1. *If we take*

$$\alpha = \frac{(1/\mathbb{D}_1(x,y))^\beta}{(1/\mathbb{D}_1(x,y))^\beta + (1/\mathbb{D}_0(x,y))^\beta} =$$

$$= 1 - \frac{(\mathbb{D}_1(x,y))^\beta}{(\mathbb{D}_1(x,y))^\beta + (\mathbb{D}_0(x,y))^\beta} = \frac{(\mathbb{D}_0(x,y))^\beta}{(\mathbb{D}_1(x,y))^\beta + (\mathbb{D}_0(x,y))^\beta}$$

then $\mathbb{D}_\alpha$ is a modified BADD-OWA operator in the sense of items 1, 3 y 4 of Definition 10.

2. *If we take*

$$\alpha = \frac{(1-\mathbb{D}_1(x,y))^\beta}{(1-\mathbb{D}_1(x,y))^\beta + (1-\mathbb{D}_0(x,y))^\beta}$$

then $\mathbb{D}_\alpha$ is a modified BADD-OWA operator in the sense of item 2 of Definition 10.

Proof:

1. Obviously, taking into account items 1,3 and 4 of Definition 10 and that $\mathbb{D}_\alpha$ is an OWA operator of dimension 2.
2. Direct $\square$.

5 Image reduction

We consider an image Q as a $N \times M$ matrix. Each coordinate of the pixels in the image Q is denoted as (i,j). The intensity or gray level of the pixel located in (i,j) is represented as q_{ij}, with $0 \leq q_{ij} \leq L-1$ for each $(i,j) \in Q$.

In our approach to image reduction we use interval-valued fuzzy sets and D_α operator. It has been shown (see [13, 6, 15]) that interval-valued fuzzy sets used in images allow the development of algorithms in several topics as edge detecion, contrast or thresholding with very good results. We propose the following algorithm:

1. Divide the image Q in blocks of size $n \times n$. If M or N are not multiple of n, we delete the minimum number of rows/columns in the boundary of the image until the new size of the image satisfies the property.
2. Associate each block with an interval in the following way: the lower bound of the interval is given by the minimum of the intensities in the block and the upper bound by the maximum.
3. Choose the α parameter in the operator D_α.
4. Associate each interval with the number obtained after applying the operator D_α.

Example: Let Q be a matrix of dimension 6×6 and let $n = 3$

$$\begin{pmatrix} q_{1,1} & q_{1,2} & q_{1,3} & q_{1,4} & q_{1,5} & q_{1,6} \\ q_{2,1} & q_{2,2} & q_{2,3} & q_{2,4} & q_{2,5} & q_{2,6} \\ q_{3,1} & q_{3,2} & q_{3,3} & q_{3,4} & q_{3,5} & q_{3,6} \\ q_{4,1} & q_{4,2} & q_{4,3} & q_{4,4} & q_{4,5} & q_{4,6} \\ q_{5,1} & q_{5,2} & q_{5,3} & q_{5,4} & q_{5,5} & q_{5,6} \\ q_{6,1} & q_{6,2} & q_{6,3} & q_{6,4} & q_{6,5} & q_{6,6} \end{pmatrix}$$

Then, the interval-valued fuzzy set associated with Q is formed by 4 elements:

$$\left(\begin{bmatrix} \bigwedge_{\substack{i=1,2,3 \\ j=1,2,3}} q_{i,j} & \bigvee_{\substack{i=1,2,3 \\ j=1,2,3}} q_{i,j} \\ \bigwedge_{\substack{i=4,5,6 \\ j=1,2,3}} q_{i,j} & \bigvee_{\substack{i=4,5,6 \\ j=1,2,3}} q_{i,j} \end{bmatrix} \begin{bmatrix} \bigwedge_{\substack{i=1,2,3 \\ j=4,5,6}} q_{i,j} & \bigvee_{\substack{i=1,2,3 \\ j=4,5,6}} q_{i,j} \\ \bigwedge_{\substack{i=4,5,6 \\ j=4,5,6}} q_{i,j} & \bigvee_{\substack{i=4,5,6 \\ j=4,5,6}} q_{i,j} \end{bmatrix} \right)$$

Remark: Notice that the symbols $\wedge$ and $\vee$ stand for minimum and maximum respectively.

Once the interval-valued fuzzy set associated with the image has been obtained, we build a fuzzy set. Applying the operator D_α to each interval we get the reduced image of size 2×2.

6 Experimental results

In this section we use the algorithm proposed in Section 5. Using the relation between the operator D_α and OWA operators of dimension 2, we propose several methods of calculating the α coefficient based on families of OWA operators.

We get two different situations according to the OWA operator used. In the first one, the value of α is constant for the whole image. This situation happens with ME-OWA operators and generalized S-OWA operators, due to their definition. In the second one, the value of α depends on the bounds of each interval, so its value varies for each block. This happens when we take BADD-OWA operators and modified BADD-OWA operators.

The tests of this section have been made with the image Lena (Figure 1) and Cameraman (Figure 2). The size of the block is $n = 3$ (submatrices 3×3). In this way, the size of the reduced image is 9 times smaller than the original.

6.1 Calculation with constant α

In this section we use ME-OWA operators and generalized S-OWA to calculate a constant value of α for the whole image. Once the value has been calculated, we apply the D_α operator to each interval in the image.

6.1.1 Reduction with ME-OWA operators

As we have seen in Section 4, the construction of ME-OWA operators is direct. For this reason, we analyze three specific cases: $\alpha = 0$, $\alpha = 0.5$ and $\alpha = 1$.

With $\alpha = 0$, we associate the lower bound of the interval to each block. With $\alpha = 0.5$, we take the mean point of the interval. Finally, with $\alpha = 1$, we associate the upper bound of the interval.

Obviously, the higher the value of α, the higher the membership degree and therefore the intensity of the image. The image is darker with $\alpha = 0$ than with $\alpha = 0.5$, which is also darker than with $\alpha = 1$.

$\alpha = 0$ $\alpha = 0.5$ $\alpha = 1$

Figure 3: Reduction using ME-OWA operators

6.1.2 Reduction with generalized S-OWA operator

To construct a generalized S-OWA operator, it is necessary, as we have seen in Definition 8, the election of two parameters $a, b \in [0, 1]$ such that $a + b \leq 1$. If we focus on the contribution of the parameters in the S-OWA operator, we can study several possibilities:

1. If $a = b$, then we have that $\alpha = 0.5$, getting the average of the bounds of the interval.
2. If $a = 1$ and $b = 0$, we get $\alpha = 1$.
3. If $a = 0$ and $b = 1$, we get $\alpha = 0$.
4. If $a + b < 1$ and $a \neq b$, when $a > b$, the upper bound of the interval is predominant over the lower bound, while when $a < b$, the importance is given to the lower.

Cases 1, 2 and 3 have been already analyzed in Section 6.1.1, so we focus in case 4. For this, we start taking $a = 0.5, b = 0.25$. As $a > b$, the importance is given to the upper bound of the interval, getting a value of $\alpha = 0.625$. If we increase the value of a, then α tends to 1. For example, if we take $a = 0.9, b = 0$, then $\alpha = 0.95$. With this value of α we get a reduced image very similar to the images studied in the last column of Figure 3. On the other side, if we take $a = 0.25, b = 0.5$, we get a value of $\alpha = 0.375$. If we increase the value of b, $\alpha \to 0$. We can see this if we take $a = 0, b = 0.9$ ($\alpha = 0.05$). Notice that as α increase, the image becomes lighter.

6.2 Calculation with variable α

In this section, the value of α is calculated by means of the bounds of the interval. This means that the value of α is variable. For this reason we use BADD-OWA and modified BADD-OWA operators.

ISBN: 978-989-95079-6-8

a=0,b=0.9 $\alpha = 0.05$ | a=0.25,b=0.5 $\alpha = 0.375$ | a=0.5,b=0.25 $\alpha = 0.625$ | a=0.9,b=0 $\alpha = 0.95$

Figure 4: Reduction using generalized S-OWA operators

6.2.1 Reduction with BADD-OWA operators

As we see in Definition 9, to construct a BADD-OWA operator it is necessary to select a value of $\beta \geq 0$. We know that if we take $\beta = 0$, then we get $\alpha = 0.5$, already studied in Section 6.1.1. In other case, if we take $\beta = 1$, the value of α is calculated as follows:

$$\alpha = \frac{\overline{x}}{\overline{x} + \underline{x}}$$

being $[\underline{x}, \overline{x}] \in L([0,1])$ the interval representing each block. We also know that $\alpha \geq 0.5$, and if we increase the value of β, $\alpha \to 1$. That is, the result tends to the upper bound of the interval. For this reason, with a high value of β, we get reduced images similar as the images analyzed in third column of Figure 3.

$\beta = 1$ | $\beta = 10$ | $\beta = 20$ | $\beta = 100$

Figure 5: Reduction using BADD-OWA operators

6.3 Reduction with modified BADD-OWA operators

If we use modified BADD-OWA operators, bearing in mind items 1 and 2 of Proposition 7, we can take two different expressions for α. As we have analyzed in BADD-OWA operators, the value of α depends on the interval and on the β parameter. As in Section 6.2.1, if $\beta = 0$, then $\alpha = 0.5$.

Under conditions of item 1 of Proposition 7 and taking $\beta = 1$, the value of α is as follows:

$$\alpha = \frac{\underline{x}}{\underline{x} + \overline{x}}$$

being $[\underline{x}, \overline{x}] \in L([0,1])$ the interval representing each block. In this case, $\alpha \leq 0.5$ and as β increases, $\alpha \to 0$ when $\beta \to \infty$ (notice that the image becomes darker as β increases and α decreases).

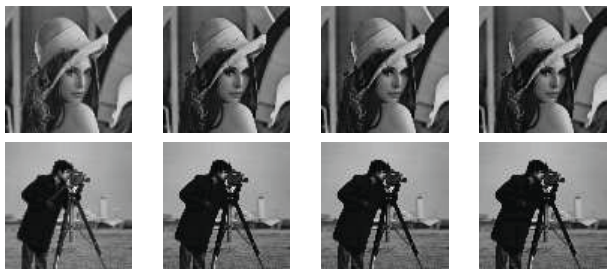
$\beta = 1$ | $\beta = 10$ | $\beta = 20$ | $\beta = 100$

Figure 6: Reduction using modified BADD-OWA operators (item 1)

If we base on item 2 of Proposition 7, for $\beta = 1$, α is as follows:

$$\alpha = \frac{1 - \overline{x}}{(1 - \overline{x}) + (1 - \underline{x})}$$

being $[\underline{x}, \overline{x}] \in L([0,1])$ the interval representing each block. In this case, the value of α also decreases when β increases.



$\beta = 1$ | $\beta = 10$ | $\beta = 20$ | $\beta = 100$

Figure 7: Reduction using modified BADD-OWA operators (item 2)

7 Conclusions and future research

In this paper, we have proved that we can obtain OWA operators of dimension 2 from Atanassov's operators. This fact has allowed us to use several families of OWA operators to get D_α operators for image reduction.

Some future lines of research can be:

1. Compare the different reductions obtained according to the value of α.
2. Compare our results with other reduction algorithms.
3. Consider different methods of reconstruction of the original image from the reduced one. Analyze which of the reduced images leads to the best reconstructed image.

***Abstract*— *In the present paper a Korovkin-type theorem is proposed for the approximation operators defined by the inverse F-transforms. These results allow us to choose between a variety of shapes to be used as atoms of the fuzzy partitions used within the F-transform's framework. In this way we can enlarge considerably the class of F-transforms proposed recently by I. Perfilieva. The new fuzzy partitions are shown to include, for example the Bernstein basis polynomials. The F-transform considered with the Bernstein basis polynomials as atoms of a fuzzy partition, is shown to be the classical Durrmeyer operator.*

***Keywords*—** F-transform, Korovkin Theorems, Bernstein Polynomial, Durrmeyer operator.

1 Introduction

The F-transform was proposed by I. Perfilieva in [4] and studied in several papers [5], [7], etc. As starting point for the F-transforms, one considers first a fuzzy partition [6]. In the present paper we enlarge the class of F-transforms by considering arbitrary shapes and not necessarily small support for the atoms of the fuzzy partition used in the F-transform as an approximation method. To study the possibility of such extension we exploit the classical Korovkin theorems, [1] which are particularized in the present paper for the F-transform. The Korovkin Theorems are very important results in classical Approximation Theory, stating that the convergence of a sequence of positive linear approximation operators on a finite set of test functions implies the convergence of the operator for any function. There are two versions of the Korovkin type results. A qualitative and a quantitative version. The quantitative versions provide error estimates, beyond proving the convergence results of qualitative type. We will adopt the quantitative approach. Further-on in the present paper we consider the F-transforms based on Bernstein basis polynomials. It turns out that the F-transform that uses Bernstein basis polynomials as atoms for the fuzzy partition under discussion, leads to the classical Durrmeyer operators [2]. In this way, the theory of fuzzy approximation and especially approximation by inverse F-transforms can be embedded and studied, as a refined part of the classical theory of approximation.

In the present paper a fuzzy partition is defined as a finite sequence of fuzzy sets $A_i : [a,b] \to [0,1]$, $i = 1, ..., k$, such that $\sum_{i=1}^{k} A_i(x) = 1$ for any $x \in [a,b]$. The following is a generalized version of the Fuzzy Transform (F-transform) proposed in [4], since the condition regarding the small support of the atoms of the fuzzy partitions occurring in the F-transform is released.

According to [4], the F-transform is given by

$$f_i = \frac{\int_a^b A_i(x) f(x) dx}{\int_a^b A_i(x) dx}, i = 1, ..., k \tag{1}$$

and the discrete F-transform is given by

$$f_i = \frac{\sum_{j=1}^{n} A_i(x_j) f(x_j)}{\sum_{j=1}^{n} A_i(x_j)}, i = 1, ..., k \tag{2}$$

where $x_j \in [a,b]$, $j = 1, ..., n$ are given data. The inverse discrete F-transform is

$$F(x) = \sum_{i=1}^{k} A_i(x) f_i. \tag{3}$$

We denote by $C(K)$ the space of continuous functions $f : K \to \mathbb{R}$ with K a compact metric space. Then the space $C(K)$ is a Banach space with the uniform norm

$$\|f\| = \sup_{x \in K} |f(x)|.$$

If $K = [a,b]$ then we use the notation

$$C[a,b] = \{f : [a,b] \to \mathbb{R}, f \text{ continuous}\}.$$

We will consider inverse F-transform as an approximation operator. Let $\mathcal{L}(C(K))$ denote the space of linear operators of the form $T : C(K) \to C(K), T(\alpha f + \beta g) = \alpha T(f) + \beta T(g)$, $\forall \alpha, \beta \in \mathbb{R}$ and $f, g \in C(K)$. An operator is said to be positive if $T(f(x)) \geq 0 \; \forall x \in K$ whenever $f(x) \geq 0, \forall x \in K$. In the present paper positive linear operators play a very important role.

The inverse F-transform will be regarded in the present paper as a sequence of positive linear operators. Indeed, let us consider $F_{n,k} : C[a,b] \to C[a,b]$, given by $F_{n,k}(f)(x) = F(x)$, where $F(x)$ is given by (3) and f_i given by (1) or (2). Then, it is easy to see that $F_{n,k}$ is a linear operator, i.e., $F_{n,k} \in \mathcal{L}(C[a,b])$. Moreover, if we assume $f(x) \geq 0$ $\forall x \in [a,b]$, we can see that both the continuous and discrete F-transforms $f_i, i = 1, ..., k$ satisfy $f_i \geq 0$, and as a consequence the inverse F-transform $F_{n,k}(f)(x) = F(x) \geq 0$ and as a conclusion $F_{n,k}$ is a positive linear operator.

In order to obtain an error estimate and the uniform convergency of the F-transforms that we intend to study, seen as approximation operators via a particularization of the Korovkin Theory related to positive linear operators. For this aim we need the modulus of continuity. Let $f : [a,b] \to \mathbb{R}$ be a continuous function. Then $\omega(f, \cdot) : [0, \infty) \to [0, \infty)$, defined by

$$\omega(f, \delta) = \bigvee \{|f(x) - f(y)|; x, y \in [a,b], \; |x - y| \leq \delta\}$$

ISBN: 978-989-95079-6-8

is called the first order modulus of smoothness (modulus of continuity) of f.

2 Korovkin type theorem for the F-transform

Let us recall Korovkin's Theorem in what follows. We can see that it is directly applicable for the F-transform, since the F-transform is a positive linear operator, however, we will deduce later particularizations of the Korovkin results for the F-transform to better understand the F-transform method and to be able to provide error estimates for them.

Theorem 1 *(Korovkin, [3]) Let $L_n \in \mathcal{L}(C[a,b])$, $n = 1,2,...$ be a sequence of positive linear operators. Then there exists a finite set of test functions S, such that $\lim_{n\to\infty} L_n(s) = s$ for any $s \in S$ implies $\lim_{n\to\infty} L_n(f) = f$, for any $f \in C[a,b]$. The finite set S is called a Korovkin set.*

If we consider a sequence of positive linear operators on $C[0,1]$, then a Korovkin set (it is not unique) consists of $e_0, e_1, e_2,$ where $e_i(x) = x^i$, $i = 0,1,2$. If we consider $\mathcal{L}(C[-\pi,\pi])$ a Korovkin set consists of e.g., $e_0(x) = 1$, $e_1(x) = \sin x$ and $e_2(x) = \cos x$.

The adaptation of Korovkin Theorem for the F-transform is as follows.

Theorem 2 *(Korovkin Theorem for the discrete inverse F-transform) Let $F_{n,k} \in \mathcal{L}(C[a,b])$, $n,k = 1,2,...$ be a sequence of inverse F-transforms. The following general error estimate holds true for any $\delta > 0$:*

$$\|F_{n,k}(f) - f\| \leq \left(1 + \frac{1}{\delta}\sqrt{e_2 - 2e_1F_{n,k}(e_1) + F_{n,k}(e_2)}\right)\omega(f,\delta),$$

where $e_1(x) = x, e_2(x) = x^2$.

Proof. The inverse discrete F-transform can be expressed as

$$F_{n,k}(f)(x) = \sum_{i=1}^{k} A_i(x)\frac{\sum_{j=1}^{n} A_i(x_j)f(x_j)}{\sum_{j=1}^{n} A_i(x_j)}.$$

Let us observe that for the inverse F-transform we have $F_{n,k}(e_0) = e_0$, where $e_0(x) = 1\ \forall x \in [a,b]$, so $f(x)$ can be written as

$$f(x) = \sum_{i=1}^{k} A_i(x)\frac{\sum_{j=1}^{n} A_i(x_j)f(x)}{\sum_{j=1}^{n} A_i(x_j)}.$$

Then we get

$$|F(x) - f(x)| \leq \sum_{i=1}^{k} A_i(x)\frac{\sum_{j=1}^{n} A_i(x_j)\,|f(x) - f(x_j)|}{\sum_{j=1}^{n} A_i(x_j)}.$$

Further, using the properties of the modulus of continuity, by standard reasoning we have

$$|F(x) - f(x)| \leq \left(1 + \frac{1}{\delta}\sum_{i=1}^{k} A_i(x)\frac{\sum_{j=1}^{n} A_i(x_j)|x - x_j|}{\sum_{j=1}^{n} A_i(x_j)}\right)\omega(f,\delta),$$

for any fixed $\delta > 0$. The error is controlled by the ratio

$$R_{n,k}(x) = \sum_{i=1}^{k} A_i(x)\frac{\sum_{j=1}^{n} A_i(x_j)|x - x_j|}{\sum_{j=1}^{n} A_i(x_j)}.$$

Using Cauchy-Schwarz inequality we have

$$\sum_{j=1}^{n} A_i(x_j)|x - x_i| \leq \left(\sum_{j=1}^{n} A_i(x_j)|x - x_j|^2\right)^{\frac{1}{2}} \cdot \left(\sum_{j=1}^{n} A_i(x_j)\right)^{\frac{1}{2}},$$

and we obtain

$$R_{n,k}(x) \leq \sum_{i=1}^{k} A_i(x)\frac{\left(\sum_{j=1}^{n} A_i(x_j)|x - x_j|^2\right)^{\frac{1}{2}}}{\left(\sum_{j=1}^{n} A_i(x_j)\right)^{\frac{1}{2}}} = \sum_{i=1}^{k} \sqrt{A_i(x)}\frac{\left(A_i(x)\sum_{j=1}^{n} A_i(x_j)|x - x_j|^2\right)^{\frac{1}{2}}}{\left(\sum_{j=1}^{n} A_i(x_j)\right)^{\frac{1}{2}}}.$$

Using Cauchy-Schwarz inequality again we obtain

$$\sum_{i=1}^{k} \sqrt{A_i(x)}\frac{\left(A_i(x)\sum_{j=1}^{n} A_i(x_j)|x - x_j|^2\right)^{\frac{1}{2}}}{\left(\sum_{j=1}^{n} A_i(x_j)\right)^{\frac{1}{2}}} \leq \left(\sum_{i=1}^{k} A_i(x)\right)^{\frac{1}{2}}\left(\sum_{i=1}^{k}\frac{A_i(x)\sum_{j=1}^{n} A_i(x_j)|x - x_j|^2}{\sum_{j=1}^{n} A_i(x_j)}\right)^{\frac{1}{2}}.$$

Taking into account that $A_i(x)\ is$ a fuzzy partition we have

$$R_{n,k}(x) \leq \left(\sum_{i=1}^{k} A_i(x)\frac{\sum_{j=1}^{n} A_i(x_j)(x^2 - 2xx_j + x_j^2)}{\sum_{j=1}^{n} A_i(x_j)}\right)^{\frac{1}{2}} = \left(x^2 - 2xF_{n,k}(e_1)(x) + F_{n,k}(e_2)(x)\right)^{\frac{1}{2}}$$

which completes the proof. ■

Corollary 3 *Let $F_{n,k} \in \mathcal{L}(C[a,b])$, $n,k = 1,2,...$ be a sequence of inverse F-transforms. If $\lim_{n,k\to\infty} F_{n,k}(e_i) = e_i$, $i = 1,2$, then $\lim_{n\to\infty} L_n(f) = f$, for any $f \in C[a,b]$.*

For the continuous case we have a similar result.

Theorem 4 *(Korovkin Theorem for the inverse F-transform) Let $F_k \in \mathcal{L}(C[a,b])$, $k = 1,2,...$ be a sequence of inverse F-transforms. The following general error estimate holds true for any $\delta > 0$:*

$$\|F_k(f) - f\| \leq \left(1 + \frac{1}{\delta}\sqrt{e_2 - 2e_1F_k(e_1) + F_k(e_2)}\right)\omega(f,\delta),$$

where $e_1(x) = x, e_2(x) = x^2$.

Corollary 5 *Let $F_k \in \mathcal{L}(C[a,b])$, $k = 1,2,...$ be a sequence of continuous inverse F-transforms. If $\lim_{k\to\infty} F_k(e_i) = e_i$, $i = 1,2$, then $\lim_{n\to\infty} L_n(f) = f$, for any $f \in C[a,b]$.*

ISBN: 978-989-95079-6-8

We observe that the inverse F-transform can be expressed as

$$F_k(f)(x) = \sum_{i=1}^{k} A_i(x) \frac{\int_a^b A_i(x) f(x) dx}{\int_a^b A_i(x) dx}$$

so, similar reasoning to the previous Theorem can be followed.

The Korovkin type Theorem above shows that if we are able to control $\sqrt{e_2 - 2e_1 F_{n,k}(e_1) + F_{n,k}(e_2)}$ for the discrete case, or $\sqrt{e_2 - 2e_1 F_k(e_1) + F_k(e_2)}$ for the continuous case, for a given sequence of fuzzy partitions A_i, $i = 1, ..., k$, then we are able to control the error for any continuous function.

3 Example

Using the Korovkin-type result shown in the previous section we consider the F-transforms, with Bernstein basis polynomials used as a fuzzy partition this time. The proposed construction leads to the well-known Durrmeyer operator. Let us recall that the Bernstein basis polynomials are

$$p_{k,i}(x) = \binom{k}{i} x^i (1-x)^{k-i},$$

$k = 1, 2, ...$ $i = 0, 1, ..., k$ $x \in [0, 1]$.

The inverse F-transform is given by

$$F_k(f)(x) = \sum_{i=0}^{k} p_{k,i}(x) \frac{\int_0^1 p_{k,i}(x) f(x) dx}{\int_0^1 p_{k,i}(x) dx},$$

that is the classical Durrmeyer operator [2]. Let us calculate $F_k(e_1)$ and $F_k(e_2)$ in this case. It is well known that $p'_{k,.i}(x) = k(p_{k-1,i-1}(x) - p_{k-1,i}(x))$. Integrating we obtain $\int_0^1 p_{k-1,i-1}(x)dx = \int_0^1 p_{k-1,i}(x)dx$, i.e., for fixed k integrals of all Bernstein basis polynomials are the same. Since $\sum_{i=0}^{k} p_{n,i}(x) = 1$ we get $\int_0^1 p_{k,i}(x)dx = \frac{1}{k+1}$. By direct calculation

$$\int_0^1 p_{k,i}(x) x dx = \int_0^1 \binom{k}{i} x^{i+1} (1-x)^{k-i} dx$$

$$= \frac{i+1}{k+1} \int_0^1 p_{k+1,i+1} dx = \frac{i+1}{(k+1)(k+2)}.$$

Also,

$$\int_0^1 p_{k,i}(x) x^2 dx = \int_0^1 \binom{k}{i} x^{i+2} (1-x)^{k-i} dx$$

$$= \frac{i+1}{k+1} \frac{i+2}{k+2} \int_0^1 p_{k+2,i+2} dx = \frac{(i+1)(i+2)}{(k+1)(k+2)(k+3)}.$$

Then we obtain

$$f_i(e_1) = \frac{\int_0^1 p_{k,i}(x) x dx}{\int_0^1 p_{k,i}(x) dx}$$

$$= \frac{i+1}{k+2} \sim \mathcal{O}\left(\frac{i}{k}\right)$$

and

$$f_i(e_2) = \frac{\int_0^1 p_{k,i}(x) x^2 dx}{\int_0^1 p_{k,i}(x) dx}$$

$$= \frac{(i+1)(i+2)}{(k+2)(k+3)} \sim \mathcal{O}\left(\frac{i^2}{k^2}\right).$$

$$F_k(e_1)(x) \sim \sum_{i=1}^{k} p_{k,i}(x) \frac{i}{k} = B_k(e_1)(x) = x,$$

where B_k denotes the usual Bernstein operator

$$B_k(f)(x) = \sum_{i=1}^{k} p_{k,i}(x) f\left(\frac{i}{k}\right)$$

and it is well known that $B_k(e_1)(x) = x$. We also have

$$F_k(e_2)(x) \sim \sum_{i=1}^{k} p_{k,i}(x) \left(\frac{i}{k}\right)^2$$

$$= B_k(e_2)(x) = x^2 + \frac{x(1-x)}{k},$$

and finally we obtain: $\sqrt{e_2 - 2e_1 F_k(e_1) + F_k(e_2)} = \sqrt{\frac{x(1-x)}{k}}$ and by the above Korovkin type results we have

$$\|F_k(f) - f\| \leq C\omega\left(f, \sqrt{\frac{x(1-x)}{k}}\right).$$

As a conclusion we observe that the F-transform is a generalization of the Durrmeyer operators. For the discrete F-transform with Bernstein basis polynomials a similar result can be proven.

4 Conclusion

Korovkin-type theorems for the discrete and continuous inverse F-transforms regarded as positive linear approximation operators were provided. As an application we have studied the F-transform with Bernstein basis polynomials as atoms of the underlying fuzzy partition. It turns out that the F-transform with Bernstein basis polynomials is the classical Durrmeyer operator. Surely one can imagine different fuzzy partitions as well, so the F-transforms can be seen as generalizations of the Durrmeyer operator.

Abstract— *A survey of fuzzy logic applications and principles in wireless communications is presented, with the aim of highlighting successful usage of fuzzy logic techniques in applied telecommunications and signal processing. To the best of our knowledge, this is the first such study of its kind. This paper will focus firstly on discerning prevalent fuzzy logic or fuzzy-hybrid approaches in the areas of channel estimation, channel equalization and decoding, and secondly outlining what conditions and situations for which fuzzy logic techniques are most suited for these approaches. Furthermore, after insights gained from isolating fuzzy logic techniques applied to real problems, this paper proposes areas for further research targeted to practice-oriented researchers.*

Keywords— Channel Equalization, Channel Estimation, Decoding, Fuzzy-hybrid systems, Fuzzy Logic, Wireless Communications

1 Introduction

Fuzzy Logic has been successfully applied in various areas pertaining to wireless communication systems. As fuzzy logic is used to model systems and situations, taking into consideration uncertainty and ambiguity, it can be an efficient tool to be utilized in problems for which knowledge of all factors is insufficient or impossible to obtain. Methods furnished with fuzzy logic have been shown to be useful in difficult conditions with respect to non-linear and time-variant systems. Additionally, the often mentioned advantages of using fuzzy logic in practical applications is to reduce complexity as well as to add robustness to the system under study.

Fuzzy logic and, more specifically, fuzzy control traditionally incorporates human expert knowledge into a rule-based framework. It may, however, be further expanded with learning algorithms to derive the fuzzy control parameters from sample data. These parameters may be obtained by combining fuzzy logic with related soft computing disciplines such as, e.g., neural networks, evolutionary computation techniques etc. On the other hand, a method developed by Wang and Mendel [1] derives the fuzzy rule base by using a combination of human experience and numerical data.

Wireless communications is a rapidly evolving industry, constantly challenging researchers for new techniques in order to meet the demands of ever higher performance and efficiency. The most obvious products of wireless communications, e.g., the worldwide adoption of the mobile telephone, wireless local area networks etc., exert a strong influence on many people's lives today.

In a wireless communication system, the *channel* is the medium by which information-bearing signals are transferred from a transmitter to a receiver. The characteristics of the channel are generally unknown, and, barring any distortion imposed by the channel, i.e., in ideal conditions, the transmitted data will be received without any errors.

In practice, however, it is unavoidable for the channel to be affected by distortion, hence degrading the performance of the receiver, severely limiting the throughput of the system. The wireless channel poses tough challenges for achieving reliable and fast transfers. While interference typically is not a major concern in wired transmission, i.e., in predicting the behavior of the signal in the transmission channel, it poses a great challenge in wireless transmission.

When there is no line-of-sight between the transmitter and the receiver, distortions to the signal in the form of effects such as scattering and reflections, etc. will follow, all of them resulting in a phenomenon called multipath propagation. Due to multipath propagation, the receiver encounters many signal paths from the transmitter, where each of these paths is delayed by an arbitrary amount and attenuated by various factors. As a result there will be a superposition of the different copies of the signal being in different phases, hence causing an amplification or attenuation of the signal power – also referred to as fading. Multipath propagation will cause previously sent data bits to smear into current data bits, referred to as intersymbol interference. The aim of the receiver in the communication system is to overcome the disturbances of the channel, intersymbol interference and noise, and correctly decode the data having been transmitted.

2 Contemporary Uses of Fuzzy Logic in Wireless Communications

In this section we will focus on fuzzy logic applications in channel estimation, channel equalization and decoding. The purpose of channel estimation is to accurately describe the channel and track its variations, and with the aid of channel equalization and decoding recover the original transmitted data. In the case of time-varying channels, adaptive techniques have to be employed and it is in this area that fuzzy techniques and/or neural networks find their main uses.

2.1 Channel Estimation

In [2] channel estimation is performed by tracking the channel coefficients, applying a fuzzy tracking method in a multipath fading Code Division Multiple Access (CDMA) [3] channel. CDMA is a spread-spectrum technology that makes it possible for transmitters to share the same frequency range. The

ISBN: 978-989-95079-6-8

fuzzy tracking method is based on Kosko's fuzzy associative memory models [4]. The fuzzy associative memory models combines fuzzy logic and a single-layer feed-forward neural network that saves the fuzzy logic rule-base in matrix form. The tracking used in [2] is iterative with the estimated symbol being used in the prediction of the coefficient. There are two inputs to the fuzzy tracker: the difference between the measured and predicted coefficients, and the change of difference between current and previous differences between the measured and predicted coefficients. The output of the fuzzy tracker yields a correction term for the next coefficient.

The motivation in [2] for using fuzzy channel estimation is due to fuzzy estimation not needing exact process models. Comparisons are made between the fuzzy tracker and a non-fuzzy tracker, a.k.a. the alpha tracker, where it is shown that the fuzzy tracker performs better under noisier multipath conditions.

Channel estimation using a fuzzy approach has also been performed with a multi-carrier modulation technique called Orthogonal Frequency Division Multiplexing (OFDM) [5]. In OFDM, multiple orthogonal subcarriers are used for the same channel. The data stream is divided into lower bit-rate data streams, each modulating a separate subcarrier.

There are two different methods for estimating the channel parameters at each subcarrier: blind channel estimation techniques and pilot assisted channel estimation, with the pilot being a reference signal used by the transmitter and the receiver. The blind channel estimation techniques do not use pilot samples and are thus more spectrally efficient, but at the cost of higher computational complexity and slower convergence rate. Pilot assisted channel estimation has typically been based either on the Minimum Mean-Square-Error (MMSE), the LS (Least Square) or the LMS (Least Mean-Square) algorithms [6], with the MMSE algorithm being more robust and performing better in time-varying channels.

In [7] a Takagi-Sugeno-Kang (TSK) [8] model is used for the pilot assisted channel estimation in an OFDM system. The TSK method is similar to that of the traditional Mamdani method – the difference being that the output of the TSK model is a linear function of the input variables instead of fuzzy sets. Pilot symbols are used in order to train the TSK fuzzy model as well updating the fuzzy model in order to track the channel. A Gaussian membership function is chosen, as it has been shown that a fuzzy system with bell-shaped Gaussians can approximate any continuous functions on compact sets to any degree of accuracy [9]. The TSK learning algorithm consists of defining the center and width of the rules dependent on the number of rules chosen, after which an adjustable parameter of the TSK model is trained from the first snapshot of the pilot subcarriers. Finally the channel transfer function is estimated and the adjustable parameter updated to track the channel. Simulation results show that the proposed TSK channel estimation model performs closely to the ideal MMSE, but with lower computational complexity.

The TSK fuzzy modeling technique used in [7] has been updated for a multiple-input multiple-output (MIMO) OFDM system in [10] with two transmit and two receive antennas. MIMO [11] is a way to increase system throughput without the need for higher transmit power or bandwidth, and has hence become a highly popular research topic. MIMO achieves increased throughput by using multiple antennas at the transmitter and the receiver. It is shown in [10] with computer simulations that the Word Error Rate (WER) is close to the MMSE method with lower computational complexity.

In [12] an MMSE linear receiver was proposed in which a fuzzy inference system was inserted into the LMS algorithm. The motivation to use fuzzy logic was for convergence and stability reasons. The LMS algorithm was modified with a fuzzy logic controlled adaptive step size and partial update. This modified algorithm was then used in simulations of noise cancellation in a space-time joint direct-sequence (DS) CDMA system in a dynamic fading multipath channel. It was shown that the performance of the authors' modified LMS algorithm was superior to that of the LMS algorithm.

The proposed algorithm in [12] was further used in [13] for channel estimation and tracking in OFDM systems for a time-variant channel. Simulation results indicated that the modified LMS algorithm had lower steady-state Mean-Square Error (MSE) and faster convergence speed compared to the ordinary LMS algorithm.

In [14], an adaptive neuro-fuzzy inference system (ANFIS) was evaluated for channel estimation in OFDM systems. The ANFIS uses a hybrid learning algorithm based on the LS and the gradient descent methods in order to train the parameters of the membership functions of a TSK fuzzy inference system. Clustering is used in order to group data and from this generate the TSK fuzzy rule-base. From the results of the computer simulations performed in [14] it can be seen that the ANFIS performs very closely to that of the MMSE algorithm albeit with less computational complexity.

2.2 Channel Equalization

Channel equalization is the process of removing the degradation caused by the channel with the aim of reconstructing the transmitted data. The wireless channel is time-variant, and in this kind of channel, non-linear distortion is usually encountered. Due to linear equalization not performing very well in these channels, efficient equalization should be both adaptive and non-linear.

The first results that seem to appear in the literature with regards to fuzzy logic applications in channel equalization are [15, 16]. Here fuzzy adaptive filters based on both the LMS and the Recursive Least Squares (RLS) algorithms are constructed and applied to channel equalization. Initially the fuzzy sets are defined over the filter input space, after which linguistic information from human experts and numerical data are combined and incorporated into the filter. The algorithms are then used to update the free parameters. The objective of using fuzzy adaptive filters is to improve the adaptation speed of the algorithms with the extra help of linguistic inference rules. The results indicate that the bit error rates of the fuzzy equalizer is close to that of the optimal equalizer.

Whereas Wang and Mendel in [15, 16] assumed a fixed delay, in [17] the delay and the membership functions are derived from training data. Two membership functions and two rules are defined that correspond to the input of the channel, which is binary, i.e. it takes on two different values. Together they form an output grounded on the conclusion of a fuzzy rule, from which an independent decision results. Test symbols are transmitted and the correlation between the de-

ISBN: 978-989-95079-6-8

sired outputs and the received signals are determined and form weights assigned to fuzzy outputs. A weighted sum of all the rules is used in the fuzzy inference, after which the defuzzified value is fed through a thresholding device for the final decision of the equalizer. The results from the simulations performed in [17] show that the fuzzy logic equalizer outperforms the LMS in non-linear channels as well as a neural network equalizer using the backpropagation algorithm. The fuzzy logic equalizer also needs fewer training samples compared to the LMS in linear channels for the same error performance.

The Wang-Mendel RLS Fuzzy Adaptive Filter [16] is extended in [18] to a complex fuzzy filter that can handle complex channel models and signals. In [19] human expert knowledge and heuristic reasoning are replaced altogether by a Multilayer Perceptron (MLP) preprocessor unit. The MLP unit consists of a 3-layer network, the training of which provides information to the fuzzy logic system. The LMS algorithm, less computationally complex than the RLS algorithm, is then used to update the free parameter of the system.

In [20] a Bayesian equalization architecture has been developed by using a fuzzy adaptive filter construction as in [15]. The adaptive equalization is visualized as a classification problem in which an observation vector is mapped to signal constellations. In contrast to a channel equalizer such as the maximum likelihood sequence estimation (MLSE) there is no need to include a channel estimator, thus making the equalization process less computationally complex. The derived fuzzy filter function in [20] using fuzzy basis functions [21], product inference, a center of gravity (COG) defuzzifier, and Gaussian membership functions, is able to properly represent the Bayesian decision solution. The performance of the fuzzy equalizer is close to the Bayesian, with the advantage of reduced computational complexity.

In [22] a further development of the fuzzy adaptive filters is presented: the type-2 fuzzy adaptive filter, which based on an unnormalized type-2 TSK fuzzy logic system using a training sequence. This is used to implement the Bayesian equalizer with a decision feedback structure, reducing the complexity of the equalizer compared to that of the transversal equalizer (TE). In contrast to a traditional transversal equalizer or filter, the decision feedback equalizer uses previous detector decisions to cancel intersymbol interference. The type-2 fuzzy sets [23] is an extension of ordinary fuzzy sets in that the membership grades are fuzzy as well. It is shown that an unnormalized output type-1 TSK fuzzy logic system is able to implement a Bayesian equalizer for a time-invariant channel, albeit being model free and not based on a Gaussian probability model. This is further developed into a more generalized form with the type-2 fuzzy adaptive filter to accommodate a time-varying channel.

To a lesser extent, work has also been conducted on blind methods for channel equalization. Blind methods are distinguished by only using information contained in the received signal, thus making both channel estimation and training data unnecessary, with the advantage of higher spectral efficiency. However, this also means that they are strongly dependent on the obtained statistical data.

In [24] the fuzzy-C-means (FCM) algorithm is used to perform joint equalization and demodulation of a signal modulated with the Quadrature Amplitude Modulation (QAM) scheme. The receiver mapping the signal onto a set of symbols can be reduced to a classification problem, rendering a clustering analysis useful. The aim of clustering analysis is to classify objects into groups or classes (clusters) with the objects in the same group having similarities. The FCM algorithm is an unsupervised algorithm, i.e., no external information outside the data itself is needed on which the algorithm operates. The membership functions are used as a measure of what degree the data is connected to the clusters, which in this particular application depends on the amplitude and the phase distances between the received symbols, i.e. the signal constellation points. The results, for a test environment with a static channel, indicate that the algorithm converges very quickly, is robust and has lower computational complexity than that of conventional MLSE receivers. One of the problems with the FCM algorithm however is that it forces points seriously degraded by noise to belong to one or more clusters with some degree, instead of giving it low or no membership in any cluster.

The FCM algorithm in [24] is improved on in [25] by introducing what is referred to as a fuzzy possibilistic C-means (FPCM) assisted blind channel equalization scheme for time-varying channels. The FPCM algorithm solves the problem with the FCM algorithm above by making it less sensitive toward the highly noisy symbol samples. The scheme also allows the receiver to take into account cluster center information in previous data, thereby improving the accuracy of the cluster centers with more data samples. However, it is also suggested that a forgetting factor might be taken into consideration to reduce the significance of cluster centers in previous data in a time-varying channel. Due to a rather large coherence time in high speed wireless transmission systems, it is stated in [25], that the accumulation of cluster centers is feasible even under time-variant conditions. The FPCM outperforms the FCM algorithm due to the former's capability of rejecting the interference of data seriously degraded by noise. It is also shown that the performance of both algorithms depend on the amount of data involved, as can be expected.

In [26] and [27] a blind equalization algorithm based on a fuzzy neural network is outlined. Equalization is performed with a combination of channel estimation and a fuzzy neural network classifier. The algorithm first blindly estimates the channel by using the fourth cumulants of the received sequences [28]. Afterward, an approximate deconvolution is carried out. The output from the deconvolution is then fed into a fuzzy neural network classifier. Simulations undertaken in time-invariant channels with 64-QAM, indicate that the convergence speed as well as BER are improved compared to that of a feedforward neural network blind equalization algorithm.

Similarly, in [29] an improvement of a feedforward neural network blind equalization algorithm is proposed by using a fuzzy neural network consisting of an input layer, a fuzzification layer, a rule layer, a normalization layer and a defuzzification layer with the aim of improving the convergence rate. Simulation results for 16-QAM shows that the fuzzy neural network has faster convergence speed and lower BER compared to that of the feedforward neural network blind algorithm.

2.3 Decoding and Equalization

In contrast to conventional communication systems where encoding/decoding and channel equalization are performed separately, turbo equalization schemes combine the two mechanisms. This combination is carried out by iterating the equalizer and the channel decoder on the same set of received data. Since turbo equalizers have been implemented with the Bayesian algorithm, and it was shown that a TSK fuzzy logic system is able to implement a Bayesian model in [22], a turbo-fuzzy equalization approach should be feasible. Such an approach was introduced in [30], where a turbo equalizer using fuzzy filters is proposed. The fuzzy turbo equalizer is introduced with the motivation that fuzzy filters could deal with uncertainty characterized by impulse noise, and also has lower computational complexity compared to the Bayesian equalizer. To adapt the parameters of the fuzzy equalizer, the back-propagation algorithm is used.

A critique against the turbo-fuzzy equalizer in [30] can be found in [31] where it is stated that the turbo-fuzzy equalizer in [30] is unable to use the *a priori* information provided by the decoder, hence not having an iterative extrinsic information exchange between the fuzzy system and the decoder. This is improved on in [31] and [32] where fuzzy turbo equalization schemes with low complexity are proposed.

In [32] a turbo equalization scheme, based on the radial basis functions (RBF), is proposed by using an extended FCM algorithm. An emphasis is made on the low computational complexity this scheme provides compared to a turbo equalization scheme based on the Jacobian RBF in the context of binary phase-shift keying (BPSK) modulation in a Rayleigh-fading channel. Simulation results show that the scheme proposed performs closely to that of the Jacobian RBF based turbo equalization scheme but with a significant reduction in computational complexity.

In [31] the Jacobian RBF turbo equalization scheme is modified by using the same Bayesian equalization architecture based on a fuzzy adaptive filter structure as introduced in [20]. The simulations are performed for BPSK and QAM in a Rayleigh fading channel, and indicate that the proposed fuzzy adaptive filter TEQ scheme considerably reduces the computational complexity with only a slight degradation in performance compared to the Jacobian RBF turbo equalization scheme, providing a trade-off for highly low complexity-oriented circuit implementation.

3 Conclusions

In this paper we have traced the research being conducted over the last two decades, leading up to current research, in which the usage of fuzzy logic in wireless communications has yielded successful results. To the best of our knowledge, this is the first such study of its kind. The three areas in wireless communications focused on in this paper have been: channel estimation, channel equalization and decoding.

In channel estimation, the fuzzy based methods to have been applied have ranged from fuzzy tracking based on Kosko's fuzzy associative memory models and the TSK model, as well as fuzzy logic used in combination with adaptive algorithms such as the LMS and RMS algorithms or a neuro-fuzzy inference system. The neural network and adaptive algorithms are commonly used in order to train the parameters of membership functions in a fuzzy inference system.

In channel equalization the research in fuzzy adaptive filters, both type-1 and more recently type-2 TSK fuzzy logic systems, from Wang and Mendel have been highly influential. These fuzzy adaptive filters are able to use input from both human experts and/or training data. Using as a foundation the adaptive fuzzy filters, a Bayesian architecture has been developed which incorporates fuzzy basis functions and Gaussian membership functions, being able to properly represent the Bayesian decision solution. Another category in channel equalization is the blind methods which uses variants of the fuzzy-C-means algorithm or a fuzzy neural network. Turbo equalization has either been based on the Bayesian equalization architecture or the clustering approach with the fuzzy-C-means algorithm.

Conclusions that can be drawn from the research collated and presented in this paper with regards to the main benefits of using fuzzy logic based methods are:

- Fuzzy logic based methods particularly perform well under non-linear and time-variant conditions, where adaptive techniques have to be employed.
- When dealing with complex models that are not completely known and varying with time, fuzzy logic based methods can be used for faster convergence and reduced complexity with a slight degradation in performance compared to that of standard methods.
- When human expert knowledge is available, a fuzzy approach is highly suitable to incorporate this knowledge to complement available numerical data.

Building on the study we have presented in this paper, there are a few research areas that we consider merit further attention. These are: fuzzy adaptive equalization techniques for time-varying MIMO-channels, and fuzzy power control in MIMO-OFDM systems. Furthermore, another interesting area in which research is being conducted, is in cognitive radio [33]. Cognitive radio is an intelligent wireless communication system that adapts to its environment with the purpose of improving the spectrum efficiency. Both signal processing and machine learning techniques are of interest in cognitive radio, with, e.g., game theory being a commonly used method to model the transmit-power control problem. Research has also been conducted in fuzzy based game theory with the aim of application in cognitive radio in [34].

The purpose of this paper has been to give a background to common problems in wireless communication systems. Moreover, a survey of relevant research has been presented in wireless communication systems in which fuzzy methods have been used successfully. The aim has been to give a condensed and clear overview of conducted research as well as highlighting the common features of the problems in which fuzzy logic has been used in order to discern future areas to be investigated further by the ambitious researcher.

Abstract *— An approach to estimate the number of rules by spectral analysis of the training dataset has been recently proposed [1]. This work presents an analysis of such a method in high performance computing environment. Two approaches for parallel implementation of the method were studied considering the structure selection genetic algorithm and the spectral decomposition. The results show that both approaches have allowed to reduce considerably the overall processing time.*

Keywords — Fuzzy rule-based classifier; genetic algorithm; spectral clustering; high performance computing.

1 Introduction

Fuzzy rule-based classifiers have been widely studied and many approaches have been reported in literature [2]. One of the main problems in the design of interpretable fuzzy rule-based models is the determination of an adequate number of rules, which is closely related to the complexity of the problem. An approach to estimate the number of rules by spectral analysis of the training dataset has been recently proposed [1]. The method employs also a genetic algorithm for structure selection, which selects the input variables and defines the number of fuzzy membership functions in the domain of each selected input variable. Although this method has obtained interpretable fuzzy rules, with good accuracy, it is very time consuming due to the numerical complexity of both the spectral decomposition and the genetic algorithm.

This work presents an analysis of the method proposed in [1] in high performance computing environment. Two approaches for parallel implementation of the method were studied considering the structure selection by the genetic algorithm and the spectral decomposition. In the first approach, only the genetic algorithm is implemented in parallel while the spectral decomposition is computed in serial. In the second approach both the genetic algorithm and the spectral decomposition are run in parallel in a two levels parallelization scheme.

This paper is organized as follows. Next section introduces the notation and parameters of the fuzzy modeling approach. In section 3 the fuzzy rule induction algorithm [1] is reviewed. In section 4 the parallel implementation is described. In section 5 the results are discussed and the conclusions are drawn in last section.

2 Fuzzy Symbolic Modeling

Consider a dataset composed of N input-output observed samples $T = \{(\mathbf{x}(t), y(t)),\ t = 1...N\}$, where $\mathbf{x} \in \mathcal{R}^p$ is a vector of input variables and $y \in \mathcal{N}$ is the output variable where a value $y = j$ refers to a class $B_j \in \mathcal{B}$.

The fuzzy symbolic model (FSM) relates a set of input symbols $\mathcal{A} = \{A_i, i = 1...n\}$ to the set of classes $\mathcal{B} = \{B_j, j = 1...m\}$ as rules in the form $A_i \rightarrow B_j$ read as:

$$\textit{if } \mathbf{x}(t) \textit{ is } A_i \textit{ then } y(t) \textit{ is } B_j. \quad (1)$$

As usual, the fuzzy model computes an approximation $\hat{y}(t) = \hat{f}(\mathbf{x}(t))$ in three steps, which are implemented as the operators:

Fuzzification:

$$\hat{\mathbf{u}}(t) = F(\mathbf{x}(t), \Xi). \quad (2)$$

Inference:

$$\hat{\mathbf{v}}(t) = I(\hat{\mathbf{u}}(t), \Phi). \quad (3)$$

Defuzzification:

$$\hat{y}(t) = D(\mathbf{v}(t)). \quad (4)$$

The operators and their parameters, which should be computed by the learning algorithm, are presented in the following [1].

2.1 Fuzzification

The compound symbol A_i in rule (1) represents a region on the input variables domain. The membership function $\mu_{A_i}(\mathbf{x}(t))$ is computed by the conjunction of p elementary symbols $\mu_{A_k^i}(x_k(t)), k = 1...p$ as:

$$u_i(t) = \mu_{A_i}(\mathbf{x}(t)) = \prod_{k=1...p} \mu_{A_k^i}(x_k(t)) \quad (5)$$

The component A_k^i in (5) is associated to an elementary fuzzy set defined in the one dimensional domain of the variable x_k. The fuzzy membership functions are supposed to be equally spaced Gaussian functions, and only the

ISBN: 978-989-95079-6-8

number of fuzzy sets in each input variable fuzzy partition is necessary to define fuzzy membership functions [1].

The table $\Xi = \{\xi_{ik}, i = 1\ldots n, k = 1\ldots p\}$ is the output of the rule induction algorithm, presented in Section 3.2. An element $\xi_{ik} \in \Xi$ defines which symbol in the partition of the variable x_k should be associated to the component A_k^i in the rule i. A value $\xi_{ik} = j$ indicates that the fuzzy set A_{kj} should be used as the component A_k^i in the rule A_i (cf. (5)).

2.2 Inference

Rule weights have been shown to allow more flexibility to the fuzzy model [3][4]. The inference operator is defined by the rule weights matrix $\mathbf{\Phi} \in [0,1]^{n \times m}$, of which each component $\varphi_{ij} = \mu_\Phi(A_i, B_j)$ represents the confidence of the rule $A_i \rightarrow B_j$. The fuzzy inference is computed by the sum-product composition operator:

$$\hat{\mathbf{v}}(t) = \hat{\mathbf{u}}(t).\mathbf{\Phi} \tag{6}$$

The rule weights matrix are computed as the solution of a bounded quadratic optimization problem, as discussed in section 3.3.

2.3 Defuzzification

In classification problems, defuzzification computes the class output index. Generally the maximum rule is used, such that the class index is computed as the component with the greatest membership value:

$$\hat{y}(t) = j : v_j(t) = \max(\hat{\mathbf{v}}(t)) \tag{7}$$

The design of the FSM is presented next.

3 Induction of Fuzzy Rules

The rule induction algorithm is based on the spectral analysis of the training dataset to determine the number of fuzzy rules. The rule-base weights are then computed by solving a bounded quadratic optimization problem.

3.1 Spectral Analysis

Consider a graph associated to the training dataset, of which the set of nodes represent the input variable samples and the set of edges is defined by the $N \times N$ adjacency (or affinity) matrix $\mathbf{A}$. The graph is undirected and weighted, hence the affinity matrix is symmetric, real valued and its elements represent the similarity between two input variable samples. In this work, the similarity metric is computed by the Gaussian function, such that each element of affinity matrix is computed as:

$$a_{ij} = \begin{cases} \exp\left(-\dfrac{\|\mathbf{x}(i) - \mathbf{x}(j)\|^2}{2\sigma^2}\right), & \text{if } i \neq j \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

where σ is a dispersion parameter that controls the spread of the similarity function, fixed in this work at $\sigma = 1$. The $N \times N$ matrix $\mathbf{D}$ is a diagonal matrix whose elements are the degree of the nodes of the graph, computed by the sum of similarities of neighbors of each node:

$$d_{ii} = \sum_{j=1..N} a_{ij} \tag{9}$$

The spectral analysis of the graph is based on the normalized Laplacian matrix, computed as [5][6]:

$$\mathbf{L} = \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2} \tag{10}$$

The rule induction algorithm is based on the spectral decomposition of the Laplacian matrix as:

$$\mathbf{L} = \mathbf{Z}\mathbf{\Lambda}\mathbf{Z}^{\mathrm{T}} \tag{11}$$

The number of positive eigenvalues of the Laplacian is used as an estimation of the number of rules [1].

3.2 The Rule Induction Algorithm

The combination of one-dimensional fuzzy sets is easier to understand than a multi-dimensional fuzzy set. Thus, the idea of the rule induction algorithm is to run a clustering algorithm on the dataset and then to associate a rule to each cluster. For each cluster, the nearest combination to the cluster center, among all possible combinations of fuzzy sets is chosen as the rule to be included in the model.

