval. In this case, the numerical result of applying the OWA operator on the bounds of an interval and the operator D_α acting on that interval is the same. While D_α operator acts over elements in L([0,1]), the domain of OWA operators is [0,1]x[0,1]. For this reason, OWA operators acting on the unit square require an ordering operation to ensure the elements to be the extremes of an interval defined in L([0,1]). That's the reason why we need the following theorems to study the relationship between these operators.

We define a new operator $\mathbb{D}_\alpha$ by composing the D_α operator with the map

$$\begin{array}{rcl} i : [0,1]^2 & \to & L([0,1]) \\ (x,y) & \to & [min(x,y), max(x,y)] \end{array}$$

Theorem 2. *1. Let $\alpha \in [0,1]$ and $\mathbb{D} = D_\alpha \circ i$ where D_α is the operator given in Definition 3. Then, if F is the OWA operator (of dimension 2) defined by the weighting vector $W = (\alpha, 1-\alpha)$, we have that*
$$\mathbb{D}_\alpha(x,y) = F(x,y) \text{ for all } x, y \in [0,1].$$

2. Let F be an OWA operator (of dimension 2) with weighting vector $W = (w_1, w_2)$. Then for any $(x,y) \in [0,1]^2$ we have that
$$F(x,y) = \mathbb{D}_\alpha(x,y), \text{ with } \alpha = w_1.$$

4 Calculation methods for α coefficient

In this section, we study how to calculate the α coefficient basing on different families of OWA operators. First, we study two measures defined in [17] and associated with any OWA operator: the orness and the dispersion.

Definition 5. *Let F be an OWA operator and W its weighting vector. The orness measure is defined as*

$$orness(F) = \frac{1}{(n-1)}\sum_{i=1}^{n}(n-i)w_i.$$

With this definition it is easy to see that $orness(F^*) = 1$, $orness(F_*) = 0$ and $orness(F_A) = 0.5$.

Proposition 2. $orness(\mathbb{D}_\alpha) = \alpha$

Proof:

$$orness(\mathbb{D}_\alpha(x)) = \frac{1}{2-1}\sum_{i=1}^{2}(2-i)w_i = w_1 = \alpha$$

Definition 6. *Let F be an OWA operator and W its weighting vector. The dispersion measure is defined as*

$$Disp(F) = -\sum_{i=1}^{n} w_i ln w_i.$$

Proposition 3. $Disp(\mathbb{D}_\alpha) = \alpha ln(\frac{1-\alpha}{\alpha}) + ln(1-\alpha)$

Proof:

$$Disp(\mathbb{D}_\alpha) = -\textstyle\sum_{i=1}^{2} w_i ln w_i =$$

$$= \alpha(ln(1-\alpha) - ln(\alpha)) - ln(1-\alpha) =$$

$$= \alpha ln(\tfrac{1-\alpha}{\alpha}) + ln(1-\alpha)$$

ISBN: 978-989-95079-6-8

Next, it is shown the relation between the coefficient α of the operator $\mathbb{D}_\alpha$ and some families of OWA operators.

Definition 7. *F is called a ME-OWA operator if F is an OWA operator such that given a desired value of orness β, it maximizes the dispersion (entropy). In particular we solve the following problem:*

$$\begin{array}{ll} \textit{Max} & -\sum_{i=1}^{n} w_i ln w_i \\ \textit{subject to} & \beta = 1/(n-1)\sum_{i=1}^{n}(n-i)w_i \\ \textit{where} & \sum_{i=1}^{n} w_i = 1,\ w_i \in [0,1]. \end{array}$$

Proposition 4. *The operator $\mathbb{D}_\alpha$ is a ME-OWA for all $\alpha \in [0,1]$, with $orness(\mathbb{D}_\alpha) = \alpha$.*

Definition 8. *F is called a generalized S-OWA operator if F is an OWA operator where*

$$\begin{array}{lcll} w_1 & = & a + \frac{1}{n}(1-(a+b)), & \\ w_i & = & \frac{1}{n}(1-(a+b)), & \textit{with } i = 2,\ldots,n-1, \\ w_n & = & b + \frac{1}{n}(1-(a+b)). & \end{array}$$

with $a, b \in [0,1]$ and $a+b \leq 1$.

Proposition 5. *Let $a, b \in [0,1]$ such that $a+b \leq 1$. If we take*

$$\alpha = \frac{1+a-b}{2}$$

then $\mathbb{D}_\alpha$ is a generalized S-OWA operator.

Definition 9. *F is called a BADD-OWA operator if F is an OWA operator where*

$$w_i = \frac{b_i^\beta}{\sum_{j=1}^{n} b_j^\beta}$$

with $\beta \geq 0$ and being b_i as in Definition 4.

Proposition 6. *Let $\beta \geq 0$. If we take*

$$\alpha = \frac{(\mathbb{D}_1(x,y))^\beta}{(\mathbb{D}_0(x,y))^\beta + (\mathbb{D}_1(x,y))^\beta}$$

with $x, y \in [0,1]$, then $\mathbb{D}_\alpha$ is a BADD-OWA operator.

Definition 10. *Let $\beta \geq 0$. F is called a modified BADD-OWA operator if F is an OWA operator where*

1. $w_i = \frac{(1/b_i)^\beta}{\sum_{j=1}^{n}(1/b_j)^\beta}$ *or*
2. $w_i = \frac{(1-b_i)^\beta}{\sum_{j=1}^{n}(1-b_j)^\beta}$ *or*
3. $w_i = \frac{1}{n-1}(1 - \frac{b_i^\beta}{\sum_{j=1}^{n} b_j^\beta})$ *or*
4. $w_i = \frac{(b_{n-i+1})^\beta}{\sum_{j=1}^{n} b_j^\beta}$

being b_i as in Definition 4.

Proposition 7. *Let $\beta \geq 0$. The following items are satisfied:*