In the spectral clustering algorithm, the standard k-means algorithm is applied over the matrix $\widehat{\mathbf{Z}}$, computed as the first K columns of the eigenvector matrix $\mathbf{Z}$. Recall that the columns of $\mathbf{Z}$ are ordered according to the corresponding eigenvalues, such that the first columns correspond to the largest eigenvalues.

The rule induction algorithm is run within an outer loop for structure selection, which defines both the variables that should be used by the model and the number of fuzzy sets in each variable's domain. At each iteration, the structure selection algorithm provides the candidate structure represented by the vector $\boldsymbol{\gamma} = [\gamma_1, \ldots, \gamma_p]$, where each component $2 \leq \gamma_k \leq \gamma_{\max}$ is the number of fuzzy sets in the fuzzy partition of variable x_k and a value $\gamma_k = 1$ indicates that the variable x_k should not be considered by the model. The rule induction algorithm is sketched out in Algorithm 1.

Algorithm 1: Rule induction

input: $\boldsymbol{\gamma} = [\gamma_1, \ldots, \gamma_p]$; $T = \{(\mathbf{x}(t), \mathbf{y}(t)), t = 1...N\}$

output: $\Xi = \{\xi_{ik}, i = 1\ldots n, k = 1\ldots p\}$;

12 end
```

ISBN: 978-989-95079-6-8

The set of rules issued by the rule induction algorithm defines the premises of rules (1). The same set of rules is used for all classes, with the classification being assigned by the rule weights, which are computed as described next.

3.3 Rule Weights Optimization

The rule weight matrix can be written as $\mathbf{\Phi} = [\boldsymbol{\varphi}_1 | \ldots | \boldsymbol{\varphi}_m]$, where the vectors $\boldsymbol{\varphi}_j$ are the rule confidence weights that relates the rule premise symbol A_i to the rule consequent (class) B_j. Optimal rule weights $\boldsymbol{\varphi}_j$ can be computed in the least squares sense, by solving the following bounded quadratic programming problem for each class B_j [1][7]:

$$\underset{\boldsymbol{\varphi}_j}{minimize}\ \tfrac{1}{2}\boldsymbol{\varphi}_j^{\mathrm{T}}\mathbf{K}\boldsymbol{\varphi}_j - \mathbf{C}^{\mathrm{T}}\boldsymbol{\varphi}_j \qquad (12)$$

$$subject\ to\ 0 \le \varphi_{ij} \le 1,\ i = 1...n$$

where $\mathbf{K} = \mathbf{U}^{\mathrm{T}}\mathbf{U}$ is a strictly positive definite matrix and $\mathbf{C}^{\mathrm{T}} = \mathbf{V}_j^{\mathrm{T}}\mathbf{U}$. The matrix $\mathbf{U} = [\mathbf{u}(1) | \ldots | \mathbf{u}(N)]^{\mathrm{T}}$ is the matrix of which each line is the fuzzy vector computed for each data sample, whose components are computed as (5). The vector $\mathbf{V}_j = [v_j(1) | \ldots | v_j(N)]^{\mathrm{T}}$ contains the memberships values of class B_j for each sample in the training set, such that $v_j(t) = \mu_{B_j}(y(t))$. The bounds attempt to constrain the weights within the $[0,1]$ interval, such that they can be interpreted as fuzzy rule confidence. The bound constrains also avoid high values for the rule weight parameters, providing the smoothness of the solution.

The quadratic optimization problem defined by (12) is widely known and the solution can be computed by efficient numerical algorithms [8].

For a fixed model structure, the more the solution values $\varphi_{ij} \approx 1$, the more certain is the classifier and also the greater is the norm of the weight vector, defined by:

$$\left\|\boldsymbol{\varphi}_j\right\|^2 = \boldsymbol{\varphi}_j^{\mathrm{T}}.\boldsymbol{\varphi}_j,\ j = 1...m \qquad (13)$$

The sum $\sum_{j=1..m}\left\|\boldsymbol{\varphi}_j\right\|^2$ is thus a measure of the amount of certain rules and also can be interpreted as a measure of the classifier quality.

3.4 Structure Selection

The structure selection is implemented by a genetic algorithm (GA). Each individual in the population represents an estimation of the structure vector $\boldsymbol{\gamma} = [\gamma_1,\ldots,\gamma_p]$, which defines the variables that must be included in the model and also the number of fuzzy sets in the domain of each variable.

The GA fitness function is computed as a trade-off between the model's accuracy and capacity according to the required complexity of the problem [1]:

$$R(\boldsymbol{\gamma}) = \frac{1}{2N}\sum_{j=1...m}\left\|\mathbf{U}(\boldsymbol{\gamma})\boldsymbol{\varphi}_j(\boldsymbol{\gamma}) - \mathbf{V}_j\right\|^2 + \frac{1}{2N}\sum_{j=1...m}\left\|\boldsymbol{\varphi}_j(\boldsymbol{\gamma})\right\|^2 \qquad (14)$$

where the firs term represent the model accuracy and the second accounts for model quality according to (13). The factor $\frac{1}{2N}$ is used to rescale the fitness function to the $[0.1]$ interval.

The GA performs simultaneously the selection of input variables to be considered in the model and the number of fuzzy sets in the domain of each (selected) variable. During the GA execution, it is frequently necessary to evaluate an individual that has been previously evaluated. The number of fuzzy rules is computed from the spectral analysis, which is a function only of the selected input variables. It is thus possible that two different individuals select the same input variables such that they will result in the same number of rules. In order to avoid the unnecessary reevaluation of the spectral analysis for individuals related to the same subset of variables, the number of rules computed by the solution of (11) is stored and related to the corresponding subset of variables. Consequently, the eigendecomposition (11) for a new individual is computed only if the corresponding subset of variables has not been evaluated before. The fitness functions for all visited individuals are also stored such that for a new individual, identical to another already evaluated, the fitness function (14) is not reevaluated.

The GA parameters for all tests described in section 5 were the same. The population was fixed at 32 individuals. An uniform crossover operator with 85% crossover rate was used. The mutation rate was set in 5%. The maximum number of iterations was fixed at 150. A value $\gamma_{\max} = 8$ was used to limit the number of fuzzy sets per variable.

All the implementation was made by free source software available on the web. The GA was implemented in Python programming language. The most computationally expensive tasks (spectral analysis and the rule weights optimization) were implemented in C using standard libraries.

4 Parallel Implementation

The structure selection GA is a very intensive computational task, since each candidate evaluation requires the solution of equation (11) and the GA itself requires the evaluation of a number of individuals during several iterations. The modern multi-core hardware platforms allow the reduction of the global processing time in complex application through parallel implementation.

Depending on the application and the available hardware resources, the parallelism can be exploited in different ways, through the partitioning of the problem with respect to data and/or tasks. In data parallelism, the same task is allocated to different processors, where each one of them works with a different portion of the data. This approach applies to problems whose solution involves a great mass of data. In task parallelism, different tasks are allocated to different

ISBN: 978-989-95079-6-8

processors. This approach applies to problems where there is interdependency among the tasks.

When designing a parallel program, the communication among the processors involved in the execution must be considered carefully. There are two main communication paradigms in parallel applications: memory sharing and message passing. The memory sharing parallel programming model is based in the same principle as the serial programming; essentially, a single memory addressing space is used during the program execution flow. The message passing programming is conceptually independent of the hardware platform, operating system and programming language. As the memory addressing spaces are different in each process the concept of message is used. A message is a set of information that can be sent from process to another through a communication channel.

One of the most known and complete libraries for message passing is the Message Passing Interface (MPI). The MPI is a standardized and portable message passing library designed for distributed memory environments, parallel machines and heterogeneous network. In MPI programs, all the parallelism is explicit, i.e., the programmer must code the synchronization points and the message passing calling the functions. Each process, receives a copy of the entire parallel program code.

In this work two parallel strategies are evaluated: in the first one only the GA is implemented in parallel; in the second one, both the GA and the spectral analysis for each individual are processed in parallel in a two levels strategy.

4.1 Parallel Genetic Algorithm

Several features of GAs allow its parallelization in a very natural way and many approaches have been reported in literature [9]. The main approaches are divided in three types: fine-grained single population GA, coarse-grained multiple population GA and single global population master-slave GA.

Fine-grained parallel genetic algorithms use just one population, but there is a special structure that limits the interaction among the individuals. An individual can only compete and operate with individuals that belong to his neighborhood, which is assigned by a predefined topology.

Coarse-grained parallelization model, also known as island model, uses several populations that occasionally change individuals through migration operator. In island GAs, each sub-population evolves as in traditional GAs, excepting for the migration operator among different islands.

The master-slave parallel genetic algorithms, also known as parallel global population GAs, use a single population and the parallelization is done in the evaluation of the individuals. As in a traditional serial GA, each individual competes and operates with any other individuals in the population. In master-slave genetic algorithms, a master process is responsible by the application of the genetic operators to the population (selection, crossing, mutation) while the slave processors are responsible by the individuals' evaluation [10]. The communication among the individuals occurs when the master process sends the individuals to the slave processes and when the slave processes return their fitness values to the master.

In this work, a master-slave parallel implementation was used for the structure selection GA. The adoption of such GA parallel model is useful, since its implementation is independent of the machine architecture and of the communication model among the processes.

4.2 Two Levels Approach: Parallel GA with Parallel SA

The complexity of a full eigenproblem like (11) is $O(N^3)$ in processing time and $O(N^2)$ in storage requirements. In Algorithm 1, the solution of (11) requires the solution of an eigenproblem of the size of the number of records of the dataset N. The two-level strategy considers thus the parallelization of the spectral analysis (SA) for each individual, within the parallel GA.

The schematic representation of the two-level strategy is shown in Fig. 1. In the higher level there is the GA parallelism, where the master performs the operations over the population and sends the individuals to the slaves. In the lower level is the SA parallelism, where each slave shares the eigenproblem solution with other processors.

The two levels strategy is possible due to the concept of communicators groups in the MPI library that allows the definition of modules that encapsulate the communication operations within a group. The communicator identifies the group of processes and the context in which a given operation must be applied. The MPI library provides a standard communicator, called MPI COMM WORLD, which identifies every processes involved in the computation through global identifiers.

The execution of the GA is performed by the processors that belong to Group 0 (cf. Fig. 1.). Each slave processor in Group 0, also belongs to another group, which is responsible for computing the SA. Thus, new sub-communicators must be created, allowing the communication within each group of slave processors.

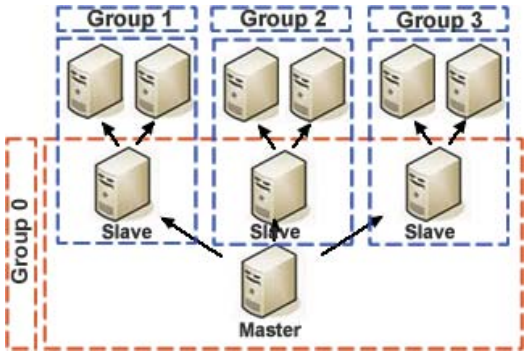

Fig. 1: Two-level Parallel Architecture

There are numbers of software libraries that implements parallel eigenproblem solution using different numerical methods. In this work, SLEPc (Scalable Library for Eingenvalue Problem Computation [11]) was adopted. SLEPc is a software package for solution of large scale problems built over PETSc (Portable, Extensible Toolkit for

ISBN: 978-989-95079-6-8

Scientific Computation), which is a set of libraries of data structure and routines for parallel scientific applications.

The Krylov-Schur solver, which implements the Arnoldi method for eigenvalues problem solution, was adopted in this work. It is probably the most robust solver in SLEPc [11].

5 Results and Discussion

5.1 Performance Results

Four benchmark datasets from the UCI Machine Learning Repository [12] were considered for the performance evaluation. Some synthetic datasets, with 18 variable and different numbers of records, were also considered. These datasets were considered in order to exploit a greater problem size.

Each benchmark evaluation was performed in 10-fold cross validation analysis. The evaluation of each benchmark was repeated 10 times to ensure the GA generalization. The average results for each dataset are shown in Table 1, where Acc. is the average accuracy (computed for the 10-fold cross validation) and Time is the average global time (in seconds) of the serial implementation. For the synthetic datasets just the time results were considered and the time values correspond to the execution time for just one GA generation.

All tests were run an 8-core Linux cluster composed of two machines, each one equipped with two dual-core Intel Xeon processors (1.6GHz) and 4GB DRAM. The serial processing time was computed using only one processor.

Table 1: Performance Results.

Dataset	p	m	N	rules	Acc.	Time
Diabetes	8	2	768	12.5	78.67	1795.72
Ionosphere	32	2	344	26.7	91.47	4752.24
Balance	4	3	625	8.3	81.41	145.69
Cancer	9	2	683	8.4	98.13	1665.62
Synthetic 1	18	-	1000	-	-	99.68
Synthetic 2	18	-	2000	-	-	580.18
Synthetic 3	18	-	3000	-	-	1952.7
Synthetic 4	18	-	4000	-	-	4339.75

As seen in Table 1, the modeling approach has obtained good accuracy with small number of rules results. The accuracy results obtained for the same datasets by other algorithms can be found in [1]. The focus of the analysis in this work is on the processing time and parallelization efficiency.

5.2 Parallel GA Results

The processing time (in seconds) of the parallel GA (with serial SA) implementation are shown in Table 2. The parallel processing time as a percentage of the serial processing time is also shown in Table 2. It can be seen that the parallel GA reduces the global execution time considerably.

Table 2: Execution time for parallel GA (with serial SA).

	2 Proc.		4 Proc.		8 Proc.	
	Time	%	Time	%	Time	%
Diabetes	1194.8	66.5	738.28	41.11	550.75	30.67
Ionosphere	2517.57	52.97	1354.1	28.49	853.56	17.96
Balance	107.29	73.64	88.35	60.64	69.51	47.71
Cancer	1070.35	64.26	696.54	41.81	476.76	28.62
Synthetic1	54.79	54.96	47.66	47.81	54.16	54.33
Synthetic2	317.14	54.66	210.73	36.32	230.89	39.79
Synthetic3	1050.2	53.78	700.89	35.89	620.05	31.75
Synthetic4	2380.84	54.86	1765.83	40.68	1486.28	34.24

The parallel efficiency of the parallel GA algorithm is shown in Fig. 2. The parallel efficiency was computed in the standard way as [13]:

$$\varepsilon_P = 100.\frac{1}{P}\frac{T_S}{T_P} \tag{15}$$

where P is the number of processors, T_S the serial processing time (in seconds) and T_P is the parallel processing time using P processors.

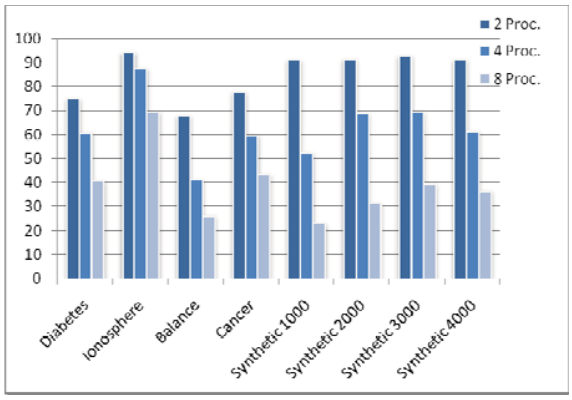

Fig. 2: Parallel Efficiency for Parallel GA With Serial SA.

The parallel efficiency decreases as the number of processors increases, due communication overhead and the load imbalance introduced by the reevaluation avoiding scheme, since the number of evaluated individuals is not the same for all the slave processes. A processor with fewer individual's evaluations will become idle waiting the other processors finish their work to synchronize in a new generation. The resulting load imbalance reflects in a great damage to the overall parallel efficiency.

The results show that this approach is not good for large datasets, since each GA individual evaluation allocates an instance of the Laplacian matrix in memory, making a bad use of the memory resources available.

5.3 Parallel GA with Parallel SA Results

The execution times (in seconds) of the two levels approach for the studied datasets are shown in Table 3 as so as the percentage of the serial processing time.

Table 3: Execution times for the two levels approach.

ISBN: 978-989-95079-6-8

The parallel efficiency of the two-level approach for the same datasets are shown in Fig. 3.

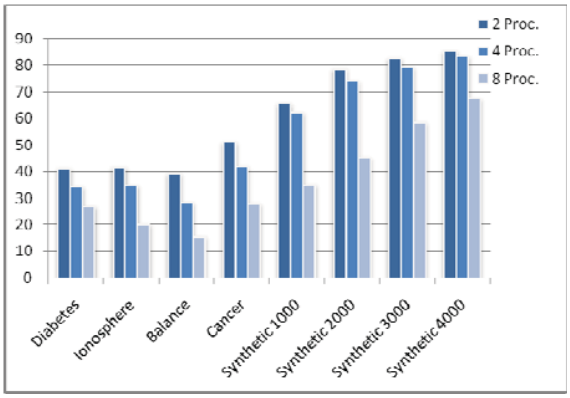

Fig. 3: Parallel Efficiency for the Two-Level Approach.

The results in Table 3 and Figure 3 show that for the four benchmark datasets studied, the global execution time is greater than the results presented for the parallel GA with serial SA. Consequently, the parallel efficiency is lower when compared to the results presented by those approach. This indicates that for small size datasets, the parallelization of the eigenproblem solution is not efficient. For larger datasets, the two levels approach shows more interesting results since the synthetic datasets present better results for the two levels approach when compared to the parallel GA with serial SA. This comparison indicates that, for datasets with a great number of records, the SA parallelization can be a good idea since it reduces the load imbalance introduced by the reevaluation avoiding strategy and makes a better use of the memory available for the method execution, since the Laplacian matrix used in the spectral analysis is sliced for the involved processes.

6 Conclusions

The design of fuzzy symbolic models [1] is focused on the interpretability and the resulting model's structure is selected by a wrapper genetic algorithm that defines the variables that should be included into the model and the number of fuzzy sets in the partition of each variable. The number of rules is determined by a spectral analysis method and rules' weights are optimized.

This work has evaluated two approaches for the parallel implementations of the fuzzy symbolic models. Both approaches have reduced the global execution time of the algorithm when compared to the serial times, which was the main drawback of the previous implementations.

The parallel efficiency results indicate that, even with the load imbalance introduced by the reevaluation avoiding strategy, the GA parallelization is an interesting approach for smaller datasets and the two-level approach is a good approach for larger datasets. Further studies may be done in order to increase the load balance among the processors and evaluate the implementation behavior for larger datasets.

Abstract—*We describe a method for edge detection in digital images based on the morphological gradient and fuzzy logic. The goal is to improve one of the basic methods for edge detection in order to obtain a better result even without applying any filter to the image. The tests were made with a type-1 fuzzy inference system (T1FIS) and with an interval type-2 fuzzy inference system (IT2FIS). We show that the images obtained with fuzzy logic are better than the ones obtained with only the morphological gradient method. In particular the IT2FIS achieved the best results, because of the flexibility to model the uncertainty in the gradient values and the gray ranges for the edge images. In both TIFIS and IT2FIS the membership function parameters were obtained directly from the images; this allows application of the proposed method to images with different gray scales.*

Keywords— digital images, edge detection, image processing, interval type-2 fuzzy logic.

1 Introduction

Edge detection is an intermediate step in image pattern recognition in digital images and has the opposite effect of noise elimination; it consists on emphasizing pixels with gray tones that are different than their neighbours [1]. Some of the existing methods for edge detection have been enhanced with type-1 fuzzy logic [2][3], fractal theory [4][5], neural networks [6][7][8] and recently with interval-valued fuzzy operators [9].

In previous works proposed by the authors, the improvement of the Sobel edge detector using an IT2FIS was achieved [10][11]. The images resulting from these experiments were used as training data for image recognition with modular neural networks, obtaining good results [12][13].

In this paper, an improvement of a traditional edge detection method based on the morphological gradient is presented. This method does not need any filter to obtain the edges, but it is necessary to perform calculations in order to find the relation of each pixel of the image with the eight neighbours pixels around it.

In section two we present a brief description of an edge detection method based in morphological gradient, in section three we explain our contribution consisting on the development and tests with a type-1 fuzzy inference system and an interval type-2 fuzzy inference system; in both cases we apply the same criteria and conditions, for a valid comparison of the results. Section four shows the obtained results with the three methods. The main topic in this paper is the comparison of the results obtained with the IT2FIS, applying different footprint of uncertainty (FOU).

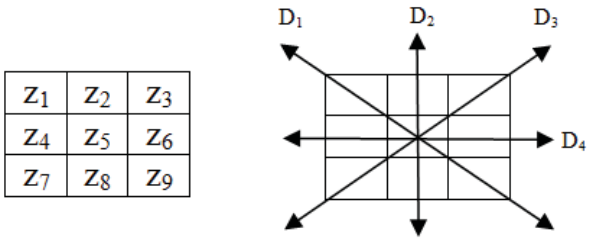
2 Edge detection using morphological gradient

The morphological gradient of a grayscale image can be viewed as the greatest absolute intensity difference between any two pixels within the structuring element, and can be defined with Equation (1) [14].

$$\left| \nabla(f) = \delta_g(f) - \varepsilon_g(f) \right| \tag{1}$$

For the discrete case, we use D_i instead $\nabla(f)$, then if we apply (1) to a 3x3 sample matrix as shown in Fig. 1, we can to obtain coefficients z_i with Equation (2), the possible edge directions D_i with (3). An approximation of (3) can be calculated without the root square using the absolute values of the differences instead the square values (4). The edges E can be calculated with Equation (5) [15][16].

$$\begin{aligned} z_1 &= f(x-1, y-1) & z_2 &= f(x, y-1) \\ z_3 &= f(x+1, y-1) & z_4 &= f(x-1, y) \\ z_5 &= f(x, y) & z_6 &= f(x+1, y) \\ z_7 &= f(x-1, y+1) & z_8 &= f(x, y+1) \\ z_9 &= f(x+1, y+1) \end{aligned} \tag{2}$$



Z1	Z2	Z3
Z4	Z5	Z6
Z7	Z8	Z9

Figure 1: A 3x3 sample matrix with coefficients and edge directions.

ISBN: 978-989-95079-6-8

$$D_1 = \sqrt{(z_5 - z_1)^2 + (z_9 - z_5)^2} \quad (3)$$
$$D_2 = \sqrt{(z_5 - z_2)^2 + (z_8 - z_5)^2}$$
$$D_3 = \sqrt{(z_5 - z_3)^2 + (z_7 - z_5)^2}$$
$$D_4 = \sqrt{(z_5 - z_4)^2 + (z_6 - z_5)^2}$$

$$D_1 = |z_5 - z_1| + |z_9 - z_5| \quad (4)$$
$$D_2 = |z_5 - z_2| + |z_8 - z_5|$$
$$D_3 = |z_5 - z_3| + |z_7 - z_5|$$
$$D_4 = |z_5 - z_4| + |z_6 - z_5|$$

$$E = D_1 + D_2 + D_3 + D_4 \quad (5)$$

The edge image obtained with Equation (5) does not consider any parameters to prevent noise or regions with very low or high contrast. Then some very dark or bright images could be a problem for this edge detector.

3 Edge detection using a fuzzy inference system

The fuzzy approach for edge detection using morphological gradient consists of using Equation (3) or (4) to obtain the gradient in the four directions, and use them as inputs for a fuzzy inference system (FIS) instead the Equation (5). This approach allows us to analyze the gray tones range of any particular image and use them as parameters to the membership functions in the FIS.

3.1 Type-1 fuzzy linguistic variables

The inputs to consider for the T1FIS are the morphological gradients D_i for each pixel with respect to a 3x3 neighbourhood matrix. The membership functions must represent the magnitude of the gradient. In order to adapt the membership functions to the range of gray tones depending on the image, we obtain the maximum, minimum and middle values of D_i, and we use these values for the centre of the membership functions, as shown in the example of Fig. 3.

The σ value for the particular example plotted in Fig. 3 is 20, the Gaussian membership functions for each D input were obtained with (9)(10) and (11), and the center of each function were obtained with (6)(7) and (8). This is the method that we propose to adapt the parameters of the membership functions depending on the contrast level of each image.

$$dlow_i = \min(D_i) \quad (6)$$
$$dhigh_i = \max(D_i) \quad (7)$$
$$dmiddle_i = dlow_i + (dhigh_i - dlow_i)/2 \quad (8)$$

$$\mu(dlow_i) = e^{\frac{-(x-dlow_i)^2}{2(\sigma_i)^2}} \quad (9)$$
$$\mu(dhigh_i) = e^{\frac{-(x-dhigh_i)^2}{2(\sigma_i)^2}} \quad (10)$$
$$\mu(dmiddle_i) = e^{\frac{-(x-dmiddle_i)^2}{2(\sigma_i)^2}} \quad (11)$$

where $\sigma_i = dhigh_i / 8$

For the outputs E (the edges), we select the range [0,255] as the gray tones scale, then we can obtain these membership functions directly with (12)(13) and (14). If some application needs a different gray tones scale, is necessary to adjust the values of *black*, *gray* and *white* of (12), (13) and (14) to the desire scale.

$$\mu_{black} = e^{\frac{-(x-black)^2}{2\sigma^2}} \quad (12)$$

where black=0

$$\mu_{gray} = e^{\frac{-(x-gray)^2}{2\sigma^2}} \quad (13)$$

where gray=255/2

$$\mu_{white} = e^{\frac{-(x-white)^2}{2\sigma^2}} \quad (14)$$

where white=255

where $\sigma = white/8$

In order to plot the membership functions for the inputs D_i of the FIS, as particular example we used the image in Fig. 2. First the image was converted to gray scale, then the following values were calculated, for each variable D.

$dlow_1$=0, $dmiddle_1$=94.7, $dhigh_1$=189.4, σ_1=23.6
$dlow_1$=0, $dmiddle_2$=87.9, $dhigh_2$=175.8, σ_2=21.9
$dlow_1$=0, $dmiddle_3$=89.8, $dhigh_3$=179.6, σ_3=22.4
$dlow_1$=0, $dmiddle_4$=75.6, $dhigh_4$=151.3, σ_4=18.9

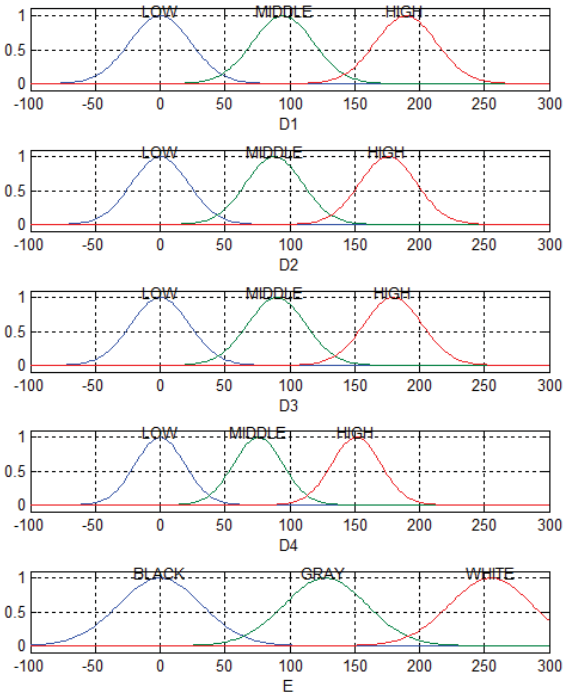

Figure 3: Linguistic variables for the TIFIS corresponding to the image in Fig. 2.

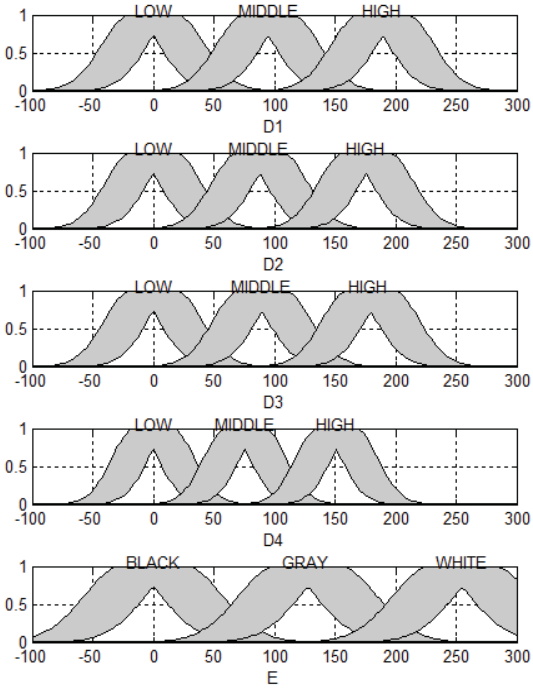

Figure 4: Linguistic variables for the IT2FIS corresponding to the image in Fig. 2, with $FOUd_i=0.4*dmiddle_i$

3.2 *Interval type-2 linguistic variables*

As we previously mentioned, the edge detection method proposed in this paper can be adapted to images with different contrast levels, but particularly the use of interval type-2 fuzzy sets enables us to handle the uncertainty by adding some FOU to the membership functions [17].

To compare the improvement of the edge detector using interval type-2 fuzzy sets, we build an IT2FIS using the same parameters than the TIFS [18]. The membership functions were obtained with Equations (6)-(14), but adding different sizes of FOU.

We made tests using different sizes of the FOU for the input variables D_i, using $dmiddle_i$ as parameter to obtain the values respect to the image contrast, in a proportional manner. The FOU sizes for D_i, then can be obtained using (15).

$$FOUd_i = \varepsilon * dmiddle_i \tag{15}$$

where ε is in (0,1)

The FOU for the output variable E, was calculated in a similar way to the inputs variables. In this case, we obtain the FOU values using *egray* as parameter (16).

$$FOUe = \varepsilon * egray \tag{16}$$

where ε is in (0,1)

The plot in Fig. 4, shows the linguistic variables with interval type-2 membership functions where the value for ε is *0.4*, adding $FOUd_i/2$ for inputs D_i and $FOUe_i/2$ for the output E, at each side of the center of the membership functions; then all the functions are symmetric.

3.3 *The rules*

The task of the fuzzy inference systems is to estimate a value for each pixel, which better describes the relation with its neighborhood.

1. If (D1 is HIGH) or (D2 is HIGH) or (D3 is HIGH) or (D4 is HIGH) then (E is WHITE)
2. If (D1 is MIDDLE) or (D2 is MIDDLE) or (D3 is MIDDLE) or (D4 is MIDDLE) then (E is WHITE)
3. If (D1 is LOW) and (D2 is LOW) and (D3 is LOW) and (D4 is LOW) then (E is BLACK)

The first rule establishes that a high gradient in any direction means an edge, the second rule is similar to the first one, because after many experiments with different images, a medium magnitude of the gradient in any direction results also in an edge, and the third rule is only to confirm the first two, because all derivatives with low magnitude means a homogeneous region in the image, that means there are not edge in this pixel. In Fig. 5 the solution surfaces for the TIFIS and IT2FIS are shown.

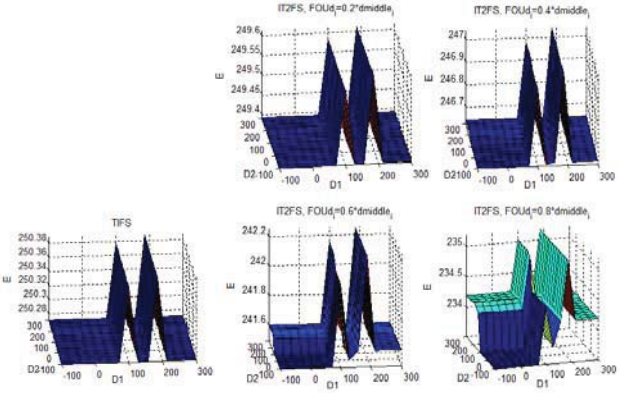

Figure 5: The solution surfaces for the image in Fig. 2, for TIFIS and IT2FIS with different FOU sizes.

ISBN: 978-989-95079-6-8

4 Experimental results

For a better appreciation of the results, we developed some programs in Matlab to obtain the edge image, under the same conditions. In all the images the morphological gradients were obtained with (2) and (3), then using the morphological gradient (MG) the edges were calculated with (5). For the fuzzy methods T1FIS and IT2FIS we use a fuzzy inference system instead of the gradient (5).

We choose Gaussian membership functions for all the variables of the both FIS (TIFIS and ITFIS), only for an easy configuration, because as we explained in section three we used the values obtained with the morphological gradient of each particular image to estimate the parameters for the membership functions.

For the first test, we used a sample of the ORL databases of faces, and selected arbitrary values for the FOU, only to demonstrate that the images obtained using IT2FIS are better that the images obtained with TIFIS. In the example of Fig. 6, we see the changes on the images with different values of the FOU. The best image is the one obtained with FOU=40, while the image obtained with T1FIS looses some details. For all the tests the use of the FIS's improve the results of the MG traditional method.

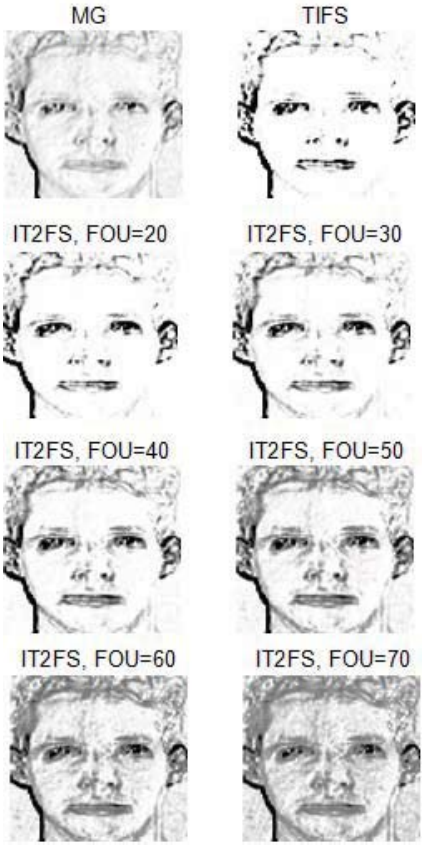

Figure 6: Edges images obtained using Morphological Gradient (MG), and the same method improved with a type-1 fuzzy system (TIFIS), and an interval type-2 fuzzy system (IT2FIS), with arbitrary FOU values.

For a better analysis of the results we plot frequency histograms for each result in Fig. 6. The histograms show that the images obtained with the IT2FIS when the FOU is increased, between 30 and 40, found more pixels corresponding to the edges preserving more details than T1FIS, but when the FOU increases more than 40, the pixels near white decreases, showing more noise in the background.

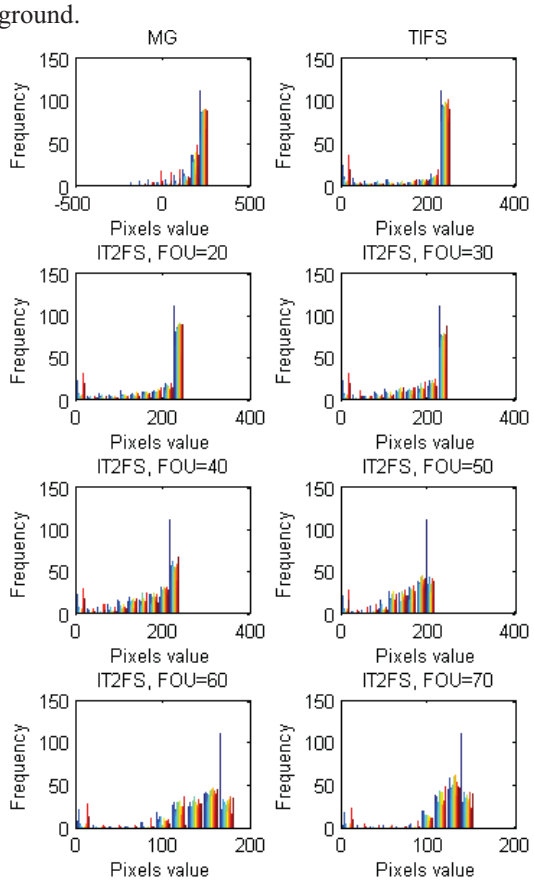

Figure 7: The frequency histograms correspond of the images shown in Fig. 6.

The second test, shown in Fig. 8, was made with an image used as benchmark for edge detection algorithms, and confirms the results obtained in Fig. 6.

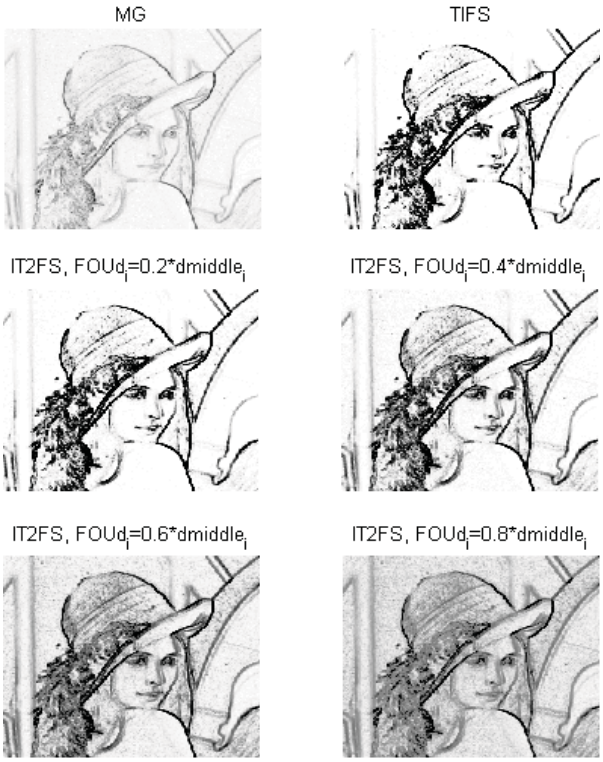

Figure 8: Edges achieved with FOU values obtained directly of the original image with equations (15) and (16).

ISBN: 978-989-95079-6-8

As we can see in Fig. 8 and Fig. 9, the edges can be seen better with the TIFIS method than de morphological gradient method, but more details of the image can be seen with the IT2FIS method when $FOUd_i=0.4*dmiddle_i$. Obviously the images obtained with a FOU near 0 are similar to the images obtained with the T1FIS. The image with $FOUd_i \geq 0.6*dmiddle_i$ show more details, but includes some textures that are not desired for edge detection.

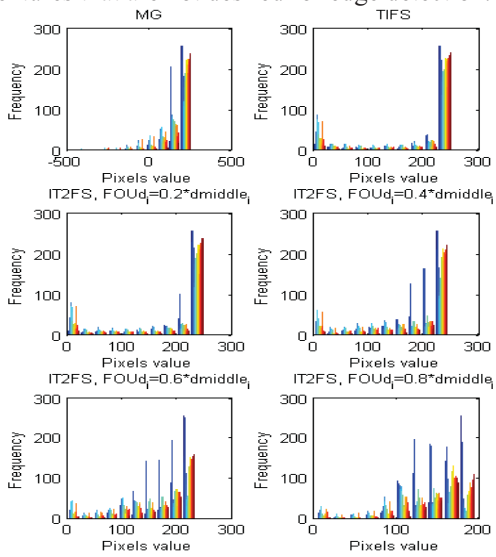

Figure 9: The frequency histograms correspond of the images shown in Fig. 8.

The parameters used for the T1FIS and IT2FIS in the tests of Fig. 8 and Fig. 9, were calculated with equations (6)-(16) and have the following values:

$dlow_1=0,\ dmiddle_1=105.9,\ dhigh_1=211.9,\ \sigma_1=26.4$
$dlow_1=0,\ dmiddle_2=109.6,\ dhigh_2=219.2,\ \sigma_2=27.4$
$dlow_1=0,\ dmiddle_3=107.5,\ dhigh_3=215.0,\ \sigma_3=26.8$
$dlow_1=0,\ dmiddle_4=74.6,\ dhigh_4=149.2,\ \sigma_4=18.6$
$\sigma e=31.8$

In Table I we show the numeric values of the FOUs used in the experiment below.

TABLE I: FOU values for the tests shown in Fig. 8.

FACTOR	$FOUd_1$	$FOUd_2$	$FOUd_3$	$FOUd_4$	$FOUE$
0.2	21.1	21.9	21.5	14.9	25.5
0.4	42.3	43.8	43.0	29.8	51.0
0.6	63.5	65.7	64.5	44.7	76.5
0.8	84.7	87.6	86.0	59.6	102

Figure 10: The original images used for the tests shown in Table II.

To finish the tests in this work, we repeat the same experiment with the images shown in Fig. 10, and compare the results with traditional algorithms [19] like the Canny and Sobel methods, as we can see in Table II.

TABLE II: Tests with Canny and Sobel methods using the Matlab defaults, and the best result using MG+IT2FIS.

Canny	Sobel	MG+IT2FIS
		

For all the tests we used the default parameters of Matlab. One of the images is a sample of the ORL database of faces

ISBN: 978-989-95079-6-8

[20], which is a set of images that are usually considered to compare the behavior of different image processing methods [21].
The other images are some of the typical images used for evaluation of edge detection algorithms, and were obtained them in the USC-SIPI Image Database [21].

In order to compare the results with the Canny and Sobel algorithms, we made modifications on the rules consequents, to obtain white edges and black background as the Matlab algorithms do it.

In all the tests we can observe that the images obtained with our method preserve more details of the original images than the traditional methods; that is good for the human observation. In the other hand, the images obtained with MG+IT2FIS are better to use in an image recognition application, because the training algorithm have more information to learn the image pattern. We can conclude that using interval type-2 fuzzy logic can improve edge detection in benchmark images, and for this reason it can be considered a good alternative for image processing.

5 Conclusions

The experiments presented in this paper show that the use of fuzzy inference systems can improve traditional methods for image processing. In particular, the morphological gradient method for edge detection, considered as one of the basic ones, when enhanced with an interval type-2 fuzzy inference system, results in a combination with satisfactory results. Especially the capability of the IT2FIS to model uncertainty in the morphological gradient and gray tone values for the edges achieved better images than the obtained with the T1FIS, because preserves more details of the original image.

Comparison of two versions of the Ferrers property of fuzzy interval orders

Susana Díaz[1] Bernard De Baets[2] Susana Montes[1]

Abstract— *We focus on the Ferrers property of fuzzy preference relations. We study the connection between the Ferrers property and fuzzy interval orders. A crisp total interval order is characterized by the Ferrers property of its strict preference relation. Also, a crisp preference structure is a total interval order if and only if its large preference relation satisfies the Ferrers property. For fuzzy relations the Ferrers property admits two non equivalent expressions. Here we compare both conditions by means of completeness. We also study if they characterize a fuzzy total interval order.*

Keywords— completeness, Ferrers property, partial interval order, total interval order, fuzzy relation

1 Introduction

Preference structures are the basis of the preference modelling theory. They formalize the answers of a decision maker over a set of alternatives. Formally, they are triplets of binary relations. For each pair of alternatives, any decision maker provides one (and only one) of the following answers: preference (by one of the alternatives), indifference (between both alternatives), inability to compare (the alternatives). These three situations lead to the three relations that make up a preference structure. Associated to a preference structure we find a relation called large preference relation that characterizes the preference structure from which it comes. Those four relations are the basis of the preference modelling ([9]).

Any preference structure can contain non-coherent relations if the decision maker gives conflicting answers. Different properties were formalized to model coherence. The Ferrers property is one of the most important ones. It has been proved to be a more realist condition than transitivity since the Ferrers property of the large preference relation does not imply the transitivity of the associated indifference relation (a non-realistic condition for some authors). However it does imply the transitivity of the strict preference relation. In a preference structure without incomparability, the large preference relation satisfies the Ferrers property if and only if the associated strict preference relation does.

A class of coherent preference structures are (total) interval orders: the alternatives can be identified with intervals not necessarily of the same length on the real line. A crisp preference structure without incomparabilities is a (total) interval order if and only if its associated large preference relation or its strict preference relation satisfy the Ferrers property.

Since several years ago, crisp relations are considered not flexible enough to model human decisions. In order to model real life situations in a more accurate way, fuzzy relations were introduced [10] and they have received a wide attention (see, e.g., [2, 3, 4, 6]). The notion of fuzzy preference structure was a topic of debate for several years. In this work we present a similar study for the notion of fuzzy interval order. This notion admits many different equivalent definitions in the classical context. We focus on the characterizations based on the Ferrers property. We first discuss the Ferrers property for fuzzy relations. This property admits two different ways to be formalized in our wider context. We compare them and we study their connection to fuzzy interval orders. In this context, a t-norm is needed to define fuzzy interval orders and the Ferrers property. Although we aim at considering any operator in our study, we prove that only two particular families have an appropriate behavior. Thus, we pay special attention to those operators. Since interval order is an important concept for the analysis of temporal events, each of which occurs over some time span (for instance, the time spans over which animal species are found or the occurrence of styles of pottery in archaeological strata), this kind of events in a fuzzy environment could be a potential application area for this study.

This work is organized as follows. In Section 2 we recall crisp relations. In Section 3 we formalize the two versions of the Ferrers property for fuzzy relations and we study their relationship. Section 4 is devoted to the completeness property. For crisp relations every reflexive Ferrers relation is complete. We study the implication for fuzzy relations. Section 5 contains the results on the connection between the first type of Ferrers property and fuzzy interval orders. Section 6 includes an analogous study for the second version of the Ferrers property. Section 7 contains some conclusions.

2 Crisp relations

2.1 Crisp preference structures

Let us consider a set of alternatives A whose elements we want to compare. In preference modeling the comparison is always carried out by pairs. When a decision maker consider two of those alternatives, the answer is always among the following ones: preference for one of the alternatives, indifference among both possibilities, inability to compare them. In the classical setting, each one of the three previous situations is identified with an $A \times A \to \{0,1\}$ application or relation. The first case is identified with the *strict preference relation*, denoted by P. We state $P(a,b) = 1$ if the decision maker prefers a to b and 0 otherwise. The second case is identified with the *indifference relation* denoted I. We assign $I(a,b) = 1$ if a and b are indifferent and $I(a,b) = 0$ if not. The *incomparability relation* is denoted J. If the alternatives a and b cannot be compared by the decision maker, $J(a,b) = 1$. Otherwise, $J(a,b) = 0$. P, I and J make up a preference structure. Let A^2 be the set of ordered pairs

ISBN: 978-989-95079-6-8

((a,b) and (b,a) are different pairs) of alternatives in A. The converse or transpose of Q is defined as $Q^t(a,b) = Q(b,a)$, its complement as $Q^c(a,b) = 1 - Q(a,b)$ and its dual as $Q^d = (Q^t)^c$. Every relation is also identified with a subset of A^2: $Q(a,b) = 1 \Leftrightarrow (a,b) \in Q$. One easily verifies that if we think of P, I and J as subsets of A^2, the quadruplet (P, P^t, I, J) establishes a particular partition of A^2. Formally [9]:

Definition 1 *A preference structure on A is a triplet (P, I, J) of relations on A that satisfy:*

(i) *P is irreflexive, I is reflexive and J is irreflexive;*

(ii) *P is asymmetrical, I and J are symmetrical;*

(iii) *$P \cap I = \emptyset$, $P \cap J = \emptyset$ and $I \cap J = \emptyset$;*

(iv) *$P \cup P^t \cup I \cup J = A^2$.*

Every preference structure is identified with a unique reflexive relation called *large preference relation* $R = P \cup I$. It connects a to b if the decision maker considers a preferred or indifferent to b. This relation leads back to the preference structure in the following way:

$$(P, I, J) = (R \cap R^d, R \cap R^t, R^c \cap R^d). \qquad (1)$$

We say that a relation R is *complete* if aRb or bRa for all a, b in the set of alternatives A. In [8] it was proven that R is complete if and only if the associated J does not connect any pair of alternatives (a,b),

$$R \text{ complete} \quad \Leftrightarrow \quad J = \emptyset.$$

A relation R is a Ferrers relation (see among others [8, 9]) if for any four alternatives a, b, c, d in A, it holds that if aRb and cRd then aRd or cRb. Another way of expressing this property is the following one: if aRb and cRd and $c \not R b$ then aRd. This property is also called biorder by some authors.

Let us remark also that the Ferrers and the completeness properties are connected.

Lemma 1 *Every reflexive Ferrers relation is complete.*

Let us denote the composition of two binary relations Q_1 and Q_2 by $Q_1 \circ Q_2$. That is, $a(Q_1 \circ Q_2)b$ if and only if there exists c such that $aQ_1c \wedge cQ_2b$. Then the equivalent compositional definition of Ferrers property is $R \circ R^d \circ R \subseteq R$.

2.2 Crisp interval orders

Interval orders are one of the most important types of "coherent" preference structures. Formally, we distinguish between partial and total interval order, depending on the possibility or impossibility of incomparable elements.

Definition 2 *A* partial interval order *is a preference structure (P, I, J) such that $P \circ I \circ P \subseteq P$. In the particular case $J = \emptyset$, (P, I, J) is said to be a* total interval order.

As commented in the introduction, this original definition admits different ways of being expressed. The following properties (among others) were shown to be equivalent in [8]:

Proposition 1 *Let $(P, I, \emptyset)$ be a preference structure without incomparability and R its large preference relation. The following conditions are equivalent.*

a) *(P, I, J) is an interval order.*

b) *P satisfies the Ferrers property.*

c) *R satisfies the Ferrers property.*

These definitions are equivalent only if the decision maker is able to compare all the pairs of alternatives, i. e., if $J = \emptyset$, equivalently if R is complete. If we do not impose this condition, we can still consider the previous properties and study their relationship. In what remains of this section we carry out this study.

It is very easy to prove that whenever R satisfies the Ferrers property, P satisfies the Ferrers property and $P \circ I \circ P \subseteq P$. It also holds that for any preference structure (P, I, J), if P satisfies the Ferrers property then $P \circ I \circ P \subseteq P$, but the converse implications do not hold.

The following proposition summarizes the relationship among the conditions of Proposition 1 when we consider any preference structure.

Proposition 2 *Let (P, I, J) be a (crisp) preference structure and let R be its large preference relation. Then,*

i) *(P, I, J) is a total interval order and R satisfies the Ferrers property are equivalent properties.*

ii) *(P, I, J) is a total interval order implies that P satisfies the Ferrers property. In addition to this, if P satisfies the Ferrers property then $P \circ I \circ P \subseteq P$. The converse implications to the ones showed in this item do not hold.*

Propositions 1 and 2 can be outlined as we show in Figure 1, where the missing implications do not hold.

$$\begin{array}{ccc} (P,I,J) \text{ total int. ord.} & \Leftrightarrow & R \text{ Ferrers} \\ & & \Downarrow \ \Updownarrow (J = \emptyset) \\ & & P \text{ Ferrers} \\ & & \Downarrow \ \Updownarrow (J = \emptyset) \\ & & (P,I,J) \text{ partial int. ord.} \end{array}$$

Figure 1: Connection among the characterizations of a crisp interval order.

3 Fuzzy preference structures

All the relations involved in a (crisp) preference structure are crisp. Then they are not always appropriate to model human decisions. They do not include intensity of preference. The lack of flexibility in crisp set theory led to introduce fuzzy relations. They allow the decision maker to encode degrees of preference rather than just its absence or presence. Fuzzy relations were introduced as a natural extension of the concept of crisp binary relation. They have been widely studied. For a complete review about fuzzy relations see [6].

Formally, a fuzzy relation is defined as a function Q from the cartesian product $A \times A$ into the interval $[0, 1]$. For every pair $(a,b) \in A \times A$, the value $Q(a,b)$ shows the degree of truth of the fact that aQb in the crisp sense. The complementary, transpose (or converse) and dual of the binary relation Q are defined for any $(a,b) \in A \times A$ as $Q^c(a,b) = 1 - Q(a,b)$, $Q^t(a,b) = Q(b,a)$ and $Q^d(a,b) = 1 - Q(b,a)$.

ISBN: 978-989-95079-6-8

The intersection of fuzzy relations is usually defined pointwisely based on some *t-norm*. We recall that the binary operator $T : [0,1] \times [0,1] \to [0,1]$ is a *triangular norm* or *t-norm* for short if it is commutative, associative, monotone and has 1 as neutral element. The three most important t-norms are the minimum operator $T_{\mathbf{M}}(x,y) = \min(x,y)$, the algebraic product $T_{\mathbf{P}}(x,y) = xy$ and the Łukasiewicz t-norm $T_{\mathbf{L}}(x,y) = \max(x+y-1,0)$. The minimum operator is the greatest t-norm; the smallest t-norm is the drastic product $T_{\mathbf{D}}$ defined by

$$T_{\mathbf{D}}(x,y) = \begin{cases} 0 & \text{if } \max(x,y) < 1\,, \\ \min(x,y) & \text{otherwise}\,. \end{cases}$$

On the other hand, we say that a value $x \in (0,1)$ is a zero-divisor of a t-norm T if there exists a value $y \in (0,1)$ such that $T(x,y) = 0$. The minimum and the product are t-norms that do not admit zero-divisors, while $T_{\mathbf{L}}$ and $T_{\mathbf{D}}$ do admit them.
An important family of t-norms that admit zero-divisors are the rotation invariant t-norms. A *rotation invariant t-norm* is a t-norm T that verifies:

$$T(x,y) \le z \;\Leftrightarrow\; T(x,1-z) \le 1-y, \quad \forall x,y,z \in [0,1].$$

The rotation invariance property for T means that the part of the space $[0,1]^3$ which is exactly below the graph of T remains invariant under an order three transformation. This transformation is indeed a rotation of $[0,1]^3$ with angle $2\pi/3$ around the axis that passes through the points $(0,0,1)$ and $(1,1,0)$. Rotation invariant t-norms satisfy in particular that $T(x,y) > 0 \Leftrightarrow x + y > 1$, i.e. the lower-left triangle of the unit square constitutes the zero-divisors of T. This excludes t-norms without zero-divisors (such as $T_{\mathbf{P}}$), nilpotent t-norms other than $T_{\mathbf{L}}$ and the drastic product $T_{\mathbf{D}}$.
As extreme members of the family we find the Łukasiewicz t-norm $T_{\mathbf{L}}$ and the nilpotent minimum $T_{\mathbf{nM}}$. This t-norm is defined as:

$$T_{\mathbf{nM}}(x,y) = \begin{cases} 0 & \text{if } x+y \le 1\,, \\ \min(x,y) & \text{otherwise}\,. \end{cases}$$

Similarly to the intersection, the union of fuzzy relations is based on a *t-conorm*, *i.e.* an increasing, commutative and associative binary operation on $[0,1]$ with neutral element 0. t-norms and t-conorms come in dual pairs: to any t-norm T there corresponds a t-conorm S through the relationship

$$S(x,y) = 1 - T(1-x, 1-y).$$

For the main three t-norms this yields the maximum operator $S_{\mathbf{M}}(x,y) = \max(x,y)$, the probabilistic sum $S_{\mathbf{P}}(x,y) = x + y - xy$ and the Łukasiewicz t-conorm (bounded sum) $S_{\mathbf{L}}(x,y) = \min(x+y,1)$. For more information on t-norms and t-conorms, we refer to [7].

The definition of a fuzzy preference structure has been discussed for many years [6]. The *assignment principle*, expressing that for any pair of alternatives (a,b) the decision maker is allowed to assign at least one of the degrees $P(a,b)$, $P(b,a)$, $I(a,b)$ and $J(a,b)$ freely in the unit interval, leads to a graduation of Definition 1 with intersection based on the Łukasiewicz t-norm and union based on the Łukasiewicz t-conorm. This definition admits the same short formulation as the classical one: a triplet (P,I,J) of fuzzy relations on A is an *additive fuzzy preference structure* on A if and only if I is reflexive ($I(a,a) = 1$ for any $a \in A$) and symmetrical, and for any $(a,b) \in A^2$ it holds that $P(a,b) + P^t(a,b) + I(a,b) + J(a,b) = 1$. This expression justifies the adjective *additive*. Note that P is irreflexive, and that J is irreflexive and symmetrical.

Another difficult point has been how to construct such a structure from a reflexive fuzzy relation. The most recent and most successful approach is that of De Baets and Fodor based on (indifference) *generators* [1].

Definition 3 *A generator i is a commutative $[0,1]^2 \to [0,1]$ mapping that satisfies $T_{\mathbf{L}} \le i \le T_{\mathbf{M}}$.*

Note that a generator always has neutral element 1. For any reflexive fuzzy relation R on A it holds that the triplet (P,I,J) of fuzzy relations on A defined by:

$$\begin{aligned} P(a,b) &= R(a,b) - i(R(a,b),R(b,a))\,, \\ I(a,b) &= i(R(a,b),R(b,a))\,, \\ J(a,b) &= i(R(a,b),R(b,a)) - (R(a,b)+R(b,a)-1)\,, \end{aligned}$$

is an additive fuzzy preference structure on A such that R is the union by the Łukasiewicz t-conorm of P and I, this is, $R(a,b) = P(a,b) + I(a,b)$. The fuzzy relation R is again called the *large preference relation*.
A family of generators that present important properties is the family of Frank t-norms (see, e.g., [6]). In the following section we will see that a particular Frank t-norm is a specially good generator: the Łukasiewicz t-norm.

Definition 4 *Given a t-norm T and a t-conorm S, a fuzzy relation Q is a type 1 T-S-*Ferrers *relation if*

$$T(Q(a,b),Q(c,d)) \le S(Q(a,d),Q(c,b)),\ \forall\, a,b,c,d, \in A.$$

The t-norm T and the t-conorm S are not necessarily connected. However, given T, the most usual t-conorm considered is the dual of T. In this case, the t-conorm is not specified and we just talk about type 1 T-Ferrers property. Along this work, this will be the setting: we will always consider as t-conorm the dual of the fixed t-norm.

Definition 5 *Given a t-norm T, a fuzzy relation Q is a* type 2 T-Ferrers *relation if*

$$T(Q(a,b),Q^d(b,c),Q(c,d)) \le Q(a,d),\ \forall\, a,b,c,d \in A.$$

The composition of two fuzzy relations Q_1 and Q_2 defined on A also involves t-norms. Given a t-norm T, the T-composition of Q_1 and Q_2 is the fuzzy relation $Q_1 \circ_T Q_2$ defined as follows

$$(Q_1 \circ_T Q_2)(a,b) = \sup\{T(Q_1(a,c),Q_2(c,b)) | c \in A\}.$$

With this notation we can also say that a fuzzy relation Q is a type 2 T-Ferrers relation if it holds that $Q \circ_T Q^d \circ_T Q \subseteq Q$.

Definition 6 [2] *An additive fuzzy preference structure is a T-*partial interval order *if it holds that*

$$P \circ_T I \circ_T P \subseteq P\,,$$

*or, equivalently, $T(T(P(a,b),I(b,c)),P(c,d)) \le P(a,d)$, $\forall\, a,b,c,d \in A$. It is a T-*total interval order *if it is a T-partial interval order and $J = \emptyset$.*

ISBN: 978-989-95079-6-8

Clearly, if $T_1 \leq T_2$, every type 1 T_2-Ferrers relation is also a type 1 T_1-Ferrers relation, every type 2 T_2-Ferrers relation is also a type 2 T_1-Ferrers relation and every T_2-interval order is also a T_1-interval order.

The equivalence between the notions of type 1 and type 2 T-Ferrers relations has already been studied in some particular cases ([5]). The following theorem further generalizes these results and characterizes all t-norms for which both notions coincide.

Theorem 1 *Consider a t-norm T. Then the following statements are equivalent:*

(i) *Any type 1 T-Ferrers relation is type 2 T-Ferrers.*

(ii) *Any type 2 T-Ferrers relation is type 1 T-Ferrers.*

(iii) *T is rotation-invariant.*

It follows from this theorem that in particular, for any reflexive relation R and for any strict preference relation P, the equivalence between the type 1 T-Ferrers property and the type 2 T-Ferrers property holds if and only if T is a rotation invariant t-norm. This justifies the importance we give to this family of t-norms in this work.

The theorem above does not apply to the minimum t-norm. However it is an important operator and the greatest t-norm. What can we say about it? Since $T_{\mathbf{nM}} \leq T_{\mathbf{M}}$, it follows immediately that any type 1 $T_{\mathbf{M}}$-Ferrers relation is a type 2 $T_{\mathbf{nM}}$-Ferrers relation and that any type 2 $T_{\mathbf{M}}$-Ferrers relation satisfies the type 1 $T_{\mathbf{nM}}$-Ferrers property. This result can be strengthened considerably.

Proposition 3

(i) *$T_{\mathbf{nM}}$ is the largest t-norm T such that any type 1 $T_{\mathbf{M}}$-Ferrers relation is also type 2 T-Ferrers.*

(ii) *$T_{\mathbf{nM}}$ is the largest t-norm T such that any type 2 $T_{\mathbf{M}}$-Ferrers relation is also type 1 T-Ferrers.*

4 Completeness of the large preference relation

We have seen that for crisp relations the completeness of the large preference relation follows from the Ferrers property. In this section we consider both types of the Ferrers property. We investigate the kind of completeness exhibited by a fuzzy reflexive relation satisfying one of the two properties.

Definition 7 *Let us consider a t-conorm S and a fuzzy relation Q defined on a set of alternatives A. Q is S-complete if it satisfies*

$$S(Q(a,b), Q(b,a)) = 1, \qquad \forall\, a, b \in A.$$

The two most important notions are based on the minimum and the Łukasiewicz t-norms. Given a relation Q we say that it is

- *Strongly complete:* if $Q(a,b) = 1$ or $Q(b,a) = 1, \forall a, b \in A$.
- *weakly complete:* if $Q(a,b) + Q(b,a) \geq 1, \forall a, b \in A$.

The weakest S-completeness condition is based on $S_{\mathbf{D}}$. Given Q, it is $S_{\mathbf{D}}$-complete if $\max(Q(a,b), Q(b,a)) > 0$ for all a, b in A.

No one of the "fuzzy notions" of completeness of R is equivalent to the condition $J = \emptyset$, but we can establish the following equivalence.

Lemma 2 [4] *Let R be a reflexive fuzzy relation and let J be the incomparability relation associated to R by means of any generator i. Then the following equivalence holds*

$$J = \emptyset \Leftrightarrow \begin{cases} R \text{ is weakly complete} \\ i|_S = T_{\mathbf{L}} \end{cases}$$

where $S = \{(u,v) \in [0,1]^2 : \exists (x,y) \in A^2$ with $R(x,y) = u, R(y,x) = v\}$.

Let us recall that when $i = T_{\mathbf{L}}$, the fuzzy preference structure obtained from a weakly complete reflexive relation R is the triplet $(P_{\mathbf{L}}, I_{\mathbf{L}}, J_{\mathbf{L}}) = (R^d, \min(R, R^t), \emptyset)$. We would like to stress the fact that the strict preference relation becomes the dual of the large preference relation.

We next focus on the completeness assured for reflexive type 1 and type 2 T-Ferrers relations.

Proposition 4 *Let T be a t-norm and S its dual t-conorm. Every type 1 T-Ferrers reflexive relation is S-complete.*

As an immediate consequence we get the following: Every type 1 T-Ferrers reflexive relation satisfies the weakest kind of completeness ($S_{\mathbf{D}}$-completeness).

Since strong and weak completeness are in fact $S_{\mathbf{M}}$-completeness and $S_{\mathbf{L}}$-completeness, it also follows from Proposition 4 that every type 1 $T_{\mathbf{L}}$-Ferrers relation is weakly complete and every type 1 $T_{\mathbf{M}}$-Ferrers relation is strongly complete. We can say more.

Theorem 2 *Consider a t-norm T. Every reflexive type 1 T-Ferrers relation is weakly complete if and only if $T(x,y) > 0$ for any pair $(x,y) \in [0,1]^2$ such that $x + y > 1$.*

This theorem applies to all rotation-invariant t-norms. In particular, it applies to $T_{\mathbf{L}}$, and hence to any $T \geq T_{\mathbf{L}}$. Theorem 2 also applies to t-norms without zero-divisors, although in that case the following much stronger result holds.

Theorem 3 *Any reflexive type 1 T-Ferrers relation is strongly complete if and only if the t-norm T has no zero-divisors.*

This theorem applies in particular to $T_{\mathbf{M}}$.

Next we repeat the same study for reflexive type 2 T-Ferrers relations.

Theorem 4 *Any reflexive type 2 T-Ferrers relation is weakly complete.*

A first comparison between types 1 and 2 of the T-Ferrers property is in favour of the type 2 definition as the previous theorem holds for any t-norm T. However, our enthusiasm is tempered by the following negative result.

Proposition 5 *Not all reflexive type 2 $T_{\mathbf{M}}$-Ferrers relations are strongly complete.*

ISBN: 978-989-95079-6-8

Despite this negative result, t-norms without zero-divisors have good properties.

Theorem 5 *Let $(P, I, \emptyset)$ be an additive fuzzy preference structure without incomparability and let R be its associated large preference relation. Let T be a t-norm. The following assertions are equivalent.*
(i) *If $(P, I, \emptyset)$ is a T-total interval order, then R is strongly complete.*
(ii) *If P is type 1 T-Ferrers, then R is strongly complete.*
(iii) *If P is type 2 T-Ferrers, then R is strongly complete.*
(iv) *If R is type 1 T-Ferrers, then R is strongly complete.*
(v) *T does not admit zero-divisors.*

The results presented in this section show that there are two important families of t-norms in the study of the Ferrers property: rotation invariant t-norms and t-norms without zero-divisors. In the two following sections we pay special attention to those two families [8].

5 Fuzzy interval orders and the type 1 Ferrers property

In this section we study the implications of Figure 1 that remain true for fuzzy relations when the Ferrers property of a crisp relation is generalized by means of the type 1 Ferrers property.

Lemma 3 [2] *Not every $T_{\mathbf{M}}$-total interval order verifies that its strict preference relation is type 1 $T_{\mathbf{M}}$-Ferrers. Not every $T_{\mathbf{L}}$-total interval order verifies that its strict preference relation is type 1 $T_{\mathbf{L}}$-Ferrers.*

Therefore, we cannot assure that for every total interval order its strict preference relation satisfies the type 1 Ferrers property.

Let us focus on the connection between the large and the strict preference relations.

Let us recall first of all that the results we present in this contribution concern a fixed generator $i = T_{\mathbf{L}}$, as it has shown an appropriate behavior (see Lemma 2).

Theorem 6 *The following statements are equivalent:*

(i) The strict preference relation obtained from a type 1 T-Ferrers reflexive relation also satisfies the type 1 T-Ferrers property.

(ii) The t-norm T satisfies $T(x, y) > 0$ for any pair $(x, y) \in [0, 1]^2$ such that $x + y > 1$.

In particular, the previous result can be applied to rotation-invariant t-norms and t-norms without zero-divisors.

The result presented in Theorem 6 can be strengthened under completeness conditions.

Theorem 7 *Consider a fuzzy reflexive relation R with corresponding fuzzy preference structure $(P_{\mathbf{L}}, I_{\mathbf{L}}, J_{\mathbf{L}})$ generated by means of $i = T_{\mathbf{L}}$. For any t-norm T, the following statements are equivalent:*

- *R weakly complete and type 1 T-Ferrers*
- *$J_{\mathbf{L}} = \emptyset$ and $P_{\mathbf{L}}$ type 1 T-Ferrers*

Proposition 6 *Let (P, I, J) be an additive fuzzy preference structure and let T be a rotation invariant t-norm. If P is a type 1 T-Ferrers relation, then (P, I, J) is a T-partial interval order.*

The previous implication cannot be extended to t-norms without zero-divisors. In [2] it was proven that not every type 1 $T_{\mathbf{M}}$-Ferrers reflexive relation satisfies that the fuzzy preference structure obtained from it (by the Łukasiewicz t-norm) is a $T_{\mathbf{M}}$-total interval order. It follows from here and Theorem 6 that the implication of Proposition 6 does not hold for the family of t-norms without zero-divisors.

Now we focus on the connection between a total interval order and the type 1 T-Ferrers property of the associated large preference relation.

Corollary 1 *Let T denote the minimum or the Łukasiewicz t-norms. Not every T-total interval order verifies that its associated large preference relation satisfies the type 1 T-Ferrers property.*

The converse implication neither holds for $T_{\mathbf{M}}$ [2]. However the implication does hold for rotation invariant t-norms.

Proposition 7 *Let T be a rotation invariant t-norm. The additive fuzzy preference structure obtained (by the Łukasiewicz t-norm) from a type 1 T-Ferrers reflexive relation is a T-total interval order.*

In Figures 2 and 3 we summarize the results obtained for the type 1 Ferrers property both for the family of rotation invariant t-norms and for the family of t-norms without zero divisors. We have proven that the implications missing do not hold.

$$\begin{array}{ccccc} (P,I,J) & T\text{-total int. ord.} & \Leftarrow & R & \text{type 1 } T\text{-Ferrers} \\ & (J=\emptyset)\nwarrow & & \not\swarrow \quad \not\nearrow & (J=\emptyset) \\ & & & P & \text{type 1 } T\text{-Ferrers} \\ & & & \Downarrow & \\ & & & (P,I,J) & T\text{-partial int. ord.} \end{array}$$

Figure 2: Connection among the type 1 T-Ferrers property and the notion of interval order for T a rotation invariant t-norm.

$$\begin{array}{ccccc} (P,I,J) & T\text{-total int. ord.} & & R & \text{type 1 } T\text{-Ferrers} \\ & (J=\emptyset) & & \not\swarrow \quad \not\nearrow & (J=\emptyset) \\ & & & P & \text{type 1 } T\text{-Ferrers} \\ & & & & \\ & & & (P,I,J) & T\text{-partial int. ord.} \end{array}$$

Figure 3: Connection among the type 1 T-Ferrers property and the notion of interval order for T a t-norm without zero-divisors.

6 Fuzzy interval orders and the type 2 Ferrers property

We already know the behaviour of the type 1 Ferrers property when dealing with interval orders. Now we focus on the type 2 Ferrers property.

ISBN: 978-989-95079-6-8

Proposition 8 *Let T be a t-norm without zero-divisors and let $(P, I, \emptyset)$ be a T-total interval order, then P satisfies the type 2 T-Ferrers property.*

However the implication cannot be extended to any t-norm.

Proposition 9 *Let T be a t-norm such that $T(x, 1-x) = 0$ for some $x \in (0,1)$. Not every T-total interval order satisfies that its strict preference relation is type 2 T-Ferrers.*

A particular type of the t-norms described in the previous proposition are the rotation invariant t-norms.

Next we study how the type 2 Ferrers property propagates between R and P.

Theorem 8 *Consider a t-norm T. Then the following statements are equivalent:*

(i) *For any reflexive relation R, if R satisfies the type 2 T-Ferrers property, then $J_{\mathbf{L}} = \emptyset$ and $P_{\mathbf{L}}$ satisfies the type 2 T-Ferrers property.*

(ii) *For any reflexive relation R, if $J_{\mathbf{L}} = \emptyset$ and $P_{\mathbf{L}}$ satisfies the type 2 T-Ferrers property, then R satisfies the type 2 T-Ferrers property.*

(iii) *T is rotation-invariant.*

We now study the relationship between the type 2 T-Ferrers property of P and a T-partial interval order.

Proposition 10 *Let (P, I, J) be an additive fuzzy preference structure and let T be a t-norm. If P is type 2 T-Ferrers then (P, I, J) is a T-partial interval order.*

It follows from the crisp case that the converse implication does not hold for any t-norm.

The characterization of total interval orders based on the Ferrers property of the associated large preference relation gets lost for fuzzy relations when considering the type 2 T-Ferrers condition.

Proposition 11 *It does not hold that for every $T_{\mathbf{M}}$-total interval order the associated large preference relation is type 2 $T_{\mathbf{M}}$-Ferrers. It neither holds that for any type 2 $T_{\mathbf{M}}$-Ferrers reflexive relation the associated by the Łukasiewicz t-norm preference structure is a $T_{\mathbf{M}}$-total interval order.*

Proposition 12 *For any type 2 $T_{\mathbf{L}}$-Ferrers reflexive relation R the associated fuzzy preference structure $(P_{\mathbf{L}}, I_{\mathbf{L}}, J_{\mathbf{L}})$ is a $T_{\mathbf{L}}$-total interval order.*
The converse implication cannot be assured for any type 2 $T_{\mathbf{L}}$-total interval order.

We draw in Figures 4 and 5 the results obtained for the type 2 Ferrers property.

7 Conclusions

We have studied the connection between the fuzzy Ferrers property and the definition of fuzzy interval orders. Since the Ferrers property admits two different ways to be formalized for fuzzy relations, we have compared those two versions by its connection to fuzzy interval orders. We have seen that we cannot identify a best definition since each property behaves better in different cases. We have seen that both properties are equivalent only when dealing with rotation invariant t-norms. For these operators, Ferrers property is a stronger condition than the notion of total interval order. For t-norms without zero-divisors, no one of them is good. The type 2 condition seems to assure the equivalence between total interval orders and the Ferrers property of the associated strict preference relation. However, type 1 behaves better if we want to propagate the Ferrers property between the large and the strict preference relations.

$$\begin{array}{ccc} (P,I,J)\ T\text{-total int. ord.} & \Leftarrow & R \text{ type 2 } T\text{-Ferrers} \\ (J=\emptyset)\nwarrow & & \swarrow\ \nearrow (J=\emptyset) \\ & P \text{ type 2 } T\text{-Ferrers} & \\ & \Downarrow & \\ & (P,I,J)\quad T\text{-partial int. ord.} & \end{array}$$

Abstract— *Transitivity is a very important property in order to provide coherence to a preference relation. Usually, t-norms are considered to define the transitivity of fuzzy relations. In this paper we deal with conjunctors, a wider family than t-norm, to define the transitivity. This more general definition allows to impove the results found in the literature. We characterize the behaviour with respect to transitivity of the strict preference and indifference relations of any fuzzy preference structure associated to any large preference relation. Those two characterizations provide very general expressions. We also obtain easier expressions in some particular cases.*

Keywords— Fuzzy preference relation, transitivity, conjunctor, indifference generator.

1 Introduction

Decision making is present in many situations in life. Preference models are an essential part of the design phase of a decision making process. The departure point in preference modelling is the comparison by pairs of possible alternatives. If this point of the process lacks of coherence, the whole process makes no sense. One of the most important property introduced to ensure coherence in the two-by-two comparison is transitivity. In this paper we focus on this property.

Given its relevance in preference modelling, transitivity has been widely studied (see [3, 13, 14], among others). In classical or crisp preference modelling there exists a basic relation R, called *large preference relation* that allows to compare a pair of possibilities: given the alternatives a and b, $(a, b) \in R$ expresses that alternative a is considered to be at least as good as alternative b. From R, three relations can be defined: the strict preference relation P, the indifference relation I and the incomparability relation J. It is well known that the transitivity of R is completely characterized by the transitivity of I and P and two additional relational inequalities involving I and P; in case of completeness, the transitivity of R is only characterized by the transitivity of I and P [2].

All those relations are crisp and therefore, they are not always appropriate to model human decisions. The lack of flexibility in crisp set theory lead to introduce fuzzy sets in preference modeling and to study the concept of fuzzy preference structure [8, 18, 24]; see [6] for a historical account of its development. Transitivity is traditionally defined for fuzzy relations by means of t-norms. In this context, the transitivity of the (fuzzy) large preference relation R has been characterized in a similar way as for crisp relations, in a particular case: when R is strongly complete [12]. But strong completeness is a quite restrictive condition. Subsequent works have treated more general preference relations [3, 4]. Those authors center their study on the translation of a fixed transitivity from a more general (fuzzy) large preference relation R to different associated indifference and strict preference relations (I and P respectively). We have continued along this line but we have treated the problem from a totally different viewpoint. On the one hand, we work with conjunctors, a wider family of operators than t-norms, so we handle a very general notion of transitivity. On the other hand, we do not study the preservation of the transitivity when decomposing R, but we explore the strongest transitivity we can assure I and P satisfy. In a previous work [15], we have fenced in the transitivity of I and P according to the transitivity R satisfies. In this work we go further: we provide an explicit expression for the transitivity that any I (respectively any P) satisfies. We prove that no stronger transitivity is fulfilled by all I (respectively for all P). Transitivity is a fundamental assumption in some decision-making models, like rational model (founded in quantitative disciplines like economics, mathematics and statistics) or political model (primarily based on the disciplines of political science, philosophy, psychology and sociology). Without this property, it is not possible to obtain a coherent order of the alternatives and therefore the choice of the best alternative is more complicate or even impossible. Thus, the study made in this work is a first step to develop a consistent theory to order the alternatives and therefore to provide a decision, when the comparison between alternatives can be graded.

The work is structured in six sections. In Section 2 we recall the most relevant concepts concerning additive fuzzy preference structures. In Section 3 we introduce conjunctors and we discuss some properties they satisfy and that will be useful in next sections. In Section 4 we include the general result we have obtained for the transitivity of the indifference relation I and we discuss the appearance of the general expression for the three most important particular cases. In Section 5 we characterize the transitivity of the strict preference relation P in a very general context. We also prove that the general expression gets much simplified for the most important particular cases. In Section 6 we briefly address some conclusions and future work.

2 Preference structures

2.1 Crisp preference structures

Let us consider a decision maker who is given a set of alternatives A. Let us suppose that this person compares the alternatives two by two. Given two alternatives, the decision maker

ISBN: 978-989-95079-6-8

can act in one of the following three ways: (i) he/she clearly prefers one to the other; (ii) the two alternatives are indifferent to him/her; (iii) he/she is unable to compare the two alternatives. According to these cases, three binary relations can be defined on A: the strict preference relation P, the indifference relation I and the incomparability relation J. Thus, for any $(a,b) \in A^2$, we classify:

$$\begin{array}{rcl}(a,b) \in P & \Leftrightarrow & \text{he/she prefers } a \text{ to } b;\\ (a,b) \in I & \Leftrightarrow & a \text{ and } b \text{ are indifferent to him/her;}\\ (a,b) \in J & \Leftrightarrow & \text{he/she is unable to compare } a \text{ and } b.\end{array}$$

We recall that for a binary relation Q on A, its converse is defined as $Q^t = \{(b,a) \mid (a,b) \in Q\}$, its complement as $Q^c = \{(a,b) \mid (a,b) \notin Q\}$ and its dual as $Q^d = (Q^t)^c$. If we consider the set A^2 ordered, *i.e.* assuming (a,b) and (b,a) as different pairs, one easily verifies that the triplet (P,I,J) and P^t establish a particular partition of A^2 [21].

Definition 1 *A preference structure on A is a triplet (P,I,J) of binary relations on A that satisfy:*

(i) *P is irreflexive, I is reflexive and J is irreflexive;*

(ii) *P is asymmetrical, I and J are symmetrical;*

(iii) *$P \cap I = \emptyset$, $P \cap J = \emptyset$ and $I \cap J = \emptyset$;*

(iv) *$P \cup P^t \cup I \cup J = A^2$.*

Every preference structure has associated a reflexive relation that completely characterizes this structure. A preference structure (P,I,J) on A is characterized by the reflexive binary relation $R = P \cup I$, its large preference relation, in the following way:

$$(P,I,J) = (R \cap R^d, R \cap R^t, R^c \cap R^d). \qquad (1)$$

Conversely, for any reflexive binary relation R on A, the triplet (P,I,J) constructed in this way from R is a preference structure on A such that $R = P \cup I$. As R is the union of the strict preference and the indifference, $(a,b) \in R$ means that a is at least as good as b.

Given a binary relation Q on A, we say that Q is transitive if $(aQb \wedge bQc) \Rightarrow aQc$, for any $(a,b,c) \in A^3$. Given two binary relations Q_1 and Q_2 on A, the composition is a binary relation denoted $Q_1 \circ Q_2$ such that for any $(a,b) \in A^2$ $a\,(Q_1 \circ Q_2)\,b \Leftrightarrow \exists c / aQ_1c \wedge cQ_2b$. Then, it is clear that Q is transitive if and only if $Q \circ Q \subseteq Q$. The transitivity of the large preference relation R can be characterized as follows [2].

Theorem 1 *For any reflexive relation R with corresponding preference structure (P,I,J) it holds that*

$$R \circ R \subseteq R \Leftrightarrow (P \circ P \subseteq P \wedge I \circ I \subseteq I \wedge P \circ I \subseteq P \wedge I \circ P \subseteq P).$$

In case R is complete, *i.e.* $R \cup R^t = A^2$, this characterization can be simplified as follows. Note that the completeness of R is equivalent to establish that any two elements are comparable, that is, $J = \emptyset$.

Theorem 2 *For any complete reflexive relation R with corresponding preference structure $(P,I,\emptyset)$ it holds that*

$$R \circ R \subseteq R \Leftrightarrow (P \circ P \subseteq P \ \wedge \ I \circ I \subseteq I).$$

Next we recall an important characterization of a preference structure. Let us consider for every relation its characteristic mapping *i.e.* $Q(a,b) = 1 \Leftrightarrow aQb$. Definition 1 can be written in the following minimal way [11]: I is reflexive and symmetrical, and for any $(a,b) \in A^2$:

$$P(a,b) + P^t(a,b) + I(a,b) + J(a,b) = 1.$$

Classical preference structures can therefore also be considered as Boolean preference structures, employing 1 and 0 for describing presence or absence of strict preferences, indifferences and incomparabilities.

2.2 Additive fuzzy preference structures

In the classical model, relations only express presence or absence of relationship, while fuzzy relations capture the nuances of human choices. In fuzzy preference modelling, strict preference, indifference and incomparability are a matter of degree. These degrees can take any value between 0 and 1 and fuzzy relations are used for capturing them (for a complete review about fuzzy relations see [18]).

The intersection of fuzzy relations is usually defined pointwisely based on some t-norm, *i.e.* an increasing, commutative and associative binary operation on $[0,1]$ with neutral element 1. The three most important t-norms are the minimum operator $T_{\mathbf{M}}(x,y) = \min\{x,y\}$, the algebraic product $T_{\mathbf{P}}(x,y) = xy$ and the Łukasiewicz t-norm $T_{\mathbf{L}}(x,y) = \max\{x+y-1,0\}$. The minimum operator is the greatest t-norm; the smallest t-norm is the drastic product defined by

$$T_{\mathbf{D}}(x,y) = \begin{cases} \min\{x,y\} & \text{, if } \max\{x,y\} = 1\,,\\ 0 & \text{, otherwise.}\end{cases}$$

The above t-norms can be ordered (usual ordering of functions) as follows: $T_{\mathbf{D}} \leq T_{\mathbf{L}} \leq T_{\mathbf{P}} \leq T_{\mathbf{M}}$. Similarly, the union of fuzzy relations is based on a t-conorm, *i.e.* a non-decreasing, commutative and associative binary operation on $[0,1]$ with neutral element 0. T-norms and t-conorms come in dual pairs: to any t-norm T there corresponds a t-conorm S through the relationship $S(x,y) = 1 - T(1-x, 1-y)$. For the above three t-norms this yields the maximum operator $S_{\mathbf{M}}(x,y) = \max\{x,y\}$, the probabilistic sum $S_{\mathbf{P}}(x,y) = x + y - xy$ and the Łukasiewicz t-conorm (bounded sum) $S_{\mathbf{L}}(x,y) = \min\{x+y,1\}$. For more information on t-norms and t-conorms, we refer to [19]. Along this paper we use the notations for t-norms presented there.

The definition of a fuzzy preference structure has been a topic of debate during several years (see e.g. [18, 23, 24]). Accepting the *assignment principle* — for any pair of alternatives (a,b) the decision maker is allowed to assign at least one of the degrees $P(a,b)$, $P(b,a)$, $I(a,b)$ and $J(a,b)$ freely in the unit interval — has finally led to a graduation of Definition 1 with the intersection based on the Łukasiewicz t-norm and the union based on the Łukasiewicz t-conorm. Interestingly, a minimal definition is identical to the classical one if we replace ordinary by fuzzy binary relations: a triplet (P,I,J) of fuzzy binary relations on A is a fuzzy preference structure on A if and only if I is reflexive and symmetrical, and for any $(a,b) \in A^2$:

$$P(a,b) + P^t(a,b) + I(a,b) + J(a,b) = 1,$$

ISBN: 978-989-95079-6-8

where $P^t(a,b) = P(b,a)$. This identity explains the name *additive fuzzy preference structures*.

Another topic of controversy has been how to construct such a structure from a reflexive fuzzy relation. Alsina [1] proved a kind of impossibility theorem showing that a construction based on a single t-norm is unfeasible. As a reaction, Fodor and Roubens adopted an axiomatic approach [18]. The most recent and most successful approach is that of De Baets and Fodor based on (indifference) generators [8].

Definition 2 *A generator i is a commutative $[0,1]^2 \to [0,1]$ mapping bounded by the Łukasiewicz t-norm $T_{\mathbf{L}}$, and the minimum operator $T_{\mathbf{M}}$: $T_{\mathbf{L}} \leq i \leq T_{\mathbf{M}}$.*

Note that the definition of a generator does not speak of monotonicity and therefore they are not necessarily t-norms, albeit having neutral element 1. For any reflexive fuzzy relation R on A it holds that the triplet (P,I,J) of fuzzy binary relations on A defined by:

$$\begin{aligned} P(a,b) &= R(a,b) - i(R(a,b),R(b,a)), \\ I(a,b) &= i(R(a,b),R(b,a)), \\ J(a,b) &= i(R(a,b),R(b,a)) - (R(a,b)+R(b,a)-1), \end{aligned}$$

is an additive fuzzy preference structure on A such that $R = P \cup_{S_{\mathbf{L}}} I$ *i.e.* $R(a,b) = P(a,b) + I(a,b)$.

Popular generators (see e.g. [18]) are the Frank t-norms. For the sake of completeness, we recall that the Frank t-norms are given by

$$T_\lambda^{\mathbf{F}}(x,y) = \begin{cases} T_{\mathbf{M}}(x,y) & \text{, if } \lambda = 0, \\ T_{\mathbf{P}}(x,y) & \text{, if } \lambda = 1, \\ T_{\mathbf{L}}(x,y) & \text{, if } \lambda = \infty, \\ \log_\lambda(1 + \frac{(\lambda^x-1)(\lambda^y-1)}{\lambda-1}) & \text{, otherwise.} \end{cases}$$

We also recall that for any $\lambda \in [0,\infty]$ and for any $(x,y) \in [0,1]^2$,

$$T_{1/\lambda}^{\mathbf{F}}(x,y) = x - T_\lambda^{\mathbf{F}}(x,1-y).$$

3 Conjunctors

3.1 Generalizing T-transitivity

The usual way of defining the transitivity of a fuzzy relation is by means of a t-norm. Recall that a fuzzy relation Q on A is T-transitive if $T(Q(a,b),Q(b,c)) \leq Q(a,c)$ for any $(a,b,c) \in A^3$. However, such a framework is too restrictive in the setting of fuzzy preference modelling. On the one hand, even when the large preference relation R is T-transitive w.r.t. a t-norm T, the transitivity of the generated P and I cannot always be expressed w.r.t. a t-norm [14, 16, 15]. On the other hand, the results we will present in the following sections also hold when R itself is transitive w.r.t. a more general operator. From a fuzzy preference modelling point of view, it is not that surprising that the class of t-norms is too restrictive, as a similar conclusion was drawn when identifying suitable generators, as briefly explained in the previous section.

As it was discussed in [15, 16], suitable operators for defining transitivity for fuzzy relations are conjunctors:

Definition 3 *A binary operation $f : [0,1]^2 \to [0,1]$ is called a conjunctor if*

1. *it coincides with the Boolean conjunction on $\{0,1\}^2$;*
2. *it is increasing in each variable.*

Given a conjunctor f, we say that a fuzzy relation Q defined on A is f-transitive if for any $(a,b,c) \in A^3$,

$$f(Q(a,b),Q(b,c)) \leq Q(a,c).$$

It is clear that the definition of conjunctor largely extends the notion of t-norm. However, conjunctors and generators are not connected. The smallest conjunctor c_S and greatest conjunctor c_G are given by

$$c_S(x,y) = \begin{cases} 0 & \text{, if } \min\{x,y\} < 1, \\ 1 & \text{, otherwise,} \end{cases}$$

and

$$c_G(x,y) = \begin{cases} 0 & \text{, if } \min\{x,y\} = 0, \\ 1 & \text{, otherwise.} \end{cases}$$

As it is logical, $c_S \leq T_{\mathbf{D}} \leq T_{\mathbf{M}} \leq c_G$. Moreover, for two conjunctors $f \leq g$, it obviously holds that g-transitivity implies f-transitivity.

Defining the composition $Q_1 \circ_f Q_2$ of two fuzzy relations Q_1 and Q_2 w.r.t. a conjunctor f by

$$Q_1 \circ_f Q_2(a,c) = \sup_b f(Q_1(a,b),Q_2(b,c)),$$

still allows us to use the shorthand $Q \circ_f Q \subseteq Q$ to denote f-transitivity.

If we restrict our study for reflexive fuzzy relations, such as a large preference relations, the set of all the conjunctors that allow us to define transitivity is a proper subset of the set of all the conjunctors. Thus, the upper bound of this subset is $T_{\mathbf{M}}$ instead of c_G.

3.2 Dominance and bisymmetry

Dominance is a well-known relation for t-norms (see e.g. [19]) and its usefulness has been demonstrated several times (see e.g. [9, 22]). It can be generalized to conjunctors without any problem.

Definition 4 *A conjunctor f_1 is said to dominate a conjunctor f_2, denoted $f_1 \gg f_2$, if for any $(x,y,z,t) \in [0,1]^4$ it holds that*

$$f_1(f_2(x,y),f_2(z,t)) \geq f_2(f_1(x,z),f_1(y,t)).$$

But conjunctors do not verify the same properties as t-norms do with respect to this property. For instance, not every conjunctor dominates itself (see [15]). Dominance and the classical order of binary operators are not related for conjunctors neither. The minimum for example (which is not the greatest conjunctor), dominates any other conjunctor (see [15]).

The notion of self-dominance of conjunctors is obviously equivalent to another well-known property: bisymmetry (see e.g. [19]).

Definition 5 *A conjunctor f is said to be bisymmetric if for any $(x,y,z,t) \in [0,1]^4$ it holds that*

$$f(f(x,y),f(z,t)) = f(f(x,z),f(y,t)).$$

ISBN: 978-989-95079-6-8

3.3 Implications

Given a t-norm T, an implication (also called R-implication or T-residuum) based on T is defined (see e.g. [18, 19]) as follows:

$$I_T(x,y) = \sup\{z \mid T(x,z) \leq y\}.$$

This concept aims at generalizing the notion of Boolean implication. The definition usually concerns only left continuous t-norms. When T is left-continuous it holds that $T(x,z) \leq y \Leftrightarrow z \leq I_T(x,y)$.

Given a t-conorm S, a co-implication based on S is defined (see again e.g. [18, 19]) as follows:

$$J_S(x,y) = \inf\{z \mid S(x,z) \geq y\}.$$

When S is right-continuous it holds that $S(x,z) \geq y \Leftrightarrow z \geq J_S(x,y)$.

Following these ideas we can introduce two operators associated not only for a t-norm or a t-conorm, but to any commutative conjunctor.

Definition 6 *Given a commutative conjunctor $f : [0,1]^2 \to [0,1]$, we define the following operator from $[0,1]^2$ into $[0,1]$:*

$$I_f(x,y) = \sup\{z \mid f(x,z) \leq y\},$$

and

$$J_f(x,y) = \inf\{z \mid f(x,z) \geq y\}.$$

Let us notice that I_f is an implication, but J_f is not a co-implication.

Lemma 1 *Given a commutative conjunctor f and its associated operators I_f and J_f, we have that*

1. *I_f and J_f are decreasing in their first arguments and increasing in their second arguments.*
2. *If f is left continuous then*

$$f(x,z) \leq y \quad \Leftrightarrow \quad z \leq I_f(x,y).$$

3. *If f is upper bounded by the minimum t-norm, then*

$$x \leq y \quad \Rightarrow \quad I_f(x,y) = 1.$$

Moreover, if f is left-continuous and has 1 as neutral element, then we have the equivalence:

$$x \leq y \quad \Leftrightarrow \quad I_f(x,y) = 1.$$

4 Transitivity of I

In this section we consider indifference relations. As it was shown in Subsection 2.2, for a generator i, the symmetric component of a large preference relation is obtained as $I = i(R, R^t)$. Here we study the transitivity we can derive for this relation I when we fix the transitivity of R defined by a conjunctor h.

We begin recalling some upper and lower bounds for the transitivity of I. We know from [15] that I is at least c_S-transitive when R is h-transitive for any conjunctor h. We also showed in that paper that the transitivity we can assure for I is defined by a conjunctor upper bounded both by the conjunctor h and by the generator i that builds I from R. These are upper and lower bounds. We next provide a characterization for the transitivity of I.

Theorem 3 *Let i be an increasing generator and h a conjunctor. For any reflexive fuzzy relation R with corresponding indifference relation I generated by means of i, it holds that*

$$R \text{ is } h\text{-transitive} \quad \Rightarrow \quad I \text{ is } f_h^i\text{-transitive,}$$

where the conjunctor f_h^i is:

$$f_h^i(x,y) = \inf_{\substack{1 \geq u \geq x \\ 1 \geq v \geq y}} \left(i\left(h(u,v), h\left(J_i(v,y), J_i(u,x)\right)\right)\right).$$

Moreover, if i is continuous, the previous one is the strongest possible implication.

An interesting problem is to know when the transitivity of R is inherited by I, that is, to know when, departing from an h-transitive R we can assure that I is also h-transitive. We have already answered that question in [15]:

Theorem 4 *Let i be an increasing generator and let h be a commutative conjunctor upper bounded by the minimum t-norm. The associated conjunctor f_h^i is equal to h if and only if i dominates h.*

In particular this result could be applied to $i = T_{\mathbf{M}}$. Thus, when the indifference relation is obtained from the reflexive relation R by the minimum t-norm, $I = \min\{R, R^t\}$, it satisfies the same transitivity as R does.

Not only dominance allows us to obtain some general result, also the usual order among conjunctor, as it is showed in the following corollary.

Corollary 1 *For any increasing and bisymmetric generator i and any conjunctor h upper bounded by the minimum t-norm, if $i \leq h$, then $f_h^i = i$.*

Since every t-norm is increasing and bisymmetric, this result can be applied in particular to any generator that is a t-norm. In that case, transitivity of R w.r.t. that t-norm is preserved.

We will now consider Theorem 4 and Corollary 1 to study the particular case of a t-norm of the Frank family as generator.

Corollary 2 *Let $T_\lambda^{\mathbf{F}}$ be a t-norm of the Frank family, for any $\lambda \in [0,\infty]$. It holds that $f_{T_{\mathbf{P}}}^{T_{\mathbf{M}}} = T_{\mathbf{P}}$, $f_{T_{\mathbf{L}}}^{T_\lambda^{\mathbf{F}}} = T_{\mathbf{L}}$ and $f_h^{T_\lambda^{\mathbf{F}}} = T_\lambda^{\mathbf{F}}$ for any $h \geq T_\lambda^{\mathbf{F}}$.*

Remark 1 *Combining the results in Corollary 2 leads to the following table, where the entries are the conjunctors f_h^i.*

$h \setminus i$	$T_{\mathbf{L}}$	$T_{\mathbf{P}}$	$T_{\mathbf{M}}$
$T_{\mathbf{L}}$	$T_{\mathbf{L}}$	$T_{\mathbf{L}}$	$T_{\mathbf{L}}$
$T_{\mathbf{P}}$	$T_{\mathbf{L}}$	$T_{\mathbf{P}}$	$T_{\mathbf{P}}$
$T_{\mathbf{M}}$	$T_{\mathbf{L}}$	$T_{\mathbf{P}}$	$T_{\mathbf{M}}$

5 Transitivity of P

In this section we focus on the strict preference relation P and the transitivity it can satisfy once the transitivity of R is fixed and defined by a conjunctor h.

Let us recall that the strict preference relation P is obtained from R by means of the generator i as follows: $P = R - i(R, R^t)$.

ISBN: 978-989-95079-6-8

We showed in [15] that the transitivity that can be assured for the strict preference relation associated to any h-transitive large preference relation R is upper bounded by the conjunctor h, i.e., we cannot assure for P a stronger transitivity than h-transitivity. Next we provide not a bound but the explicit expression for the transitivity of P.

Theorem 5 *Let i be an increasing 1-Lipschitz generator and h a commutative conjunctor with neutral element 1. For any reflexive fuzzy relation R with corresponding strict preference relation P generated by means of i, it holds that*

$$R \text{ is } h\text{-transitive} \quad \Rightarrow \quad P \text{ is } g_h^i\text{-transitive}\,,$$

where the conjunctor g_h^i is:

$$g_h^i(x,y) = \inf_{\substack{1 \geq u \geq x \\ 1 \geq v \geq y}} (h(u,v) - i(h(u,v), \min\{I_h(v, I_i(u, u-x)), I_h(u, I_i(v, v-y))\}))\,.$$

Moreover, the previous one is the strongest possible implication.

According to our result from [15], g_h^i should always be not greater than h. Again, we will focus our attention on the cases the transitivity of R is totally inherited by P.

Proposition 1 *Let h be a rotation-invariant conjunctor, i.e., for all $(x,y,z) \in [0,1]^3$ it holds that*

$$h(x,y) \leq z \quad \Leftrightarrow \quad h(y, 1-z) \leq 1-x.$$

If $i = T_{\mathbf{L}}$, then $g_h^{T_{\mathbf{L}}} = h$.

Two well-known rotation-invariant t-norms are $T_{\mathbf{L}}$ and the minimum nilpotent $T_{\mathbf{nM}}$ defined by $T_{\mathbf{nM}}(x,y) = \min\{x,y\}\chi_{\{(x,y)|x+y>1\}}$, where χ_B denotes the characteristic function of any set B. Therefore, from Proposition 1, $g_{T_{\mathbf{L}}}^{T_{\mathbf{L}}} = T_{\mathbf{L}}$ and $g_{T_{\mathbf{nM}}}^{T_{\mathbf{L}}} = T_{\mathbf{nM}}$. This last conjunctor was directly obtained in [16].

If $i = T_{\mathbf{M}}$, only some special conjuntors satisfy the equality $g_h^{T_{\mathbf{M}}} = h$. The minimum t-norm is one of those t-norms. The following theorem characterizes all the conjunctors that verify the previous equality.

Proposition 2 *Let h be a commutative conjunctor with neutral element 1. Then h satisfies the equality $g_h^{T_{\mathbf{M}}} = h$ if and only if h is of the form*

$$h_k^d(x,y) = \begin{cases} 0 & \text{if } max(x,y) < d \\ k \cdot min(x,y) & \text{if } max(x,y) = d \\ min(x,y) & \text{otherwise} \end{cases}$$

where $k \in \{0,1\}$ and $d \in [0,1) \cup \{k\}$.

For the particular case when the conjunctor defining the transitivity of R and the indifference generator i are the same continuous t-norm the thorny general expression obtained in Theorem 5 gets much simpler.

Theorem 6 *Let T be a continuous t-norm. For any reflexive fuzzy relation R with corresponding strict preference relation P generated by means of T, it holds that*

$$R \text{ is } T\text{-transitive} \quad \Rightarrow \quad P \text{ is } g_T^T\text{-transitive}\,,$$

where

$$g_T^T(x,y) = \inf_{0 \leq \alpha \leq \min\{1-x, 1-y\}} \max\{T(x+\alpha, y+\alpha) - \alpha, 0\}$$

and this is the strongest possible implication.

In [5] the operator g_T^T was studied in depth not only for a t-norm T but in general for any binary aggregation operator A. In that general case, it was denoted as $\mathcal{D}[A]$. We can find there that for the Frank family of t-norms the expression can be simplified:

Proposition 3 *In case $i = T_\lambda^{\mathbf{F}} = h$ for $\lambda \in [0,\infty]$, it holds that*

$$g_{T_\lambda^{\mathbf{F}}}^{T_\lambda^{\mathbf{F}}}(x,y) = \begin{cases} T_\lambda^{\mathbf{F}}(x,y), & \text{if } x+y > 1\,, \\ S_M(T_\lambda^{\mathbf{F}}\left(\frac{1+x-y}{2}, \frac{1+y-x}{2}\right) - \frac{1-x-y}{2}\,,\, 0), & \text{otherwise}. \end{cases}$$

In particular, it holds that $g_{T_{\mathbf{L}}}^{T_{\mathbf{L}}} = T_{\mathbf{L}}$ (also obtained as a consequence of Proposition 1) , $g_{T_{\mathbf{M}}}^{T_{\mathbf{M}}} = T_{\mathbf{M}}$ (directly obtained in [13]) and

$$g_{T_{\mathbf{P}}}^{T_{\mathbf{P}}}(x,y) = \begin{cases} T_{\mathbf{P}}(x,y) - \left(\frac{T_{\mathbf{L}}(1-x,1-y)}{2}\right)^2, \text{ if } \sqrt{x} + \sqrt{y} > 1 \\ 0, \text{ otherwise.} \end{cases}$$

Other particular cases involving the three most important t-norms, i.e. concerning $h \in \{T_{\mathbf{L}}, T_{\mathbf{P}}, T_{\mathbf{M}}\}$ and $i \in \{T_{\mathbf{L}}, T_{\mathbf{P}}, T_{\mathbf{M}}\}$ are presented in the following propositions.

Proposition 4 *If $i = T_\lambda^{\mathbf{F}}$ for $\lambda \in [0,\infty]$ and $h = T_{\mathbf{L}}$, it holds that*

$$g_{T_{\mathbf{L}}}^{T_\lambda^{\mathbf{F}}}(x,y) = T_{1/\lambda}^{\mathbf{F}}(T_{\mathbf{L}}(x,y), S_{\mathbf{M}}(x,y)).$$

Proposition 5 *If $i = T_\lambda^{\mathbf{F}}$ and $h = T_{\mathbf{M}}$, it holds, for any $\lambda \in [0,\infty]$, that*

$$g_{T_{\mathbf{M}}}^{T_\lambda^{\mathbf{F}}}(x,y) = T_{\mathbf{nM}}^{\varphi_{1/\lambda}}(x,y)$$

where φ_λ is the automorphism of the interval $[0,\infty]$ defined as follows

$$\varphi_\lambda(x) = \begin{cases} x & \text{if } \lambda = 0, \\ \sqrt{x} & \text{if } \lambda = 1, \\ \frac{x+1}{2}\chi_{(0,1]}(x) & \text{if } \lambda = \infty, \\ \log_\lambda\left(\sqrt{\frac{\lambda^x - 1}{\lambda - 1}}\,(\lambda - 1) + 1\right) & \text{otherwise}, \end{cases}$$

and $T_{\mathbf{nM}}^{\varphi_{1/\lambda}}$ is the transformation by the automorphism $\varphi_{1/\lambda}$ of the t-norm $T_{\mathbf{nM}}$. Moreover, it holds that $g_{T_{\mathbf{M}}}^{T_\lambda^{\mathbf{F}}}$ is a t-norm.

As a consequence of this proposition, we obtain that $g_{T_{\mathbf{M}}}^{T_{\mathbf{L}}} = T_{\mathbf{nM}}$ and

$$g_{T_{\mathbf{M}}}^{T_{\mathbf{P}}}(x,y) = T_{\mathbf{nM}}^{\varphi_1}(x,y) = \begin{cases} \min\{x,y\} & \text{if } \sqrt{x} + \sqrt{y} > 1, \\ 0 & \text{otherwise}\,. \end{cases}$$

ISBN: 978-989-95079-6-8

In order to complete the study of all the combinations of the three most important t-norms, two cases are missing, namely $g_{T_{\mathbf{P}}}^{T_{\mathbf{L}}}$ and $g_{T_{\mathbf{P}}}^{T_{\mathbf{M}}}$, which will be revisited in Propositions 6 and 7.

Proposition 6 *It holds that*

$$g_{T_{\mathbf{P}}}^{T_{\mathbf{L}}}(x,y) = T_{\mathbf{M}}\left(T_{\mathbf{P}}(x,y), \frac{T_{\mathbf{L}}(x,y)}{T_{\mathbf{M}}(x,y)}\right) \cdot \chi_{(0,1]}(T_{\mathbf{M}}(x,y)).$$

When $T_{\mathbf{L}}$ is replaced by $T_{\mathbf{M}}$ as generator, the expression of $g_{T_{\mathbf{P}}}^{i}$ gets much more complicated.

Proposition 7 *It holds that*

$$g_{T_{\mathbf{P}}}^{T_{\mathbf{M}}}(x,y) = \max\{\min_{\substack{1 \geq u \geq x \\ 1 \geq v \geq y}} \left[uv - \min\left\{\tfrac{u-x}{v}, \tfrac{v-y}{u}\right\}\right], 0\} \cdot \chi_{(0,1]^2}(x,y).$$

Remark 2 *Combining the results in Propositions 1, 3, 4, 5, 6 and 7 leads to the following table, where the entries are the conjunctors g_h^i.*

$h \setminus i$	$T_{\mathbf{L}}$	$T_{\mathbf{P}}$	$T_{\mathbf{M}}$
$T_{\mathbf{L}}$	$T_{\mathbf{L}}$	$T_{\mathbf{P}}(T_{\mathbf{L}}, S_{\mathbf{M}})$	$T_{\mathbf{L}}(T_{\mathbf{L}}, S_{\mathbf{M}})$
$T_{\mathbf{P}}$	$g_{T_{\mathbf{P}}}^{T_{\mathbf{L}}}$	$g_{T_{\mathbf{P}}}^{T_{\mathbf{P}}}$	$g_{T_{\mathbf{P}}}^{T_{\mathbf{M}}}$
$T_{\mathbf{M}}$	$T_{\mathbf{nM}}$	$T_{\mathbf{nM}}^{\varphi_1}$	$T_{\mathbf{M}}$

6 Conclusions

This paper combines very general results with propositions concerning the most relevant particular cases. The general results can be applied to any conjunctor employed to define the transitivity of a large preference relation and any generator used to decompose that relation. The specific results concern the most important particular cases: those for which the conjunctors and the generators are the most important t-norms. The most general theorems we have introduced close the study of the transitivity that can satisfy the symmetric and asymmetric components of a (large) preference relation since those theorems involve (almost) any conjunctor and any generator we can use. The results concerning more particular operators provide more easy-to-use expressions for the most usual conjunctors and generators, i.e. for some t-norms. Only the last example leads to an unwieldy expression.

Despite the ugly general formulae obtained in Theorems 3 and 5, we have already proven that those conjunctors satisfy interesting properties for some particular cases. In future works we would like to study in depth the general expressions and the properties they satisfy.

Abstract *- For modeling of change of terminal server load, the approach including representation of time series of server parameters in the form of fuzzy time series is used. Further in the article the analysis of fuzzy time series is considered. The model of fuzzy tendencies is offered for terminal server traffic modeling. This model reflects change of the volume of terminal server traffic expressed linguistically, and it is used for its forecasting. The results of the forecast permit to determine linguistically expressed fuzzy tendencies on the basis of the offered model.*

Keywords— Fuzzy Time Series, Fuzzy Tendency, Fuzzy Neural Network, Forecasting, Terminal Server.

1 Introduction

During the last decade development of computing networks (CN) of different levels (from local area networks to global area networks) has resulted in the fact that the quality of production processes depends on the quality of network services more and more. Correspondence of scales of trade processes to the computer network can be achieved due to constant analysis of quality of CN functioning (including the application layer) and forecasting its development. Such analysis of existent network often rests upon results of time series (TS) analysis of server parameters.

Time series of server parameters have a number of peculiarities: non-stationarity, non-homogeneity, the complex form of dynamics, which limit the applicability of classical statistic methods of TS analysis such as regression and spectral analysis, exponential smoothing. In this connection, at present promising technologies of time series analysis are intelligent methods which permit to use expert knowledge and have no rigid requirements to initial data.

Modeling of experts' knowledge in the form of linguistic terms (evaluations) formalized as fuzzy sets became a prerequisite to TS modeling in the form of fuzzy time series.

Since 1993 a number of works have been dedicated to forecasting of fuzzy TS [1 - 4] constructed on the basis of numerical TS. In these investigations let us note the following problems which can be solved: increase of accuracy of numerical forecast owing to specification of the quantity and form of membership functions, decrease of computing owing to decrease of the number of fuzzy rules, increase of the level of automation when solving forecast problems. The indicated problems can be solved owing to application of methods of intelligent data analysis such as a fuzzy cluster analysis, genetic algorithms and neural networks.

The study [5] proposes the fuzzy neural network with initial weights generated by genetic algorithm (GFNN) for the sake of learning fuzzy IF–THEN rules. The result from GFNN is further integrated with an ANN artificial neural networks (ANN) forecast using the time series data from another ANN. Model evaluation results for a convenience store (CVS) company indicate that the proposed system can perform more accurately than the conventional statistical method and a single ANN.

In the work [6] the method of forecasting of TS inflation on the basis of fuzzy systems and a neural network is offered. To determine the fuzzy relation of the first-order fuzzy time series model, the neural network with SCL clustering technique was used to derive the rules directly from the database. The method may be of real usefulness in practical applications, where usually the expert can not explain linguistically, what control actions the process takes or there is no knowledge of the process.

To forecast fuzzy time series, in study [7] a backpropagation neural network is applied because of its nonlinear structures. Authors propose a hybrid model consisting of a neural network approach to forecast the known patterns as well as a simple method to forecast the unknown patterns.

Then the authors published the work [8] in which they proposed bivariate models in order to improve forecasting. The stock index and its corresponding index futures were taken as the inputs to forecast the stock index for the next day.

In this work there is offered a new hybrid forecasting model of TS in the form of a time series of fuzzy tendencies representing context-dependent interval linguistic evaluations of the traffic of the terminal server of a complex network. For the time series of FT, the model of forecasting of the first order is defined in terms of fuzzy tendencies to make more reasonable decisions on planning of network structure change.

In the part 2 the model and base operations of FT processing are defined.

In the part 3 a fuzzy neural network for generation of fuzzy rules of forecasting fuzzy tendencies is offered. The developed mathematical simulation model of the terminal server as an element of a computing network on the basis of time series of fuzzy tendencies presented in part 4 permits to forecast the traffic of the terminal server both in terms of fuzzy tendencies and in terms of the initial TS.

2 Models and base operations of fuzzy tendencies processing

In the work [8] the evaluation of TS is analyzed which is expressed in linguistic terms, the concepts fuzzy time series (FTS) and fuzzy tendency (FT) are introduces for that. The fuzzy tendency of a fuzzy time series is the fuzzy label which expresses the dynamics (systematic motion) of a fuzzy time series. The concept "tendency", being modeled by the fuzzy set, can be described by the set of constructed empiric rules. To find the fuzzy tendencies, it is offered to use Fuzzy Neurons Network (FNN). The analysis of the FT permits to forecast the behavior of the time series on the basis of process dynamics by means of prediction of tendencies of development of the object being studied. With it forecasting of numerical values of TS is not foreseen, and it can be considered as a shortcoming of the offered methods.

The base operations of fuzzy tendencies processing are algorithmic operations of fuzzy tendencies processing, namely the operation of forming the time series of fuzzy tendencies by the initial time series and the inverse operation of generation of the series – a representative of the fuzzy tendency.

Definition 1. A fuzzy time series $\widetilde{Y}$ is the ordered sequence of observations of some phenomenon the character of which changes in the course of time if values which some quantity takes on at the instant of time are expressed by the fuzzy label:

$$\widetilde{y}_t^i = \{(\widetilde{y}^i, U_y, \mu_i(y_t)), t\},$$

where $\widetilde{y}^i$ is the *i*-th element of the term-set of the linguistic variable $(\widetilde{Y}, T_y, U_y, G_y, M_y)$.

Thus, a FTS is the vector time series of values of all fuzzy variables:

$$\widetilde{Y} = \{\widetilde{y}_t\},$$

where $\widetilde{y}_t = \{\widetilde{y}_t^1, ..., \widetilde{y}_t^n\}$, *n* is the number of terms.

Definition 2. Fuzzy tendency. Let $\widetilde{y}_\Delta = \{\widetilde{y}_1, ..., \widetilde{y}_m\}$ be the fuzzy time series of the linguistic variable $(\widetilde{Y}, T_y, U_y, G_y, M_y)$, $\widetilde{Y}_\Delta = \{\widetilde{y}_\Delta\}$ is the set of fuzzy time series of the same length. Then the fuzzy tendency τ, determined on the $\widetilde{Y}_\Delta$, is the aggregate of ordered pairs:

$$\tau = \{\widetilde{y}_\Delta, \mu_\tau(\widetilde{y}_\Delta)\},$$

where $\mu_\tau(\widetilde{y}_\Delta)$ is the degree of membership of $\widetilde{y}_\Delta$ to FT.

Determining the fuzzy tendency on all intervals [*t-m+1, t*] of the time series and positioning the beginning and the end of the interval to the time scale, we receive the time series of the fuzzy tendency.

Definition 3. The time series of a fuzzy tendency (TSFT). Let $\{\widetilde{y}_{\Delta t}\}$ be the set of fuzzy time series which length is equal to *m*, where $\widetilde{y}_{\Delta t} = \{\widetilde{y}_{t-m+1}, ..., \widetilde{y}_t\}$, $\widetilde{y}_t \in \widetilde{Y}$ t. Then the time series of a fuzzy tendency is the ordered in time fuzzy set:

$$\tau_t = \{t, \mu_\tau(\widetilde{y}_{\Delta t})\}.$$

For the linguistic variable FT, the time series of fuzzy tendencies is determined as the vector TS of values of all kinds of fuzzy tendencies:

$$\tau_t = \{t, \tau_t^1, ..., \tau_t^p\}.$$

Let us assume that there is dependence between fuzzy tendencies observed at different instants of time. Using the scheme of the differed equation (1) let us represent the model of the time on the basis of FT for one variable:

$$\tau_t = f(\tau_{t-1}, ...\tau_{t-l}), \quad (1)$$

where *l* is the time interval. For construction of the model of TS on the basis of FT, it is necessary to solve the following problems:

-to determine the procedure of fuzzyfication and defuzzyfication of the TS;

-to determine the procedure of description and identification of the FT;

-to determine the procedure of receiving the crisp time series from values of FT;

-to identify the functional dependence.

Receiving a FTS from a crisp TS is based on the operation of fuzzyfication, i.e. transition from quantitative values to linguistic evaluations. The procedure of fuzzyfication is widely enough described in literature. Let us denote the process of finding the value of membership function of elements *Uy* to the terminal set T_y by the functional Fuzzy:

$$\widetilde{Y} = Fuzzy[Y].$$

The functional supposes solving the problems of linguistic terms description and rules of use, choosing the corresponding membership functions. When determining the linguistic terms the following methods can be used: subjective description of the universe U_y on the basis of expert knowledge about the system and descriptive terminology accepted in the field being investigated; uniform partition of the universe (into 3-7 intervals, as a rule); clusterisation of values of the time series for determination of the most significant intervals on the universe.

Defuzzyfication is the problem inverse to fuzzyfication, i.e. receiving the crisp TS from a fuzzy one, is given by the functional deFuzzy:

$$Y' = deFuzzy[\widetilde{Y}].$$

The problem of determination of the FT is fundamental in the construction of the system of data analysis, decision of which will permit to start disclosing the connections between parameters of the object being investigated. This problem consists of the following sub-problems:

-determination of linguistic variables of the FT;

-construction of the time series of the FT.

Let us denote solving the problem by the functional Tend:

$$\tau = Tend[\widetilde{Y}_\Delta]$$

For determination of the linguistic variable expressing the fuzzy tendency, it is necessary to single out the typical behavior of the fuzzy time series, that is to make up the terminal set. The analysis of the initial series for evaluation of the dynamics can be done by the following methods:

-using the evaluations of the dynamics (increase, decrease, stability);

ISBN: 978-989-95079-6-8

-subjective description on the basis of expert knowledge about the systematic behavior of system parameters;

-clusterisation of values of the fuzzy time series for determination of the most significant tendencies on the universe.

For construction of TSFT, it is necessary not only to single them out (to denote linguistic terms), but to give a description and be able to find the tendency on the FTS. Thus, the functional Tend includes the tool of FT description, the algorithm of finding the correspondence of fuzzy time series to the chosen description, that is the algorithm of fuzzy evaluation.

For the analysis and construction of crisp TS by the fuzzy model, the operation of receiving the FTS from tendency evaluation is necessary. Let us denote solving of this problem by the functional *deTend*, which is inverse to the functional Tend:

$$\widetilde{Y}`_{\Delta} = deTend[\tau],\ \widetilde{Y}`_{\Delta} \in \widetilde{Y}_{\Delta},$$

where $\widetilde{Y}`_{\Delta} = \{\widetilde{y}`_{\Delta}\}$ is the set of typical (characteristic) fuzzy time series for FT which have the maximum value of membership function $\mu_{\tau}(\widetilde{y}`_{\Delta}) = \max(\mu_{\tau}[\widetilde{Y}_{\Delta}])$.

Using the functional of defuzzyfication *deFuzzy*, receiving the fuzzy time series from tendencies *deTend* solves the problem of crisp TS forecasting.

Let us denote the aggregate of components and equations:

$$\widetilde{y}_t^i = Fuzzy[y_t],\ y_t = deFuzzy[\widetilde{y}_t^1,...\widetilde{y}_t^n], i = 1..n,$$

$$\tau_t^j = Tend[\widetilde{y}_{t-m_j+1},...,\widetilde{y}_t],$$

$$\widetilde{y}_t^i = deTend[\tau_t,...,\tau_{t+m-1}], m = \max(m_j),\ j = 1..p,$$

$$\tau_t = f(\tau_{t-1},...\tau_{t-l}),$$

where n is the number of terms of FTS, p is the number of terms of FT, m_j is the interval of definition of FT, l is the time log, by the *model of fuzzy tendencies* (MFT) with characterizing parameters (n, p, m, l). In more detailed form these parameters can be denoted as (n, $\{p_k\}$, $\{m_k\}$, l), where p_k is the number of kinds of tendencies which have the interval of definition m_k.

For the analysis and construction of the crisp time series by the fuzzy model (the functional *deTend)* let us make the fuzzy time series which has the maximum value of membership function in the form of the rule $\widetilde{y}_{\Delta t} = (\tau_t) \circ R_2$ correspond to each kind of fuzzy tendency. For a example, the procedure *deTend* can be represented in the form of the system of rules:

if τ_t is jump, then y_{t-2} is low,

if τ_t is jump, then y_{t-1} is high,

if τ_t is jump, then y_t is low.

Let us represent the equation (1) also by the fuzzy relation:

$$\tau_t = (\tau_{t-1},...\tau_{t-l}) \circ R_3.$$

The MFT is realized by multilevel system of logical relations:

$$R_1 \Rightarrow R_3 \Rightarrow R_2,$$

where outputs in the form of fuzzy variables of one set of rules are applied to inputs of the next set of rules without defuzzyfication and fuzzyfication. Transformation into fuzzy and crisp values happens only in relations R_1 and R_2 correspondingly.

3 Fuzzy neural network

Let us use classical fuzzy neurons in which operations of addition and multiplication are replaced by triangular norms:

AND-neuron $\beta = T(S(\tau_1, w_1), S(\tau_2, w_2))$,

OR-neuron $\tau^0 = S(T(\beta_1, z_1), T(\beta_2, z_2))$.

It can be interpreted in the linguistic form correspondingly as:

if ($\tau 1$ or $w1$) and (τ_2 or w_2) then β,

if (β_1 *and* z_1) or (β_2 *and* z_2) then τ_0.

On the basis of such neurons it is possible to construct the network of logical inference by Mamdani for finding the fuzzy tendency τ by adding weight coefficients. In a formalized way such network can be expressed in the following form:

$$\tau^0 = \underset{i=1}{\overset{k}{S}}[T(\beta_i, z_i)],\ \beta_i = \underset{j=1}{\overset{m}{T}}[S(\tau_j, w_{j,i})],$$

where T is the operator of conjunction, S is the operator of disjunction, k is the number of rules, m is the number of inputs. Weight coefficients are interpreted in the following way: z_i is the degree of influence of i-th rule on the general result (0 – has no influence, 1 – has influence); $w_{j,i}$ are degrees of no influence of j-th input on i-th rule (0 – has influence, 1 – has no influence). The basic idea of FNN learning consists in the iterative procedure of weights optimization (z_i, $w_{j,i}$) and removal of insignificant connections (network reduction), as a result of which the necessary composition and number of rules are formed.

The order of search fuzzy dependences on the basis of FNN is the following:

-Initialization of the fuzzy neural network.

-Learning: optimization of network weights.

-Analysis of the network: network reduction.

At the initialization stage it is necessary to determine input variables: kinds of tendencies and the time log. It is necessary to generate an excessive number of "complete" rules, which include all inputs with arbitrary weights in the interval (0,1).

The stage of learning is the process of FNN weights change on the basis of the learning sample. Network learning is possible by the method of back error propagation. For this purpose let us determine the function of error $E = \frac{1}{2}(\tau^0 - \tau)^2$ which is to be minimized by the method of gradient lowering. For decrease of the squared error E, it is necessary to change weights (z_i, $w_{j,i}$) in the direction of antigradient of the function E:

$$w_{j,i}^{+1} = w_{i,j} - \eta \frac{\partial E}{\partial w_{j,i}},\ z_i^{+1} = z_i - \eta \frac{\partial E}{\partial z_i},$$

where η is the speed of learning with the limitation $w_{j,i}^{+1} \in [0,1]$, $z_i^{+1} \in [0,1]$. For calculation of the derivative error, it is necessary to choose the corresponding functions of t-norms and t-conorms. The indication of completion of learning is reaching the error level.

ISBN: 978-989-95079-6-8

At the stage of analysis processing of FNN is carried out with the purpose of its simplification. The principle of removal of insignificant connections and neurons from the network forms the basis of reduction algorithms. One of simplest reduction methods is the method of projections which is realized in the following way. The synoptic weight is nulled if its value has fallen into the given range

$$w_{j,i} = \begin{cases} 1, w_{j,i} \geq (1-\varepsilon) \\ w_{j,i}, w_{j,i} < \varepsilon \end{cases}, \; z_i = \begin{cases} 0, z_i \leq \varepsilon \\ z_i, z_i > \varepsilon \end{cases},$$

where ε is some constant. On the basis of the chosen level of weights ε connections "input – AND-neuron", when $w_{j,i}=1$, and "AND-neuron – OR-neuron", when $z_i = 0$, are removed. Not used inputs and rules are also removed.

As a result the system of logical inference is got, which is the explaining function in the model of time series. Fuzzy rules are easily interpreted for an expert since they are expressed in terms inherent to the investigated field.

4 Server traffic modeling on the basis of the time series of fuzzy tendencies

For time series analysis on the basis of the offered model of a fuzzy time series, the software *FuzzyTendNet* is created.

Thus, for each time series a user assigns the set of linguistic terms with corresponding membership functions (trapezoid function form is used) and the set of fuzzy tendencies. The possibility of using several rules of identification and inverse rules for each tendency permits to describe various interval expert evaluations flexibly enough.

The equation of the model of a time series is the fuzzy neural network which has subnetworks for each output tendency. Each subnetwork is the system of logical deduction which consists of the set of rules. These rules can be formed manually and in the automatic mode with optimization on the basis of the algorithm of back error propagation. The method of projections is used for cancellation of the network. The following logical connectives (functions of triangular norms) are used: minimum and maximum — for rules of identification and inverse rules, product and probabilistic sum — for FNN.

For modeling of the traffic of the terminal server on the basis of the offered approach, seven parameters of the work of the terminal server were chosen, and time series were formed from them.

So, the server parameters of work were chosen (Table 1) and the statistics with 15 seconds interval during one day was collected.

Table 1. Description of variables

Parameter
X1 - Memory\ Pages exchange per second
X2 - Record accesses to disc per second
X3 - Read accesses from disc per second
X4 - % of processor load
X5 - Reading operations
X6 - Recording operations
Y - Traffic

For all parameters fuzzy variables of FTS describing the values "high" and "low" are determined. Fuzzy tendencies "load", "idle" are determined. Additional fuzzy tendencies "increase" and "decrease" are also determined for traffic. In Table 2 description of functionals of the MFT is presented.

Let us note the following:

-the functional deTend is described only for the dependent variable (traffic);

-FT determined on the unit interval, which have the semantic load analogous to variables of FTS, are used in the model.

Table 2. Description of tendencies of terminal-server model parameters change

Parameter	FTS	TSFT	
	$\tilde{y}$	τ	Tend
X1	low	idle	low(1) &low(2)
	high	load	high(1) & high(2)
X2	low	idle	low(1) & low(2)
	high	load	high(1) & high(2)
X3	low	idle	low(1) & low(2)
	high	load	high(1) & high(2)
X4	low	idle	low(1) & low(2)
	high	load	high(1) & high(2)
X5	low	idle	low(1) & low(2)
	high	load	high(1) & high(2)
X6	low	idle	low(1) & low(2)
	high	load	high(1) & high(2)
Y	low	idle	low(1) & low(2)
	high	load	high(1) & high(2)
		increase	low(1) & high(2)
		decrease	high(1) & low(2)

For comparison of models on the basis of fuzzy time series and fuzzy tendencies, a number of experiments were conducted.

The conclusion can be made that the model based on fuzzy tendencies describes the modeled process more successfully. On Fig. 1 the forecast for one step forward is presented for two models.

ISBN: 978-989-95079-6-8

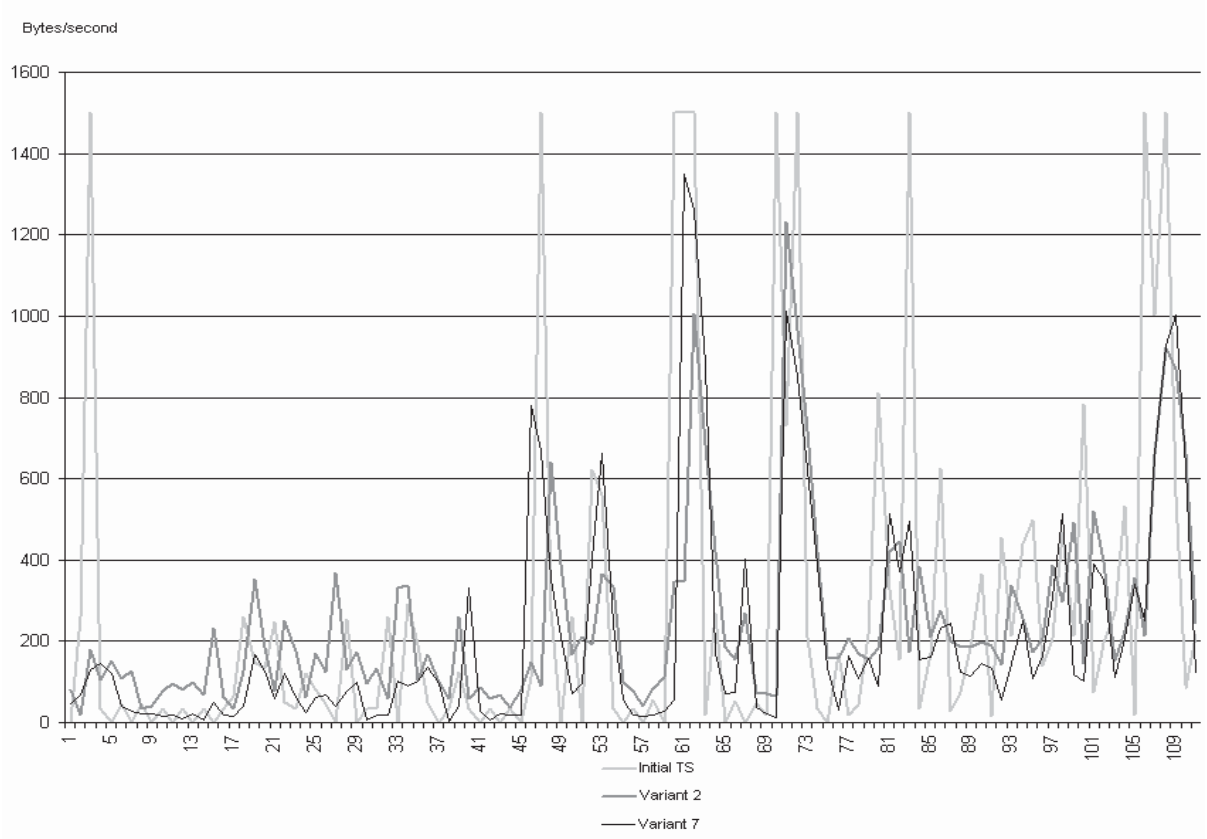

Figure 1:The graph of tested and forecasted TS

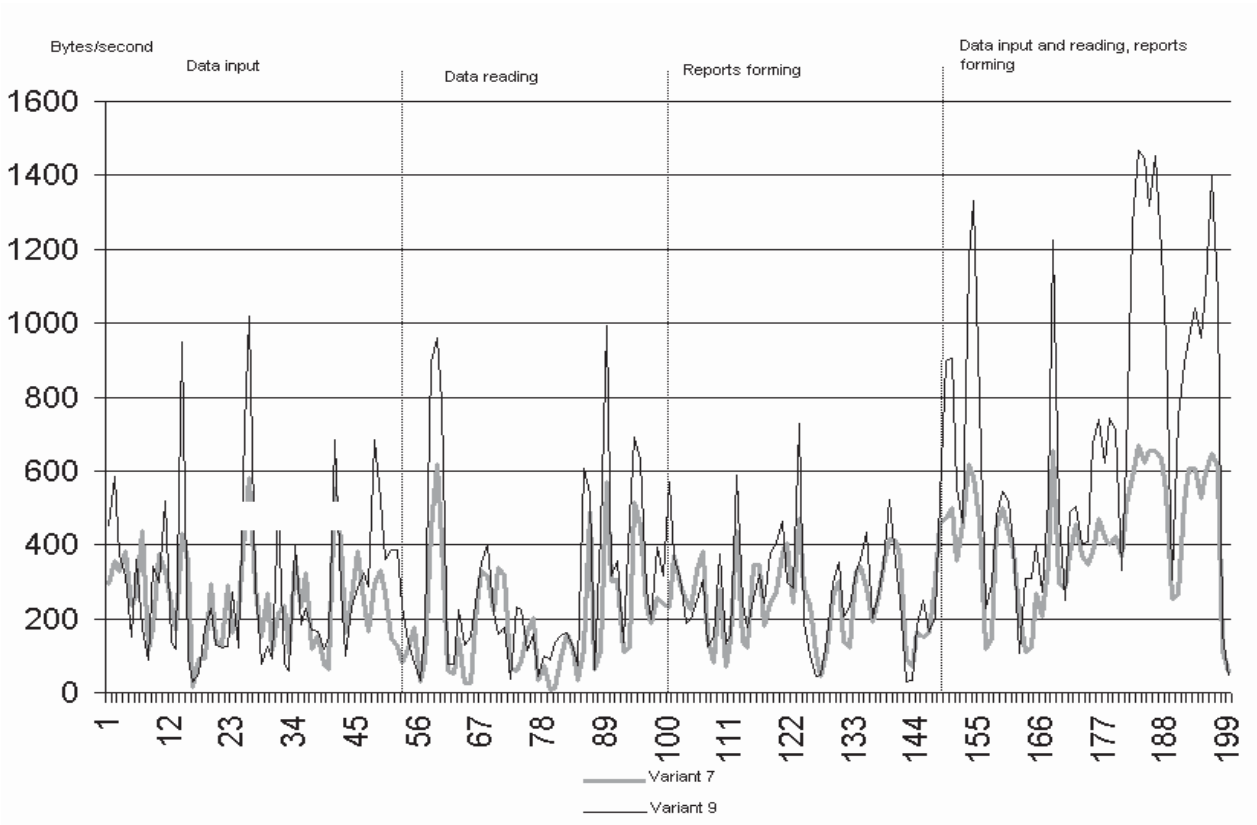

Figure 2:Load modeling

For server traffic volume modeling, the following modes of server work were described by the expert: data input, data reading, reports forming — with high values of corresponding groups of parameters. On Fig 2 results of modeling are presented.

By fuzzy tendencies low and high values of the traffic and its crisp values have been forecasted in different modes of work. The analysis of linguistic series of fuzzy tendencies showed increase of the traffic of the terminal server in the mode of data input and reports forming.

ISBN: 978-989-95079-6-8

Thus the conclusion can be made that increase of users performing the mentioned operations will be accompanied by increase of the traffic. When performing all operations on the server simultaneously, we can simultaneously observe both high and low traffic of the network, which can be explained by instability in this mode of work.

5 Conclusions

Thus, the time series of fuzzy tendencies is an effective indicator of development of a modeled process in a complex technical system described qualitatively by linguistic terms. Basic operations of fuzzy tendencies processing are algorithmic operations of fuzzy tendencies processing, namely the operation of forming the time series of fuzzy tendencies by initial time series and the inverse operation of generation of the series — a representative of the fuzzy tendency. The fuzzy neural network of the offered architecture is an effective generator of rules of fuzzy tendencies identification. The developed mathematical simulation model of the terminal-server as the element of the computing network on the basis of time series of fuzzy tendencies permits to forecast processor load, the outgoing and incoming traffic of the server.

Abstract— *The nearest trapezoidal fuzzy number to a fuzzy number, with respect to a well-known metric and preserving the expected interval, was determined in recent articles. In the present paper the properties of additivity and continuity of the trapezoidal approximation operator are studied.*

Keywords— Additivity, Approximation, Continuity, Fuzzy number, Trapezoidal fuzzy number.

1 Introduction

In the papers [1] and [10] the problem to find the nearest (with respect to a well-known metric) trapezoidal fuzzy number $T(A)$ to a fuzzy number A such that $EI(T(A)) = EI(A)$, where $EI(B)$ denotes the expected interval of a fuzzy number B, was completely solved. Algorithms for computing the proper approximations are proposed in [6]. The properties of translation and scale invariance, identity, nearness criterion, expected interval invariance, order invariance, correlation invariance, uncertainty invariance, value and ambiguity invariance were considered in [1]. The properties of additivity and continuity are studied in the present paper.

In Section 3 we prove, by a simple example, that the additivity is not satisfied. The main result in this section contains a property of partial additivity. In the paper [5] the property of continuity of the approximations of fuzzy numbers is considered of extreme importance in applications, especially in fuzzy control systems, where it is sometimes indicated as robustness. The authors of the paper [2] pointed out that the method to study the continuity of the trapezoidal approximation without condition in [11] is not applicable in the case of trapezoidal approximation preserving the expected interval. In Section 4 we prove that the discussed approximation operator has the property to be Lipschitz, such that it is continuous.

2 Preliminaries

A fuzzy number A is a fuzzy subset of the real line $\mathbb{R}$ with the membership function μ_A which is normal, fuzzy convex, upper semicontinuous and supp A is bounded, where supp $A = cl\{x \in \mathbb{R} : \mu_A(x) > 0\}$ and cl is the closure operator.

Every λ-cut, $\lambda \in]0,1]$ of a fuzzy number A is a closed interval $A_\lambda = [A^-(\lambda), A^+(\lambda)]$, where

$$A^-(\lambda) = \inf\{x \in \mathbb{R} : \mu_A(x) \geq \lambda\},$$
$$A^+(\lambda) = \sup\{x \in \mathbb{R} : \mu_A(x) \geq \lambda\}.$$

We denote

$$A_0 = \left[A^-(0), A^+(0)\right] = \text{supp } A.$$

For two arbitrary fuzzy numbers A, B

$$A_\lambda = \left[A^-(\lambda), A^+(\lambda)\right]$$

and

$$B_\lambda = \left[B^-(\lambda), B^+(\lambda)\right]$$

the addition $A + B$ is introduced by

$$(A+B)_\lambda = \left[A^-(\lambda) + B^-(\lambda), A^+(\lambda) + B^+(\lambda)\right]$$

and the quantity

$$D^2(A,B) = \int_0^1 \left(A^-(\lambda) - B^-(\lambda)\right)^2 d\lambda + \int_0^1 \left(A^+(\lambda) - B^+(\lambda)\right)^2 d\lambda \quad (1)$$

gives a distance between A and B (see, e.g., [4]). The expected interval $EI(A)$ of a fuzzy number $A, A_\lambda = [A^-(\lambda), A^+(\lambda)]$, is defined by (see [3], [7])

$$EI(A) = \left[\int_0^1 A^-(\lambda)\, d\lambda, \int_0^1 A^+(\lambda)\, d\lambda\right].$$

An often used fuzzy number is the trapezoidal fuzzy number, completely characterized by four real numbers $t_1 \leq t_2 \leq t_3 \leq t_4$, denoted by $T = (t_1, t_2, t_3, t_4)$, with

$$T^-(\lambda) = t_1 + (t_2 - t_1)\lambda,$$
$$T^+(\lambda) = t_4 - (t_4 - t_3)\lambda, \lambda \in [0,1].$$

Sometimes (see [10]) a trapezoidal fuzzy numbers is denoted by $T = (l, u; x, y)$, with $l, u, x, y \in \mathbb{R}$ such that $x, y \geq 0, x + y \leq 2(u - l)$,

$$T^-(\lambda) = l + x\left(\lambda - \frac{1}{2}\right),$$
$$T^+(\lambda) = u - y\left(\lambda - \frac{1}{2}\right), \lambda \in [0,1].$$

It is immediate that

$$l = \frac{t_1 + t_2}{2}, \quad (2)$$
$$u = \frac{t_3 + t_4}{2}, \quad (3)$$
$$x = t_2 - t_1, \quad (4)$$
$$y = t_4 - t_3, \quad (5)$$

ISBN: 978-989-95079-6-8

the expected interval of a trapezoidal fuzzy number represented in this way is the real interval $[l,u]$ and the distance between $T=(l,u;x,y)$ and $T'=(l',u';x',y')$ becomes ([10])

$$D^2(T,T') = (l-l')^2 + (u-u')^2 + \frac{1}{12}(x-x')^2 + \frac{1}{12}(y-y')^2. \quad (6)$$

We denote by $F(\mathbb{R})$ the set of all fuzzy numbers, by $F^T(\mathbb{R})$ the set of all trapezoidal fuzzy numbers and by $T(A)$ the nearest (with respect to the metric D) trapezoidal fuzzy number to fuzzy number A preserving the expected interval of A. To express in a simplified form the approximation operator $T: F(\mathbb{R}) \to F^T(\mathbb{R})$ we denote

$$I(A) = I = \int_0^1 A^-(\lambda)d\lambda, \quad (7)$$

$$S(A) = S = \int_0^1 A^+(\lambda)d\lambda, \quad (8)$$

$$L(A) = L = \int_0^1 \lambda A^-(\lambda)d\lambda \quad (9)$$

and

$$U(A) = U = \int_0^1 \lambda A^+(\lambda)d\lambda, \quad (10)$$

for every fuzzy number $A, A_\lambda = [A^-(\lambda), A^+(\lambda)], \lambda \in [0,1]$ and we consider the following sets of fuzzy numbers

$$\Omega_1 = \{A \in F(\mathbb{R}) : 2I+S-3L-3U>0\},$$
$$\Omega_2 = \{A \in F(\mathbb{R}) : -I-2S+3L+3U>0\},$$
$$\Omega_3 = \{A \in F(\mathbb{R}) : -I+S+3L-3U\le 0\},$$
$$\Omega_4 = \Omega_1^c \cap \Omega_2^c \cap \Omega_3^c.$$

The set $\{\Omega_1,\Omega_2,\Omega_3,\Omega_4\}$ is a partition of $F(\mathbb{R})$ (see the proof of Theorem 7 in [1]).

The following result was proved in [1] and [10].

Theorem 1 (i) *If* $A \in \Omega_1$ *then*

$$T(A) = T_1(A) = (I, I, I, 2S-I);$$

(ii) *If* $A \in \Omega_2$ *then*

$$T(A) = T_2(A) = (2I-S, S, S, S);$$

(iii) *If* $A \in \Omega_3$ *then*

$$T(A) = T_3(A) = (4I-6L, -2I+6L, -2S+6U, 4S-6U);$$

(iv) *If* $A \in \Omega_4$ *then*

$$T(A) = T_4(A) = (3I+S-3L-3U, -I-S+3L+3U, -I-S+3L+3U, I+3S-3L-3U).$$

Four different operators $T_i, i \in \{1,2,3,4\}$ give us the nearest trapezoidal approximation preserving the expected interval: T_1 and T_2 lead to triangular fuzzy numbers with right side only or left side only, respectively, T_3 produces proper trapezoidal fuzzy numbers and T_4 produces triangular fuzzy numbers.

3 Additivity

The approximation operator $T: F(\mathbb{R}) \to F^T(\mathbb{R})$ given in Theorem 1 is scale invariant (see [1], Theorem 12, (ii)) and invariant to translations (see [1], Theorem 12, (i)), that is

$$T(\alpha A) = \alpha T(A)$$

and

$$T(A+z) = T(A) + z,$$

for every $A \in F(\mathbb{R}), z \in \mathbb{R}$ and $\alpha \in \mathbb{R} \setminus \{0\}$. In this section we point out a partial result of additivity and prove, be a simple example, that the operator T is not additive.

Example 2 *Let us consider the fuzzy numbers* A *and* B *given by*

$$A^-(\lambda) = 1+\sqrt{\lambda},$$
$$A^+(\lambda) = 30-27\sqrt{\lambda},$$
$$B^-(\lambda) = -1+\sqrt{\lambda},$$
$$B^+(\lambda) = 1-\sqrt{\lambda}, \lambda \in [0,1].$$

Then (see [1], Example 10 and Example 11) $A \in \Omega_1$,

$$T(A) = \left(\frac{5}{3}, \frac{5}{3}, \frac{5}{3}, \frac{67}{3}\right)$$

$B \in \Omega_4$,

$$T(B) = \left(-\frac{2}{3}, 0, 0, \frac{2}{3}\right),$$

therefore

$$T(A)+T(B) = \left(1, \frac{5}{3}, \frac{5}{3}, 23\right).$$

Because

$$(A+B)^-(\lambda) = 2\sqrt{\lambda},$$
$$(A+B)^+(\lambda) = 31-28\sqrt{\lambda}, \lambda \in [0,1],$$

we obtain

$$I(A+B) = \frac{4}{3},$$
$$S(A+B) = \frac{37}{3},$$
$$L(A+B) = \frac{4}{5}$$

and

$$U(A+B) = \frac{43}{10}.$$

We get $A+B \in \Omega_4$ *and*

$$T(A+B) = \left(\frac{31}{30}, \frac{49}{30}, \frac{49}{30}, \frac{691}{30}\right)$$

which implies

$$T(A+B) \neq T(A)+T(B).$$

Theorem 3 *If* $A, B \in \Omega_i$ *(*$i \in \{1,2,3,4\}$*) then*

$$T(A+B) = T(A)+T(B).$$

ISBN: 978-989-95079-6-8

Proof. The equalities

$$I(A+B) = I(A) + I(B),$$
$$S(A+B) = S(A) + S(B),$$
$$L(A+B) = L(A) + L(B),$$
$$U(A+B) = U(A) + U(B), A, B \in F(\mathbb{R})$$

are immediate. Then $A, B \in \Omega_i$ ($i \in \{1,2,3,4\}$) implies $A+B \in \Omega_i$ and $T(A)+T(B) = T(A+B)$ in every case $(i)-(iv)$ in Theorem 1. ■

4 Continuity

An extended trapezoidal fuzzy number ([10]) is an order pair of polynomial functions of degree less than or equal to 1. An extended trapezoidal fuzzy number may be not a fuzzy number, but the distance between two extended trapezoidal fuzzy numbers is similarly defined as in (1) or (6). The extended trapezoidal approximation $T_e(A) = (l_e, u_e; x_e, y_e)$ of a fuzzy number A is defined ([10]) as the extended trapezoidal fuzzy number which minimizes the distance $D(A,B)$, where B is an extended trapezoidal fuzzy number, and preserves the expected interval of A. The real numbers x_e and y_e are non-negative (see [11]). In [5], the authors proved that $T_e(A) = T_3(A)$.

Let us denote by $T(A) = (l_0, u_0; x_0, y_0)$ the nearest (with respect to the metric D) trapezoidal fuzzy number to fuzzy number A, preserving the expected interval, given in Theorem 1, in the form proposed in [10] (see also Section 2). We have ([10])

$$l_0 = l_e = \int_0^1 A^-(\lambda)d\lambda \tag{11}$$

$$u_0 = u_e = \int_0^1 A^+(\lambda)d\lambda. \tag{12}$$

Let us consider in the Euclidean space $\mathbb{R}^2$ (it is a finite dimensional Hilbert space) the points $A_e(x_e, y_e)$, $A_0(x_0, y_0)$ and the set

$$M = \{(x,y) \in \mathbb{R}^2 : x \geq 0, y \geq 0, x + y \leq 2u_e - 2l_e\}$$

which is a closed convex subset of $\mathbb{R}^2$. Then $P_M(A_e)$ is the unique element in M (see e.g. [8], Theorem 4.10, p. 79) which minimizes the Euclidean distance in $\mathbb{R}^2$, $D_E(A_e, P)$, where $P \in M$. Taking into account the remarks in [10] we get

$$A_0 = P_M(A_e). \tag{13}$$

We present the main result of this section.

Theorem 4 *The nearest trapezoidal approximation operator preserving the expected interval $T : F(\mathbb{R}) \to F^T(\mathbb{R})$ is continuous.*

Proof. Let us consider two fuzzy numbers A and B,

$$A_\lambda = \left[A^-(\lambda), A^+(\lambda)\right],$$
$$B_\lambda = \left[B^-(\lambda), B^+(\lambda)\right], \lambda \in [0,1],$$

$T_e(A) = (l_e, u_e; x_e, y_e)$, $T_e(B) = (l'_e, u'_e; x'_e, y'_e)$ the extended trapezoidal approximations of A and B and $T(A) = (l_0, u_0; x_0, y_0)$, $T(B) = (l'_0, u'_0; x'_0, y'_0)$ the trapezoidal approximations preserving the expected interval of A and B. The relations (11) and (12) imply

$$D^2(T(A), T(B)) = (l_0 - l'_0)^2 + (u_0 - u'_0)^2 + \frac{1}{12}(x_0 - x'_0)^2 + \frac{1}{12}(y_0 - y'_0)^2$$
$$= (l_e - l'_e)^2 + (u_e - u'_e)^2 + \frac{1}{12}(x_0 - x'_0)^2 + \frac{1}{12}(y_0 - y'_0)^2$$

Because (see [9], Proposition 4.4)

$$D(T_e(A), T_e(B)) \leq D(A,B) \tag{14}$$

we obtain

$$D^2(T(A), T(B)) \leq D^2(A,B) + \frac{1}{12}(x_0 - x'_0)^2 + \frac{1}{12}(y_0 - y'_0)^2$$

or

$$D^2(T(A), T(B)) \leq D^2(A,B) + \frac{1}{12}D_E^2(A_0, B_0), \tag{15}$$

where $D_E(A_0, B_0)$ denotes the Euclidean distance between $A_0(x_0, y_0)$ and $B_0(x'_0, y'_0)$. Let us assume (contrariwise the proof is similar)

$$2u'_e - 2l'_e \geq 2u_e - 2l_e.$$

We consider

$$M_A = \{(x,y) \in \mathbb{R}^2 : x \geq 0, y \geq 0, x + y \leq 2u_e - 2l_e\},$$
$$M_B = \{(x,y) \in \mathbb{R}^2 : x \geq 0, y \geq 0, x + y \leq 2u'_e - 2l'_e\}$$

and

$$C(2u_e - 2l_e, 0),$$
$$C'(0, 2u_e - 2l_e),$$
$$G(2u'_e - 2l'_e, 0),$$
$$G'(0, 2u'_e - 2l'_e),$$

the points which define the closed convex sets M_A and M_B in the Euclidean space $\mathbb{R}^2$. The pairs (l_e, u_e), (l'_e, u'_e) being already fixed ((11), (12)), we denote $A_e(x_e, y_e)$ and $B_e(x'_e, y'_e)$ the points in $\mathbb{R}^2$ which represent the others components of the extended trapezoidal approximations of A and B, respectively. It is known that $x_e, y_e, x'_e, y'_e \geq 0$.

According to (13) we get

$$A_0 = P_{M_A}(A_e)$$
$$B_0 = P_{M_B}(B_e)$$

We denote by B_1 the projection of B_0 on the convex set M_A, that is the unique element in M_A which minimizes $D_E(B_0, Q)$, where $Q \in M_A$. We prove that B_1 is the

ISBN: 978-989-95079-6-8

projection of B_e on the set M_A, that is $B_1 \in M_A$ and $\min_{R \in M_A} D_E(B_e, R) = D_E(B_e, B_1)$, and

$$D_E(B_1, B_0) \leq D_E(C, G) = D_E(C', G').$$

Indeed, if $x'_e + y'_e \leq 2(u_e - l_e)$ then $B_e \in M_A$. Because $M_A \subseteq M_B$ we get

$$B_e \in M_B,$$
$$B_0 = B_1 = B_e$$

and

$$D_E(B_1, B_0) = 0 \leq D_E(C, G).$$

Contrariwise, if $x'_e + y'_e > 2(u_e - l_e)$ then the following situations are possible:

(i) $x'_e - y'_e > 2(u'_e - l'_e)$. Then

$$B_0 = G,$$
$$P_{M_A}(B_e) = C$$

and

$$B_1 = P_{M_A}(B_0) = P_{M_A}(G) = C.$$

In addition,

$$D_E(B_1, B_0) = D_E(C, G).$$

(ii) $2(u_e - l_e) \leq x'_e - y'_e \leq 2(u'_e - l'_e)$. Then

$$B_1 = P_{M_A}(B_e) = P_{M_A}(B_0) = C$$

and

$$D_E(B_1, B_0) = D_E(C, B_0) \leq D_E(C, G).$$

(iii) $-2(u_e - l_e) < x'_e - y'_e < 2(u_e - l_e)$. Because $B_e B_0$ is perpendicular on GG', $B_e B_1$ is perpendicular on CC' and GG', CC' are parallel we get

$$B_1 = P_{M_A}(B_e).$$

In addition,

$$D_E(B_1, B_0) < D_E(C, G).$$

(iv) $-2(u'_e - l'_e) \leq x'_e - y'_e \leq -2(u_e - l_e)$. Then

$$B_1 = P_{M_A}(B_e) = P_{M_A}(B_0) = C'$$

and

$$D_E(B_1, B_0) = D_E(C', B_0) \leq D_E(C', G').$$

(v) $x'_e - y'_e < -2(u'_e - l'_e)$. Then

$$B_0 = G',$$
$$P_{M_A}(B_e) = C'$$

and

$$B_1 = P_{M_A}(B_0) = P_{M_A}(G') = C'.$$

In addition,

$$D_E(B_1, B_0) = D_E(C', G').$$

We have

$$\begin{aligned} & D_E^2(C, G) \\ &= (2u'_e - 2l'_e - 2u_e + 2l_e)^2 \\ &= 4\left[(u'_e - u_e) - (l'_e - l_e)\right]^2 \\ &= 4\left[\int_0^1 \left(B^+(\lambda) - A^+(\lambda)\right) d\lambda \right. \\ &\quad \left. - \int_0^1 \left(B^-(\lambda) - A^-(\lambda)\right) d\lambda\right]^2 \\ &\leq 8\left[\int_0^1 \left(B^+(\lambda) - A^+(\lambda)\right) d\lambda\right]^2 \qquad (16) \\ &\quad + 8\left[\int_0^1 \left(B^-(\lambda) - A^-(\lambda)\right) d\lambda\right]^2 \\ &\leq 8\int_0^1 \left(B^+(\lambda) - A^+(\lambda)\right)^2 d\lambda \qquad (17) \\ &\quad + 8\int_0^1 \left(B^-(\lambda) - A^-(\lambda)\right)^2 d\lambda \end{aligned}$$

therefore

$$D_E^2(B_1, B_0) \leq 8D^2(A, B).$$

Because M_A is a closed convex subset of R^2 we obtain (see [11], Appendix C)

$$D_E(P_{M_A}(A_e), P_{M_A}(B_e)) \leq D_E(A_e, B_e)$$

that is

$$D_E(A_0, B_1) \leq D_E(A_e, B_e).$$

We get

$$\begin{aligned} D_E(A_0, B_0) &\leq D_E(A_0, B_1) + D_E(B_1, B_0) \\ &\leq D_E(A_e, B_e) + 2\sqrt{2}D(A, B). \end{aligned}$$

From (14) we obtain

$$D_E^2(A_e, B_e) \leq 12D^2(A, B), \qquad (18)$$

therefore

$$D_E(A_0, B_0) \leq 2(\sqrt{2} + \sqrt{3})D(A, B). \qquad (19)$$

The inequalities (15) and (19) imply

$$D(T(A), T(B)) \leq \sqrt{1 + \frac{(\sqrt{2} + \sqrt{3})^2}{3}} D(A, B) \qquad (20)$$

and the proof is complete. ■

If $D(A, B) = 0$ then (20) becomes equality.

If

$$D(T(A), T(B)) = \sqrt{1 + \frac{(\sqrt{2} + \sqrt{3})^2}{3}} D(A, B)$$

ISBN: 978-989-95079-6-8

then (16)-(18) must be equalities (contrariwise, inequality (20) becomes strict). Equality in (16) implies

$$\int_0^1 \left(B^+(\lambda) - A^+(\lambda)\right) d\lambda + \int_0^1 \left(B^-(\lambda) - A^-(\lambda)\right) d\lambda = 0 \quad (21)$$

and equality in (17) implies

$$B^+(\lambda) - A^+(\lambda) = k^+, \text{ a.e. } \lambda \in [0,1]$$

and

$$B^-(\lambda) - A^-(\lambda) = k^-, \text{ a.e. } \lambda \in [0,1],$$

where $k^+, k^- \in \mathbb{R}$. Substituting in (21) we get $k^+ + k^- = 0$, therefore

$$B^+(\lambda) = A^+(\lambda) + k, \text{ a.e. } \lambda \in [0,1]$$

and

$$B^-(\lambda) = A^-(\lambda) - k, \text{ a.e. } \lambda \in [0,1],$$

where $k \in \mathbb{R}$. According to (7)-(10) we obtain

$$I(B) = I(A) - k,$$
$$S(B) = S(A) + k,$$
$$L(B) = L(A) - \frac{k}{2},$$

and

$$U(B) = U(A) + \frac{k}{2}.$$

Taking into account Theorem 1 (iii) and (4), (5),

$$x_e^{'} = -6I(B) + 12L(B) = -6I(A) + 12L(A) = x_e,$$

$$y_e^{'} = 6S(B) - 12U(B) = 6S(A) - 12U(A) = y_e.$$

We get $A_e = B_e$ and equality in (18) implies $D(A,B) = 0$.

We conclude that equality in (20) holds if and only if $D(A,B) = 0$.

5 Conclusion

Many approximation methods for fuzzy numbers were proposed in the last years. Because the quality of approximation is important, a list of criteria that the approximation operator should or just can possess has been given in [5]. Continuity and additivity of nearest trapezoidal approximation operator which preserves the expected interval are studied in the present paper. Because the property of scale invariance was already proved in [1], the property of partial additivity, given in Theorem 3, assures the linearity of the trapezoidal approximation operator, when the fuzzy numbers under study are all with the same kind of asymmetry of membership functions (see [6]). The property of continuity, given in Theorem 4, means that if two fuzzy numbers are close, with respect to metric D, then their approximations are also close, with respect to metric D. Continuity is of extreme importance in applications, especially in fuzzy control systems, where it is sometimes indicated as robustness and discontinuous approximation operators seem unnatural.

***Abstract*— Obtaining fuzzy rules from low quality data is a topic that has been recently formalized. This paper contains the first application of these principles to classification problems. We intend that the classifier proposed here serves as a baseline for future developments in the field. For that reason, we have extended a simple crisp genetic fuzzy classifier to imprecise data, paying special attention to the computational details. In particular, we will discuss some issues about the fuzzy-valued fitness function that is used in our formalism. A synthetic problem, plus two real-world datasets of low and medium complexities are also proposed, and used to evaluate the algorithm.**

1 Introduction

The term "low quality data" refers to datasets where some or all of the features are imprecisely perceived. It embodies different concepts: censored data, binning, missing values, significant digits, confidence intervals, contradictory information from different sources, fuzzy numbers, linguistic information, and others.

We are interested in those cases where the imprecision in the perception of the data is defined by a family of confidence intervals. This includes most of the preceding situations as particular cases. For instance, we can model few significant digits, censored or missing data by means of a single interval that spans the range of the unknown measure: "the weight of an object is in $[1.1, 1.2]$" or "the pressure is lower than 3". We can also reconcile different measurements of the same feature by means of a set of confidence intervals [8]. Certain (but not all) kinds of fuzzy data can also be regarded as imprecise perceptions of crisp values, known through a family of α-cuts [1].

To make clear the extent of this concept, let us recall the statistical framework of a standard Artificial Intelligence-based classifier. The purpose of a classifier is to predict the class of an object, given the values of other properties of the same object. To that end, a probability distribution is defined on the set of objects, and the mentioned properties are assumed to be random variables. The classifier, in turn, is a decision rule that depends on the posterior probability of each class, given a vector of properties.

The algorithms in this paper differ from the standard case because we do not suppose that we can accurately observe all the properties of the object. Otherwise, the same assumptions hold. In the most simple case (interval-valued data) we will perceive sets that contain these values. In the general case, we will be given a nested family of sets, each one of them containing the true value with certain probability. From a theoretical point of view, we hence understand that low quality data is a kind of data for which we can not achieve a precise knowledge about the posterior probability distributions induced by the mentioned random variables, but we can obtain families of probability distributions that are compatible with them. Accordingly, the mentioned decision rule can be inconclusive if the input data is not specific enough.

Recent works in fuzzy statistics suggest using a fuzzy representation when the data is known through a family of confidence intervals [1]. This representation assumes that a fuzzy set can be interpreted as a possibility distribution (which, in turn, is a family of probability distributions) and each α-cut of a fuzzy feature is a random set that contains the unknown crisp value of the feature with probability $1 - \alpha$. [7, 8].

1.1 GFS and Fuzzy fitness functions

Our particular fuzzy representation of low quality data is tied to the use of a fuzzy or interval-valued measurement of the accuracy of a classifier or model. Let us use an example: we have a classification system, defined by these rules:

$$\begin{array}{l}\text{if } x < 1 \text{ then class is } A\\ \text{if } x \in [1,2] \text{ then class is } B\\ \text{if } x > 2 \text{ then class is } C\end{array} \quad (1)$$

and the input that follows:

$$x < 1.8 \quad (2)$$

The output of the classifier is the set of classes $\{A, B\}$. If the object being classified is of class C, we know that the classifier has failed. Otherwise, we cannot know. Nonetheless, we can use a set-valued variable "number of errors", and state that the error of the classifier in that example is the set $\{0, 1\}$. The number of errors of the whole classifier can be obtained by adding these individual errors with interval arithmetic operators. If the output of the classifier is a fuzzy set, the number of errors is a fuzzy number too, and we must use fuzzy arithmetic [6].

Roughly speaking, estimating a classifier from data requires a numerical technique that finds the minimum of the classification error with respect to the free parameters of the classifying system. In our case, this function is interval-valued or fuzzy. But there are not many techniques for optimizing interval-valued or fuzzy valued functions. In the genetic algorithms field, the solutions are related to precedence operators between imprecise values [3, 4, 11]. We have previous works where we have jointly optimized a mix of crisp and fuzzy objectives with genetic algorithms [7]. We have also proposed a number of different algorithms for learning regression models from low quality data and the fuzzy representation mentioned before [5, 10, 8]. However, to the best of our knowledge there

3      weight[class[example]] = weight[class[example]] + m
4    end for example
5    mostFrequent = 0
6    for c in {1, ..., N_c}
7      if (weight[c]>weight[mostFrequent]) then
8        mostFrequent = c
9      end if
10   end for c
11   Consequent = mostFrequent
return rule
```

Figure 2: The consequent of a rule is not codified in the GA, but it is assigned the most frequent class label, between those compatible with the antecedent of the rule [2].

have not been previous GFSs where those principles have been applied to learn classification problems.

1.2 Summary

The structure of this paper is as follows: in the next section we generalize the crisp GFS defined in [2] to low quality data. In Section 3 we evaluate the generalized algorithm in both crisp and imprecise datasets, and propose two real-world datasets of classification with imprecise data. The paper finishes with the concluding remarks, in Section 4.

2 Generalizing a Genetic Fuzzy Classifier to imprecise data

Generalizing a GFS to imprecise data involves, at the very least, changes in the inference mechanism and the fitness function, as we have discussed in [6]. In this section we will generalize the GFS outlined in Figure 1, which was introduced in [2]. This is a very compact algorithm that allows us to focus in the subject of this paper (extending Genetic Fuzzy Classifiers to imprecise data) without getting lost in the details.

Observe that this algorithm depends on two functions: "assignConsequent" (line 6) and "assignFitness" (line 9). These functions are also listed in Figures 2 and 3. This algorithm does not codify the consequent of the fuzzy rules in the genetic individual. Instead, the function "assignConsequent"

```
function assignFitness(population,dataset)
1    for example in {1, ..., N}
2      winnerRule = 0
3      bestMatch = 0
4      for rule in {1, ..., M}
5        m = membership(Antecedent[rule],example)
6        if (m>bestMatch) then
7          winnerRule = rule
8          bestMatch = m
9        end if
10     end for rule
11     if (consequent(winnerRule)==class(example)) then
12       fitness[winnerRule] = fitness[winnerRule] + 1
13     end if
14   end for example
return fitness
```

Figure 3: The fitness of an individual is the number of examples that it classifies correctly. Single-winner inference is used, thus at most one rule changes its fitness when the rule base is evaluated in an example [2].

determines the class label that matches an antecedent with a maximum confidence. The function "assignFitness," in turn, determines the winner rule for each object in the training set and increments the fitness of the corresponding individual if its consequent matches the class of the object. In the remainder of this section, we will study the impact of the imprecise knowledge about the independent and dependent variables in the structure of the rules, and how to extend these two functions. That is to say: we analyze the reasoning method, the assignment of the consequents, the computation of a set-valued fitness and the genetic selection and replacement of the worst individuals.

2.1 Analysis of the reasoning method

The objective of the extended GFS is to obtain a fuzzy rule base from objects, when there is imprecise knowledge about some or all of the attributes of these objects. The set of classes that is produced when the input value is a fuzzy set can be computed in some different ways, but not all of them are consistent with our representation of an imprecise value.

Having an imprecise knowledge about the input variables differs from the standard case because:

1. The output of the FRBS will not be completely determined.

2. The number of errors of the FRBS in the training data will be partially known. The same happens if any other quality function is used instead of the number of errors, i.e. likelihood, logistic loss functions, etc.

Both issues have been introduced with the crisp classifier commented in the introduction: if the input is a set X that contains a range of inputs $x \in X$, the output is not a class but a set of classes:

$$\text{class(X)} = \{\text{class}(x) \mid x \in X\}. \tag{3}$$

The first difference is apparently a trivial issue: after all, one of the advantages of fuzzy rules is dealing with imprecision. Nevertheless, the standard reasoning method does not produce

ISBN: 978-989-95079-6-8

the set of classes that we need. To make our point clearer, let us study a fuzzy classifier comprising M rules:

$$\textbf{if } (x \textbf{ is } \widetilde{A}_i \,) \textbf{ then class is } C_i, \tag{4}$$

and let us use the single-winner inference mechanism:

$$\text{class(x)} = C_{\arg\max_i \{\widetilde{A}_i(x)\}}. \tag{5}$$

Observe that, classifying the set X by means of the standard mechanism produces the class label that follows:

$$\text{class'(X)} = C_{\arg\max_i \{\min\{\widetilde{A}_i(x) | x \in X\}\}} \tag{6}$$

while we need this set of labels:

$$\text{class(X)} = \{C_{\arg\max_i \{\widetilde{A}_i(x)\}} \mid x \in X\} \tag{7}$$

which is different than 6. Furthermore, the fuzzy set of classes obtained when aggregating the rules, before the defuzzification stage, is not what we need either, because our set class(X) does not coincide with the fuzzy set

$$\sum C / \max\{\min\{\widetilde{A}_i(x) \mid x \in X\} | C_i = C\}. \tag{8}$$

The code we propose to use is included in lines 2–23 in Figure 5, that we will explain later.

It is remarked that, in this paper, each rule will contain a single consequent. This is a result of our interpretation of "low quality" as a family of confidence intervals. In words: in this paper, if a point is labeled as "class {A,C}" we are not stating that it belongs to both categories at the same time (which is not an imprecise assert). We are expressing that we are not sure about the class of the object, i.e. we only know that it is not in class "B". Therefore, it makes not sense in this context to produce a rule with a double consequent, since this rule necessarily will have non-zero error at any example.

2.2 Assignment of consequents

```
function assignImpreciseConsequent(rule)
1    for example in {1,...,N}
2      m̃ = fuzMembership(Antecedent,example)
3      weight[class[example]] = weight[class[example]] ⊕ m̃
4    end for example
5    mostFrequent = {1,...,Nc}
6    for c in {1,...,Nc}
7      for c1 in {c+1,...,Nc}
8        if (weight[c] dominates weight[c1]) then
9          mostFrequent = mostFrequent - { c1}
10       end if
11     end for c1
12   end for c
13   Consequent = select(mostFrequent)
return rule
```

Figure 4: If the examples are imprecise, we might not know the most frequent class label –lines 5 to 12–. In this paper we have used the dominance proposed in [4] to reduce this set to one element.

The assignment of consequents seen in Figure 2 is extended in Figure 4. The original assigment consists in computing the confidences of the rules "if (x is $\widetilde{A}$) then class is C" for all the values of "C", then selecting the alternative with maximum confidence. In this case, the confidence of a rule is a set of values. The operation "dominates" used in line 8 can have different meanings, ranging from the strict dominance (A dominates B iff $a < b$ for all $a \in A, b \in B$) [11] to other definitions that induce a total order in the set of confidences. Generally speaking, we have to select one of the values in the set of nondominated confidences and use its corresponding consequent. In this paper, we have used the uniform dominance defined in [4], that induces a total order and thus the set of nondominated consequents has size 1.

2.3 Computation of fitness

```
function assignImpreciseFitnessApprox(population,dataset)
1    for example in {1,...,N}
2      setWinnerRule = ∅
3      for r in {1,...,M}
4        dominated = FALSE
5        rule.m̃ = fuzMembership(Antecedent[r],example)
6        for sRule in setWinnerRule
7          if (sRule dominates rule) then
8            dominated = TRUE
9          end if
10       end for sRule
11       if (not dominated) then
12         for sRule in setWinnerRule
13           if (m̃ dominates sRule) then
14             setWinnerRule = setWinnerRule −{ sRule }
15           end if
16         end for sRule
17         setWinnerRule = setWinnerRule ∪{ rule }
18       end if
19     end for r
20     setOfCons= ∅
21     for sRule in setWinnerRule
22       setOfCons= setOfCons ∪{ consequent(rule) }
23     end for sRule
24     deltaFit= 0
25     if ({class(example)} == setOfCons and
           size(setOfCons)==1) then
26       deltaFit = {1}
27     else
28       if ({class(example)}∩ setOfCons ≠ ∅) then
29         deltaFit = {0, 1}
30       end if
31     end if
32     Select winnerRule ∈ setWinnerRule
33     fitness[winnerRule] = fitness[winnerRule] ⊕ deltaFit
34   end for example
return fitness
```

Figure 5: Generalization of the function "assignFitness" to imprecise data. If the example is imprecisely perceived, there are three ambiguities that must be resolved: (a) some different crisp values compatible the same example might correspond to different winner rules –lines 3 to 19—, (b) these rules might have different consequent, thus we do not know if the rule base fails in the example –lines 20 to 31– and (c) we must assign credit to just one of these rules –lines 32 and 33–.

The output of the FRBS at the i-th object of the training set

ISBN: 978-989-95079-6-8

is a set of classes:

$$C_{\text{FRBS}}(X_i) = \{C_{\arg\max_j\{\widetilde{A}_j(x)\}} \mid x \in X_i\}. \quad (9)$$

The theoretical expression of the fitness function of the FRBS is:

$$\text{fitness} = \bigoplus e_i \quad (10)$$

where

$$e_i = \begin{cases} 1 & C_{\text{FRBS}}(X_i) = C_i \text{ and } \#(C_i) = 1 \\ 0 & C_{\text{FRBS}}(X_i) \cap C_i = \emptyset \\ \{0,1\} & \text{else} \end{cases} \quad (11)$$

In words, if the output of the FRBS is a single class label that matches the class label of the example, this point scores 1. If the set of classes emitted by the FRBS does not intersect with that of the object, this point scores 0. Otherwise, it scores the set $\{0,1\}$.

The evaluation of this function is computationally very expensive, and we will use an approximation, described in Figure 5. This algorithm computes an interval of values of matching between each rule and the input, then discards all rules that can not be the winner rule, and approximates the output of the FRBS by the set of the consequents of the non-discarded rules. This set includes the theoretical output, but sometimes it also includes extra class labels. In Figure 6 we have also included a more accurate approximation which is based on a sample of values of the support of the input. This second approximation will be used in the next section to better determine the quality of a classifier, but our learning will be guided by the function in Figure 5, because of its lower cost.

2.4 Genetic selection and replacement

There are two other parts in the original algorithm that must be altered in order to use an imprecise fitness function: (a) the selection of the individuals in [2] is based on a tournament, that depends on a total order on the set of fitness values. And (b) the same happens with the removal of the worst individuals. In both cases, we have used the uniform dominance defined in [4] to impose such a total order. We leave for future works the application of a multicriteria genetic algorithm similar to those used in our previous works in regression modeling [8, 10].

3 Numerical results

This section contains a brief numerical analysis of the generalized algorithm. We have performed the experiments that follow:

1. Synthetic datasets: Gaussian distribution, known Bayesian error, and different amounts of observation error.

2. Crisp datasets: three standard benchmarks, for testing that the extended algorithm has the same performance as the original version in crisp problems.

3. Imprecise, real world datasets: we propose two real world datasets, of small and medium size. One of them has been specifically designed for the purpose of this research, and the other is part of a practical problem of medical diagnosis.

```
function assignImpreciseFitnessExhaustive(population,dataset)
1     for example in {1,...,N}
2       S = sample(example)
3       maxScore = 0
4       for s in S
5         winnerRule = 0
6         bestMatch = 0
7         for rule in {1,...,M}
8           m = membership(Antecedent[rule],s)
9           if (m > bestMatch) then
10            winnerRule = rule
11            bestMatch = m
12          end if
13        end for rule
14        if (consequent(winnerRule) == class(example)) then
15          score[winnerRule] = score[winnerRule] ⊕ 1
16        elif (consequent(winnerRule) ⊂ class(example)) then
17          score[winnerRule] = score[winnerRule] ⊕ {0,1}
18        end if
19        if (max(score[winnerRule]) > max(score[maxScore]))
20          then maxScore = winnerRule
21        end if
22      end for s
23      if (score[maxScore] > 0) then
24        if (score[maxScore] == size(S)) then
25          fitness[maxScore] = fitness[maxScore] ⊕ 1
26        else
27          fitness[maxScore] = fitness[maxScore] ⊕ {0,1}
28        end if
29      end if
30    end for example
return fitness
```

Figure 6: Other generalization of the function "assignFitness" to interval-valued data. This function is computationally too expensive for being used as a fitness function; it will be used instead for obtaining better estimations of the train and test errors of the final rule bases. Lines 14–18 deal with the case where an object has imprecise output, i.e. "the class is A or C"; otherwise, the value of the variable "score" is crisp.

All the datasets used in this paper are available in the website of the KEEL project: `http://www.keel.es`. All the experiments have been run with a population size of 100, probabilities of crossover and mutation of 0.9 and 0.1, respectively, and limited to 200 generations. The fuzzy partitions of the labels are uniform and their size is 3, except when mentioned otherwise.

3.1 Synthetic datasets

The set "Gaussian" comprises 699 points of two classes. The distribution of both classes is bidimensional Gaussian, with unity covariance matrix, and centered in $(0,0)$ and $(3,0)$ respectively. To this data we have added interval-valued imprecision of sizes $\beta = 0.03, 0.05, 0.1, 0.2, 0.5$. A 10-cv experimental design was applied, and the mean values of the test errors are shown in Table 1. The training error has been also included, to show the differences between the approximation of the fitness function seen before and the exhaustive computation that has been used to compute the test error. Observe that the approximate error computed by the fitness function is less specific than the actual error, and the difference is relevant

Table 1: Results of the extended GFS in the synthetic dataset "Gauss" for crisp data (first column) and different degrees of observation error (second column). The approximate error computed by the fitness function is less specific than the actual error, and the difference is relevant when the observation error is high ($\beta = 0.2$ and $\beta = 0.5$, nevertheless it still guides the evolution correctly.

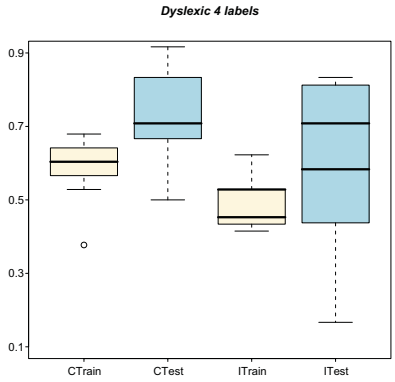

Figure 7: Boxplots illustrating the dispersion of the 10 repetitions of crisp and extended GFS in the problem "dyslexia-12", with 4 labels/partition. The boxplot of the imprecise experiments is not standard: we show respectively the 75% of the maximum and 25% percentile of the minimum fitness, thus the box displays at least the 50% of data; there are two marks inside the box, because the median of the data is an interval.

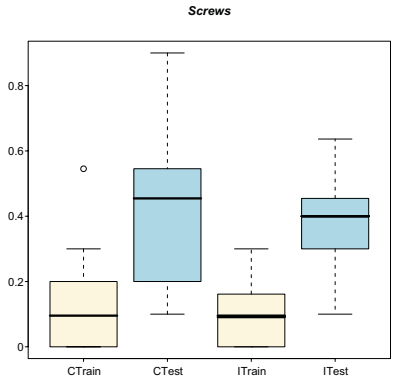

Figure 8: Boxplots illustrating the dispersion of the 10 repetitions of crisp and extended GFS in the problem "screws-50".

when the observation error is high ($\beta = 0.2$ and $\beta = 0.5$), nevertheless it still guides the evolution correctly.

3.2 Crisp datasets

Crisp datasets are included for assessing the performance of the generalized algorithm in standard problems. Since, in this case, the particularization of the algorithm to crisp data recovers the original algorithm in [2], the results are expected to be adequate. Nonetheless, we have included some estimations in Table 2. As expected, the results of both algorithms are similar; the differences are originated in the different random seeds.

3.3 Real world datasets

We propose two datasets for testing this and future learning algorithms with low quality data:

1. Dataset "Screws-50": 21 objects, 3 classes, 2 features (weight and length). We have weighed and measured 21 screws of three different types, taking into account the accuracy of the physical measurement: each feature is an interval. The class labels are precise. There are not outliers, i.e. 0% of error is attainable in absence of imprecision.

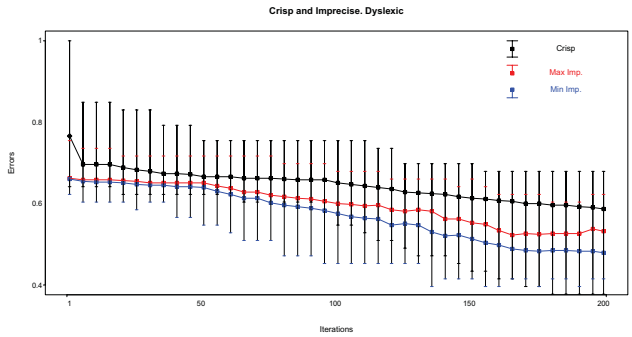

Figure 9: Compared evolution of crisp and imprecise GFS in the dataset "dyslexia-12". The ranges and means of 10 repetitions of the learning are shown, for both the crisp and the imprecise versions of the algorithm. The upper bound of the mean imprecise fitness is consistently lower than the mean of the crisp fitness.

2. Dataset "Dyslexia-12": 65 objects, 4 classes, 12 features. This is a selection of the original dataset described in [9], where the 12 most relevant variables have been hand-picked by a psychologist. There are imprecision in both the input and the output. The theoretical error is

ISBN: 978-989-95079-6-8

	Crisp		Low Quality		
Dataset	Train	Test	Exh. Train	Exh. Test	Approx. Train
Pima	0.254	0.287	[0.258,0.258]	[0.288,0.288]	[0.258,0.258]
Glass	0.323	0.365	[0.321,0.321]	[0.352,0.352]	[0.321,0.321]
Haberman	0.239	0.255	[0.238,0.238]	[0.248,0.248]	[0.238,0.238]

Table 2: Results in some crisp benchmarks, where the imprecise fitness function reduces to the crisp fitness function. The results of "crisp" and "low quality" columns are similar.

Crisp			Low Quality		
Dataset	Train	Test	Exh. Train	Exh. Test	Approx. Train
Screws-50	0.133	0.427	[0.096,0.096]	[0.377,0.377]	[0.068,0.106]
Dyslexia-12 (4 labels)	0.584	0.724	[0.481, 0.616]	[0.541, 0.675]	[0.477,0.516]
Dyslexia-12 (5 labels)	0.745	0.658	[0.581,0.667]	[0.608,0.641]	[0.537,0.549]

Table 3: Means of 10 repetitions of the generalized GFS for the imprecise datasets "Screws-50" and "Dyslexia-12" with 4 and 5 labels/variable

unknown.

We have compared the performance of the generalized algorithm to that of the original crisp algorithm. To that end, we have built a crisp dataset by removing the uncertainty in the imprecise dataset: each imprecise measurement was replaced by the mid-point of the corresponding interval, and those examples with imprecision in the independent variable were replicated for the different options. For instance, a point $(X = [1,3], C = \{A,B\})$ is converted into two points $(x = 2, c = A)$, $(x = 2, c = B)$.

We have used a 5x2cv design for the first problem, because of its small size, and 10cv for the second. The boxplots of the compared results, in both train and test sets, are depicted in Figures 7 and 8. Observe that the boxplots of the imprecise experiments are not standard. We propose using a box showing the 75% of the maximum and 25% percentile of the minimum fitness (thus the box displays at least the 50% of data) and also drawing two marks inside the box, because the median of the data is an interval. In Figure 9 the ranges and means of 10 repetitions of the learning are shown, for both the crisp and the imprecise versions of the algorithm. The upper bound of the mean imprecise fitness is consistently lower than the mean of the crisp fitness.

4 Concluding remarks

Extending a GFS to imprecise data in classification problems is based on the use of an interval or fuzzy valued fitness function. Most GFSs can be extended to low quality data if some changes are made in their reasoning method, and the genetic algorithm can deal with an imprecisely known fitness function. We have shown in detail how to apply this changes to a simple GCCL-type algorithm, and evaluated it with some synthetic and real-world benchmarks. The numerical results are as expected for an elementary algorithm like this; there is room for improvement and future works will address more complex GFSs that are based on a multicriteria fitness function.

Abstract—*Linear Blur Motion is one of the most common degradation functions that corrupt images. Since 1976 many researchers have tried to estimate blur motion parameters and this problem can be solved for noise free images but in the case of noisy images this can be done when the image SNR is low. In this paper, we consider pattern recognition with ensemble neural networks for the case of fingerprints; we propose the use of fuzzy methods for Response Integration in Ensemble Neural Networks for blur motion noisy images. An ensemble neural network of three modules is used; each module is a local expert on person recognition based on a biometric measure (the fingerprints). The Response Integration method of the ensemble neural networks has the goal of combining the responses of the modules to improve the recognition rate of the individual modules when the SNR rate blur motion signal increases to a high level.*

Keywords— Pattern Recognition, Ensemble Neural Networks, Fuzzy Logic, Ratio SNR.

1 Introduction

Blur Motion occurs when there is relative motion between the camera and the object being captured [1]. When a changing scene is observed by a camera, all the classical algorithms assume that is possible to take pictures every δt instant, which means that every picture is taken with a dt ≈ 0 exposure time. If that is not the case, then the exposure time (dt = T) is large enough that different points in the scene are moving far enough and consequently their corresponding projections on the image plane travel several pixels. Therefore, during the capture process of an image, at any single image point, a certain number of scene points is projected during the exposure time, each one contributing to the final brightness of the image point; this effect is shown in figure 1. More formally, during the exposure time T in front of the pixel $P_{i,j}$ we could assume that they pass k scene points with brightness (C_1….C_k) respectively, then the resulting brightness value for pixel $P_{i,j}$ is given in equation (1), in the case it continues movement the summation is replaced by integration. This holds in general for every pixel that is moving points in the scene. It is clear that the blurring of the image exists only across the direction of the motion; this one dimensional blur is called Blur Motion.

$$P_{i,j} = \frac{1}{K}\sum_{l=1}^{k} C_l \qquad (1)$$

The Result of blur motion is shown in figure 1b where an image consistent of different value pixels is shown in figure 1a and then the blurred image is shown in figure 1b.

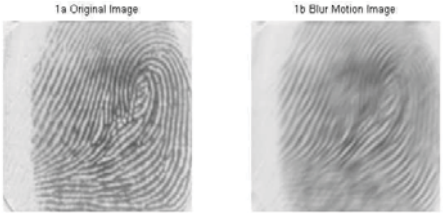

Figure 1: a) Original Image without noise, b) Blur Motion with 20 pixels distance d and 50 degrees angle α.

The blur motion can be described mathematically as the result of a linear filter b(x, y) = i(x, y)*h(x, y) where i is the theoreticalcal image taken with an exposure time T_e=0, b **is** the real blurred image and h the point spread function (PSF**).** Given an angle = α and the length d = V_o x T_e, which is the number of scene points that affect a specific pixel, the point spread function of blur motion is given in equation (2).

$$h(x,y) = \begin{cases} \frac{1}{d}, 0 \le |x| \le d * \cos(\alpha)\ \ y = \sin(\alpha) * d \\ 0, \text{otherwhise} \end{cases} \qquad (2)$$

In practical terms, this mean computing accurate estimates for the two parameters of the blur motion PSF, namely the length, d, and the angle, α. From these quantities, the relative velocity at this point can be easily recovered knowing the exposure time. In this paper for the experimental results we use fingerprint images and adding different levels of blur motion noise from 10 to 90 pixels in distance d and the angle α is zero. The measurement for noise in an image is the signal-to-noise ratio, SNR. The SNR measures the relative strength of the signal in a blurred and noisy image to the strength of the signal in a blurred image without noise. A SNR of 16 db is a low noise level, while a SNR of 4 db is a high noise level [1].

2 Noise and Registration Error

2.1 Signal-to-noise ratio

Noise is present in all digital imaging systems due to a number of sources such as photon shot noise, readout noise, dark current noise and quantization noise. While some sources can be effectively suppressed, such as the dark

ISBN: 978-989-95079-6-8

current noise by cooling and the quantization noise by using more bits, others not. Photon shot noise, for example, is unavoidable due to the particle nature of light. Readout noise increases with a higher readout rate, which is desirable in high-speed cameras. In equation 3 the calculus of the Variance and Standard deviation of the image are shown [2].

$$\sigma_I{}^2 = \frac{1}{2}\, var(I_1 - I_2), where\ I_1 = I + \eta_1, I_2 = I + \eta_2 \quad (3)$$

σ_I = the Standard deviation of the Fingerprint Image Original.
var = the variance between the Fingerprint Image Original and The Fingerprint Image with Blur Motion Noise.
$\eta_1 = 0$, is the noise to the Fingerprint Image Original.
η_2 = blur motion noise 10 to 90 distance pixels.
I_2 , is the Fingerprint Image with Blur Motion Noise.

The Signal-to-Noise Ratio (SNR) of an image I is then computed as:

$$SNR = 10\log\left(\frac{varI}{\sigma^2 I}\right) \quad (4)$$

The combined effect of these noise sources is often modeled from two images of the same scene captured under the same degradation is shown in figure 2.

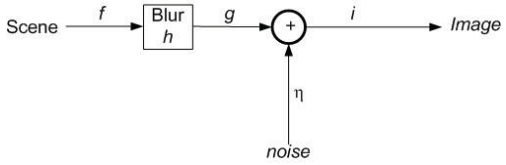

Figure 2: Image degradation by blur and additive noise.

2.2 Calculus of the SNR for Fingerprint Images

In this paper we use fingerprint images from the FCV2000 database of the Biometric System Laboratory at the University of Bologna [3, 4]. The image size is 300 pixels wide and 300 pixels high with a resolution of 500 ppi, and of a gray scale representation. The fingerprints were acquired by using a low-cost optical sensor; up to four fingers were collected from each volunteer (forefinger and middle finger of both the hands). The database is 10 fingers wide (w) and 8 impressions per finger deep (d) (80 fingerprints in all); the acquired fingerprints were manually analyzed to assure that the maximum rotation is approximately in the range [-15°, 15°] and that each pair of impressions of the same finger have a non-null overlapping area.
We added Blur Motion Level Noise from 10 to 90 distance pixels to all 80 fingerprint images, based on equations (3) and (4) the calculus of the Average SNR in decibels for the Fingerprint Image of each of the person obtained is shown in table 1.

Table I: The Average SNR in db of the Fingerprint Images.

Average SNR in db Person N° Fingerprint Image	Blur Motion Distance Pixels								
	10	20	30	40	50	60	70	80	90

In figure 3 we show the plot of the Average SNR of the Person Fingerprint with the blur motion level noise from 10 to 90 distance pixels.

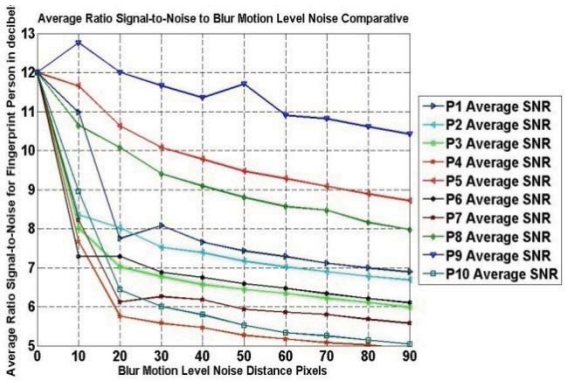

Figure 3: Average SNR with blur motion noise.

3 Ensemble Neural Networks Architecture

3.1 ANN´s Architecture

The Ensemble ANN´s architecture consists of three main modules [5, 6], in which each of them in turn consists of a set of neural networks trained with the same data (fingerprints image), If we now using different parameters for each module of the Ensemble Neural Networks, for module 1 the used parameters are learning rate =.001 , Goal Error=.001, for the module 2 learning rate =.0001 , Goal Error=.0001, for the module 3 the learning rate =.0001, and Goal Error=.00001, using 2 hidden layers, 36 neurons in the first layer and 17 neurons in the second layer for each module of the Ensemble Neural Network and is shown in figure 4.

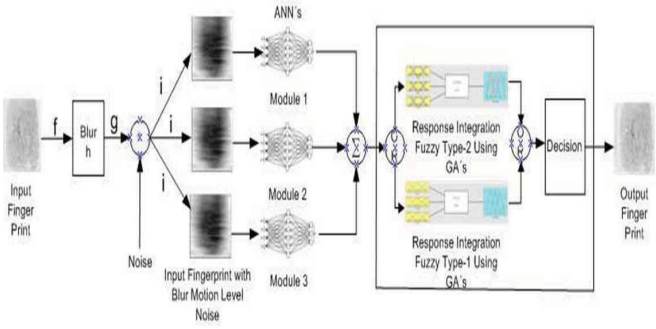

Figure 4: Ensemble Neural Networks with blur Motion Level Noise Added.

ISBN: 978-989-95079-6-8

The procedure to perform the tests was first to train the modules of the ensemble neural networks with the databases of the fingerprints without noise, in total using 8 fingerprints of 10 people, that is 80 fingerprints in total, until being able to find which architecture of the ensemble neural network responded better to arrive to the desired error.

We Added Blur Motion Level Noise from 10 to 90 distance pixels to the Fingerprint Input, to obtain a blur motion image that went into each of three modules ensemble neural networks. The output of each of the ensemble neural networks was obtained response integration with type-1 or type-2 fuzzy logic, and finally with the decision module obtained the output fingerprint.

3.2 Response Integration with Type-1 Fuzzy Logic

We also used a Type-1 Fuzzy Inference System as method of response integration of the ensemble neural network output, considering as input three linguistic variables, Activation Low, Activation Medium, and Activation High, and one output linguistic variable, Winning Activation of the three modules.

We show below one of the rules for the fuzzy inference system.

If (Module1 is ActMod1Low) and (Module2 is ActMod2Medium) and (Module3 is ActMod3Medium) then (Winner Module is Module3)

Three membership functions were used for each linguistic variable (input and output) of the triangular type, to be managed in a range from 0 to 1.

We show in figure 5 the membership functions designed using the editor of the fuzzy logic toolbox of MATLAB [14].

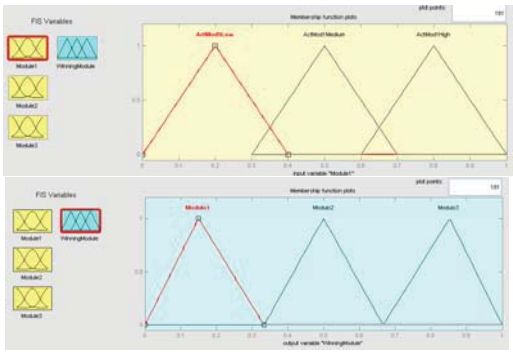

Figure 5: The Input Membership function and The Output Membership function of Fuzzy Logic Type-1.

Once the Ensemble Neural Network is trained, the fuzzy inference system integrates the outputs of the modules. We used the same 80 people's images to which we had applied noise with blur motion, and the type-1 fuzzy inference system gives an answer for the stage of the final decision.

3.3 Response Integration with Type-2 Fuzzy Logic

We used a Type-2 Fuzzy Inference System as method of response integration of the ensemble neural network output, considering as input three linguistic variables, Activation Low, Activation Medium, and Activation High, and one output linguistic variable, Winning Activation of the three modules, used the same rules of the type-1 fuzzy logic.

Three membership functions were used for each linguistic variable of the input and output of the Gaussian type managed in a range from 0 to 1.

We show in figure 6 the membership functions designed using the editor of IT2FUZZY fuzzy logic toolbox [12, 13].

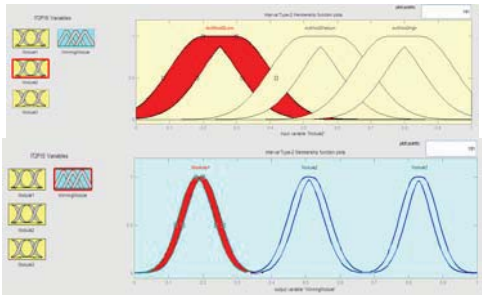

Figure 6: The Input Membership function and The Output Membership function of Type-2 Fuzzy Logic.

4 Simulation Results

4.1 Response Integration with Type-1 Fuzzy Logic

Once the Ensemble Neural Network is trained, the fuzzy inference system integrates the outputs of the modules. We used the same 80 persons images to which we had applied different levels of noise with blur motion, the type-1 inference systems give an output for the stage of the final decision, and we show the result if the fingerprint input was recognized. We show in figure 7 the simulation results.

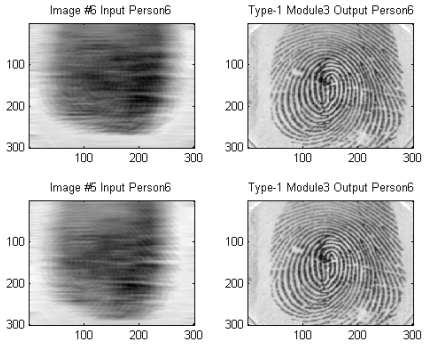

Figure 7: Simulation results for the fingerprints using the type-1 Fuzzy Inference System (blur motion 50 distance pixels).

4.2 Response Integration with Type-2 Fuzzy Logic

In the same way when the Ensemble Neural Network is trained, the fuzzy inference system integrates the outputs of the modules. We used the same 80 persons images to which we had applied different levels of noise with blur motion, the type-2 inference systems give an output for the stage of the final decision, and show the result if the fingerprint input was recognized. We show in figure 8 the simulation results.

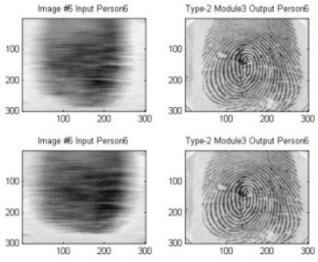

Figure 8: Simulation results for the fingerprints using the type-2 Fuzzy Inference System (blur motion 50 distance pixels).

ISBN: 978-989-95079-6-8

4.3 Comparison Pattern Recognition Blur Motion Noisy Images using Fuzzy Methods for Response Integration in Ensemble Neural Networks

The Response Integration method of the ensemble neural networks has the goal of combining the responses of the modules to improve the recognition rate of the individual modules when the blur motion signal increases to high level 10 to 90 distance pixels. In Table 2 we show a Comparison between Response Integration with Type-2 and Type-1 Fuzzy logic when the blur motion level noise increases and the Average SNR in db decrease.

Table II: Comparison Response Integration Type-2 and Type-1 Fuzzy Logic with Blur Motion Level Noise and the Average SNR in db of the Fingerprint Images.

# Person Fingerprint	Blur Motion Level Noise								
	10	20	30	40	50	60	70	80	90

5 Conclusions

Based on the experimental results, we can conclude that the behavior of the type-2 and type-1 fuzzy systems, as methods of response integration of ensemble neural networks for the fingerprints when added blur motion level noise increase and the Average SNR of the Fingerprint decrease, we obtain excellent results.

The identification rates obtained are between 37.5% to 100%for response integration type-2 fuzzy logic and 0% to 100% for response integration with type-1 fuzzy logic. The difference between the type-1 fuzzy and type-2 fuzzy inference systems for response integration of ensemble neural networks is appreciated when we uses the blur motion level noise. We think that there is an advantage in using a type-2 fuzzy inference system to manage the uncertainty of the knowledge base in pattern recognition problems. Future work will include, testing with more kinds of noise, other methods of response integration, using feature extraction, and image compression, with the goal of improving the identification rate.

Acknowledgment

Abstract— *We describe in this paper a new hybrid approach for optimization combining Particle Swarm Optimization (PSO) and Genetic Algorithms (GAs) using Fuzzy Logic to integrate the results. The new evolutionary method combines the advantages of PSO and GA to give us an improved FPSO+FGA hybrid method. Fuzzy Logic is used to combine the results of the PSO and GA in the best way possible. The new hybrid FPSO+FGA approach is compared with the PSO and GA methods with a set of benchmark mathematical functions. The proposed hybrid method is also tested with the problem of modular neural network optimization. The new hybrid FPSO+FGA method is shown to be superior with respect to both the individual evolutionary methods.*

Keywords— Fuzzy Logic, Evolutionary Computing, Genetic Algorithms**.**

1 Introduction

We describe in this paper a new evolutionary method combining PSO and GA, to give us an improved FPSO+FGA hybrid method. We apply the hybrid method to mathematical function optimization to validate the new approach. Also in this paper, the application of a Genetic Algorithm (GA) [1] and Particle Swarm Optimization (PSO) [2] for the optimization of mathematical functions is considered. In this case, we are using the Rastrigin's function, Rosenbrock's function, Ackley's function, Sphere's function Griewank's function, Michalewics's function and Zakharov's function [4][13] to compare the optimization results between a GA, PSO and FPSO+FGA. We also consider the problem of neural network architecture optimization, which is very important in the applications.

The paper is organized as follows: in section 2 a description about the Genetic Algorithms for optimization problems is given, in section 3 the Particle Swarm Optimization is presented, the neural networks is presented in section 4, in section 5 we can appreciate the proposed method FPSO+FGA and the fuzzy system, in section 6 we can appreciate the full model of FPSO+FGA that was used for this research, in section 7 the simulations results are described, finally we can see in section 8 the conclusions reached after the study of the proposed evolutionary computing methods.

2 Genetic Algorithms for Optimization

John Holland, from the University of Michigan initiated his work on genetic algorithms at the beginning of the 1960s. His first achievement was the publication of *Adaptation in Natural and Artificial System* [7] in 1975.

He had two goals in mind: to improve the understanding of natural adaptation process, and to design artificial systems having properties similar to natural systems [8].

The basic idea is as follows: the genetic pool of a given population potentially contains the solution, or a better solution, to a given adaptive problem. This solution is not "active" because the genetic combination on which it relies is split between several subjects. Only the association of different genomes can lead to the solution.

Holland's method is especially effective because it not only considers the role of mutation, but it also uses genetic recombination, (crossover) [9]. The crossover of partial solutions greatly improves the capability of the algorithm to approach, and eventually find, the optimal solution.

The essence of the GA in both theoretical and practical domains has been well demonstrated [1]. The concept of applying a GA to solve engineering problems is feasible and sound. However, despite the distinct advantages of a GA for solving complicated, constrained and multi-objective functions where other techniques may have failed, the full power of the GA in application is yet to be exploited [12] [14].

In Fig. 1 we show the reproduction cycle of the Genetic Algorithm.

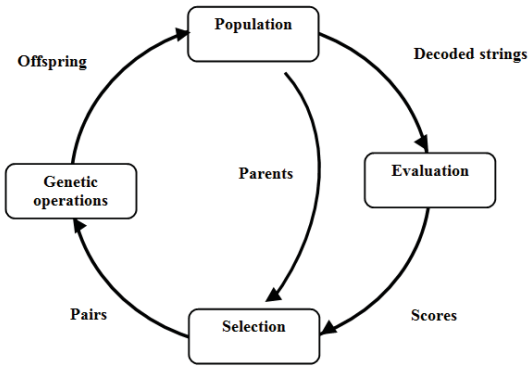

Figure 1: The Reproduction cycle

ISBN: 978-989-95079-6-8

3 Particle Swarm Optimization

Particle swarm optimization (PSO) is a population based stochastic optimization technique developed by Eberhart and Kennedy in 1995, inspired by social behavior of bird flocking or fish schooling [3].

PSO shares many similarities with evolutionary computation techniques such as Genetic Algorithms (GA) [6]. The system is initialized with a population of random solutions and searches for optima by updating generations.

However, unlike GA, the PSO has no evolution operators such as crossover and mutation. In PSO, the potential solutions, called particles, fly through the problem space by following the current optimum particles [10].

Each particle keeps track of its coordinates in the problem space, which are associated with the best solution (fitness) it has achieved so far (The fitness value is also stored). This value is called *pbest*. Another "best" value that is tracked by the particle swarm optimizer is the best value, obtained so far by any particle in the neighbors of the particle. This location is called *lbest*. When a particle takes all the population as its topological neighbors, the best value is a global best and is called *gbest* [19].

The particle swarm optimization concept consists of, at each time step, changing the velocity of (accelerating) each particle toward its p*best* and *lbest* locations (local version of PSO). Acceleration is weighted by a random term, with separate random numbers being generated for acceleration toward *pbest* and *lbest* locations [17].

In the past several years, PSO has been successfully applied in many research and application areas. It is demonstrated that PSO gets better results in a faster, cheaper way compared with other methods [11] [18].

Another reason that PSO is attractive is that there are few parameters to adjust. One version, with slight variations, works well in a wide variety of applications. Particle swarm optimization has been used for approaches that can be used across a wide range of applications, as well as for specific applications focused on a specific requirement [20].

4 Neural Networks

The discipline of neural networks originates from an understanding of the human brain. The average human brain consists of 3 × 1010 neurons of various types, with each neuron connecting to up to 104 synapses [21]. Many neural-network models, also called connectionist models, have been proposed [6].

Neural networks are attractive since they consist of many neurons, with each one processing information separately and simultaneously. All the neurons are connected by synapses with variable weights. Thus, neural networks are actually parallel distributed processing systems.

Research on neural networks dates back to the 1940s when McCulloch and Pitts found that the neuron can be modeled as a simple threshold device to perform logic function [22].

In this paper, we used a supervised learning for training the neural network. Supervised learning is based on a direct comparison between the actual network output and the desired output. Some recent advances in supervised learning have been reviewed in [5].

5 FPSO+FGA Method

This method combines the characteristics of PSO and GA using several fuzzy systems for integration of results and parameter adaptation. In this section, the proposed FPSO+FGA method is presented.

The general idea of the proposed FPSO+FGA method can be seen in Fig. 2. The method can be described as follows:

1. A problem optimization to be considered is received in this case; we are testing with a modular neural network and mathematical functions.
2. The method is randomly initialized to start with FPSO or FGA.
3. The system will solve the problem by FPSO or FGA depending of Error (E) and Derivate of Error (DE) generated after applying FPSO or FGA.
4. The function evaluated is called FEVAL, then the system records the Errors (E and DE) obtained to compare with the value desired.
5. After that the function is evaluated, E and DE are taken as inputs to one fuzzy system called 'FSDM', which the main function is to decide if is suitable to continue solving the problem with FPSO or FGA depending of the information generated by the fuzzy rules to calculate when can be necessary do a change
6. Another two fuzzy systems receive the values of Error and DError as inputs to evaluate if it is necessary to change the values of the parameters in FPSO or FGA depending of the fuzzy rules. The fuzzy systems responsible to do change the value of parameters in FPSO and FGA are called 'fuzzyga' and 'fuzzypso'. On Fig. 2 the two fuzzy systems are represented by el block FSPA (Fuzzy System Parameter Adaptation) but while the method is running in the FPSO the fuzzy system changes the values of the cognitive acceleration 'c_1', and social acceleration 'c_2'; and while the method is running in the FGA the fuzzy system change the value of crossover and mutation.
7. Repeat the above steps until the termination criterion of the algorithm is met. Finally BVALUE receive the best value obtained and when the method is finished we are obtaining the best result.

The fundamental characteristic of this method is to adapt the parameters to reach the best result, in this case; we are doing changes on the parameters of crossover (cr), mutation (mu), cognitive acceleration (c_1) and social acceleration (c_2). We are taking this parameters because are very important to the convergence with good results of the method, for example 'c_1' and 'c_2' are working as a memory able of record the knowledge of the particles more important in a population in the FPSO; also 'cr' and 'mu' are important to reach the best solution in the FGA. The values of these four parameters are fuzzy because depending of the output of a fuzzy system able of adaptation parameters.

ISBN: 978-989-95079-6-8

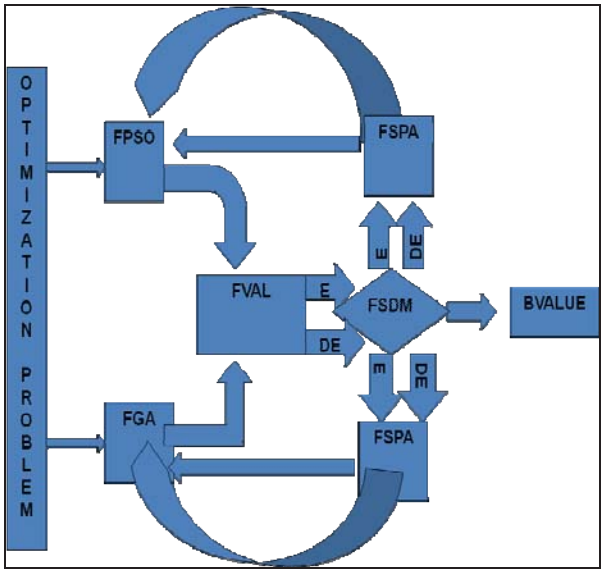

Figure 2: The FPSO+FGA scheme

6 Full Model of FPSO+FGA

The basic idea of the FPSO+FGA scheme is to combine the advantages of the individual methods using a fuzzy system for decision making and the others two fuzzy systems to improve the parameters of the FGA and FPSO when is necessary.

As can be seen in the proposed hybrid FPSO+FGA method, it is the internal fuzzy system structure, which has the primary function of receiving as inputs (Error and DError) the results of the outputs FGA and FPSO. The fuzzy system is responsible for integrating and deciding which are the best results being generated at run time of the FPSO+FGA. It is also responsible for selecting and sending the problem to the "fuzzypso" fuzzy system when the FPSO is activated or to the "fuzzyga" fuzzy system when FGA is activated. Also activating or temporarily stopping depending on the results being generated. The fuzzy system is of Mamdani type because it is more common in this type of fuzzy control and the defuzzification method is the centroid. In this case, we are using this type of defuzzification because in other papers we have achieved good results [4]. Also, the membership functions in the fuzzy main system were chosen of triangular form based on past experiences in this type of fuzzy control. However, in the simulation results we can see different architectures to the 'fuzzyga' and the 'fuzzypso'; where, we are changing the membership functions to observe which is more reliable to this application. In this research, we are testing with triangular and gaussian membership functions.

6.1 FPSO (Fuzzy Particle Swarm Optimization)

This section presents a detailed description of the FPSO model. The classical representation scheme for GAs is binary vectors of fixed length. In the case of an n_x – dimensional search space, each individual consists of n_x variables with each variable encoded as a binary string. The swarm is typically modeled by particles in multidimensional space that have a position and a velocity. These particles fly through hyperspace (i.e., R^n) and have two essential reasoning capabilities: their memory of their own best position and knowledge of the global or their neighborhood's best. In Fig. 3 we can see a simulation of Ackley's function. In a minimization optimization problem, "best" simply means the position with the smallest objective value. Members of a swarm communicate good positions to each other and adjust their own position and velocity based on these good positions. So a particle has the following information to make a suitable change in its position and velocity:

- A global best that is known to all and immediately updated when a new best position is found by any particle in the swarm.
- The neighborhood best that the particle obtains by communicating with a subset of the swarm.
- The local best, which is the best solution that the particle has seen.

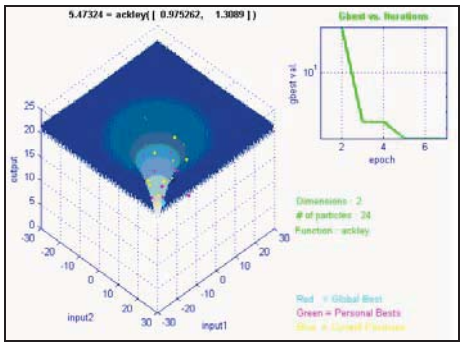

Figure 3: Simulation of ackley's function with FPSO

In this case, the social information is the best position found by the swarm, referred as $\hat{y}(t)$. For gbest FPSO, the velocity of particle i is calculated as

$$v_{ij}(t+1) = vi_j(t) + c_1 r_{1j}(t)[y_{ij}(t) - x_{ij}(t)] + c_2 r_{2j}(t)[\hat{y}_j(t) - x_{ij}(t)] \quad (1)$$

Where $vi_j(t)$ is the velocity of particle i in dimension j = 1,…,n_x at time step t, $xi_j(t)$ is the position of particle i in dimension j at time step t, 'c_1' and 'c_2' represents the cognitive and social acceleration. In this case, these values are fuzzy because they are changing dynamically when the FPSO is running, and $r_{1j}(t)$, r_{2j}~U(0,1) are random values in the range [0,1]. We are adding a fuzzy system called 'fuzzypso' that is able of change the 'c_1' and 'c_2' rate.

6.2 FGA (Fuzzy Genetic Algorithm)

This section presents a brief description of the FGA model. Several crossover operators have been developed for GAs, depending on the format in which individuals are represented. For binary representations, uniform crossover, one point crossover and two point crossover are the most popular. In this case we are using two points crossover with fuzzy crossover rate because we are adding a fuzzy system called 'fuzzyga' that is able of change the crossover and mutation rate.

6.3 Definition of the Fuzzy Systems used in FPSO+FGA

'fuzzypso': In this case we are using a fuzzy system called 'fuzzypso', and the structure of this fuzzy system is as follows:

Number of Inputs: 2
Number of Outputs: 2
Number of membership functions: 3

ISBN: 978-989-95079-6-8

Type of the membership functions: Triangular and Gaussian
Number of rules: 9
Defuzzification: Centroid
The main function of the fuzzy system called 'fuzzypso' is to adjust the parameters of the PSO. In this case, we are adjusting the following parameters: 'c_1' and 'c_2'; where:
'c_1' = Cognitive Acceleration
'c_2' = Social Acceleration
We are changing these parameters to test the proposed method. In this case, with 'fuzzypso' is possible to adjust in real time the 2 parameters that belong to the PSO.
'fuzzyga': In this case we are using a fuzzy system called **'fuzzyga'**, the structure of this fuzzy system is as follows:
Number of Inputs: 2
Number of Outputs: 2
Number of membership functions: 3
Type of membership functions: Triangular and Gaussian
Number of rules: 9
Defuzzification: Centroid
The main function of the fuzzy system called 'fuzzypso' is to adjust the parameters of the GA. In this case, we are adjusting the following parameters: 'mu', 'cr'; where:
'mu' = mutation
'cr' = crossover
'fuzzymain': In this case, we are using a fuzzy system called **'fuzzymain'**. The structure of this fuzzy system is as follows:
Number of Inputs: 2
Number of Outputs: 1
Number of membership functions: 3
Type of membership functions: Triangular
Number of rules: 9
Defuzzification: Centroid
The main function of the fuzzy system, called 'fuzzymain' is to decide on the best way for solving the problem, in other words if it is more reliable to use the FPSO or FGA. This fuzzy system is able to receive two inputs, called error and derror, it is to evaluate the results that are generated by FPSO and FGA in the last step of the algorithm. Fig. 4 shows the membership functions of the main fuzzy system that is implemented in this method. All fuzzy system consists of 9 rules. For example, one rule is if error is P and DError is P then best value is P (view Fig. 5). Fig. 6 shows the fuzzy system rule viewer. Fig. 7 shows the surface corresponding to the fuzzy main system. The other two fuzzy systems are similar to the main fuzzy system.

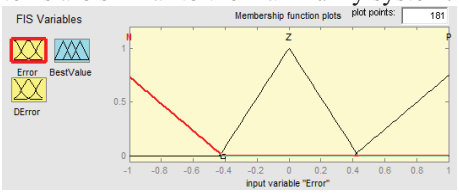

Figure 4: Fuzzy system membership functions

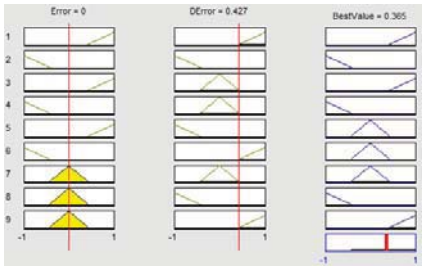

Figure 6: Fuzzy system rules viewer

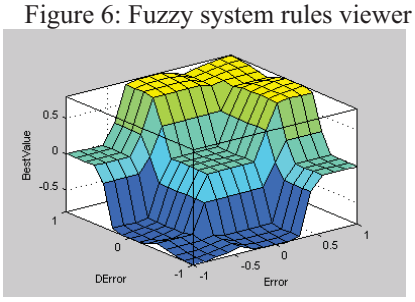

Figure 7: Surface of fuzzy system

7. Simulation Results for Modular Neural Network for Optimization

Several tests of the FPSO+FGA method for MNN optimization were made in the Matlab programming language.

All the implementations were developed using a computer with processor Intel core 2 quad of 64 bits that works to a frequency of clock of 2.5 GHz, 4 GB of RAM Memory and Windows Vista operating system.

We describe below simulation results of our approach for face recognition with modular neural networks (MNNs). We used two-layer feed-forward MNNs with the Conjugated-Gradient training algorithm [4]. The challenge is to find the optimal architecture of this type of neural network, which means finding out the optimal number of layers and nodes of the neural network [6]. We are using the Yale face database [20] that contains 165 grayscale images in GIF format of 15 individuals, for this paper only 10 subjects were used for training the MNN. There are 5 images per subject, one per different facial expression: center-light, happy, left-light, normal and right-light. In total 50 images were used (view Fig. 8). Three images per subject were used for training the MNN and the other two for the recognition. Regarding the genetic algorithm for NN evolution, we used a hierarchical chromosome for representing the relevant information of the network. First, we have the bits for representing the number of layers of the MNN; in this case, the initial topology was of 3 modules with 2 layers per module with 500 neurons in the first layer, 300 neurons in the second layer in each module. Therefore we used a representation the 2415 bits in total (view Fig. 9). The PSO is organized in a similar fashion, but there is less number of parameters. In Fig. 10 we can see the architecture of a MNN that we are using with the evolutionary proposed method FPSO+FGA.

The fitness function used in this case for the MNN combines the information of the error objective and also the information about the number of nodes as a second objective. This is shown in the following equation.

$$f(z) = \left(\frac{1}{\alpha * Ranking(ObjV1) + \beta * ObjV2} \right) * 10 \qquad (1)$$

ISBN: 978-989-95079-6-8

The first objective is basically the average sum of squared of errors as calculated by the predicted outputs of the MNN compared with real values of the function. This is given by the following equation.

$$f_1 = \frac{1}{N}\sum_{i=1}^{N}(Y_i - y_i)^2 \qquad (2)$$

The second objective is the complexity of the neural network, which is measured by the total number of nodes in the architecture.

The final topology of the neural network for the problem of face recognition is obtained by the hybrid evolutionary method FPSO+FGA. The comparison of the final objective values (errors) will be shown in the following section. In the final architecture, the result of the MNN evolution is a particular architecture with different number of nodes by layers. Several tests were made; we obtained optimized different architectures for this Modular Neural Network; the best architecture obtained was the following:

Layers = 2 x module

NNL1M1 = 90, NNL2M1 = 50. NNL1M2 = 100, NNL2M2 = 150. NNL1M3 = 70, NNL2M3 = 90. Total bits = 565

Where: NNL1M1= Number of neurons of the layer 1 in module 1. NNL1M1= Number of neurons of the layer 1 in module 1. NNL2M1= Number of neurons of the layer 2 in module 1. NNL1M2= Number of neurons of the layer 1 in module 2. NNL2M2= Number of neurons of the layer 2 in module 2. NNL1M3= Number of neurons of the layer 1 in module 3. NNL2M3= Number of neurons of the layer 2 in module 3. We can see in the Fig. 11 the binary representation for this optimized architecture. With this final topology the Neural Network was trained and the ten images were recognized. It can be seen in Table 1 the different architectures obtained with this method using a 'fuzzyga' and a 'fuzzypso' with triangular membership functions and a 'fuzzymain' with triangular membership functions, the other parameters to the 3 fuzzy systems are above described. Table 2, shows the simulation results with all fuzzy systems with gaussian membership functions. The proposed method optimizes the initial architecture proposed for the problem of face recognition.

Figure 8: Images of the Yale face database

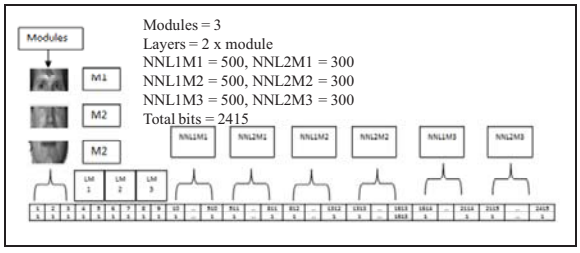

Figure 9: Binary representation for FPSO+FGA (No optimized)

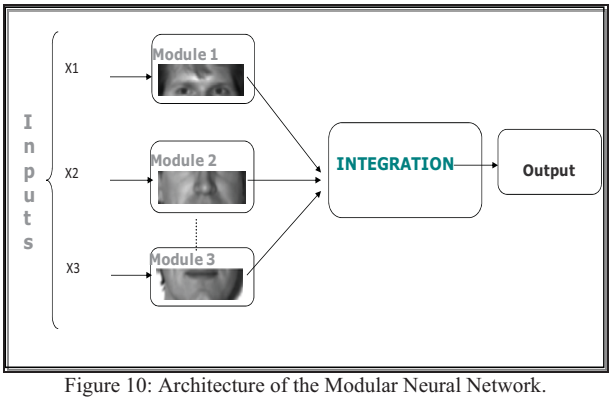

Figure 10: Architecture of the Modular Neural Network.

The Parameters of Table 1 and 2, are as follows:

LMod = Layers per module

NNL = Number of neurons Layer 1, 2 or 3.

GE = Goal Error.

RE = Reached Error.

IDENT = Number of images recognized.

VAR = Number of variables for the mathematical function.

It can be seen in Table 1 and Table 2 that this method is good alternative to solve this type of problems, in our case to optimize Modular Neural Networks. Also this FPSO+FGA have been applied, for optimization of complex mathematical functions to validate our approach. The parameters in FPSO+FGA; as crossover, mutation, cognitive acceleration and social are fuzzy, the population size was of 100 individuals, Table 3 shows the simulation results with 7 mathematical functions to testing this hybrid evolutionary method. The mathematical functions are evaluated with 2, 4, 8 and 16 variables.

8 Conclusions

The analysis of the simulation results of the evolutionary method considered in this paper, FPSO+FGA lead us to the conclusion that for the optimization of Modular Neural Networks with this method is a good alternative because it is easier to optimize the architecture of Modular Neural Network than to try it with PSO or GA separately. This is, because the combination PSO and GA with fuzzy rules gives a new hybrid method FPSO+FGA. It can be seen in Table 1 that the second and five architectures obtained after applying FPSO+FGA recognizes the ten images; we are demonstrating that it is reliable uses for this type of applications. Recently we are working with more images for test the effectiveness of this approach. In Table 4 it can be seen a comparison with PSO and GA used separately, we can observed as FPSO+FGA was better.

Abstract— *There exists a generalization of the Teichmüller space of a covering group. In this paper we combine this generalized Teichmüller space $T(G)$ and any fuzzy subgroup $\mathcal{A}: G \longrightarrow \mathcal{F}$ where G is a subgroup of the group consisting of such orientation preserving and orientation reversing Möbius transformations which act in the upper half-plane of the extended complex plane. A partially ordered set $\mathcal{F} = (\mathcal{F}, \leq)$ consists of stabilizers of G and all of their intersections. After preliminaries we present two new results concerning this special case of fuzzy subgroups. These conclusions are then applied to the known theory of the parametrization of the generalized Teichmüller space . As consequence, the equivalence classes of fuzzy subgroups (with an equivalence relation) become the elements of $T(G)$ where G is generated by a finite set of hyperbolic Möbius transformations. Let the number of the generators be n. Then there is an embedding $\psi: T(G) \longrightarrow \mathbb{R}^{3n-3}$ and therefore a homeomorphism $T(G) \longrightarrow \psi(T(G))$. Through parametrization of $T(G)$ $\psi(\mathcal{A}(G))$ has $3n-3$ real coordinates which are also the coordinates of $\mathcal{A}(G)$ up to identification.*

Keywords— Fuzzy subgroups, Möbius groups, Möbius transformations, compact Riemann surfaces, Teichmüller spaces.

1 Introduction

Orientation preserving and orientation reversing Möbius transformations form a group denoted by $\widehat{M}$. Following [2], we say that every subgroup of $\widehat{M}$ is a Möbius group. In Section 2 we first take some basic knowledge of Möbius transformations and then list all the types of Möbius transformations acting in the upper half-plane H which means that they are self-mappings of H. Let G and G' be Möbius groups fixing H. Then we define geometric isomorphisms $j: G \longrightarrow G'$ which play an important role in our representation.

In Section 3 we present two new Propositons 1 and 2 which the author of this paper has proved in [1]. It is not relevant to give the proofs in this connection because they are too long to show as well as many preliminaries are required. The propositions constitute the relationship between subgroups of the group of Möbius transformations and certain kind of fuzzy subgroups.

Let G, G', G_1 and G_2 be Möbius groups with a fixed G. Defining a delation $\delta(j)$ of an isomorphism $j: G \longrightarrow G'$ by means of multipliers of Möbius transformations $g \in G$ we say that any two isomorphisms $j_1: G \longrightarrow G_1$ and $j_2: G \longrightarrow G_2$ with some properties are equivalent precisely when $\delta(j_2 j_1^{-1}) = 1$. The set $E(G)$ of equivalence classes $[j]$ forms a metric space $(E(G), d)$ with a metric d. In the theory of compact Riemann surfaces this space can be regarded as a generalization of the Teichmüller space of a covering group G. So, $(E(G), d)$ is denoted by $T(G)$. All the presented premiliminaries and the parametrization of the generalized Teichmüller space can be found from [2], [3] and [4]. We will consider them in Section 4 so much as needed for Section 5.

Suppose that there exists a set F in G such that the parametrization condition in Proposition 3 is satisfied. Then we obtain an embedding $\psi: T(G) \longrightarrow \mathbb{R}^{3n-3}$ where G is finitely generated by n hyperbolic elements. More precisely, $T(G) \longrightarrow \psi(T(G))$ is a homeomorphism. Then, up to homeomorphism, $[j]$ is an element of $\mathbb{R}^{3n-3}$ with coordinates $k(j(g))$ which are the multipliers of Möbius transformations $j(g)$ for every $g \in F$.

In Section 5 we apply fuzzy subgroups to the theory of the parametrization of the generalized Teichmüller space. According to Corollary 1 the type-preserving isomorphisms $j_1: G \longrightarrow G_1$ and $j_2: G \longrightarrow G_2$ as well as the fuzzy subgroups $\mathcal{A}(j_1(g))$ and $\mathcal{A}(j_2(g))$ are simultaneously equivalent. The definition of the fuzzy subgroups is given by (3) in Proposition 1 and the equivalence between two fuzzy subgroups is defined by conjugation with a Möbius transformation. Roughly speaking, it is now possible to replace any element $[j]$ by the corresponding $[\mathcal{A}(j(g))]$ in Proposition 4. This leads to the representation of $[\mathcal{A}(j(g))]$ with real coordinates (up to identification) in the Euclidean space $\mathbb{R}^{3n-3}$.

In the following special case, we refer to [3]: If G is a covering group of the upper half-plane H over some compact Riemann surface S, then $[j]$ has coordinates in $\mathbb{R}^{6s-6+3n}$ where S is of genus s and n is the number of conformal disks removed from S. The coordinates of $[\mathcal{A}(j(g))]$ are given in subsection 5.2.

2 Preliminaries for Möbius transformations

In this section we refer to [2].

2.1 Möbius transformations

Directly conformal automorphisms of the extended complex plane $\widehat{\mathbb{C}}$ are orientation preserving Möbius transformations

$$g(z) = \frac{az+b}{cz+d} \quad a,\, b,\, c,\, d \in \mathbb{C}, \quad ad-bc = 1, \qquad (1)$$

and $g(-\frac{d}{c}) = \infty$, $g(\infty) = \frac{a}{c}$.

Indirectly conformal automorphisms of $\widehat{\mathbb{C}}$ are of the form

$$g(z) = \frac{a\bar{z}+b}{c\bar{z}+d} \quad a,\, b,\, c,\, d \in \mathbb{C}, \quad ad-bc = -1 \qquad (2)$$

which are orientation reversing Möbius transformations. The mappings (1) and (2) form the group $\widehat{M}$. Two transformations g_1 and g_2 in $\widehat{M}$ are conjugate if $g_1 = h g_2 h^{-1}$ for some Möbius transformation h.

ISBN: 978-989-95079-6-8

A point z is said to be a fixed point of g if $g(z) = z$. Every non-identity orientation preserving Möbius transformation g has one fixed point or two fixed points. Then

- g with one fixed point is parabolic and it is conjugate to $z \mapsto z+1$.
- If g has two fixed points and it is conjugate to $z \mapsto kz$ for some $k \in \mathbb{C} \setminus \{0\}$, then g is loxodromic if $|k| \neq 1$ and elliptic if $|k| = 1, k \neq 1$.
- Loxodromic transformations fixing the upper half-plane H are called hyperbolic. Otherwise they are strictly loxodromic.

In the loxodromic case we set

$$P(g) = \lim_{n\to\infty} g^n \text{ and } N(g) = \lim_{n\to\infty} g^{-n},$$

which are the attracting and repelling fixed points of g. Because the fixed points of any loxodromic g are real iff $g(H) = H$, hyperbolic transformations have fixed points on the real axis $\mathbb{R}$. Therefore $P(g)$ and $N(g)$ are real if g is hyperbolic. A circle or line in H perpendicular to to the real axis is a non-Euclidean line. Now the non-Euclidean line through $P(g)$ and $N(g)$ is called the axis $ax(g)$ of g. In the elliptic case $g(H) = H$ iff the fixed points of g are complex conjugates.

The multiplier of a Möbius transformation g is defined by means of the cross-ratio

$$k(g) = (g(z), z, x, y) = \frac{g(z)-x}{g(z)-y}\,\frac{z-y}{z-x},$$

where x and y are two different fixed points of g. In the parabolic case we set $k(g) = 1$. For the above complex number k we have $k = k(g)$. The multiplier is invariant in conjugation.

We are only interested in such orientation reversing Möbius transformations which act in H (fix H). This leads to the next consideration: the axis $ax(\sigma) = \{z \mid \sigma(z) = z\}$ of a reflection σ fixing H is also a circle or line orthogonal to $\mathbb{R}$. Denote by x and y the real fixed points of σ. Then

- the reflection $\sigma(z) = \eta(\bar{z})$ where η is the elliptic transformation defined by $k(\eta) = -1$, $\eta(x) = x$ and $\eta(y) = y$,
- a glide-reflection s fixing H is of the form $s = \tau\sigma$ where τ is a hyperbolic transformation fixing H, σ is a reflection fixing H and $ax(\tau) = ax(\sigma)$.

The reflection σ has an infinite number of fixed points but two real fixed points (if $ax(\sigma)$ is not a line). For the multiplier we set $k(\sigma) = -1$. The glide-reflection s and the hyperbolic τ have the same two fixed points. Moreover, the multiplier $k(s) = -k(\tau)$.

It is known that transformations (1) and (2) fix the upper-half plane H iff the coefficients a, b, c, d are real. In fact, there are the following types of Möbius transformations fixing H: hyperbolic, parabolic and elliptic transformations, the identity transformation, reflections and glide-reflections.

Suppose that G and G' are groups of Möbius transformations (or Möbius groups) acting in H. An isomorphism $j : G \longrightarrow G'$ is induced by a Möbius transformation h if $j(g) = hgh^{-1}$ for all $g \in G$. We say that $j : G \longrightarrow G'$ is type-preserving if g and $j(g)$ are of the same type for all $g \in G$. A type-preserving isomorphism $j : G \longrightarrow G'$ is geometric on $\mathbb{R}$ if there exists a homeomorphism $\varphi : \widehat{\mathbb{R}} \longrightarrow \widehat{\mathbb{R}}$ inducing j on $\widehat{\mathbb{R}}$, which is the boundary of the upper half-plane. Especially $\varphi(P(g)) = P(j(g))$ and $\varphi(N(g)) = N(j(g))$ for any hyperbolic g. Since every Möbius transformation is a homeomorphism $\widehat{\mathbb{C}} \longrightarrow \widehat{\mathbb{C}}$, then for every φ which induces a geometric isomorphism j we have $h \mid \widehat{\mathbb{R}} = \varphi$ ($h : \widehat{\mathbb{C}} \longrightarrow \widehat{\mathbb{C}}$ is a Möbius transformation).

3 Connection between fuzzy subgroups and Möbius transformations

Let $(P, \leq)$ be a partially ordered set and A a nonempty set.

(i) A mapping $\mathcal{A} : A \longrightarrow P$ is a P-(fuzzy)set on A.

(ii) For every $p \in P$, $A_p = \{x \in A \mid \mathcal{A}(x) \geq p\}$ is a p-level set subset (in short a level subset) of $\mathcal{A}$.

(iii) Let $\mathcal{G} = (G, \circ)$ be a group such that $(A_p, \circ)$ is a subgroup of $\mathcal{G}$ for every $p \in P$. Then a P-set on G, $\mathcal{A} : G \to P$, is said to be a P-(fuzzy) subgroup of $\mathcal{G}$.

Proposition 1. *[1] Let G be a subgroup of the group of Möbius transformations and let $G_z = \{g \in G \mid g(z) = z\}$ be a stabilizer of G at $z \in \widehat{\mathbb{C}}$. If $\mathcal{F}$ is a set of stabilizers of G and all of their intersections, and $\mathcal{F} = (\mathcal{F}, \leq)$ is a partially ordered set under $p \leq q$ iff $p \supseteq q$ ($p, q \in \mathcal{F}$), then $\mathcal{A} : G \to \mathcal{F}$*

$$\mathcal{A}(g) = \bigcap (p \in \mathcal{F} \mid g \in p) = \bigcap (G_z \mid g \in G_z) \qquad (3)$$

is a $\mathcal{F}$-subgroup of G.

We set an equivalence relation between fuzzy subgroups (3) by conjugation: $\mathcal{A}(g_1) \sim \mathcal{A}(g_2)$ iff there exists a Möbius transformation h such that $\mathcal{A}(g_1) = h\mathcal{A}(g_2)h^{-1}$. Observe that stabilizers form a group and the conjugation of the intersection of the groups G_z occurs by elements in formula (3). Recall that a Möbius group is a subgroup of the group $\widehat{M}$.

Proposition 2. *[1] Let G and G' be Möbius groups acting in the upper half-plane, $\mathcal{F}$ a set of stabilizers of G and all of their intersections. Let $\mathcal{A} : G \longrightarrow \mathcal{F}$ be defined by (3) and suppose that there is a type-preserving isomorphism $j : G \longrightarrow G'$. Then the following conditions are equivalent:*

(i) $\mathcal{A}(g) \sim \mathcal{A}(j(g))$ for every $g \in G$,

(ii) $k(g) = k(j(g))$ for every $g \in G$,

(iii) j is induced by a Möbius transformation,

(iv) $j : G \longrightarrow G'$ is a geometric isomorphism.

Further, let $j_1 : G \longrightarrow G_1$ and $j_2 : G \longrightarrow G_2$ be type-preserving isomorphisms. Then

$$\mathcal{A}(j_1(g)) \sim \mathcal{A}(j_2(g)) \quad \text{for every } g \in G$$

iff

$$j_2 j_1^{-1} : G_1 \longrightarrow G_2 \quad \text{is induced by a Möbius transformation.}$$

4 Coordinates of the generalized Teichmüller space

In this section we refer to [3].

ISBN: 978-989-95079-6-8

4.1 The set E

Let G and G' be Möbius groups acting in the upper half-plane H and $j : G \longrightarrow G'$ an isomorphism. We suppose that G has a set $E = \{g_1, g_2, \cdots\}$ of hyperbolic generators satisfying the following conditions:

(i) $ax(g_1) \cap ax(g_2)$ is a set of two points,

(ii) $(ax(g_1) \cup ax(g_2)) \cap ax(g_i) = \emptyset$, $i = 3,4,\cdots$,

(iii) $(N(g_i), P(g_i), N(g_1), P(g_1)) < 1$, $i = 3,4,\cdots$.

4.2 The dilation

Let $j : G \longrightarrow G'$ be an isomorphism between Möbius groups. The dilation $\delta(j)$ of j is the smallest number of the numbers $a \geq 1$ satisfying

$$|k(g)|^{\frac{1}{a}} \leq |k(j(g))| \leq |k(g)|^a \tag{4}$$

for all $g \in G$. If there exists no number $a \geq 1$ we define $\delta(j) = \infty$.

For a fixed G, let $J(G)$ be a set of all isomorphisms $j : G \longrightarrow G'$ with the following properties:

(i) G and G' are Möbius groups acting in H,

(ii) the dilation $\delta(j)$ is finite,

(iii) there exists a homeomorphism $\varphi : \widehat{\mathbb{R}} \longrightarrow \widehat{\mathbb{R}}$ such that $\varphi(P(g_i)) = P(j(g_i))$ and $\varphi(N(g_i)) = N(j(g_i))$ for all $g_i \in E$.

Define in $J(G)$ an equivalence relation $\sim$ by setting $j_1 \sim j_2$ iff $\delta(j_2 j_1^{-1}) = 1$. Then the set $E(G)$ of equivalence classes $[j]$ becomes a metric space $(E(G), d)$ with the dilation metric d defined by $d([j_1],[j_2]) = log\ \delta(j_2 j_1^{-1})$ [4].

Definition 1. *[3] The space $T(G) = (E(G), d)$ is called the generalized Teichmüller space of a Möbius group G.*

4.3 Parametrization of the Teichmüller space $T(G)$

Let us construct a set F containing the next elements:

(1) g_i, $i = 1,2,\cdots$,

(2) $g_i g_1$, $i = 2,3,\cdots$,

(3) $g_2 g_i g_2^{-1} g_i^{-1}$, $i = 3,4,\cdots$,

where every $g_i \in E$. The following proposition shows the significance of the set F if we want to find the condition for the parametrization of $T(G)$. We say that F parametrizes the space $T(G)$ or the set $J(G)$.

Proposition 3. *[3] Suppose that there exists a homeomorphism $\varphi : \widehat{\mathbb{R}} \longrightarrow \widehat{\mathbb{R}}$ for which $\varphi(P(g_i)) = P(j(g_i))$ and $\varphi(N(g_i)) = N(j(g_i))$ for all $g_i \in E$. If*

$$k(j(g)) = k(g)$$

for all $g \in F$, then j is induced by a Möbius transformation $h : \widehat{\mathbb{C}} \longrightarrow \widehat{\mathbb{C}}$.

Since multipliers are invariant in conjugation the converse holds trivially.

Proposition 4. *[3] Suppose that $E = \{g_1, \cdots, g_n\}$ is finite. Then there is an embedding*

$$\psi : T(G) \longrightarrow \mathbb{R}^{3n-3},\ \psi([j]) = (x_1, \cdots, x_{3n-3}),$$

where

$$\begin{aligned} x_i &= k(j(g_i)),\ i = 1,\cdots,n, \\ x_{n-1+i} &= k(j(g_i)j(g_1)),\ i = 2,\cdots n, \\ x_{2n-3+i} &= k(j(g_2)j(g_i)j(g_2)^{-1}j(g_i)^{-1}),\ i = 3,\cdots,n. \end{aligned}$$

Proof. The mapping $\psi : T(G) \longrightarrow \mathbb{R}^{3n-3}$ is continuous with the dilation metric d [3], [4]. By Proposition 3, ψ is injective [3]. Furthermore, the inverse $\psi^{-1} : \psi(T(G)) \longrightarrow T(G)$ is continuous. Hence $\psi : T(G) \longrightarrow \psi(T(G))$ is a homeomorphism. □

5 Fuzzy subgroups in the Teichmüller space

5.1 The main results

Let G, G_1 and G_2 be Möbius groups. According to Proposition 2 and inequalities (4) we conclude

Corollary 1. *Let $j_1 : G \longrightarrow G_1$ and $j_2 : G \longrightarrow G_2$ be type-preserving isomorphisms. Then the following statements are equivalent:*

(i) $j_1 \sim j_2$,

(ii) $\delta(j_2 j_1^{-1}) = 1$,

(iii) $k(j_2 j_1^{-1}(g)) = k(g)$ *for every* $g \in G$,

(iv) $j_2 j_1^{-1} : G_1 \longrightarrow G_2$ *is induced by a Möbius transformation,*

(v) $\mathcal{A}(j_1(g)) \sim \mathcal{A}(j_2(g))$ *for every* $g \in G$.

Let $j \in J(G)$ and suppose that $j : G \longrightarrow G'$ is geometric. Then j is type-preserving and satisfies the condition *(iii)* in subsection 4.2. Following the definition of $E(G)$, let us denote the set of equivalence classes $[\mathcal{A}(j(g))]$ by $E'(G)$. By Corollary 1,*(i)*,*(v)*, $(E'(G), d)$ becomes also a metric space having the same metric d. This leads to the new form of the generalized Teichmüller space, $T'(G) = (E'(G), d)$. Reformulation of Proposition 4 for the fuzzy subgroups $\mathcal{A}(j(g))$ yields

Proposition 5. *Suppose that $E = \{g_1, \cdots, g_n\}$ is finite. Then there is an embedding*

$$\psi' : T'(G) \longrightarrow \mathbb{R}^{3n-3},\ \psi'([\mathcal{A}(j(g)]) = (x_1, \cdots, x_{3n-3}),$$

for every $g \in G$, and where

$$\begin{aligned} x_i &= k(j(x_i)),\ i = 1,\cdots,n, \\ x_{n-1+i} &= k(j(g_i)j(g_1)),\ i = 2,\cdots n, \\ x_{2n-3+i} &= k(j(g_2)j(g_i)j(g_2)^{-1}j(g_i)^{-1}),\ i = 3,\cdots,n. \end{aligned}$$

ISBN: 978-989-95079-6-8

5.2 The covering group of a compact Riemann surface

Let G be a Möbius group acting in the upper half-plane H and suppose that G is a covering group of H over the compact Riemann surface S. Since any non-identity cover transformation of G has no fixed points in H, we know that all elements of G are hyperbolic or parabolic Möbius transformations, or it is the identity mapping. We say that G is of signature (s,n) if $S = H/G$ is of genus s from which n conformal disks are removed.

Assume that G is a fixed covering group of signature (s,n) with $s > 0$ and $n > 0$. Then G has $2s+n$ hyperbolic generators satisfying the defining relation:

$$c_n \cdots c_1\, b_s^{-1}\, a_s^{-1}\, b_s\, a_s \cdots b_1^{-1}\, a_1^{-1}\, b_1\, a_1 \;=\; id$$

from which c_n can be solved. As conclusion the set

$$E \;=\; \{a_1, b_1, a_2^{-1}, b_2, \cdots, a_s^{-1}, b_s, c_1^{-1}, \cdots, c_{n-1}^{-1}\}$$

generates G freely. Moreover, E satisfies the conditions $(i)-(iii)$ in subsection 4.1. Then the mapping $\psi' : T'(G) \longrightarrow \mathbb{R}^{3n-3}$ in Proposition 5 takes the form

$$\psi' : T'(G) \longrightarrow \mathbb{R}^{6s-6+3n},\;\; \psi'([\mathcal{A}(j(g)]) = (x_1, \cdots, x_{6s-6+3n})$$

with coordinates

$$\begin{aligned}
x_t \;=\;& k(j(a_i)),\;\; i = 1, \cdots, s,\\
& k(j(b_i)),\;\; i = 1, \cdots, s\\
& k(j(c_i)),\;\; i = 1, \cdots, n-1,\\
& \text{for } t = 1, \cdots, 2s+n-1,\\
x_{2s+n-2+t} \;=\;& k(j(b_i)j(a_1)),\;\; i = 1, \cdots, s,\\
& k(j(a_i)^{-1})j(a_1)),\;\; i = 2, \cdots, s,\\
& k(j(c_i)^{-1})j(a_1))\;\; i = 1, \cdots, n-1,\\
& \text{for } t = 2, \cdots 2s+n-1,\\
x_{4s+2n-5+t} \;=\;& k(j(b_1)j((a_i)^{-1})j((b_1)^{-1})j(a_i)),\\
& i = 2, \cdots, s\\
& k(j(b_1)(j(b_i)j((b_1)^{-1})j((b_i)^{-1})),\\
& i = 2, \cdots, s\\
& k(j(b_1)j((c_i)^{-1})j((b_1)^{-1})j(c_i)),\\
& i = 1, \cdots, n-1,\\
& \text{for } t = 3, \cdots, 2s+n-1.
\end{aligned}$$

Example 1. Let us construct a compact Riemann surface $S = H/G$ with a covering group G of signature $(1,1)$. Then S consists of one handle from which one conformal disk is removed. Therefore G has a set $E = \{a, b, c^{-1}\}$ of hyperbolic generators with the defining relation

$$c^{-1}\, a\, b \;=\; id,$$

where c is a boundary mapping of the disk satisfying $c = ab$. Then a and b generates G freely, $G =< a, b >$. In fact, the hyperbolic a and b have no comman fixed points and G is a purely hyperbolic group. It does not contain parabolic or elliptic elements. The first one is concluded from [3] and the second one holds because G is a covering group.

An embedding

$$\begin{aligned}
&\psi' : E'(G) \longrightarrow \mathbb{R}^3,\\
&\psi'([\mathcal{A}(j(g)]) = (k(j(a_1)), k(j(b_1)), k(j(b_1)j(a_1)))
\end{aligned}$$

gives the coordinates $(k(j(a_1)), k(j(b_1)), k(j(b_1)j(a_1)))$ of $[\mathcal{A}(j(g)]$ up to homeomorphism for any $g \in G$ and some geometric isomorphism j of G and $j \in J(G)$.

Abstract— *Reasoning in the presence of imprecision and vagueness is inevitable in many real-world applications including those in robotics and intelligent agents. Although, reasoning about actions is a major component in these real-world applications, current actions languages for reasoning about actions lack the ability to represent and reason about actions in the presence of imprecision and vagueness that stem from effects of actions in these real-world applications. In this paper we present a new action language called fuzzy action language, $\mathcal{A}_F$, that allows the representation and reasoning about actions with vague (fuzzy) effects. In addition we define the notions of fuzzy planning and fuzzy plan in the fuzzy action language $\mathcal{A}_F$. Furthermore, we describe a fuzzy planner based on the fuzzy action language A_F that is developed by translating a fuzzy action theory,* $\mathbf{FT}$*, in A_F into a normal logic program with answer set semantics,* Π*, where trajectories in* $\mathbf{FT}$ *are equivalent to the answer sets of* Π*. In addition, we formally prove the correctness of our translation. Furthermore, we show that fuzzy planning problems can be encoded as a SAT problem.*

Keywords— Answer set programming, fuzzy planning, reasoning about actions with fuzzy effects, reasoning under uncertainty.

1 Introduction

Reasoning about the properties of actions is fundamental in many real-world applications. Therefore, many action languages that allow representing and reasoning about actions have been developed which include [2, 5, 9, 10, 11, 12, 18, 21, 22, 24]. Furthermore, uncertainty is a main issue in representing and reasoning about actions in these real-world applications. Uncertainty in these real-world applications stems from different sources including incompleteness, erroneous, or imprecision (vagueness). For reasoning under uncertainty, probability theory is used to reason in the presence of incompleteness or erroneous, however, fuzzy set theory is used to reason in the presence of imprecision or vagueness. To deal with probabilistic uncertainty in reasoning about actions, different proposals have been presented. These proposals include [2, 5, 12, 21, 22]. Although, these proposals deal with uncertainty probabilistically, they are inappropriate in situations where actions have imprecise or vague effects, which need a different formalism from the one required in reasoning about actions with probabilistic effects as in [2, 5, 12, 21, 22]. This is because the underlying formalism in reasoning about actions with probabilistic effects is the probability theory, however, the formalism required for reasoning about actions with imprecise effects is the fuzzy set theory. Actions with imprecise effects appear in many domains including robotics and intelligent agents. Consider the following example adapted from [23]. Consider a planner that controls an autonomous car that is moving in a highway with the goal to keep the car close to the middle of a lane. The autonomous car planner's uses the action navigate whose effect is to make the car close to the middle of the lane. The effect of the action navigate is neither probabilistically nor precisely defined. Therefore, action languages, for example [9, 10, 11, 18, 24], that reason about actions whose effects are precisely defined (either entirely true or entirely false), and action languages, for example [2, 5, 12, 21, 22], that reason about actions whose effects are probabilistically defined (either true or false to a probabilistic degree), can not be used to correctly represent and reason about these kind of actions whose effects are imprecisely or vaguely defined.

In this paper we present a new action language called fuzzy action language, $\mathcal{A}_F$, that allows the representation and reasoning about actions with vague (fuzzy) effects. In addition, we define the notions of fuzzy planning and fuzzy plan in the fuzzy action language $\mathcal{A}_F$. Furthermore, we describe a fuzzy planner based on the fuzzy action language $\mathcal{A}_F$ that is developed by translating a fuzzy action theory, $\mathbf{FT}$, in $\mathcal{A}_F$ into a normal logic program with answer set semantics, Π, where trajectories in $\mathbf{FT}$ are equivalent to the answer sets of Π. In addition, we formally prove the correctness of our translation. Furthermore, we show that fuzzy planning problems can be encoded as SAT problems.

This paper is organized as follows. Section 2 reviews the answer set semantics of normal logic programs and the fundamental notions of the fuzzy set theory. The syntax and semantics of the fuzzy action language, $\mathcal{A}_F$, is introduced in section 3. In section 4, a translation from a fuzzy planning problem in the fuzzy action language $\mathcal{A}_F$ into a normal logic program with answer set semantics is presented. The correctness of the translation is introduced in section 5. Finally, conclusion and related work is presented in section 6.

2 Preliminaries

In this section we review the answer set semantics of normal logic programs [7] and the basic notions of fuzzy set theory [27].

2.1 Normal Logic Programs with Answer Set Semantics

Let $\mathcal{L}$ be a first-order language with finitely many predicate symbols, function symbols, constants, and infinitely many variables. The Herbrand base of $\mathcal{L}$ is denoted by $\mathcal{B}$. A Her-

ISBN: 978-989-95079-6-8

brand interpretation is a subset of the Herbrand base $\mathcal{B}$. A normal logic program is a finite set of rules of the form

$$a \leftarrow a_1, \ldots, a_n, not\ b_1, \ldots, not\ b_m$$

where a, $a_1, \ldots, a_n, b_1, \ldots, b_m$ are atoms and not is the negation-as-failure. Intuitively, the meaning of the above rule is that if it is believable (provable) that a_i is true and it is not believable that b_i is true then it is believable that a is true. A normal logic program is ground if no variables appear in any of its rules.

Let Π be a ground normal logic program, S be a Herbrand interpretation, and r be a rule as above. Then, we say that

- S satisfies a_i (denoted by $S \models a_i$) iff $a_i \in S$.
- S satisfies $not\ b_j$ (denoted by $S \models not\ b_j$) iff $b_j \notin S$.
- S satisfies $(a_1, \ldots, a_n, not\ \ b_1, \ldots, not\ \ b_m)$ (denoted by $S \models (a_1, \ldots, a_n, not\ \ b_1, \ldots, not\ \ b_m)$) iff $\{a_1, \ldots, a_n\} \subseteq S$ and $\{b_1, \ldots, b_m\} \nsubseteq S$.
- S satisfies $a \leftarrow a_1, \ldots, a_n, not\ b_1, \ldots, not\ b_m$ iff $S \models a$ or $S \not\models (a_1, \ldots, a_n, not\ b_1, \ldots, not\ b_m)$.

A Herbrand interpretation is said to satisfy a normal logic program Π iff it satisfies every rule in Π. A Herbrand model of a normal logic program Π is a Herbrand interpretation of Π that satisfies Π. A Herbrand interpretation S of a normal logic program Π is said to be an answer set of Π if S is the minimal Herbrand model (with respect to the set inclusion) of the reduct, denoted by Π^S, of Π w.r.t. S, where Π^S is a set of rules of the form

$$a \leftarrow a_1, \ldots, a_n$$

such that

$$a \leftarrow a_1, \ldots, a_n, not\ b_1, \ldots, not\ b_m \in \Pi$$

and $\{b_1, \ldots, b_m\} \nsubseteq S$

Intuitively, for any $not\ \ b_j$ in the body of a rule in Π with $b_j \notin S$ is simply satisfied by S, and $not\ b_j$ is safely removed from the body of the rule. If $b_j \in S$ then the body of the rule is not satisfied and the rule is trivially ignored.

2.2 Fuzzy Sets

In this section we review the basic notions of fuzzy sets as presented in [27]. Let U be a set of objects. A fuzzy set, F, in U is defined by the grade membership function $\mu_F : U \rightarrow [0, 1]$, where for each element $x \in U$, μ_F assigns to x a value $\mu_F(x)$ in $[0, 1]$. The support for F denotes the set of all objects x in U for which the grade membership of x in F is a non-zero value. Formally, $support(F) = \{x \in U \mid \mu_F(x) > 0\}$. The intersection (conjunction) of two fuzzy sets F and F' in U, denoted by $F \wedge_f F'$ is a fuzzy set G in U where the grade membership function of G is $\mu_G(x) = \min(\mu_F(x), \mu_{F'}(x))$ for all $x \in U$. However, the union (disjunction) of two fuzzy sets F and F' in U, denoted by $F \vee_f F'$ is a fuzzy set G in U where the grade membership function of G is $\mu_G(x) = \max(\mu_F(x), \mu_{F'}(x))$ for all $x \in U$. The complement (negation) of a fuzzy set F in U is a fuzzy set in U denoted by $\overline{F}$ where the grade membership function of $\overline{F}$ is $\mu_{\overline{F}}(x) = 1 - \mu_F(x)$ for all $x \in U$. A fuzzy set F in U is said to be contained in another fuzzy set G in U if and only if $\mu_F(x) \leq \mu_G(x)$ for all $x \in U$. Notice that we use the notations $\wedge_f$ and $\vee_f$ to denote fuzzy conjunction and fuzzy disjunction respectively to distinguish them from $\wedge$ and $\vee$ for propositional conjunction and disjunction respectively. Furthermore, other function characterizations for the fuzzy conjunction and fuzzy disjunction operators can be used. However, we will stick with the min and max function characterizations for the fuzzy conjunction and fuzzy disjunction as originally proposed in [27].

3 Fuzzy Action Language $\mathcal{A}_F$

In this section we develop a novel action language, called *fuzzy action language*, $\mathcal{A}_F$, that allows the representation of actions with vague (fuzzy) effects. An action theory in $\mathcal{A}_F$ is capable of representing the grade membership distribution of the possible initial states, the executability conditions of actions, and the grade membership distribution of the fuzzy effects of actions. The semantics of $\mathcal{A}_F$ is based on a transition function that maps an action and a set of states to a set of states. The fuzzy action language $\mathcal{A}_F$ is inspired by the action languages in [21, 22].

3.1 Language syntax

A predicate that describes a property of the environment, which may contain variables, is called a fluent. Let $\mathcal{A}$ be a set of action names that can contain variables and $\mathcal{F}$ be a set of fluents. A fluent $f \in \mathcal{F}$ or $\neg f$, the negation of f is called a fluent literal. A conjunction of fluent literals of the form $l_1 \wedge \ldots \wedge l_n$ is called a conjunctive fluent formula, where $l_1, \ldots, l_n$ are fluent literals. Sometimes we abuse the notation and refer to a conjunctive fluent formula as a set of fluent literals ($\emptyset$ denotes $true$).

A fuzzy action theory, $\mathbf{FT}$, in $\mathcal{A}_F$ is a tuple of the form $\mathbf{FT} = \langle S_0, \mathcal{AD} \rangle$, where S_0 is a proposition of the form (1), $\mathcal{AD}$ is a set of propositions from (2-3) as follows:

$$\textbf{initially} \begin{cases} \psi_1 \ : \ v_1 \\ \psi_2 \ : \ v_2 \\ \quad \ldots \\ \psi_n \ : \ v_n \end{cases} \tag{1}$$

$$\textbf{executable}\ a\ \textbf{if}\ \psi \tag{2}$$

$$a\ \textbf{causes} \begin{cases} \phi_1 \ : \ v_1\ \textbf{if}\ \psi_1 \\ \phi_2 \ : \ v_2\ \textbf{if}\ \psi_2 \\ \quad \ldots \\ \phi_n \ : \ v_n\ \textbf{if}\ \psi_n \end{cases} \tag{3}$$

where $\psi, \psi_1, \ldots, \psi_n, \phi_1, \ldots, \phi_n$ are conjunctive fluent formulae, $a \in \mathcal{A}$ is an action, and for all $1 \leq i \leq n$, we have $v_i \in [0, 1]$. The set of all ψ_i must be mutually exclusive. Let $\mathcal{S}$ be the set of all states formed from the fluents in $\mathcal{F}$.

Proposition (1) is a fuzzy set in the set of all states $\mathcal{S}$. It represents the grade membership of the possible initial states. We consider that only ψ_i with grade membership that is non-zero is listed in (1). Proposition (1) says that the grade membership of the possible initial state ψ_i is v_i for all $1 \leq i \leq n$. Proposition (2) represents the *executability condition* of actions, where each variable that appears in a also appears in ψ. It states that an action a is executable in any state in which ψ holds. A proposition of the form (3) represents the fuzzy (vague) effects resulting from executing an action a in the

ISBN: 978-989-95079-6-8

states in which a is executable. For each $1 \leq i \leq n$, all variables that appear in ϕ_i also appear in a and ψ_i. It describes that a causes ϕ_i to hold with grade membership v_i in a successor state to a state in which a is executed and ψ_i holds for all $1 \leq i \leq n$. For each $1 \leq i \leq n$, ψ_i is called a precondition of an action a that corresponds to an effect ϕ_i, ϕ_i is called an effect of a, v_i is the grade membership that ϕ_i holds given that ψ_i holds, where v_i is a non-zero value in $[0, 1]$. For any proposition of the form (3), the set of ground preconditions ψ_i are mutually exclusive and exhaustive.

It will be more convenient for the subsequent results to represent an action a as a set of the form $a = \{a_1, \ldots, a_n\}$, where each a_i corresponds to ϕ_i, v_i, and ψ_i. Therefore, alternatively, for each $1 \leq i \leq n$, proposition (3) can be represented as

$$a_i \textbf{ causes } \phi_i \ : \ v_i \textbf{ if } \psi_i$$

A fuzzy action theory is ground if it does not contain any variables.

3.2 Semantics

A consistent set of ground literals ϕ is a set of literals that does not contain a pair of complementary literals, i.e., l and $\neg l \notin \phi$. If a literal $l \in \phi$, then we say l is true (holds) in ϕ (denoted by $\phi \models l$), and l is false (does not hold) in ϕ if $\neg l$ is in ϕ (denoted by $\phi \models \neg\, l$). If a set of literals σ is contained in ϕ then we say σ is true (holds) in ϕ (denoted by $\phi \models \sigma$), otherwise, σ is false (does not hold) in ϕ (denoted by $\phi \not\models \sigma$). A state s is a complete and consistent set of literals that describes the world at a certain time point.

Definition 1 *Let $\mathbf{FT} = \langle S_0, \mathcal{AD} \rangle$ be a ground fuzzy action theory, $\mathcal{S}$ is the set of all states in $\mathbf{FT}$, s be a state whose grade membership $\mu_S(s)$ is v, a_i **causes** ϕ_i : v_i : **if** ψ_i ($1 \leq i \leq n$) be a proposition in $\mathcal{AD}$, and $a = \{a_1, \ldots, a_n\}$ be an action, where each a_i corresponds to ϕ_i, v_i, and ψ_i for $1 \leq i \leq n$. Then, $s' = \Phi(a_i, s)$ is the state resulting from executing a in s, given that a is executable in s, where:*

- *$l \in \Phi(a_i, s)$ and $\neg\ l \notin \Phi(a_i, s)$ if $l \in \phi_i$ and the precondition ψ_i holds in s.*
- *$\neg\ l \in \Phi(a_i, s)$ and $l \notin \Phi(a_i, s)$ if $\neg\ l \in \phi_i$ and the precondition ψ_i holds in s.*
- *Otherwise, $l \in \Phi(a_i, s)$ iff $l \in s$ and $\neg\ l \in \Phi(a_i, s)$ iff $\neg\ l \in s$.*

where the grade membership of the resulting state $s' = \Phi(a_i, s)$ is $\mu_{\mathcal{S}}(s') = \min(\mu_{\mathcal{S}}(s), v_i) = \min(v, v_i)$. We call Φ a fuzzy transition function.

Example 1 *Consider the following fuzzy planning task adapted from [14]. An arm of a robot is grasping a block from a table, where the* pickup *action the robot performs has effects that are imprecisely defined. The arm is able to tightly hold a block (hb) with a grade membership 0.9 after executing the* pickup *action in the state in which the gripper is dry (gd), and the arm tightly cannot hold the block ($\neg hb$), after executing the* pickup *action in the same state, with grade membership value 0.4. On the other hand, when executing the* pickup *action in the state while the gripper is not dry ($\neg\ gd$) causes the block to be tightly held (hb) with grade of membership equal to 0.3 and tightly not held ($\neg\ hb$) with grade membership 0.6. We assume the initial grade membership distribution of the initial states of the world is given by the grade membership function $\mu_{\mathcal{S}}$ such that $\mu_{\mathcal{S}}(s_1) = 0.9$ and $\mu_{\mathcal{S}}(s_2) = 0.5$, where $s_1 = \{gd, \neg hb\}$ and $s_2 = \{\neg gd, \neg hb\}$, with the understanding that the grade membership of the other states of the world is 0. This fuzzy planning domain can be represented in the fuzzy action language $\mathcal{A}_F$ as the fuzzy action theory $\mathbf{FT} = \langle S_0, \mathcal{AD} \rangle$ where*

$$S_0 = \textbf{initially} \left\{ \begin{array}{lcl} \{gd, \neg hb\} & : & 0.9 \\ \{\neg gd, \neg hb\} & : & 0.5 \end{array} \right.$$

and $\mathcal{AD}$ consists of:

$$\textbf{executable } pickup \textbf{ if } \emptyset$$

$$pickup \textbf{ causes} \left\{ \begin{array}{lcllll} \{hb\} & : & 0.9 & \textbf{if} & \{gd\} \\ \{\neg hb\} & : & 0.4 & \textbf{if} & \{gd\} \\ \{hb\} & : & 0.3 & \textbf{if} & \{\neg\, gd\} \\ \{\neg\, hb\} & : & 0.6 & \textbf{if} & \{\neg\, gd\} \end{array} \right.$$

The $pickup$ action can be represented as the set $pickup = \{pickup_1, pickup_2, pickup_3, pickup_4\}$, where

$$\begin{array}{llllll} pickup_1 & \textbf{causes} & \{hb\} & : & 0.9 & \textbf{if } \{gd\} \\ pickup_2 & \textbf{causes} & \{\neg hb\} & : & 0.4 & \textbf{if } \{gd\} \\ pickup_3 & \textbf{causes} & \{hb\} & : & 0.3 & \textbf{if } \{\neg\, gd\} \\ pickup_4 & \textbf{causes} & \{\neg\, hb\} & : & 0.6 & \textbf{if } \{\neg\, gd\} \end{array}$$

The grade membership distribution resulting from executing the $pickup$ action in the initial states s_1 and s_2 is given by:

- $s_1^{'} = \{gd, hb\} = \Phi(pickup_1, \{gd, \neg hb\})$, where $\mu_S(s_1^{'}) = \min(\mu_S(s_1), 0.9) = \min(0.9, 0.9) = 0.9$.
- $s_2^{'} = \{gd, \neg hb\} = \Phi(pickup_2, \{gd, \neg hb\})$, where $\mu_S(s_2^{'}) = \min(\mu_S(s_1), 0.4) = \min(0.9, 0.4) = 0.4$.
- $s_3^{'} = \{\neg gd, hb\} = \Phi(pickup_3, \{\neg gd, \neg hb\})$, where $\mu_S(s_3^{'}) = \min(\mu_S(s_2), 0.3) = \min(0.5, 0.3) = 0.3$.
- $s_4^{'} = \{\neg gd, \neg hb\} = \Phi(pickup_4, \{\neg gd, \neg hb\})$, where $\mu_S(s_4^{'}) = \min(\mu_S(s_2), 0.6) = \min(0.5, 0.6) = 0.5$.

Definition 2 (Fuzzy Plan) *A sequence of actions $\langle a_0, a_1, \ldots, a_{n-1} \rangle$ is called a fuzzy plan, where each $(0 \leq i \leq n-1)$ a_i is an action with fuzzy effects.*

The grade membership that a fuzzy plan P satisfies a conjunctive fluent formula $\mathcal{G}$ after executing P in a given state s is given by the following definition.

Definition 3 *Let $\mathbf{FT}$ be a ground fuzzy action theory, s, s' be states, s_I be a variable ranging over the possible initial states, $\mathcal{G}$ be a conjunctive fluent formula, and $\langle a_0, a_1, \ldots, a_{n-1} \rangle$ be a fuzzy plan. Then the grade membership that $\mathcal{G}$ is true in a state s' that results after executing $\langle a_0, a_1, \ldots, a_{n-1} \rangle$ in the possible initial states s_I is given by*

$$\mu'_{\mathcal{P}}(s' | s_I, \langle a_0, a_1, \ldots, a_{n-1} \rangle) =$$

$$\max_{s''}(\min_{s_I = s}(\mu'_{\mathcal{P}}(s'' | s, a_0),\ \mu'_{\mathcal{P}}(s' | s'', \langle a_1, \ldots, a_{n-1} \rangle)))$$

where $\mathcal{P}$ is the set of all plans in $\mathbf{FT}$, and $\mu'_{\mathcal{P}}(s'' | s, a_0) = \mu_{\mathcal{S}}(s'') = \min(\mu_S(s), v)$ such that $s'' = \Phi(a_0, s)$. In general, for any action $a \in \mathcal{A}$, $\mu'_{\mathcal{P}}(s'' | s, a) = \mu_{\mathcal{S}}(s'') = \min(\mu_S(s), v)$ such that $s'' = \Phi(a, s)$.

ISBN: 978-989-95079-6-8

Definition 4 *A fuzzy planning problem is a 4-tuple* $\mathbf{FP} = \langle S_0, \mathcal{AD}, \mathcal{G}, \mathcal{T} \rangle$*, where* S_0 *is a fuzzy set in the set of all states* S *that represents the initial agent knowledge about the world states at the time of execution (the initial grade membership distribution over states),* $\mathcal{AD}$ *is a fuzzy action description,* $\mathcal{G}$ *is conjunctive fluent formula represents the goal to be satisfied, and* $0 \leq \mathcal{T} \leq 1$ *is the fuzzy threshold for the goal* $\mathcal{G}$ *to be achieved. We say* $\langle a_0, \ldots, a_{n-1} \rangle$ *is a fuzzy plan for* $\mathbf{FP}$ *iff each* a_i *appears in* $\mathcal{AD}$ *and* $\mu'_{\mathcal{P}}(s'|s_I, \langle a_0, a_1, \ldots, a_{n-1} \rangle) \geq \mathcal{T}$*, where* s_I *is a variable ranging over the possible initial states, and* $\mathcal{G}$ *is true in* s'*.*

4 Fuzzy Planning Using Answer Set Programming

This section presents a translation from a fuzzy planning problem $\mathbf{FP} = \langle S_0, \mathcal{AD}, \mathcal{G}, \mathcal{T} \rangle$ into a normal logic program with answer set semantics, $\Pi_{\mathbf{FP}}$, where the rules in $\Pi_{\mathbf{FP}}$ encode (1) the initial grade membership distribution S_0, (2) the fuzzy transition function Φ, (3) the fuzzy action description $\mathcal{AD}$, (4) and the goal $\mathcal{G}$. The answer sets of $\Pi_{\mathbf{FP}}$ correspond to valid trajectories in $\mathbf{FP}$. The normal logic program translation of a fuzzy planning problem $\mathbf{FP}$ is mainly adapted from [25]. We assume that the length of the fuzzy plan that we are looking for is known. We use the predicates $holds(L, T)$ to represent the fact that a literal L holds at time moment T and $occ(AC, T)$ to describe that an action AC executes at time moment T. We use lower case letters to represent constants and upper case letters to represent variables.

Let $\Pi_{\mathbf{FP}}$ be the normal logic program translation of a fuzzy planning problem $\mathbf{FP} = \langle S_0, \mathcal{AD}, \mathcal{G}, \mathcal{T} \rangle$, where $\Pi_{\mathbf{FP}}$ is the set of rules described as follows. In addition, given p is a predicate and $\psi = \{l_1, \ldots, l_n\}$, we use $p(\psi)$ to denote $p(l_1), \ldots, p(l_n)$.

- For each action $a = \{a_1, \ldots, a_n\} \in \mathcal{A}$, we add to $\Pi_{\mathbf{FP}}$ the set of facts

$$action(a_i) \leftarrow \tag{4}$$

for each $1 \leq i \leq n$. States of the world are described by literals that are encoded in $\Pi_{\mathbf{FP}}$ by the rules

$$literal(A) \leftarrow atom(A) \tag{5}$$
$$literal(\neg A) \leftarrow atom(A) \tag{6}$$

where $atom(A)$ is a set of facts that describe the properties of the world. To present that A and $\neg A$ are contrary literals, the following rules are added to $\Pi_{\mathbf{FP}}$.

$$contrary(A, \neg A) \leftarrow atom(A) \tag{7}$$
$$contrary(\neg A, A) \leftarrow atom(A) \tag{8}$$

- The initial grade membership distribution **initially** ψ_i : v_i for $1 \leq i \leq n$ is represented in $\Pi_{\mathbf{FP}}$ as follows. Consider that $s_1, s_2, \ldots, s_n$ form the set of possible initial states, where for each $1 \leq i \leq n$, $s_i = \{l_1^i, \ldots, l_m^i\}$, and the grade membership of s_i is $\mu_{\mathcal{S}}(s_i) = v_i$. Moreover, let $s = s_1 \cup s_2 \cup \ldots \cup s_n$, $s' = s_1 \cap s_2 \cap \ldots \cap s_n$, $\widehat{s} = s - s'$, and $s'' = \{\, l \,|\, l \in \widehat{s} \vee \neg l \in \widehat{s}\}$. To generate the set of all possible initial states, the following set of rules are added to $\Pi_{\mathbf{FP}}$. For each literal $l \in s'$, the fact

$$holds(l, 0) \leftarrow \tag{9}$$

is in $\Pi_{\mathbf{FP}}$. This fact presents that the literal l holds at time moment 0. This set of facts specifies the set of literals that hold in every possible initial state. Moreover, for each literal $l \in s''$, we add to $\Pi_{\mathbf{FP}}$ the rules

$$holds(l, 0) \leftarrow not\ holds(\neg l, 0) \tag{10}$$
$$holds(\neg l, 0) \leftarrow not\ holds(l, 0) \tag{11}$$

The above rules say that the literal l (similarly $\neg l$) holds at time moment 0, if $\neg l$ (similarly l) does not hold at the time moment 0.

- Each executability condition proposition of an action $a = \{a_1, \ldots, a_n\}$ of the form (2) is encoded in $\Pi_{\mathbf{FP}}$ for each $1 \leq i \leq n$ as

$$exec(a_i, T) \leftarrow holds(\psi, T) \tag{12}$$

- For each proposition of the form a_i **causes** ϕ_i : v_i **if** ψ_i ($1 \leq i \leq n$), in $\mathcal{AD}$, we proceed as follows. Let $\phi_i = \{l_i^1, \ldots, l_i^m\}$. Then, $\forall$ $(1 \leq i \leq n)$, we have for each $1 \leq j \leq m$,

$$holds(l_i^j, T+1) \leftarrow occ(a_i, T), exec(a_i, T), holds(\psi_i, T) \tag{13}$$

belongs to $\Pi_{\mathbf{FP}}$. This rule states that if the action a occurs at time moment T and the precondition ψ_i holds at the same time moment, then the literal l_i^j holds at the time moment $T+1$.

- The frame axioms are presented in $\Pi_{\mathbf{FP}}$ as below. For any literal L we have the rule

$$holds(L, T+1) \leftarrow holds(L, T), not\ holds(L', T+1), contrary(L, L') \tag{14}$$

in $\Pi_{\mathbf{FP}}$. The above rule states that L holds at the time moment $T+1$ if it holds at the time moment T and its contrary does not hold at the time moment $T+1$.

- To encode the fact that a literal A and its negation $\neg A$ cannot hold at the same time, we add the following rule to $\Pi_{\mathbf{FP}}$

$$\leftarrow holds(A, T), holds(\neg A, T) \tag{15}$$

- Action generation rules are described by

$$occ(AC^i, T) \leftarrow action(AC^i), not\ abocc(AC^i, T) \tag{16}$$
$$abocc(AC^i, T) \leftarrow action(AC^i), action(AC^j), occ(AC^j, T), AC^i \neq AC^j \tag{17}$$

The above rules generate action occurrences once at a time, where AC^i and AC^j are variables representing actions.

- Let $\mathcal{G} = g_1 \wedge \ldots \wedge g_m$ be a goal expression, then $\mathcal{G}$ is encoded in $\Pi_{\mathbf{FP}}$ as

$$goal \leftarrow holds(g_1, T), \ldots, holds(g_m, T) \tag{18}$$

Example 2 *The normal logic program translation, $\Pi_{\mathbf{FP}}$, of the fuzzy planning problem $\mathbf{FP} = \langle S_0, \mathcal{AD}, \mathcal{G}, \mathcal{T} \rangle$, described in Example 1 proceeds as follows, where S_0 and $\mathcal{AD}$ are as presented in Example 1, $\mathcal{G} = \{hb\}$, and $\mathcal{T} \in [0,1]$. In addition to the rules (5), (6), (7), (8), (14), (15), (16), and (17), $\Pi_{\mathbf{FP}}$ contains the rules*

$$\begin{aligned} action(pickup_1) &\leftarrow \\ action(pickup_2) &\leftarrow \\ action(pickup_3) &\leftarrow \\ action(pickup_4) &\leftarrow \end{aligned}$$

where pickup is in $\mathcal{A}$. Properties of the world are described by the atoms gd (gripper dry) and hb (holding block), which are encoded in $\Pi_{\mathbf{FP}}$ by the rules

$$\begin{aligned} atom(gd) &\leftarrow \\ atom(hb) &\leftarrow \end{aligned}$$

Executability conditions of action pickup are encoded in $\Pi_{\mathbf{FP}}$ by the rules

$$\begin{aligned} exec(pickup_1, t) &\leftarrow \\ exec(pickup_2, t) &\leftarrow \\ exec(pickup_3, t) &\leftarrow \\ exec(pickup_4, t) &\leftarrow \end{aligned}$$

where $0 \leq t \leq n$. The set of possible initial states are encoded in $\Pi_{\mathbf{FP}}$ by the rules:

$$\begin{aligned} holds(\neg hb, 0) &\leftarrow \\ holds(gd, 0) &\leftarrow not\ holds(\neg gd, 0) \\ holds(\neg gd, 0) &\leftarrow not\ holds(gd, 0) \end{aligned}$$

Effects of the pickup action are encoded in $\Pi_{\mathbf{FP}}$ by the rules

$$\begin{aligned} holds(hb, T+1) &\leftarrow occ(pickup_1, T), \\ &\quad exec(pickup_1, T), holds(gd, T) \\ holds(\neg hb, T+1) &\leftarrow occ(pickup_2, T), \\ &\quad exec(pickup_2, T), holds(gd, T) \\ holds(hb, T+1) &\leftarrow occ(pickup_3, T), \\ &\quad exec(pickup_3, T), holds(\neg gd, T) \\ holds(\neg hb, T+1) &\leftarrow occ(pickup_4, T), \\ &\quad exec(pickup_4, T), holds(\neg gd, T) \end{aligned}$$

The goal is encoded in $\Pi_{\mathbf{FP}}$ by the rule

$$goal \leftarrow holds(hb, T)$$

5 Correctness

In this section we prove the correctness of our translation. We show that the answer sets of the normal logic program translation, $\Pi_{\mathbf{FP}}$, of a fuzzy planning problem, $\mathbf{FP}$, correspond to trajectories in $\mathbf{FP}$. Consider that the domain of T is $\{0, \ldots, n\}$. Assume that Φ is the fuzzy transition function associated with $\mathbf{FP}$, s_0 is a possible initial state, and $a_0, \ldots, a_{n-1}$ be a set of actions in $\mathcal{A}$. Any action a_i can be represented as a set where $a_i = \{a_{1_i}, \ldots, a_{m_i}\}$. Therefore, a trajectory in $\mathbf{FP}$ is $s_0\ a_{j_0}\ s_1 \ldots a_{j_{n-1}}\ s_n$ for $(1 \leq j \leq m)$ and $(0 \leq i \leq n)$, such that $\forall (0 \leq i \leq n)$, s_i is a state, a_i is an action, $a_{j_i} \in a_i = \{a_{1_i}, \ldots, a_{m_i}\}$, and $s_i = \Phi(a_{j_{i-1}}, s_{i-1})$.

Theorem 1 *Let $\mathbf{FP} = \langle S_0, \mathcal{AD}, \mathcal{G}, \mathcal{T} \rangle$ be a fuzzy planning problem, P be a fuzzy plan in $\mathbf{FP}$, and T_P be the set of all trajectories in P. Then, $s_0\ a_{j_0}\ s_1 \ldots a_{j_{n-1}}\ s_n$ is a trajectory in T_P iff $occ(a_{j_0}, 0), \ldots, occ(a_{j_{n-1}}, n-1)$ is true in an answer set of $\Pi_{\mathbf{FP}}$.*

Theorem 1 presents that any fuzzy planning problem, $\mathbf{FP}$, can be translated into a normal logic program with answer set semantics, $\Pi_{\mathbf{FP}}$, such that a trajectory in $\mathbf{FP}$ is equivalent to an answer set of $\Pi_{\mathbf{FP}}$. Theorem 1 shows that normal logic programs with answer set semantics can be used to find fuzzy plans for fuzzy planning problems in two steps. The first step is to translate a fuzzy planning problem, $\mathbf{FP}$, into a normal logic program whose answer sets correspond to valid trajectories in $\mathbf{FP}$. From the answer sets of the normal logic program translation of $\mathbf{FP}$, the set of trajectories T_P that correspond to a fuzzy plan P in $\mathbf{FP}$ is determined. The second step is to calculate the grade membership of the fuzzy plan P using the formula

$$\max_{s_0\ a_{j_0}\ s_1 \ldots a_{j_{n-1}}\ s_n \in T_P} \left(\min_{0 \leq i \leq n-1} (\mu_{\mathcal{S}}(s_i), \mu_{\mathcal{S}}(s_{i+1})) \right)$$

Furthermore, we show that any fuzzy planning problem can be encoded as a SAT formula. Hence, state-of-the-art SAT solvers can be used to find fuzzy plans for fuzzy planning problems. Any normal logic program, Π, can be translated into a SAT formula, $\mathcal{S}$, where the models of $\mathcal{S}$ are equivalent to the answer sets of Π [19]. Therefore, the normal logic program translation of a fuzzy planning problem $\mathbf{FP}$ can be encoded into an equivalent SAT formula, where the models of $\mathcal{S}$ correspond to valid trajectories in $\mathbf{FP}$.

Theorem 2 *Let $\mathbf{FP}$ be a fuzzy planning problem and $\Pi_{\mathbf{FP}}$ be the normal logic program encoding of $\mathbf{FP}$. Then, the models of the SAT encoding of $\Pi_{\mathbf{FP}}$ are equivalent to valid trajectories in $\mathbf{FP}$.*

6 Conclusions and Related Work

We described a novel action language called fuzzy action language, $\mathcal{A}_F$, that allows the representation and reasoning about actions with fuzzy effects. In addition we introduced the notions of fuzzy planning and fuzzy plan in the fuzzy action language $\mathcal{A}_F$. Furthermore, we described a fuzzy planner based on the fuzzy action language A_F that is developed by translating a fuzzy planning problem, $\mathbf{FP}$, in $\mathcal{A}_F$ into a normal logic program with answer set semantics, $\Pi_{\mathbf{FP}}$, where trajectories in $\mathbf{FP}$ are equivalent to the answer sets of $\Pi_{\mathbf{FP}}$. In addition, we formally proved the correctness of our planner. Furthermore, we showed that a fuzzy planning problem can be encoded as a SAT problem.

The literature is rich with action languages that are capable of representing and reasoning about actions in the presence of probabilistic uncertainty, which include [2, 3, 5, 12, 14, 21, 22]. In [22], a probabilistic action language $\mathcal{P}$ is described that allows the representation of imperfect sensing actions (with probabilistic outcomes), non-sensing actions with probabilistic effects, the initial probability distribution over the possible initial states, and the indirect effects of actions. The action language $\mathcal{E}^+$ [12] allows sensing actions under the assumption that the agent's sensors are perfect, actions with probabilistic effects, and actions with non-deterministic effects. In

ISBN: 978-989-95079-6-8

addition, the semantics of $\mathcal{E}^+$ is based on description logic. Other high level probabilistic action description languages are described in [2, 5]. These languages are similar to $\mathcal{E}^+$ in the sense that they represent and reason about actions with probabilistic effects, except that they do not allow actions with non-deterministic effects or sensing actions. In [21], a high level action language called $\mathcal{A}_{MD}$ is presented that allows the factored representation and reasoning about Markov Decision Processes for reinforcement learning. In addition to the fact that $\mathcal{A}_F$ is a high level language, the major difference between $\mathcal{A}_F$ and these languages is that $\mathcal{A}_F$ represent and reason about actions under the presence of fuzzy uncertainty or imprecision. This is achieved in $\mathcal{A}_F$ by allowing description of actions with fuzzy effects, the executability conditions of actions, and the initial grade membership distribution of the initial states.

Abstract— *In this work we use interval-valued fuzzy sets in the Fuzzy C-Means algorithm for image segmentation. We introduce interval-valued restricted equivalence functions as a way of measuring the equivalence between the intervals associated to different pixels. We propose two construction methods for those new functions. We also prove experimentally that with these new concepts, the algorithm provides better results in ultrasound image segmentation that than those not using intervals.*

Keywords— Decomposability, Fuzzy C-Means, Interval-Valued Fuzzy Sets, Restricted Equivalence Functions, Ultrasound image.

1 Introduction

Ultrasound images are used to evaluate breast anomalies during the diagnosis in breast exams. When any breast anomaly is studied to determine whether it is benign or not, the radiologist studies its size, area and other morphological characteristics [12]. In this sense, the development of algorithms that automatically separates the lesion and the rest of the image is very important for a quick and correct diagnosis.

Ultrasound images segmentation is very limited by its bad quality. Speckle noise, shades and attenuation make the segmentation problem a very difficult topic [10]. There exist some methods used for this purpose; a comprehensive survey can be found in [9].

A very common method for segmenting images is clustering. The purpose of this work is to adapt the well known algorithm Fuzzy C-Means (FCM) [1, 2] to ultrasound image segmentation. This algorithm tries to classify a set of objects, in this case image pixels, in a determined number of clusters. That number must be chosen a priori. The main idea is to find as many centers as clusters must be, trying to minimize the distance between each pixel and the cluster centroids.

Due to the complexity of ultrasound images, there exists a lot of uncertainty within them. This uncertainty is also present in the images obtained after processing the ultrasound images. We are going to use interval-valued fuzzy sets [13] in the FCM algorithm to deal with this uncertainty.

As already mentioned, our proposed algorithm is based on the FCM. The new contributions we propose are: the use of interval-valued fuzzy sets and the search of the greatest interval equivalence between the image pixels and the centroids of the clusters. To find the greatest equivalence between intervals we introduce the concept of interval-valued restricted equivalence function.

This paper is organized in the following way: first of all we present some preliminary concepts. In Section 3 we define the concept of interval-valued restricted equivalence functions. In Section 4, we explain the way to apply these functions to ultrasound images segmentation and we show some experimental results. Finally some conclusions and future researchs are shown.

2 Preliminaries

We know that in fuzzy set theory a function $n : [0,1] \to [0,1]$ with $n(0) = 1$, $n(1) = 0$ that is strictly decreasing and continuous is called strict negation. If, in addition, n is involutive, then it is said that it is a strong negation.

We denote by $L([0,1])$ the set of all closed subintervals of the closed interval $[0,1]$; that is,

$$L([0,1]) = \{\mathbf{x} = [\underline{x}, \overline{x}] \mid (\underline{x}, \overline{x}) \in [0,1]^2 \text{ and } \underline{x} \leq \overline{x}\}$$

$L([0,1])$ is a partially ordered set with respect to the relation $\leq_L$ defined in the following way: given $\mathbf{x}, \mathbf{y} \in L([0,1])$,

$$\mathbf{x} \leq_L \mathbf{y} \text{ if and only if } \underline{x} \leq \underline{y} \text{ and } \overline{x} \leq \overline{y};$$

$$\mathbf{x} =_L \mathbf{y} \text{ if and only if } \underline{x} = \underline{y} \text{ and } \overline{x} = \overline{y};$$

The relation above is transitive, antisymmetric and it expresses the fact that $\mathbf{x}$ strongly links to $\mathbf{y}$, so that $(L([0,1]), \leq_L)$ is a complete lattice, where the smallest element is $0_L = [0,0]$, and the largest is $1_L = [1,1]$.

Definition 1 *An interval-valued fuzzy set A on the universe $U \neq \emptyset$ is a mapping $A : U \to L([0,1])$.*

Definition 2 *An IV negation is a function $N : L([0,1]) \to L([0,1])$ that is decreasing (with respect to $\leq_L$) and such that $N(1_L) = 0_L$ and $N(0_L) = 1_L$. If for all $\boldsymbol{x} \in L([0,1])$, $N(N(\boldsymbol{x})) = \boldsymbol{x}$, it is said that N is involutive.*

Theorem 1 *[7, 3] A function $N : L([0,1]) \to L([0,1])$ is an involutive IV negation if and only if there exists an involutive negation n such that*

$$N(\boldsymbol{x}) = [n(\overline{x}), n(\underline{x})].$$

Definition 3 *[4] A function $REF : [0,1]^2 \to [0,1]$ is called a restricted equivalence function, if it satisfies the following conditions:*

(1) $REF(x,y) = REF(y,x)$ for all $x, y \in [0,1]$;

(2) $REF(x,y) = 1$ if and only if $x = y$;

ISBN: 978-989-95079-6-8

(3) $REF(x,y) = 0$ *if and only if* $x = 1$ *and* $y = 0$ *or* $x = 0$ *and* $y = 1$*;*

(4) $REF(x,y) = REF(n(x), n(y))$ *for all* $x, y \in [0,1]$*,* n *being a strong negation;*

(5) For all $x, y, z \in [0,1]$*, if* $x \leq y \leq z$*, then* $REF(x,y) \geq REF(x,z)$ *and* $REF(y,z) \geq REF(x,z)$*.*

Definition 4 *[8] A function* $F : L([0,1])^2 \to L([0,1])$ *is said decomposable if there exist two functions* $F_1, F_2 : [0,1]^2 \to [0,1]$ *such that for all* $[\underline{x}, \overline{x}], [\underline{y}, \overline{y}] \in L([0,1])$ *they satisfy that*

$$F([\underline{x}, \overline{x}], [\underline{y}, \overline{y}]) = [F_1(\underline{x}, \underline{y}), F_2(\overline{x}, \overline{y})]$$

Definition 5 *[6] A binary aggregation function is defined as a function* $Ag : [0,1]^2 \to [0,1]$ *such that:*

(1) $Ag(x_1, x_2) \leq Ag(y_1, y_2)$ *whenever* $x_1 \leq y_1$ *and* $x_2 \leq y_2$*;*

(2) $Ag(0,0) = 0$ *and* $Ag(1,1) = 1$*.*

This is an idempotent aggregation function if

(3) $Ag(x,x) = x$ *for all* $x \in [0,1]$

3 Interval Valued Restricted Equivalence Functions

Definition 6 *An Interval Valued Restricted Equivalence Function (*REF_{IV}*) is a function*

$$REF_{IV} : L([0,1]) \times L([0,1]) \to L([0,1])$$

such that:

(1) $REF_{IV}(\boldsymbol{x}, \boldsymbol{y}) = REF_{IV}(\boldsymbol{y}, \boldsymbol{x})$ *for all* $\boldsymbol{x}, \boldsymbol{y} \in L([0,1])$*;*

(2) $REF_{IV}(\boldsymbol{x}, \boldsymbol{y}) = 1_L$ *if and only if* $\boldsymbol{x} = \boldsymbol{y}$*;*

(3) $REF_{IV}(\boldsymbol{x}, \boldsymbol{y}) = 0_L$ *if and only if* $\boldsymbol{x} = 1_L$ *and* $\boldsymbol{y} = 0_L$ *or* $\boldsymbol{x} = 0_L$ *and* $\boldsymbol{y} = 1_L$*;*

(4) $REF_{IV}(\boldsymbol{x}, \boldsymbol{y}) = REF_{IV}(N(\boldsymbol{x}), N(\boldsymbol{y}))$ *being N an involutive IV negation;*

(5) For all $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z} \in L([0,1])$*, if* $\boldsymbol{x} \leq_L \boldsymbol{y} \leq_L \boldsymbol{z}$*, then* $REF_{IV}(\boldsymbol{x}, \boldsymbol{y}) \geq_L REF_{IV}(\boldsymbol{x}, \boldsymbol{z})$ *and* $REF_{IV}(\boldsymbol{y}, \boldsymbol{z}) \geq_L REF_{IV}(\boldsymbol{x}, \boldsymbol{z})$*.*

Theorem 2 *There is not any decomposable* REF_{IV}*.*

Proof. We suppose there exists a decomposable REF_{IV}. This means that there exist two functions $F_1, F_2 : [0,1] \times [0,1] \to [0,1]$ such that:

$$REF_{IV}([\underline{x}, \overline{x}], [\underline{y}, \overline{y}] = [F_1(\underline{x}, \underline{y}), F_2(\overline{x}, \overline{y})]$$

in such form that REF_{IV} fulfills the five properties demanded in Definition 6. It means:

(1) As $REF_{IV}(\mathbf{x}, \mathbf{y}) = REF_{IV}(\mathbf{y}, \mathbf{x})$, then F_1 and F_2 must satisfy that $F_1(a,b) = F_1(b,a)$ and $F_2(a,b) = F_2(b,a)$ for all $a, b \in [0,1]$.

(2) As $REF_{IV}([\underline{x}, \overline{x}], [\underline{y}, \overline{y}]) = 1_L$ if and only if $\underline{x} = \underline{y}$ and $\overline{x} = \overline{y}$, then $F_1(\underline{x}, \underline{x}) = 1$ and $F_2(\overline{x}, \overline{x}) = 1$, so for all $x \in [0,1]$ $F_1(x,x) = F_2(x,x) = 1$.

(3) As $REF_{IV}([\underline{x}, \overline{x}], [\underline{y}, \overline{y}]) = 0_L$ if and only if $\mathbf{x} = 0$ and $\mathbf{y} = 1$ or vice versa, then $F_1(0,1) = 0$ and $F_2(0,1) = 0$.

(4) As $REF_{IV}([\underline{x}, \overline{x}], [\underline{y}, \overline{y}]) = REF_{IV}([n(\overline{x}), n(\underline{x})], [n(\overline{y}), n(\underline{y})]$ then $[F_1(\underline{x}, \underline{y}), F_2(\overline{x}, \overline{y})] = [F_1(n(\overline{x}), n(\overline{y})), F_2(n(\underline{x}), n(\underline{y}))]$. Separating each term, $F_1(\underline{x}, \underline{y}) = F_1(n(\overline{x}), n(\overline{y}))$ and $F_2(\overline{x}, \overline{y}) = F_2(n(\underline{x}), n(\underline{y}))$. In particular, if $\underline{x} = 1$ and $\underline{y} = 0$, and $\overline{x} = \overline{y} = 1$ then $F_2(\overline{x}, \overline{y}) = F_2(1,1) = 1$ and $F_2(n(\underline{x}), n(\underline{y})) = F_2(0,1) = 0$. $1 \neq 0$, so there is not any decomposable REF_{IV}.

Theorem 3 *Let* REF *be a restricted equivalence function, and* Ag_1 *and* Ag_2 *be two symmetric, idempotent aggregation functions such that:*

(i) $Ag_1 \leq Ag_2$*;*

(ii) $Ag_1(a,b) = 1$ *if and only if* $a = b = 1$*;*

(iii) $Ag_2(a,b) = 0$ *if and only if* $a = b = 0$*.*

Under these conditions, the function

$$REF_{IV} : L([0,1]) \times L([0,1]) \to L([0,1])$$

given by

$$REF_{IV}(\boldsymbol{x}, \boldsymbol{y}) = \begin{array}{l}[Ag_1(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y})), \\ Ag_2(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y}))]\end{array}$$

is an interval-valued restricted equivalence function in the sense of Definition 6.

Proof. By hypothesis, $Ag_1 \leq Ag_2$, so the REF_{IV} is a well defined interval.

(1) REF, Ag_1 and Ag_2 are commutative functions, so REF_{IV} is a commutative function too.

(2) (Sufficiency) If $REF_{IV}(\mathbf{x}, \mathbf{y}) = 1_L$, then $Ag_1(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y})) = 1$. So, by (ii), $REF(\underline{x}, \underline{y}) = REF(\overline{x}, \overline{y}) = 1$. Any REF is 1 if and only if both arguments are equal, so $\underline{x} = \underline{y}$ and $\overline{x} = \overline{y}$. This means $\mathbf{x} = \mathbf{y}$.

(Necessity) If $\mathbf{x} = \mathbf{y}$, it means $\underline{x} = \underline{y}$ and $\overline{x} = \overline{y}$, then $REF_{IV}(\mathbf{x}, \mathbf{x}) = \begin{array}{l}[Ag_1(REF(\underline{x}, \underline{x}), REF(\overline{x}, \overline{x})), \\ Ag_2(REF(\underline{x}, \underline{x}), REF(\overline{x}, \overline{x}))]\end{array}$ $[Ag_1(1,1), Ag_2(1,1)]$ and by the property (2) in Definition 5 this is $[1,1]$.

(3) (Sufficiency) If $REF_{IV}(\mathbf{x}, \mathbf{y}) = 0_L$, then $Ag_2(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y})) = 0$, therefore, by (iii), $REF(\underline{x}, \underline{y}) = REF(\overline{x}, \overline{y}) = 0$. Any REF is 0 if and only if one of the arguments is 0 and the other is 1, so $\underline{x} = 1$ and $\underline{y} = 0$ or vice versa, and $\overline{x} = 1$ and $\overline{y} = 0$ or vice versa. This means $\underline{x} = \overline{x} = 1$ and $\underline{y} = \overline{y} = 0$ or vice versa.

(Necessity) If $\mathbf{x} = 1_L$ and $\mathbf{y} = 0_L$, then $REF_{IV}(\mathbf{x}, \mathbf{y}) = [Ag_1(REF(1,0), REF(1,0)), Ag_2(REF(1,0), REF(1,0))] = [Ag_1(0,0), Ag_2(0,0)]$, which is equal to $[0,0]$ by property (2) in Definition 5.

ISBN: 978-989-95079-6-8

(4) $REF_{IV}(N(\mathbf{x}), N(\mathbf{y})) = [Ag_1(REF(n(\overline{x}), n(\overline{y})), REF(n(\underline{x}), n(\underline{y}))), Ag_2(REF(n(\overline{x}), n(\overline{y})), REF(n(\underline{x}), n(\underline{y})))]$. As $REF(\underline{x}, \underline{y}) = REF(n(\underline{x}), n(\underline{y}))$ and $REF(\overline{x}, \overline{y}) = REF(n(\overline{x}), n(\overline{y}))$, then $REF_{IV}(N(\mathbf{x}), N(\mathbf{y})) = [Ag_1(REF(\overline{x}, \overline{y}), REF(\underline{x}, \underline{y})), Ag_2(REF(\overline{x}, \overline{y}), REF(\underline{x}, \underline{y}))]$. As Ag_1 and Ag_2 are commutative functions, this expression is equal to $[Ag_1(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y})), Ag_2(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y}))] = REF_{IV}(\mathbf{x}, \mathbf{y})$.

(5) If $\mathbf{x} \leq_L \mathbf{y} \leq_L \mathbf{z}$, then $\underline{x} \leq \underline{y} \leq \underline{z}$ and $\overline{x} \leq \overline{y} \leq \overline{z}$. By (5) in Definition 3, $REF(\underline{x}, \underline{y}) \geq REF(\underline{x}, \underline{z})$ and $REF(\overline{x}, \overline{y}) \geq REF(\overline{x}, \overline{z})$. By (1) in Definition 5 $Ag_1(REF(\underline{x}, \underline{z}), REF(\overline{x}, \overline{z})) \leq Ag_1(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y}))$ and $Ag_2(REF(\underline{x}, \underline{z}), REF(\overline{x}, \overline{z})) \leq Ag_2(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y}))$, so $REF_{IV}(\mathbf{x}, \mathbf{z}) \leq REF_{IV}(\mathbf{x}, \mathbf{y})$. The reasoning for $REF_{IV}(\mathbf{x}, \mathbf{z}) \leq REF_{IV}(\mathbf{y}, \mathbf{z})$ is analogous.

Corollary 1 *Given a restricted equivalence function REF, and given T and S any t-norm and any t-conorm,*

$$REF_{IV}(\boldsymbol{x},\boldsymbol{y}) = [T(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y})), S(REF(\underline{x}, \underline{y}), REF(\overline{x}, \overline{y}))]$$

is an interval-valued restricted equivalence function.

Proof. We need to see that any t-norm fulfills the properties demanded to Ag_1 and any t-conorm fulfills the properties demanded to Ag_2.

For the t-norm T it is necessary that $T(a, b) = 1$ if and only if $a = b = 1$. (Sufficiency) If the t-norm is the minimum, if $min(a, b) = 1$, then $a = b = 1$. As the minimum is the greatest of all t-norms, to be 1 the arguments of any t-norm must be greater than or equal to 1. As they are defined in the unit interval, both arguments must be 1.

(Necessity) We know that $T(1, x) = x$ for any $x \in [0, 1]$. If $x = y = 1$, then $T(1, 1) = 1$.

For the t-conorm S it is necessary that $S(a, b) = 0$ if and only if $a = b = 0$. (Sufficiency) If the t-conorm is the maximum, if $max(a, b) = 0$, then $a = b = 0$. As the maximum is the smallest of all t-conorms, to be 0 the arguments of any t-conorm must be smaller than or equal to 0. As they are defined in the unit interval, both arguments must be 0.

(Necessity) We know that $S(x, 0) = x$ for any $x \in [0, 1]$. If $x = y = 0$, then $S(0, 0) = 0$.

Example 1 *If we choose $T = min$, $S = max$ and $REF(x, y) = 1 - |x - y|$, we have that:*

$$REF_{IV}(\boldsymbol{x},\boldsymbol{y}) = [min(1 - |\underline{x} - \underline{y}|, 1 - |\overline{x} - \overline{y}|), max(1 - |\underline{x} - \underline{y}|, 1 - |\overline{x} - \overline{y}|)] =$$

$$[1 - max(|\underline{x} - \underline{y}|, |\overline{x} - \overline{y}|), 1 - min(|\underline{x} - \underline{y}|, |\overline{x} - \overline{y}|)] =$$

$$N([min(|\underline{x} - \underline{y}|, |\overline{x} - \overline{y}|), max(|\underline{x} - \underline{y}|, |\overline{x} - \overline{y}|)].$$

4 Application of $\mathbf{REF_{IV}}$ to clustering algorithm

The algorithm proposed in this paper is a modification of the Fuzzy C-Means (FCM) algorithm [1, 2], which aims to find the most characteristic point of each cluster, considered its centroid. Such a way, the membership degree of every object to each cluster is achieved via minimizing the target function:

$$J_m(U, V) = \sum_{j=1}^{n} \sum_{i=1}^{K} w_{ij}^m \parallel x_j - C_i \parallel^2$$

In the new algorithm we propose, the function to minimize is quite similar. The only difference is the way of calculating the distance between each pixel and the cluster centroids. Instead of using the euclidean distance, we use a negation of an interval restricted equivalence function. Therefore, our objective function to minimize is:

$$J_m(U, V) = \sum_{j=1}^{n} \sum_{i=1}^{K} w_{ij}^m (1 - Ag(REF_{IV}(\mathbf{x_j}, \mathbf{C_i})))$$

The main purpose of the new algorithm is to segment the image into K areas represented by K interval centroids, maximizing the equivalence in each area, using the interval valued restricted equivalence functions, that we have previously defined. As the algorithm is partially supervised, the number of areas must be selected by the user before the execution. Notice that the REF_{IV} is an interval. As we want to maximize the equivalence, we are going to use an aggregation of the bounds of the equivalence interval.

The algorithm starts with the initialization of all the required parameters. First of all it is necessary to build the interval-valued fuzzy set associated with the image. For that, each pixel is assigned an interval depending on the values of its neighborhood. The rest of the parameters to be initialized are the number of areas to be found, the fuzzification degree, the weight matrix, the maximum number of iterations and the finishing threshold.

After the initialization, the algorithm runs in a loop. In this loop the centroid of each cluster and the weight matrix are calculated until the improvement is not significant. To update that weight matrix, we use the interval-valued restricted equivalence functions.

When the loop is finished, the algorithm labels each pixel to show the results. For this purpose, each pixel is associated to the cluster with the biggest weight.

4.1 Algorithm structure

1. Given an image X with n pixels, build its interval-valued fuzzy set $A = \{[\underline{x_i}, \overline{x_i}] | x_i \in X\}$ with $i = 1 \ldots n$.
2. Initialize
   - 2.1 K = number of areas to be segmented.
   - 2.2 T = maximum number of iterations.
   - 2.3 m = fuzzification degree, $1 \leq m \leq \infty$.
   - 2.4 ε = finishing threshold, $\varepsilon > 0$.
   - 2.5 W = weight matrix, $0 \leq w_{ij} \leq 1$ with $i = 1 \ldots n$ and $j = 1 \ldots K$.

ISBN: 978-989-95079-6-8

2.6 t = current iteration = 0.

3. REPEAT

3.1 Increase current iteration

3.2 Calculate the centroids

$$C_j = \frac{\sum_{i=1}^{n} w_{ij}^m [\underline{x_i}, \overline{x_i}]}{\sum_{i=1}^{n} w_{ij}^m}$$

3.3 Update the weight matrix

$$w_{ij} = \left(\sum_{k=1}^{K} \left(\frac{1 - (Ag(REF_{IV}(\mathbf{x_i}, \mathbf{C_j})))}{1 - (Ag(REF_{IV}(\mathbf{x_i}, \mathbf{C_k})))} \right)^{\frac{1}{m-1}} \right)^{-1}$$

where $\mathbf{x_i} = [\underline{x_i}, \overline{x_i}]$, $\mathbf{C_j} = [\underline{C_j}, \overline{C_j}]$, $\mathbf{C_k} = [\underline{C_k}, \overline{C_k}]$ and $Ag(REF_{IV}(\mathbf{x}, \mathbf{y})) = \frac{REF_{IV}(\mathbf{x},\mathbf{y}) + \overline{REF_{IV}(\mathbf{x},\mathbf{y})}}{2}$.

3.4 Calculate the error.

UNTIL $t = T$ or $error \leq \varepsilon$.

4. Label the image.

4.2 Preprocessing

To prove the performance of the new algorithm, we are going to segment some ultrasound images. In this case we work with breast ultrasound images, where the goal is to classify every pixel of the image. It means, decide whether they belong to the lesion or not.

Due to the characteristics of these images, which may contain several similar regions, it is necessary to select the central pixel of the desired zone. Since the user has to contribute with some information, we say that the proposed system is partially supervised.

To improve the results the images are preprocessed. In order to do so, we create two new images for every ultrasound image. The first one is a false edges image while the second one is a enhanced image. An example of these new images can be seen in Fig. 1.

Figure 1: False edges and enhanced images.

4.2.1 Enhanced image

To create the enhanced image we use the algorithm proposed by Sahba et al. [11] for ultrasound images. The main idea is to remove the image noise and to enhance the gray level in the selected area. First of all the noise is removed using the median filter (7x7 or 9x9). After that, every pixel is fuzzified depending on its gray level using a membership function considering the average gray level in the pixel neighborhood and the position of the central pixel selected.

4.2.2 False Edges image

The false edges image represents to what degree each pixel is part of an edge. In [5] a method is presented to extract false edges from t-norms and t-conorms. For each pixel, the first step is to build a submatrix (3x3, 5x5, etc.). Applying any t-norm to the elements of that submatrix, the lower bound of an interval is obtained. Analogously, the upper bound is got applying any t-conorm to the same submatrix. The width of that interval, it means, the upper bound minus the lower bound, is called false edge. If the t-norm and the t-conorm chosen are the minimum and maximum respectively, the false edge is basically the substraction of the biggest element in the submatrix minus the lowest one.

4.3 Experiment

The experiment we show in this section is based on 8 ultrasound images, shown in Fig. 2. They are breast images in which there exist some zones that can be tumors. To create the interval-valued fuzzy set associated to the image, we use a net of 5x5 neighbors for every pixel. In this sense, each pixel is corresponded with an interval value that depends not only on its value but also on its neighbors' values. To construct the lower bound we take the minimum of the values of the mesh, and to calculate the upper bound we take the greatest one.

The REF_{IV} we use is the one shown in example 1:

$$\begin{aligned} REF_{IV}(\mathbf{x}, \mathbf{y}) = \quad & [min(1 - |\underline{x} - \underline{y}|, 1 - |\overline{x} - \overline{y}|), \\ & max(1 - |\underline{x} - \underline{y}|, 1 - |\overline{x} - \overline{y}|)] = \\ N([min(|\underline{x} - \underline{y}|, |\overline{x} - \overline{y}|), & max(|\underline{x} - \underline{y}|, |\overline{x} - \overline{y}|)]. \end{aligned}$$

To calculate the performance of the segmentation method we propose, we use the areas overlapping measure (S_A) between the image we have obtained and the ideal one. The latter is created by an expert radiologist.

$$S_A = \frac{|Ideal \ \& \ Obtained|}{|Ideal \ + \ Obtained|} \tag{1}$$

where $Ideal$ is the binary image segmented by the expert radiologist and $Obtained$ is the binary image got by the studied method.

We are going to compare the results from our algorithm with the ones obtained with the FCM algorithm by comparing their accuracy with respect to the ideal images. In Fig. 2 some results are illustrated. The first column matches the original image, while the second and the third columns match the segmentation using the FCM algorithm and the proposed one respectively. Finally, the fourth column shows the ideal segmentation.

As it can be seen, the results from our algorithm are more similar to the ideal ones than the ones got by the FCM. This improvement can be numerically observed by the areas overlapping percentage between each image and its corresponding ideal one (see table 1, where A, B, ...H refer to the images shown in Fig. 2).

With these results, our proposed algorithm improves the results obtained by the FCM in 8%. This percentage is the difference between the average overlap of the ideal image with the one obtained by the simple FCM and with the one obtained by our method in the images of Fig. 2. We can say this is a very good result, as it means a significant progress towards the correct segmentation of this kind of images.

ISBN: 978-989-95079-6-8

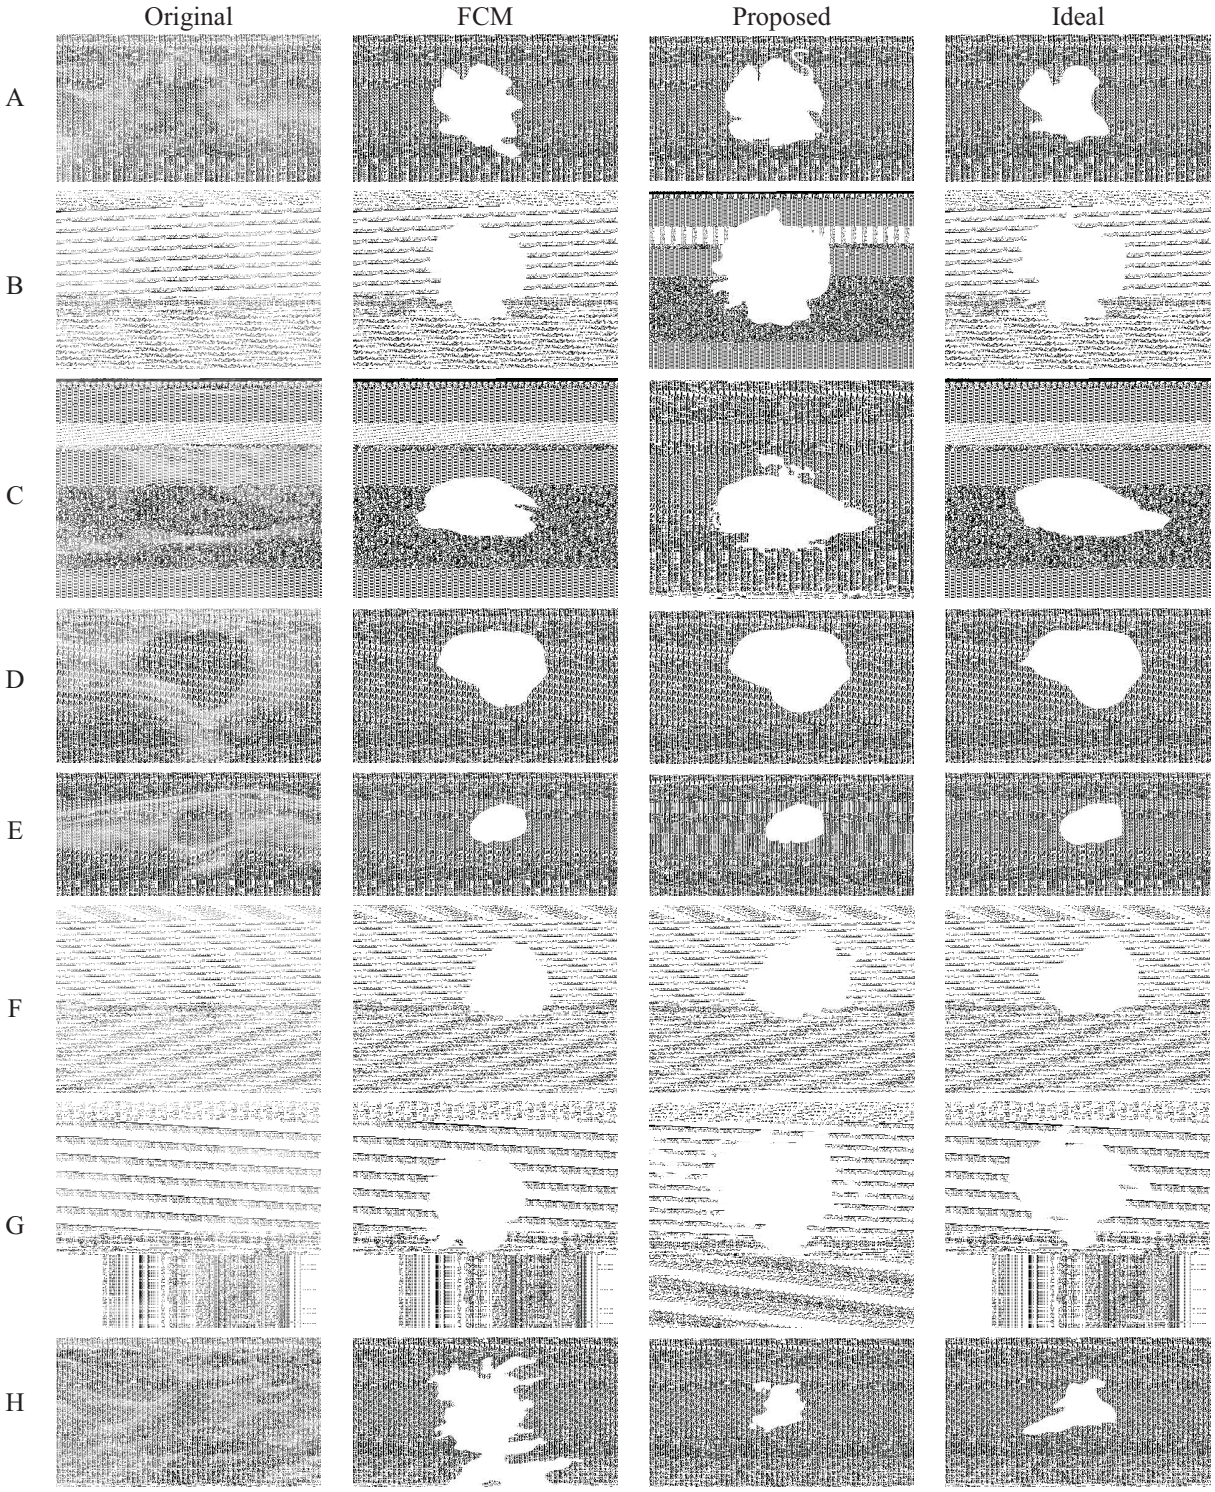

Figure 2: Obtained results.

Table 1: Analytic solutions.

	A	B	C	D
FCM	75.17	76.73	73.28	84.48
Proposed	70.81	89.43	76.37	91.47
	E	F	G	H
FCM	74.11	72.65	57.87	27.55
Proposed	76.77	79.63	71.68	51.33

The use of interval-valued fuzzy sets in this sort of images increases the accuracy of the segmentation. In some cases, it allows us to discover regions that are not easily identified at first sight, as it can be seen in the images we have segmented.

5 Conclusions and future research

In this work we show the advantage of using interval-valued fuzzy sets in the FCM algorithm. For this reason, we have introduced the concept of interval-valued restricted equivalence function and we have presented two different construction

ISBN: 978-989-95079-6-8

methods. The effectiveness of this method has been proved with the experimental results.

As future research we want to work with intervals within the FCM instead of aggregating the bounds of the equivalence interval. Also, we are going to study other processings of ultrasound images to improve the results.

Abstract— *This paper introduces some concepts of interval-valued fuzzy relations and some of their properties: reflexivity, symmetry, T-transitivity, composition and locally reflexivity. It is also introduced the concept of T-transitive closure for an interval-valued fuzzy relation. An algorithm to compute the T-transitive closure of finite interval-valued relations, some properties and some examples are given.*

Keywords— Generalized t-norms, Interval-valued Fuzzy Relations, Interval-valued Fuzzy Sets, t-norms, t-representable t-norms, t-transitive closure.

1 Introduction

Fuzzy sets, $\mathcal{FS}$, were introduced by Zadeh in 1.965 [1]. Since then many generalizations of fuzzy sets have been proposed to model the uncertainty and the vagueness in linguistic variables replacing the unit interval by another structure such as posets or lattices [2, 3, 4]. One of these generalizations are type-2 fuzzy sets, $\mathcal{FS}2$, [5, 6, 7] were introduced by Zadeh. A Type-2 fuzzy set on a universe of discourse X, $\mathcal{FS}2$, is a fuzzy set whose membership function is another fuzzy set on [0,1]:

$$A = \{((x,u), \mu_A(x,u)) \mid \forall x \in X, \forall u \in [0,1]\}$$

Type-2 fuzzy sets have been widely studied and applied since in many cases the uncertainty can be better expressed by a fuzzy set than by a single numeric value. The problem with type2 fuzzy sets though is their computational complexity and the difficulty for an expert to select the adequate fuzzy subset as membership degree of an object to a linguistic label. This is why some simplifications have been proposed, such as the use of only some families of fuzzy sets such as triangular and trapezoidal ones. One of the most popular and useful simplification is the use of interval-valued fuzzy sets.

Interval-valued fuzzy sets ($\mathcal{IVFS}$) were introduced in the 60s by Grattan-Guinness [8], Jahn [9], Sambuc [10] and Zadeh [5]. They are extensions of classical fuzzy sets where the membership value between 0 and 1 is replaced an interval in [0,1]. They easily allow to model uncertainty and vagueness because sometimes it is easier for experts to give a "membership interval" than a membership degree to objects on a universe. $\mathcal{IVFS}$ are a special case of type-2 fuzzy sets that simplifies the calculations while preserving their richness as well. Intuitionistic fuzzy sets on X ($\mathcal{IFS}$) introduced by Atanassov [11]. In intuitionistic fuzzy sets each element has a membership degree, μ, and a non-membership degree, ν satisfying: $\mu + \nu \leq 1$.

$A = \{(x, \mu(x), \nu(x)) \mid x \in X, \mu(x), \nu(x) \in [0,1]\}$

The value $\pi = 1 - \mu - \nu$ is a measure of the uncertainty. This paper is organized as follows: In section three we introduce some important properties of interval-valued fuzzy relations such as reflexivity, symmetry, T-transitivity, composition and local reflexivity. Traditionally, the study of conjunctions between interval-valued fuzzy sets has been reduced to be modeled with t-representable t-norms. However, not all generalized t-norms are t-representable. Moreover, some of the non t-representable t-norms sometimes satisfy even more properties than t-representable t-norms [12]. Probably the most important property a fuzzy relation can fulfil is transitivity with respect a given t-norm. Since many times the data are given by a proximity relation P (i.e.: a reflexive and symmetric but not necessarily transitive fuzzy relation), there are some methods to obtain a transitive relation close to P to replace it when transitivity is required. The most popular way to do this is calculating its transitive closure. In section four we introduce the concept of T-transitive closure for an interval-valued fuzzy relation and its expression in a finite universe for any t-norm. A few methods to compute it and some examples are given.

2 Preliminaries

2.1 Interval-valued fuzzy sets

Definition 2.1 *[13] Let $\mathcal{L}^I = (L, \leq_L)$ be a lattice that satisfies:*

1. $L = \{[x_1, x_2] \in [0,1]^2$ *with* $x_1 \leq x_2\}$.
2. $[x_1, x_2] \leq_L [y_1, y_2]$ *if and only if* $x_1 \leq y_1$ *and* $x_2 \leq y_2$

Trivially:

$[x_1, x_2] <_L [y_1, y_2] \Leftrightarrow x_1 < y_1, x_2 \leq y_2$ or $x_1 \leq y_1, x_2 < y_2$
$[x_1, x_2] =_L [y_1, y_2] \Leftrightarrow x_1 = y_1, x_2 = y_2$.

$0_L =_L [0,0]$ and $1_L =_L [1,1]$ are the smallest and the greatest elements in L respectively.

$\mathcal{L}^I$ is a complete lattice an the supremum and infimum are defined as follows.

Definition 2.2 *[12] Let $\{[v_i, w_i]\}$ be a set of intervals on L. Then*

1. *Infimum:*
   $Inf_L\{[v_i, w_i]\} \equiv [infimun\{v_i\}, infimun\{w_i\}]$
2. *Supremum:*
   $Sup_L\{[v_i, w_i]\} \equiv [supremun\{v_i\}, supremun\{w_i\}]$

Definition 2.3 *[13] An interval-valued fuzzy set A on a universe X is a mapping:*

ISBN: 978-989-95079-6-8

$$A = \{(a, [x_1, x_2]) \mid a \in X, [x_1, x_2] \in L\}$$

Definition 2.4 *[13] Let X be a universe and A and B two interval-valued fuzzy sets. The equality between A and B is defined as: $A =_L B$ if and only if $A(a) =_L B(a)\ \forall a \in X$.*

Definition 2.5 *[13] Let X be a universe and A and B two interval-valued fuzzy sets. The inclusion of A in to B is defined as: $A \subseteq_L B$ if and only if $A(a) \leq_L B(a)\ \forall a \in X$.*

Definition 2.6 *[13] A negation function for interval-valued fuzzy sets $\mathcal{N}$ is a decreasing function, $\mathcal{N} : L \to L$, that satisfies:*

1. $\mathcal{N}(0_L) =_L 1_L$
2. $\mathcal{N}(1_L) =_L 0_L$

If $\mathcal{N}(\mathcal{N}([x_1, x_2])) =_L [x_1, x_2]$ for all $[x_1, x_2]$ in L then $\mathcal{N}$ is called an involutive negation.

Definition 2.7 *A strong negation function for interval-valued fuzzy sets, $\mathcal{N}$, is a involutive function, $\mathcal{N} : L \to L$, that satisfies:*

1. $\mathcal{N}(0_L) =_L 1_L$
2. $\mathcal{N}(1_L) =_L 0_L$

T-norms are generalized to the lattice $\mathcal{L}^I$ in a straightforward way.

Definition 2.8 *A generalized t-norm function [13], $\mathcal{T}$, is a monotone increasing, symmetric and associative operator, $\mathcal{T} : L^2 \to L$, that satisfies: $\mathcal{T}(1_L, [x_1, x_2]) =_L [x_1, x_2]$ for all $[x_1, x_2]$ in L.*

Due to monotony, it is easy to show:

$$\mathcal{T}(Sup_L\{[v_i, w_i]\}, [y_1, y_2]) \geq_L Sup_L\{\mathcal{T}([v_i, w_i], [y_1, y_2])\}$$
$$\mathcal{T}(Inf_L\{[v_i, w_i]\}, [y_1, y_2]) \leq_L Inf_L\{\mathcal{T}([v_i, w_i], [y_1, y_2])\}$$

Due to the associativity of $\mathcal{T}$ the conjunction of three or more intervals can be defined inductively as:

$$\mathcal{T}(a, \mathcal{T}(b, c)) =_L \mathcal{T}(\mathcal{T}(a, b), c) =_L a \triangle b \triangle c \text{ where } \triangle =_L \mathcal{T}.$$

where $a =_L [a_1, a_2]$, $b =_L [b_1, b_2]$ and $c =_L [c_1, c_2]$.

$\underline{T([x_1, x_2], [y_1, y_2])}$ and $\overline{T([x_1, x_2], [y_1, y_2])}$ will denote the lower and the higher values of $T([x_1, x_2], [y_1, y_2])$.

Definition 2.9 *[14] Let $\{x_i\}$ in $[0, 1]$. A t-norm T in $([0, 1], \leq)$ is left-continuous if it satisfies:*

$$T(Sup\ x_i, y) = Sup\ T(x_i, y)$$

Right-continuity can be defined in a similar way. This property is also called sup-preserving.

Definition 2.10 *[13] A generalized t-norm operator $\mathcal{T}$ is t-representable in $\mathcal{L}^I$ if there are two t-norms: T_1 and T_2 (T_1, T_2, in ([0,1],$\leq$)) that satisfy:*

$$\mathcal{T}([x_1, x_2], [y_1, y_2]) =_L [T_1(x_1, y_1), T_2(x_2, y_2)]$$

where $T_1(v, w) \leq T_2(v, w)\ \forall v, w \in [0, 1]$.

Let $x =_L [x_1, x_2]$ and $y =_L [y_1, y_2]$ be two intervals on L:

Example 2.1
$Inf_L(\{[x_1, x_2], [y_1, y_2]\}) =_L [min(x_1, y_1), min(x_2, y_2)]$ is t-representable by means of $T = min$ in ([0,1],$\leq$):

Example 2.2 *The following product generalized t-norm $*_L$ is t-representable:*

$$*_L([x_1, x_2], [y_1, y_2]) =_L [x_1 * y_1, x_2 * y_2]$$

Example 2.3 *There are two generalizations of the Lukasiewicz t-norm [12]:*

- $T_w([x_1, x_2], [y_1, y_2]) =_L$ $[max(0, x_1 + y_1 - 1), max(0, x_2 + y_2 - 1)]$
- $T_W([x_1, x_2], [y_1, y_2]) =_L$ $[max(0, x_1 + y_1 - 1), max(0, x_1 + y_2 - 1, x_2 + y_1 - 1)]$

Note that T_w is t-representable but T_W is not.

Definition 2.11 *[13] A generalized t-conorm $\mathcal{S}$ is an increasing, commutative, and associative operator $\mathcal{S} : L^2 \to L$, that satisfies: $\mathcal{S}(0_L, [x_1, x_2]) =_L [x_1, x_2]$ and $\mathcal{S}(1_L, [x_1, x_2]) =_L 1_L$.*

Due to the associativity of $\mathcal{S}$ we can write:

$\mathcal{S}(a, \mathcal{S}(b, c)) =_L \mathcal{S}(\mathcal{S}(a, b), c) =_L a \bigtriangledown b \bigtriangledown c$ where $\bigtriangledown =_L \mathcal{S}$.

For example, $\mathcal{S} = Sup_L$ is a generalized t-conorm.
In this paper the next definition is proposed.

Definition 2.12 *Let $\{[v_i, w_i]\}$ be in L. A generalized t-norm operator $\mathcal{T}$ is left-continuous if and only if:*

$$\mathcal{T}(Sup_L\{[v_i, w_i]\}, [y_1, y_2]) =_L Sup_L\{\mathcal{T}([v_i, w_i], [y_1, y_2])\}$$

Right-continuity can be defined in a similar way. A t-norm, a negation and the dual t-conorm of $\mathcal{T}$ with respect to $\mathcal{N}$ is called a De Morgan triplet.

3 Interval-valued fuzzy relations

This section contains some definitions on interval-valued fuzzy relations that generalize the ones of fuzzy relations valued on [0,1]. In the next section, $\mathcal{T}$-transitive relations will be generated using the $Sup - \mathcal{T}$ product.

Definition 3.1 *[15] Let X_1 and X_2 be two universes of discourse. An interval-valued fuzzy relation $R : X_1 \times X_2 \to L$ (where $\mathcal{L}^I = (L, \leq_L)$ is a lattice) is a mapping:*

$$R = \{((a, b), [x, y]) \mid a \in X_1, b \in X_2, [x, y] \in L\}$$

where $x = \underline{R(a, b)}$ and $y = \overline{R(a, b)}$.
In the rest of the paper, it is assumed that $X_1 = X_2 = X$.

Definition 3.2 *An interval-valued relation $R : X^2 \to L$ is reflexive if:*

$$R(a, a) =_L 1_L\ \forall a \in X$$

ISBN: 978-989-95079-6-8

Definition 3.3 *An interval-valued relation $R : X^2 \to L$ is $[\alpha_1 - \alpha_2]-$reflexive if:*

$$R(a,a) \geq_L [\alpha_1, \alpha_2] \; \forall a \in X$$

where $\alpha_1, \alpha_2 \in [0,1]$ and $\alpha_1 \leq \alpha_2$.

Definition 3.4 *An interval-valued relation $R : X^2 \to L$ is symmetric if:*

$$R(a,b) =_L R(b,a) \; \forall a, b \in X$$

Definition 3.5 *Let $\mathcal{T}$ be a generalized t-norm operator and let R interval-valued fuzzy relation on X. R is $\mathcal{T}$-transitive if:*

$$\mathcal{T}(R(a,b), R(b,c)) \leq_L R(a,c) \; \forall a, b, c \in X$$

Proposition 3.1 *If $\mathcal{T}$ is t-representable with T_1 and T_2 ($\mathcal{T} = [T_1, T_2]$) then an interval-valued relation $R : X^2 \to L$ is $\mathcal{T}$-transitive if and only if $\underline{R}$ is T_1-transitive and $\overline{R}$ is T_2-transitive:*

Definition 3.6 *Let $\mathcal{T}$ a generalized t-norm. Let $\mathcal{S}$ a generalized t-conorm from $\mathcal{S}$ and let be $\bigtriangledown$ the n-ary generalized t-conorm defined by associativity. Let R_1 and R_2 be two interval-valued fuzzy relations on a finite set $X = \{c_1, ...c_m\}$. The $\mathcal{S} - \mathcal{T}$-composition of R_1 and R_2 is defined as follows:*

$$(R_1 \diamond_{(\mathcal{ST})} R_2)(c_q, c_r) =_L \bigtriangledown_{c_k \in X} \mathcal{T}(R_1(c_q, c_k), R_2(c_k, c_r))$$

where $\bigtriangledown_{c_k \in X} \mathcal{T}(R_1(c_q, c_k), R_2(c_k, c_r)) =_L \mathcal{T}(R_1(c_q, c_1), R_2(c_1, c_r)) \bigtriangledown ... \bigtriangledown \mathcal{T}(R_1(c_q, c_m), R_2(c_m, c_r))$.

Definition 3.7 *The local equality relation of a fuzzy interval-valued fuzzy relation R on X is the fuzzy relation E_R is:*

$$E_R(a,b) = \begin{cases} Sup_{L\ \forall c \in X} max(R(a,c), R(c,a)) & a = b; \\ [0,0], & a \neq b. \end{cases}$$

Definition 3.8 *An interval-valued relation R is locally reflexive if $E_R \subseteq_L R$.*

It is easy to prove that if R is an reflexive interval-valued relation then R is a locally reflexive interval-valued relation.

4 $\mathcal{T}$-transitive closure for IVFSs

In this section it is proved the existence of the $\mathcal{T}$-transitive closure of an interval valued fuzzy relation and its calculation via $sup - \mathcal{T}$. The $sup - \mathcal{T}$ product is associative if $\mathcal{T}$ is left continuous of the universe is finite. Moreover, it is proved that the $sup - \mathcal{T}$ product is continuous and so is the calculation of the $\mathcal{T}$-transitive closure for finite universes. An algorithm to calculate the $\mathcal{T}$-transitive closure is provided.

Definition 4.1 *Let $\mathcal{T}$ be a generalized t-norm and let $R : X^2 \to L$ be an interval-valued relation on a finite universe X. The $\mathcal{T}$-transitive closure of R is the relation $R^{\mathcal{T}} : X \times X \to L$ that satisfies:*

1. $R \subseteq_L R^{\mathcal{T}}$.
2. *If $R \subseteq_L R'$ and R' is $\mathcal{T}$-transitive then $R^{\mathcal{T}} \subseteq_L R'$.*

Lemma 4.1 *R is $\mathcal{T}$-transitive if and only if $R \diamond_{Sup_L \mathcal{T}} R \subseteq_L R$.*

Proof.

- R is $\mathcal{T}$-transitive $\Rightarrow R \diamond_{Sup_L \mathcal{T}} R \subseteq_L R$:
  $(R \diamond_{Sup_L \mathcal{T}} R)(a,b) =_L$
  $Sup_{L\ c \in X}\{\mathcal{T}(R(a,c), R(c,b))\} \leq_L R(a,b)$
  due to $\mathcal{T}(R(a,c), R(c,b)) \leq_L R(a,b) \; \forall a, b, c \in X$
- $R \diamond_{Sup_L \mathcal{T}} R \subseteq_L R \Rightarrow R$ is $\mathcal{T}$-transitive:
  $Sup_{L\ d \in X}\{\mathcal{T}(R(a,d), R(d,b))\} \leq_L R(a,b) \; \forall a, b \in X$
  Then $\forall c \in X \; \mathcal{T}(R(a,c), R(c,b)) \leq_L R(a,b) \square$

Lemma 4.2 *Let R be an interval-valued relation. If $R^{\mathcal{T}}$ exists then it is unique.*

Proof. Let S_1 and S_2 be two relations. If S_1 and S_2 are transitive closures of R then according to definition 4.1: $S_1 \subseteq_L S_2$ and $S_2 \subseteq_L S_1$, consequently $S_1 =_L S_2 \square$.

Lemma 4.3 *Let R be an interval-valued relation in a universe X and an let $\mathcal{T}$ be an arbitrary generalized t-norm. Then the transitive closure of R always exists.*

Proof. Consider the set Ω_R of $\mathcal{T}$-transitive fuzzy relations containing R. Let us define the fuzzy relation $S_R^*(a,b) =_L Inf_{L;S \in \Omega_R}\{S(a,b)\}$. We will prove that S_R^* is $\mathcal{T}$-transitive. Due to monotony of generalized $\mathcal{T}$-norms it is obtained:
$\mathcal{T}(S_R^*(a,b), S_R^*(b,c)) =_L$
$\mathcal{T}(Inf_{L\ S_1 \in \Omega_R}\{S_1(a,b)\}, Inf_{L\ S_2 \in \Omega_R}\{S_2(b,c)\})$
$\leq_L Inf_{L\ S_1 \in \Omega_R} Inf_{L\ S_2 \in \Omega_R}\{\mathcal{T}(S_1(a,b), S_2(b,c))\}$
$\leq_L Inf_{L\ S \in \Omega_R}\{\mathcal{T}(S(a,b), S(b,c))\} =_L S_R^*(a,c) \square$

Proposition 4.1 *Let X be an arbitrary universe. Let $\{S_1, ..., S_n\}$ a set of interval-valued relations. If $\mathcal{T}$ is a left-continuous generalized $\mathcal{T}$-norm, then it satisfies:*

$$R \diamond_{Sup_L \mathcal{T}} (Sup_{L\ \forall i=1..n}\{S_i\}) =_L Sup_{L\ \forall i=1..n}\{R \diamond_{Sup_L \mathcal{T}} S_i\}$$

Proof.

$$\begin{aligned} &R \diamond_{Sup_L \mathcal{T}} (Sup_{L\ \forall i=1..n}\{S_i\})(a,c) =_L \\ &Sup_{L\ b \in X}\{\mathcal{T}(R(a,b), Sup_{L\ \forall i=1..n}\{S_i(b,c)\})\} \\ &=_L Sup_{L\ \forall i=1..n}\ Sup_{L\ b \in X}\{\mathcal{T}(R(a,b), S_i(b,c))\} \\ &=_L (Sup_{L\ \forall i=1..n}\{R \diamond_{Sup_L \mathcal{T}} S_i\})(a,c) \square \end{aligned}$$

Definition 4.2 *Given a generalized t-norm $\mathcal{T}$, the $\mathcal{T}$-power $R^{(n)_{\mathcal{T}}}$ of a fuzzy relation R on X is recursively defined as follows:*

1. $R^{(1)_{\mathcal{T}}} \equiv R$
2. $R^{(n)_{\mathcal{T}}} \equiv R^{(n-1)_{\mathcal{T}}} \diamond_{Sup_L \mathcal{T}} R$

Lemma 4.4 *If $A \subseteq_L B$ then $A^{(k)} \subseteq_L B^{(k)}$*

Proof.
Trivial due to monotony of $\mathcal{T} \square$.

Theorem 4.1 *Let X be an arbitrary universe and $\mathcal{T}$ a left-continuous t-norm. The transitive closure of R is:*

$$R^{\mathcal{T}} =_L Sup_{L\ \forall k \in \mathbb{N}}\{R^{(k)_{\mathcal{T}}}\}$$

Proof.
Let $S = Sup_{L\ \forall k \in \mathbb{N}}\{R^{(k)_{\mathcal{T}}}\}$ be. By proposition 4.1:

ISBN: 978-989-95079-6-8

$$S^{(2)_\mathcal{T}} =_L$$
$$(Sup_{L\ \forall k\in\mathbb{N}}\{R^{(k)_\mathcal{T}}\}) \diamond_{Sup_L\mathcal{T}} (Sup_{L\ \forall l\in\mathbb{N}}\{R^{(l)_\mathcal{T}}\}) =_L$$
$$Sup_{L\ \forall k,l\in\mathbb{N}}\{R^{(k+l)_\mathcal{T}}\} =_L Sup_{L\ \forall m\in\mathbb{N}\setminus\{0,1\}}\{R^{(m)_\mathcal{T}}\} \subseteq S$$

By lemma 4.1, it follows that S is T-transitive.

Moreover, if $R \subseteq S'$ and S' is T-transitive, then again by lemma 4.1 and 4.4 it holds that:

$$R^{(2)_\mathcal{T}} \subseteq_L S'^{(2)_\mathcal{T}} \subseteq_L S', ..., R^{(k)_\mathcal{T}} \subseteq_L S'^{(k)_\mathcal{T}} \subseteq_L S'$$

hence $S \subseteq_L S'$ and $R^\mathcal{T} =_L S\Box$.

Lemma 4.5 *Let $\mathcal{T}$ be any generalized t-norm, then:*

$$\mathcal{T}([x_1,x_2],[y_1,y_2]) \leq_L Inf_L([x_1,x_2],[y_1,y_2])$$
$$\forall [x_1,x_2],[y_1,y_2] \in L$$

Proof.
$\mathcal{T}([x_1,x_2],[y_1,y_2]) \leq_L \underline{\mathcal{T}([x_1,x_2],1_L) =_L [x_1,x_2]}$
$\Rightarrow [\underline{\mathcal{T}([x_1,x_2],[y_1,y_2])}, \overline{\mathcal{T}([x_1,x_2],[y_1,y_2])}] \leq_L [x_1,x_2]$
$\underline{\mathcal{T}([x_1,x_2],[y_1,y_2])} =_L \overline{\mathcal{T}([y_1,y_2],[x_1,x_2])} \leq_L$
$\underline{\mathcal{T}([y_1,y_2],1_L) =_L [y_1,y_2]}$
$\Rightarrow [\underline{\mathcal{T}([x_1,x_2],[y_1,y_2])}, \overline{\mathcal{T}([x_1,x_2],[y_1,y_2])}] \leq_L [y_1,y_2]$
Therefore:
$\underline{\mathcal{T}([x_1,x_2],[y_1,y_2])} \leq minimum[x_1,y_1]$
$\overline{\mathcal{T}([x_1,x_2],[y_1,y_2])} \leq minimum[x_2,y_2] \Rightarrow$
$\mathcal{T}([x_1,x_2],[y_1,y_2]) \leq_L Inf_L([x_1,x_2],[y_1,y_2])\Box$

Lemma 4.6 *Let $\mathcal{S}$ be any generalized t-conorm, then:*

$$\mathcal{S}([x_1,x_2],[y_1,y_2]) \geq_L Sup_L([x_1,x_2],[y_1,y_2])$$
$$\forall [x_1,x_2],[y_1,y_2] \in L$$

Proof.
$\mathcal{S}([x_1,x_2],[y_1,y_2]) \geq_L \underline{\mathcal{S}([x_1,x_2],1_L) =_L [x_1,x_2]}$
$\Rightarrow [\underline{\mathcal{S}([x_1,x_2],[y_1,y_2])}, \overline{\mathcal{S}([x_1,x_2],[y_1,y_2])}] \geq_L [x_1,x_2]$
$\underline{\mathcal{S}([x_1,x_2],[y_1,y_2])} =_L \overline{\mathcal{S}([y_1,y_2],[x_1,x_2])} \geq_L$
$\underline{\mathcal{S}([y_1,y_2],1_L) =_L [y_1,y_2]}$
$\Rightarrow [\underline{\mathcal{S}([x_1,x_2],[y_1,y_2])}, \overline{\mathcal{S}([x_1,x_2],[y_1,y_2])}] \geq_L [y_1,y_2]$
Therefore:
$\underline{\mathcal{S}([x_1,x_2],[y_1,y_2])} \geq maximun[x_1,y_1]$
$\overline{\mathcal{S}([x_1,x_2],[y_1,y_2])} \geq maximun[x_2,y_2] \Rightarrow$
$\mathcal{S}([x_1,x_2],[y_1,y_2]) \geq_L Sup_L([x_1,x_2],[y_1,y_2])\Box$

Due associativity of $\mathcal{T}$:

$$\mathcal{T}([x_1,x_2],\mathcal{T}([y_1,y_2],[z_1,z_2])) =_L$$
$$\mathcal{T}(\mathcal{T}([x_1,x_2],[y_1,y_2]),[z_1,z_2]) =_L [x_1,x_2] \triangle [y_1,y_2] \triangle [z_1,z_2]$$
$$Inf_L([x_1,x_2],Inf_L([y_1,y_2],[z_1,z_2])) =_L$$
$$Inf_L(Inf_L([x_1,x_2],[y_1,y_2]),[z_1,z_2])) =_L [x_1,x_2] \triangle_{L-inf} [y_1,y_2] \triangle_{L-inf} [z_1,z_2]$$

Lemma 4.7 *Let $\mathcal{T}$ be an arbitrary generalized t-norm. Let P be a path with a cycle:*

$$P \equiv R(a,a_1) \triangle R(a_1,a_2) \triangle ... \triangle R(a_{t-1},a_t) \triangle R(a_t,c_1) \triangle R(c_1,c_2) \triangle ... \triangle R(c_q,a_t) \triangle R(a_t,a_{t+1}) \triangle ... \triangle R(a_k,b)$$

then

$$P \equiv R(a,a_1) \triangle R(a_1,a_2) \triangle ... \triangle R(a_{t-1},a_t) \triangle R(a_t,c_1) \triangle R(c_1,c_2) \triangle ... \triangle R(c_q,a_t) \triangle R(a_t,a_{t+1}) \triangle ... \triangle R(a_k,b) \leq_L R(a,a_1) \triangle R(a_1,a_2) \triangle ... \triangle R(a_{t-1},a_t) \triangle R(a_t,a_{t+1}) \triangle ... \triangle R(a_k,b)$$

Proof.
Trivial due to $\mathcal{T}([x_1,x_2],[y_1,y_2]) \leq_L [y_1,y_2]$ forall $[x_1,x_2],[y_1,y_2]$ in L and associativity of $\mathcal{T}\Box$.

Theorem 4.2 *Let X be a finite universe with cardinality n. The transitive closure of R, $R^\mathcal{T}$, is:*

$$R^\mathcal{T} =_L Sup_{L\ k=1..n}\{R^{(k)_\mathcal{T}}\}$$

Proof.

$R^{(k)_\mathcal{T}}(a,b) =_L$

$=_L Sup_{L\ a_1,a_2,...,a_{k-1}} R(a,a_1) \triangle R(a_1,a_2) \triangle ... \triangle R(a_{k-1},b) \leq_L$
$=_L Sup_{L\ a_1,a_2,...,a_{k-1}} R(a,a_1) \triangle_{Inf_L} R(a_1,a_2) \triangle_{Inf_L} ... \triangle_{Inf_L} R(a_{k-1},b)$ according to lemma 4.5.

Now suppose $k > n$. Then $R^{(k)} \subseteq_L R^{(n)}$ because it exists a cycle (lemma 4.7). Therefore, the cases $k > n$ need not be considered $\Box$.

Corollary 4.1 *Let X be a finite universe with cardinality n. If R is a locally reflexive relation, the transitive closure of R is:*

$$R^\mathcal{T} =_L Sup_{L\ k=1..n-1}\{R^{(k)_\mathcal{T}}\}$$

Proof
If R is a locally reflexive relation then $R(a,b) \leq_L R(a,a)$. Consider a cycle of length n, then its strength is:
$R^{(n)_\mathcal{T}}(a,a) =_L$

$=_L Sup_{L\ a_1,a_2,...,a_{k-1}} R(a,a_1) \triangle R(a_1,a_2) \triangle ..., \triangle R(a_{k-1},a) \leq_L$
$Sup_{L\ a_1,a_2,...,a_{k-1}} R(a,a_1) \triangle_{Inf_L} R(a_1,a_2) \triangle_{Inf_L} ... \triangle_{Inf_L} R(a_{k-1},a) \leq_L R(a,a)\Box$

Theorem 4.3 *Let X be a finite universe with cardinality n. If R is a reflexive fuzzy relation on X then the transitive closure of R is:*

$$R^\mathcal{T} =_L R^{(n-1)_\mathcal{T}}$$

Proof.
$R(a,b)^{(k)_\mathcal{T}} =_L$

$=_L \mathcal{T}(R(a,a), R^{(k)_\mathcal{T}}(a,b))$
$\leq_L Sup_{L\ c\in X}\{T(R(a,c), R^{(k)_\mathcal{T}}(c,b))\}$
$=_L R^{(k+1)_\mathcal{T}}(a,b)$

Therefore $R(a,b)^{(k)_\mathcal{T}} \leq_L R^{(k+1)_\mathcal{T}}(a,b) \Leftrightarrow R^{(k)_\mathcal{T}} \subseteq R^{(k+1)_\mathcal{T}}\Box$

Theorem 4.4 *Let $\mathcal{T}$ be a t-representable t-norm ($\mathcal{T} = [T_1,T_2]$) and let $R = [\underline{R},\overline{R}]$ be a interval-valued relation. Then $R^\mathcal{T} = [\underline{R}^{T_1}, \overline{R}^{T_2}]$.*

Proof.

$R^{(k)_\mathcal{T}}(a,b) =_L$

$=_L \ Sup_{L\ a_1,a_2,...,a_{k-1}} R(a,a_1) \ \triangle \ R(a_1,a_2) \ \triangle$
$..., \triangle \ (a_{k-1},b)$
$=_L \ Sup_{L\ a_1,a_2,...,a_{k-1}} [\underline{R(a,a_1)} \ \triangle_1 \ \underline{R(a_1,a_2)} \ \triangle_1$
$..., \triangle_1 \ \underline{R(a_{k-1},b)}, \overline{R(a,a_1)} \ \triangle_2 \ \overline{R(a_1,a_2)} \ \triangle_2$
$..., \triangle_2 \ \overline{R(a_{k-1},b)}]$
$=_L \ [max_{a_1,a_2,...,a_{k-1}} \underline{R(a,a_1)} \ \triangle_1 \ \underline{R(a_1,a_2)} \ \triangle_1$
$..., \triangle_1 \ \underline{R(a_{k-1},b)}$
$, max_{a_1,a_2,...,a_{k-1}} \overline{R(a,a_1)} \ \triangle_2 \ \overline{R(a_1,a_2)} \ \triangle_2 ..., \triangle_2$
$\overline{R(a_{k-1},b)}]$
$=_[\ \underline{R^{(k)_{T_1}}(a,b)}, \overline{R^{(k)_{T_2}}(a,b)}]$

where $\triangle = [\triangle_1, \triangle_2]$. Then $\mathcal{T} = [T_1, T_2] \Rightarrow R^{\mathcal{T}} = [\underline{R}^{T_1}, \overline{R}^{T_2}]\Box$.

Definition 4.3 *The distance d of the supremum on L is defined for all $x_1, x_2, y_1, y_2 \in [0,1]$ by $d([x_1,x_2],[y_1,y_2]) = max(|x_1 - y_1|, |x_2 - y_2|)$.*

Definition 4.4 *Let R,S be two interval-valued fuzzy relatons on a set X. The distance d between R and S us defined by:*

$$d(R,S) = sup_{x,y \in X} d(R(x,y), S(x,y))$$

Lemma 4.8 *d is a distance on the set R_X of interval-valued fuzzy relations on X $\Box$.*

Proof.
The supremum of distances is a distance.

Theorem 4.5 *Let T be a generalized continuous t-norm and R_X the set of interval-valued fuzzy relations on X. R_X with the sup-$\mathcal{T}$ product is an ordered topological semigroup.*

Proof.

- Associativity is a straightforward exercise.
- The interval-valued relation $E(x,y) = \begin{cases} [1,1], & x=y; \\ [0,0], & \text{otherwise.} \end{cases}$ is the identity element of R_X.
- Continuity: Since T is defined on a compact set, it is uniformly continuous. Therefore:

$$\forall \epsilon > 0, \exists \delta > 0 \text{ such that}$$
$$\forall m, n, m', n', a, b, a', b' \in [0,1]$$
$$max(|m-a|, |m'-a'|, |n-b|, |n'-b'|) \Rightarrow$$
$$|\mathcal{T}([m,m'],[n,n']) - \mathcal{T}([a,a'],[b,b'])| < \epsilon (*)$$

We want to prove that given two interval-valued fuzzy relations $A, B \in R_X$:

$$\forall \epsilon > 0, \exists \delta > 0 \text{ such that } \forall M, N \in R_X$$
$$max(d(M,A), d(N,B)) < \delta \Rightarrow d(M \circ N, A \circ B) < \epsilon$$

Given ϵ, we take $\delta > 0$ satisfying (*). Then:

$$d(M \circ N, A \circ B) =$$
$$sup_{x,y \in X} |sup_{z \in X} \mathcal{T}(M(x,z), N(z,y)) -$$
$$sup_{z \in X} \mathcal{T}(A(x,z), B(z,y))| \leq$$
$$sup_{x,y \in X} sup_{z \in X} |\mathcal{T}(M(x,z), N(z,y)) -$$
$$\mathcal{T}(A(x,z), B(z,y))| \leq \epsilon$$

- Monotonicity is an immediate consequence of the monotonicity of $\mathcal{T}\Box$.

Corollary 4.2 *For any positive integer n the map assigning to an interval-values fuzzy relation M on a finite set its n^{th} power is non-decreasing and continuous if the corresponding generalized t-norm $\mathcal{T}$ is continuous.*

Corollary 4.3 *If a generalized t-norm $\mathcal{T}$ is continuous, the map that assigns the $\mathcal{T}$-transitive closure to the interval-valued fuzzy relations on a finite set is non-decreasing and continuous.*

Theorem 4.6 *Given a method to calculate the transitive closure of a fuzzy relation. Nevertheless, there are more effective methods and algorithms. For example it is possible to use an extension of the Floyd-Warshall algorithm [16]*

4.1 Algorithm to compute the transitive closure of an interval-valued fuzzy relation

Let R be an interval-valued relation on a finite universe X with cardinality n and let $\mathcal{T}$ be a generalized t-norm. It is possible to compute $R^{\mathcal{T}}$ using the next algorithm:

for k $\leftarrow$ 1 **until** n **do**
  for i $\leftarrow$ 1 **until** n **do**
    for j $\leftarrow$ 1 **until** n **do**
      R(i,j)$\leftarrow Sup_L(R(i,j), \mathcal{T}(R(i,k), R(k,j)))$
    end for
  end for
end for

Example 4.1 *Let $\mathcal{T}$ be a generalized t-norm $T_w([x_1,x_2],[y_1,y_2]) =_L [max(0, x_1 + y_1 - 1), max(0, x_2 + y_2 - 1)]$ and let $R : X \times X \rightarrow L$ be the following interval-valued relation:*

$$R = \begin{pmatrix} [1,1] & [0.6,0.8] & [0.6,0.9] & [0,0] \\ & [1,1] & [0.4,0.9] & [0.6,0.9] \\ & & [1,1] & [0.6,0.9] \\ & & & [1,1] \end{pmatrix}$$

The computation of the $\mathcal{T}$-transitive closure of R is the following:

$$R^{\mathcal{T}} = \begin{pmatrix} [1,1] & [0.6,0.8] & [0.6,0.9] & [0.2,0.8] \\ & [1,1] & [0.4,0.9] & [0.6,0.9] \\ & & [1,1] & [0.6,0.9] \\ & & & [1,1] \end{pmatrix}$$

Note that by theorem 4.4, $R^{\mathcal{T}} = [\underline{R^W}, \overline{R^W}]$

Example 4.2 *Let $\mathcal{T}$ be a generalized t-norm $T([x_1,x_2],[y_1,y_2]) =_L [W(x_1,y_1), Min(x_2,y_2)]$ and let $R : X \times X \rightarrow L$ be the following interval-valued relation:*

$$R = \begin{pmatrix} [1,1] & [0.6,0.8] & [0.6,0.9] & [0,0] \\ & [1,1] & [0.4,0.9] & [0.6,0.9] \\ & & [1,1] & [0.6,0.9] \\ & & & [1,1] \end{pmatrix}$$

The computation of the $\mathcal{T}$-transitive closure of R is the following:

ISBN: 978-989-95079-6-8

$$R^{\mathcal{T}} = \begin{pmatrix} [1,1] & [0.6,0.8] & [0.6,0.9] & [0.2,0.9] \\ & [1,1] & [0.4,0.9] & [0.6,0.9] \\ & & [1,1] & [0.6,0.9] \\ & & & [1,1] \end{pmatrix}$$

Note that by theorem 4.4, $R^{\mathcal{T}} = [\underline{R^W}, \overline{R^{Min}}]$

Example 4.3 *Let* $\mathcal{T}$ *be a generalized t-norm* $T_W([x_1,x_2],[y_1,y_2]) =_L [max(0, x_1 + y_1 - 1), max(0, x_1 + y_2 - 1, x_2 + y_1 - 1)]$ *and let* $R : X \times X \to L$ *be the following interval-valued relation:*

$$R = \begin{pmatrix} [1,1] & [0.6,0.8] & [0.6,0.9] & [0,0] \\ & [1,1] & [0.4,0.9] & [0.6,0.9] \\ & & [1,1] & [0.6,0.9] \\ & & & [1,1] \end{pmatrix}$$

The computation of the $\mathcal{T}$*-transitive closure of* R *is the following:*

$$R^{\mathcal{T}} = \begin{pmatrix} [1,1] & [0.6,0.8] & [0.6,0.9] & [0.2,0.5] \\ & [1,1] & [0.4,0.9] & [0.6,0.9] \\ & & [1,1] & [0.6,0.9] \\ & & & [1,1] \end{pmatrix}$$

Note that the generalized $\mathcal{T}$*-norm in this example is not t-representable.*

5 An Application

It is possible to model social relations using Interval-valued Fuzzy Sets. For example, it is possible to model "friendship". Let R be a relation which describes the degree of friendship between pairs of people. If A and B are friends and B and C are friends, then it will probably exist some degree of friendship between A and C. In this context, the $\mathcal{T}$-transitive closure can be used to learn friendship of individuals from a chain of friends, for example, from common friends.

Example 5.1 *Let* R *be an interval-valued relation which models the degree of friendship between four people* $\{a, b, c, d\}$*. It is possible to model the transitivity of friendship using the generalized t-norm* $*_L([x_1,x_2],[y_1,y_2]) =_L [x_1 * y_1, x_2 * y_2]$*:*

$$R = \begin{pmatrix} [1,1] & [0.6,0.9] & [0.6,0.7] & [0,0] \\ & [1,1] & [0,0] & [0.2,0.8] \\ & & [1,1] & [0,0] \\ & & & [1,1] \end{pmatrix}$$

Initially, d *has only friendship with* b*. In addition, the uncertainty of degree of friendship between* b *and* d *is wide. It is interesting to see how friendship is propagated.*

$$R^{\mathcal{T}} = \begin{pmatrix} [1,1] & [0.6,0.9] & [0.6,0.7] & [0.16,0.72] \\ & [1,1] & [0.48,0.63] & [0.2,0.8] \\ & & [1,1] & [0.096,0.5] \\ & & & [1,1] \end{pmatrix}$$

In $R^{\mathcal{T}}$ d *has some degree of friendship with* a, c *learned by a common friend* b*. The uncertainty of degree of friendship of* d *with the rest of them has been propagated as well.*

6 Conclusions

Traditionally, the study of interval-valued fuzzy sets has been reduced to t-representable t-norms. We have generalized the main properties of interval-valued fuzzy relations: reflexivity, symmetry, composition, local reflexivity and t-transitivity. We also have generalized the T-transitive closure for any t-norm and an algorithm to compute it is provided. It is analyzed the case of t-representable t-norms and proved that in this case the T-transitive closure of R can be obtained from the two classical T-transitive closures of the lower and higher relations (theorem 4.4). Some examples are provided.

Choquet-integral-based Evaluations by Fuzzy Rules

Eiichiro Takahagi

School of Commerce, Senshu University,
Tamaku, Kawasaki 214-8580, Japan
Email: takahagi@isc.senshu-u.ac.jp

Abstract— *Choquet-integral-based evaluation models are proposed. The evaluation parameters – fuzzy measures – are assigned from a fuzzy rule table. There are three variations in this model: TF-, BP-, and AV-type models. The TF-type model is a natural extension of ordinal Choquet integrals. The BP-type model involves an evaluation using a reference point. The AV-type model involves a neutral evaluation method. These methods have a number of advantages: Output values are continuous and piecewise linear; If the fuzzy rules have monotonicity, output values are also monotone. We compare these models with some fuzzy reasoning models.*

Keywords— Choquet Integral, Fuzzy rule, Simplified fuzzy reasoning, Cumulative prospect theory, Choquet integral with respect to bi-capacities

1 Introduction

Fuzzy reasoning models are very useful tools for developing fuzzy control models. A part of a fuzzy control model involves sensing status, evaluation using fuzzy reasoning models, and producing output. By repeatedly applying the feedback process, fuzzy control models help approach the control goal (Approach Principal [1]). However, to be applied in the social sciences, evaluation models must be able to determine one global evaluation value by a single calculation process. It is important that the global evaluation values adhere obsequiously to fuzzy rules. For example, if a fuzzy rule is monotone with respect to the inputs, the output of the evaluation model must satisfy the monotonicity property with respect to the inputs. Almost all the fuzzy reasoning models do not satisfy the monotonicity property [2].

In this paper, we propose Choquet-integral-based evaluation methods by using fuzzy rules. The fuzzy rule table is of the same form as ordinal simplified fuzzy reasoning models, but the calculations use (extended) Choquet integrals instead of min-max calculations or product-sum calculations. The global evaluation values satisfy continuous and piecewise linear outputs. Moreover, if fuzzy rules are monotone respect to the inputs, the output values also satisfy the monotonicity property.

2 Definitions

2.1 Notations

X**:** Set of evaluation items (n: number of evaluation items)

x_i**:** Input value of the i^{th} item

y**:** Global evaluation value

2.2 Fuzzy Space Division Constraint

Each input i is divided into m_i fuzzy sets in which the membership functions are p_i^j for $i = 1, \ldots, n, j = 1, \ldots, m_i$. For each input item, all the membership functions satisfy the following conditions:

1. All fuzzy sets are normal and convex. The vertex of a membership function is unique $\forall i, j$, that is, there is a unique point v_i^j, where $p_i^j(v_i^j) = 1\ \forall i$ and j.

2. The sum of the membership values is 1:

$$\sum_j p_i^j(x_i) = 1, \forall x_i, i. \tag{1}$$

3. There are one or two active membership functions – $p_i^j(x_i) > 0 - \forall x_i, \forall i$.

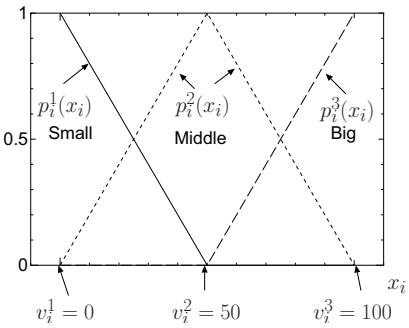

Figure 1: Fuzzy space division ($i = 1, 2$)

An example of the fuzzy space division is shown in figure 1. In this example, there are two inputs, $X = \{1, 2\}$, the membership functions are of the triangle type, and the membership functions are the same for all inputs, $v_i^1 = 0, v_i^2 = 50, v_i^3 = 100, i = 1, 2$.

2.3 Fuzzy Rule Table

Representative points $(k_1, \ldots, k_n)$ are defined as pairs of vertex numbers. For example, the representative point $(2, 3)$ $(n = 2)$ is the point at which input 1 is "Middle" and input 2 is "Big." The fuzzy rule table c is defined as a function from the representative points to the output values:

$$c : \{1, \ldots, m_1\} \times \ldots \times \{1, \ldots, m_n\} \to \mathbb{R}. \tag{2}$$

Table 1 is an example of the fuzzy rule tables,

- If input 1 is "Big" and input 2 is "Big," the output is 100.

ISBN: 978-989-95079-6-8

- If input 1 is "Big" and input 2 is "Middle," the output is 80.
- ...

Table 1: Fuzzy rule table

Input 2 \ 1	Small (1)	Middle (2)	Big (3)
Small (1)	0 (= $c(1,1)$)	50 (= $c(2,1)$)	80 (= $c(3,1)$)
Middle (2)	30 (= $c(1,2)$)	60 (= $c(2,2)$)	90 (= $c(3,2)$)
Big (3)	70 (= $c(1,3)$)	80 (= $c(2,3)$)	100 (= $c(3,3)$)

2.4 Choquet Integral and Extended Choquet Integral

The Choquet integral [3] is a useful tool for use in global evaluation methods. The integral can be used to represent complementary and substitute relations among evaluation items [4]. A fuzzy measure $\mu^\dagger$ is defined as

$$\mu^\dagger : 2^X \to \mathbb{R} \tag{3}$$

$$\mu^\dagger(\emptyset) = 0. \tag{4}$$

In ordinal fuzzy measure definitions, this definition is known as a non-monotonicity fuzzy measure, but in this paper, the monotonicity of the fuzzy measure is not assumed.

The Choquet integral is defined as

$$y = (\mathrm{C}) \int h d\mu \equiv \int_0^\infty \mu(\{x \mid h(x) > r\}) dr. \tag{5}$$

The extended fuzzy measure and extended Choquet integral [5, 6] are proposed for handling the cases in which $\mu(\emptyset) \neq 0$. An extended fuzzy measure μ is defined as

$$\mu : 2^X \to \mathbb{R}. \tag{6}$$

Since it is not assumed by definition that $\mu(\emptyset) = 0$, the integration interval is limited to $[0, 1]$. The extended Choquet integral is defined as

$$y = (\mathrm{EC}) \int h d\mu \equiv \int_0^1 \mu(\{x \mid h(x) > r\}) dr. \tag{7}$$

The extended Choquet integral can be calculated by using an ordinal Choquet integral:

$$(\mathrm{EC}) \int h d\mu = (\mathrm{C}) \int h d\mu^\dagger + \mu(\emptyset) \tag{8}$$

$$\text{where } \mu^\dagger(A) = \mu(A) - \mu(\emptyset), \forall A \in 2^X.$$

3 Segment Division Calculation Method

3.1 Segmentation and Segment Selection

Segmentation is performed at vertex points v_i^j for all inputs. Figure 2 shows an example of the segmentation. Segment $S_{(k_1,\ldots,k_n)}(k_i < m_i, \forall i)$ is the n-th rectangle whose vertices are the representative points $(k_1 + l_1, \ldots, k_2 + l_n), \forall l_i \in \{0, 1\}, i = 1, \ldots, n$. In the example, there are four segments, $S_{(1,1)}$, $S_{(2,1)}$, $S_{(1,2)}$ and $S_{(2,2)}$.

First, we select the segment that includes the input values $((x_1, \ldots, x_n))$. If $x_1 = 40$ and $x_2 = 20$, $S_{(1,1)}$ is selected.

In this model, each segment has a different extended fuzzy measure $\mu^{(k_1,\ldots,k_n)}$ and integrand $h^{(k_1,\ldots,k_n)}$, but the Choquet integral is caclculated only for the selected segment.

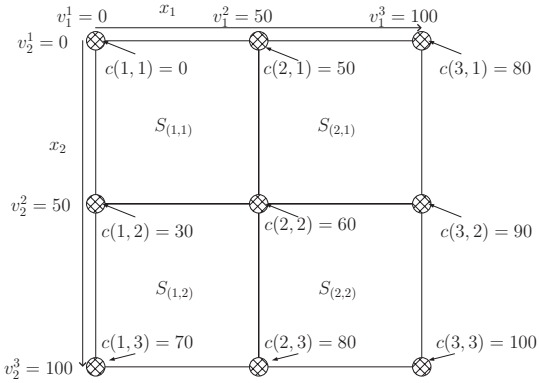

Figure 2: Segmentation

3.2 Segment Calculation

Figure 3 shows segment $S_{(1,1)}$. The output is calculated by interpolating the output values of four representative points; those values are $c(1,1), c(2,1), c(1,2)$, and $c(2,2)$.

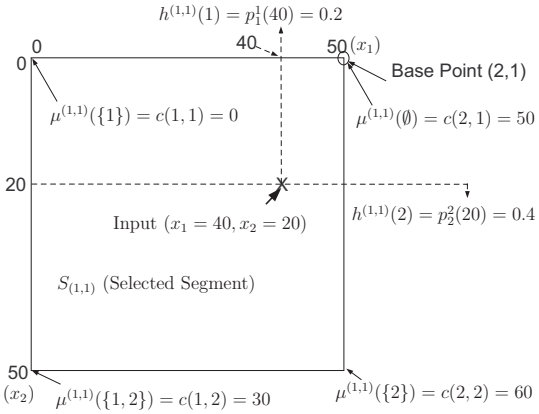

Figure 3: Calculation process (Base Point: $(2,1)$)

Base point selection The base point is the origin of the fuzzy measure and integrand for the segment. First, the base point is selected from among the representative points in the segment. Alternative base points of segment $S_{(k_1,\ldots,k_n)}$ are $(k_1 + l_1, \ldots, k_n + l_n), \forall l_i \in \{0, 1\}, i = 1, \ldots, n$.

Alternative base points of segment $S_{(1,1)}$ in figure 3 are $(1,1)$,$(2,1)$,$(1,2)$, and $(2,2)$.

Extended fuzzy measure $\mu^{(k_1,\ldots,k_n)}$ assignment When the segment $S_{(k_1,\ldots,k_n)}$ and the base point $(q_1, \ldots, q_n)$ are selected, extended fuzzy measures $\mu^{(k_1,\ldots,k_n)}$ are assigned as follows:

$$\mu^{(k_1,\ldots,k_n)}(A) = c(l_1, \ldots, l_n), \forall A \in 2^X \tag{9}$$

$$\text{where } l_i = \begin{cases} q_i & \text{if } i \notin A \\ k_i & \text{if } i \in A \text{ and } k_i \neq q_i \\ k_i + 1 & \text{if } i \in A \text{ and } k_i = q_i. \end{cases}$$

If $(2,1)$ is selected as the base point in figure 3,

$$\mu^{(1,1)}(\emptyset) = c(2,1),\ \mu^{(1,1)}(\{1\}) = c(1,1)$$
$$\mu^{(1,1)}(\{2\}) = c(2,2),\ \mu^{(1,1)}(\{1,2\}) = c(1,2)$$

ISBN: 978-989-95079-6-8

Integrand $h^{(k_1,\ldots,k_n)}$ assignment When the segment $S_{(k_1,\ldots,k_n)}$ and the base point $(q_1,\ldots,q_n)$ are selected, integrands $h^{(k_1,\ldots,k_n)}$ are assigned as follows:

$$h^{(k_1,\ldots,k_n)}(i) = p_i^j(x_i), i = 1,\ldots,n \quad (10)$$
$$\text{where } j = \begin{cases} k_i & \text{if } k_i \neq q_i \\ k_i + 1 & \text{otherwise.} \end{cases}$$

If $(2,1)$ is selected as the base point of segment $S_{(1,1)}$,

$$h^{(1,1)}(1) = p_1^1(x_1), \;\; h^{(1,1)}(2) = p_2^2(x_2) \quad (11)$$

Extended Choquet integral The output value y is calculated from the extended Choquet integral by using the fuzzy measure $\mu^{(k_1,\ldots,k_n)}$ and integrand $h^{(k_1,\ldots,k_n)}$ of the selected segment.

$$y = (\mathrm{EC}) \int h^{(k_1,\ldots,k_n)} d\mu^{(k_1,\ldots,k_n)} \quad (12)$$

The output values change with the methods for selection the base points. We propose the following type of Choquet-integral-based evaluation methods: TF-, BP- and BP-type.

3.3 TF-type

In TF-type models, the smallest (upper left) representative points are selected as base points for all segments, that is, the base point of a segment $S_{(k_1,\ldots,k_n)}$ is $(k_1,\ldots,k_n)$.

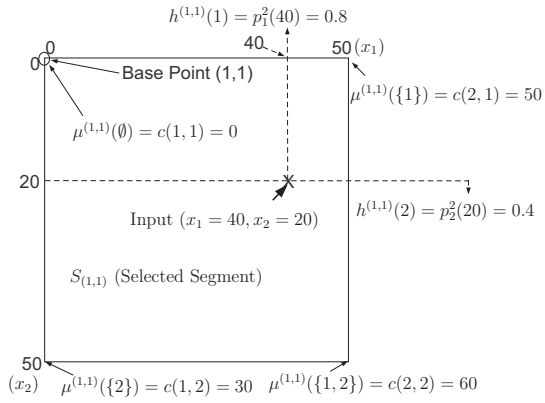

Figure 4: Extended fuzzy measure assignment in TF-type models

When $x_1 = 40$ and $x_2 = 20$, from figure 2, segment $S_{(1,1)}$ is selected. In the TF-type model, $(1,1)$ is selected as the base point. Figure 4 shows an example of the calculation process. Since the origin is $(1,1)$, the membership functions "Middle" ($p_1^2(x_1)$ and $p_2^2(x_2)$) are used. Therefore, the integrand $h^{(1,1)}(1) = p_1^2(x_1) = 0.8$ and $h^{(1,1)}(2) = p_2^2(x_2) = 0.4$. Since the origin is $(1,1)$, $\mu^{(1,1)}(\emptyset) = c(1,1) = 0$, $\mu^{(1,1)}(\{1\}) = c(2,1) = 50$, $\mu^{(1,1)}(\{2\}) = c(1,2) = 30$, and $\mu^{(1,1)}(\{1,2\}) = c(2,2) = 60$ (figure 4). The output is calculated as

$$y = (\mathrm{EC}) \int h^{(1,1)} d\mu^{(1,1)}. \quad (13)$$

Since $\mu^{11}(\emptyset) = 0$, this equation is calculated by using the ordinal Choquet integral.

$$y = [h^{(1,1)}(1) - h^{(1,1)}(2)]\mu^{(1,1)}(\{1\}) + h^{(1,1)}(2)\mu^{(1,1)}(\{1,2\}) = 44. \quad (14)$$

Table 2 lists integrands and extended fuzzy measures for all segments. Figure 5 shows a graph corresponding to Table1.

Table 2: Integrand and extended fuzzy measure for TF ($n = 2$)

		Integrand		μ			
Segment	Base Point	$h(1)$	$h(2)$	$\emptyset$	$\{1\}$	$\{2\}$	$\{1,2\}$
$S_{(1,1)}$	$(1,1)$	$p_1^2(x_1)$	$p_2^2(x_2)$	$c(1,1)$	$c(2,1)$	$c(1,2)$	$c(2,2)$
$S_{(2,1)}$	$(2,1)$	$p_1^3(x_1)$	$p_2^2(x_2)$	$c(2,1)$	$c(3,1)$	$c(1,2)$	$c(3,2)$
$S_{(1,2)}$	$(1,2)$	$p_1^2(x_1)$	$p_2^3(x_2)$	$c(1,2)$	$c(2,2)$	$c(1,3)$	$c(2,3)$
$S_{(2,2)}$	$(2,2)$	$p_1^3(x_1)$	$p_2^3(x_2)$	$c(2,2)$	$c(3,2)$	$c(2,3)$	$c(3,3)$

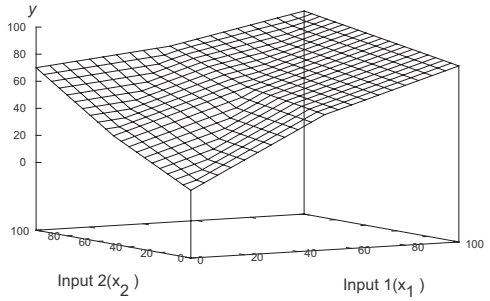

Figure 5: 3D graph corresponding to Table1 (TF-Type)

3.4 Base Point Change

The output values y are dependent on the selection of the base point. If the base point $(2,1)$ is selected for segment $S_{(1,1)}$, the extended fuzzy measure $\mu^{(1,1)}$ is

$$\mu^{(1,1)}(\emptyset) = c(2,1) = 50, \;\; \mu^{(1,1)}(\{1\}) = c(1,1) = 0,$$
$$\mu^{(1,1)}(\{2\}) = c(2,2) = 60, \;\; \text{and } \mu^{(1,1)}(\{1,2\}) = c(1,2) = 30.$$

If the input values are $x_1 = 40, x_2 = 20$, $h^{(1,1)}(1) = p_1^1(x_1) = 0.2$ and $h^{(1,1)}(2) = p_2^2(x_2) = 0.4$. The output value is

$$y = (\mathrm{EC}) \int h^{(1,1)} d\mu^{(1,1)} = 48,$$

which is not the equal to the output value 44 given by the TF-type models (14).

3.5 BP-type

In cumulative prospect theory [7], the evaluation methods differ for values above and below the reference point. The model has been developed for analyzing such situations. BP-type calculations can represent the generalized Choquet integral with respect to bi-capacity [8, 9], and the generalized Choquet integral is an extension of cumulative prospect theory.

In the BP-type model, each input has three membership functions: negative, reference, and positive; $m_i = 3, \forall i$. In prospect theory, it is important to evaluate the distance from the reference point, and therefore, the base point for the all segments is the reference point (figure 6 and table 4), namely $(2,\ldots,2)$.

ISBN: 978-989-95079-6-8

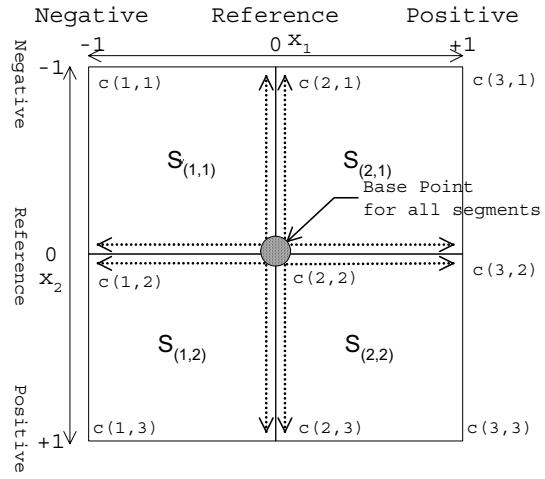

Figure 6: BP-type

BP type model Table 3 is an example of a BP-type evaluation rule table. In thoose BP-type models, membership functions are of the triangle type, such as figure 1; the base points for all segments is the reference point $(2,\ldots,2)$, and the output of the reference point is 0, that is, $c(2,\ldots,2) = 0$ and $x_i \in [-1,1]$. The integrands $h^{(k_1,\ldots,k_n)}$ are

$$h^{(k_1,\ldots,k_n)}(i) = \mid x_i \mid, \forall(k_1,\ldots,k_n), i = 1,\ldots,n. \quad (15)$$

Table 4 lists the integrands and extended fuzzy measures for all segments when $n = 2$. If $x_1 = 0.2$ and $x_2 = -0.6$, $S_{(2,1)}$ is selected and $h^{(2,1)}(1) = 0.2$ and $h^{(2,1)}(2) = 0.6$;

$$y = (\mathrm{EC}) \int h^{(2,1)} d\mu^{(2,1)} = -0.44.$$

Figure 7 shows a graph corresponding to table 3.

Table 3: BP-type fuzzy rule table

Input 2 \ 1	Negative	Reference	Positive
Negative	-1.0	-0.8	-0.6
Reference	-0.8	0	$+0.6$
Positive	-0.6	$+0.8$	$+1.0$

Table 4: Integrands and extended fuzzy measures for BP

		Integrands		μ			
Segments	Base Points	$h(1)$	$h(2)$	$\emptyset$	$\{1\}$	$\{2\}$	$\{1,2\}$
$S_{(1,1)}$	$(2,2)$	$-x_1$	$-x_2$	$c(2,2)$	$c(1,2)$	$c(2,1)$	$c(1,1)$
$S_{(2,1)}$	$(2,2)$	x_1	$-x_2$	$c(2,2)$	$c(3,2)$	$c(2,1)$	$c(3,1)$
$S_{(1,2)}$	$(2,2)$	$-x_1$	x_2	$c(2,2)$	$c(1,2)$	$c(2,3)$	$c(1,3)$
$S_{(2,2)}$	$(2,2)$	x_1	x_2	$c(2,2)$	$c(3,2)$	$c(2,3)$	$c(3,3)$

Bi-capacity Model Let $Q(X) = \{(A,B) \in 2^X \times 2^X \mid A \cap B = \emptyset\}$. Bi-capacity [8] is defined as a function $v : Q(X) \to [-1,1]$ that satisfies the following conditions:

- If $A \subset A'$, $v(A,B) \leq v(A',B)$ and if $B \subset B'$, $v(A,B) \geq v(A,B')$,
- $v(\emptyset,\emptyset) = 0$ and

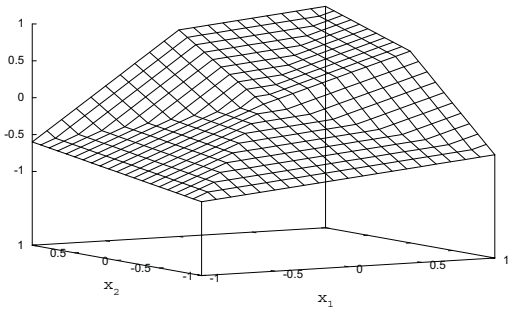

Figure 7: Outputs corresponding to Table 3 (BP-type))

- $v(X,\emptyset) = 1, v(\emptyset,X) = -1$.

The Choquet integral with respect to bi-capacity[9] is defined as

$$C_v(x) = \sum_{i=1}^{n} \mid x_{\sigma(i)} \mid [v(A_{\sigma(i)} \cap X^+, A_{\sigma(i)} \cap X^-) - v(A_{\sigma(i+1)} \cap X^+, A_{\sigma(i+1)} \cap X^-)] \quad (16)$$

where $X^+ \equiv \{i \in X \mid x_i \geq 0\}$, $X^- = X \setminus X^+$ and σ is a permutation on X satisfying $\mid x_{\sigma(1)} \mid \leq \ldots \leq \mid x_{\sigma(n)} \mid$ and $A_{\sigma(i)} \equiv \{\sigma(i),\ldots,\sigma(n)\}$.

BP type and bi-capacity model If a fuzzy rule table c is assigned from a bi-capacity v in the following manner:

$$c(k_1,\ldots,k_n) = v(A,B), \quad (17)$$
$$\text{where } A = \{i \mid k_i = 3\}, B = \{i \mid k_i = 1\},$$

the output y is equal to $C_v(x)$. Table 5 shows the correspondence when $n = 2$.From (17), the extended fuzzy measures are as follows:

$$\mu^{(k_1,\ldots,k_n)}(A) = v(E,F), \forall(k_1,\ldots,k_n), \forall A \in 2^X \quad (18)$$

where $E = \{i \mid k_i = 2\} \cap A$ and $F = \{i \mid k_i = 1\} \cap A$

For the input $x_1,\ldots,x_n$, the selected segment is $(k_1,\ldots,k_n)$, where

$$k_i = \begin{cases} 1 & \text{if } x_k < 0 \\ 2 & \text{otherwise} \end{cases} \quad (19)$$

Since $h^{(k_1,\ldots,k_n)}(i) = \mid x_i \mid$, $\mu^{(k_1,\ldots,k_n)}(\emptyset) = 0$, and from (18) and (19), $\mu^{(k_1,\ldots,k_n)}(A_{\sigma(i)}) = v(A_{\sigma(i)} \cap X^+, A_{\sigma(i)} \cap X^-)$,

$$\begin{aligned} y &= (\mathrm{C}) \int h^{(k_1,\ldots,k_n)} d\mu^{(k_1,\ldots,k_n)} \\ &= \sum_{i=1}^{n} \mid x_{\sigma(i)} \mid [\mu^{(k_1,\ldots,k_n)}(A_{\sigma(i)}) - \mu^{(k_1,\ldots,k_n)}(A_{\sigma(i+1)})] \\ &= C_v(x). \end{aligned}$$

3.6 AV-type

TF-type and BP-type calculations depend on the selection of the base points. Since the output value in the AV-type model is the average value for all base point selections, this output

ISBN: 978-989-95079-6-8

Table 5: Fuzzy rule table by a bi-capacity ($n = 2$)

Input 2 \ 1	Negative	Reference	Positive
Negative	$v(\emptyset, \{1,2\})$	$v(\emptyset, \{2\})$	$v(\{1\}, \{2\})$
Reference	$v(\emptyset, \{1\})$	$v(\emptyset, \emptyset)$	$v(\{1\}, \emptyset)$
Positive	$v(\{2\}, \{1\}))$	$v(\{2\}, \emptyset)$	$v(\{1,2\}, \emptyset)$

does not depend on the base point selection. Therefore, the AV-type method is a neutral evaluation method in terms of the selection of base points.

If $n = 2$, there are four options for selections the base point for each segment. For $S_{(1,1)}$, $(1,1)$, $(2,1)$, $(1,2)$, and $(2,2)$ are the options for selecting the base points. Table 6 lists the integrands and extended fuzzy measures for each base point selection.

Table 6: Integrand and extended fuzzy measure for AV ($S_{(1,1)}$)

	Integrand		μ			
Base Point	$h(1)$	$h(2)$	$\emptyset$	$\{1\}$	$\{2\}$	$\{1,2\}$
$(1,1)$	$p_1^2(x_1)$	$p_2^2(x_2)$	$c(1,1)$	$c(2,1)$	$c(1,2)$	$c(2,2)$
$(2,1)$	$p_1^1(x_1)$	$p_2^2(x_2)$	$c(2,1)$	$c(1,1)$	$c(2,2)$	$c(1,2)$
$(1,2)$	$p_1^2(x_1)$	$p_2^1(x_2)$	$c(1,2)$	$c(2,2)$	$c(1,1)$	$c(2,1)$
$(2,2)$	$p_1^1(x_1)$	$p_2^1(x_2)$	$c(2,2)$	$c(1,2)$	$c(2,1)$	$c(1,1)$

The calculation process when $x_1 = 30$, $x_2 = 40$, and the rule in table 1 is followed is given in Table 7. The output value of AV-type model, 44, is the average value for four selected base points. Figure 8 shows the graph of the AV-type outputs.

Table 7: Calculation process for $x_1 = 30$ and $x_2 = 40$

	Integrand		μ				output

			Average (y)				44

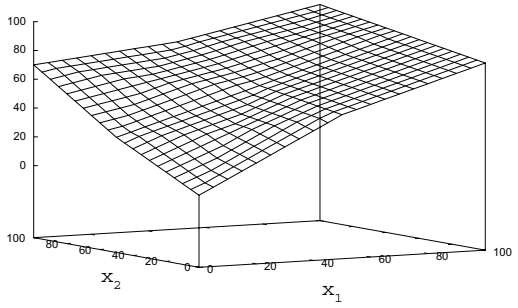

Figure 8: AV-type corresponding to Table 1

4 Properties

Continuity Choquet integral models satisfy the continuity property. Therefore, the proposed models satisfy the continuity property in each segment. For calculating the output values of a point on a bordering hyperplane, there are two or more options for selecting the calculation segment. However, in TF-, BP- and AV-type models, the output values remains the same regardless of the selected segment, that is, the output value on a bordering hyperplane does not depend on the selection of segments (The proof is omitted.) Therefore, Choquet integral based evaluations satisfy the continuity property.

Monotonicity It is known that almost all fuzzy reasoning models do not satisfy the monotonicity property when the fuzzy rule table is monotone. Choquet-integral-based evaluations satisfy the monotonicity property when the fuzzy rule table is monotone. A monotone fuzzy rule table is defined as $c(k_1, \ldots, k_n) \geq c(k'_1, \ldots, k'_n), \forall k_i \geq k'_i$. Examples of monotone rule tables are Table 1 and 3. When the fuzzy rule table is monotone, it is easy to confirm that the values of the extended Choquet integral are monotone and continuous for each segment. From the continuity of the proposed model, it follows that the Choquet-integral-based evaluation models have monotonicity if the fuzzy rule table is monotone.

Piecewise linear If the all membership functions are linear in that case in figure 1, the outputs are piecewise linear. This property is derived from the piecewise linearity of the Choquet integral.

5 Comparisons with Fuzzy Reasoning models

Fuzzy-rule-based global evaluation methods have been developed by using fuzzy reasoning models [10] such as "Min-Max Gravity Method," "Product-Sum Gravity Method," and "Simplified Fuzzy Reasoning." The outputs of the fuzzy rules for the min-max gravity method and product-sum gravity method are fuzzy sets. Therefore, to obtain the output (non fuzzy) value, a defuzzfication (gravity) calculation is performed. However, these calculations are complex. To analyze properties, the simplified fuzzy reasoning is utilized.

Simplified fuzzy reasoning is based on the product-sum method [11]. In the simplified method, it is possible to use min-max calculations instead of product-sum calculations. To demonstrate the properties of min-max and product-sum calculations, we utilize the two types of simplified fuzzy reasoning models.

5.1 Product-sum-type Simplified Fuzzy Reasoning

Simplified fuzzy reasoning is the most popular type of fuzzy reasoning. If the membership function shown in figure 1 and monotone fuzzy rules are assumed, product-sum-type simplified fuzzy reasoning satisfies the monotonicity property.

Product-sum-type simplified fuzzy reasoning can also be perfoermed using the segment division method. If $S_{(1,1)}$ in figure 2 is selected, the output given by the method is

$$\begin{aligned} y = & [1 - p_1^2(x_1)][1 - p_2^2(x_2)]c(1,1) \\ + & p_1^2(x_1) \times [1 - p_2^2(x_2)]c(2,1) \\ + & [1 - p_1^2(x_1)]p_2^2(x_2)c(1,2) + p_1^2(x_1)p_2^2(x_2)c(2,2) \end{aligned} \quad (20)$$

This equation involves an expectation calculation, that is, $p_1^2(x_1)$ and $p_2^2(x_2)$ are random variables, and the expected value of four events ($c(1,1), c(2,1), c(1,2)$, and $c(2,2)$) is calculated by this eqation.

In the segment, if the fuzzy rules are monotone, the outputs satisfy the monotonicity and continuities. Therefore, product-sum methods with monotone fuzzy rules satisfy the monotonicity property.

ISBN: 978-989-95079-6-8

Since product-sum-type calculations involve random variables calculation, output values vary unpredictably. Table 8 lists the AND-type fuzzy rule "If Input 1 and 2 are big, the output is 1." Figure 9 shows the output values for the rule table. Product-sum-type calculations are nonlinear because of product calculations. The input variation from $x_1 = x_2 = 0$ to $x_1 = x_2 = 0.01$ increases the output value by only 0.001, but the variation from $x_1 = x_2 = 0.99$ to $x_1 = x_2 = 1$ increases the output value by 0.0199. These results are inconsistent with the rule.

Table 8: AND-type rule table

Input 2 \ Input 1	Small	Big
Small	0.0	0.0
Big	0.0	1.0

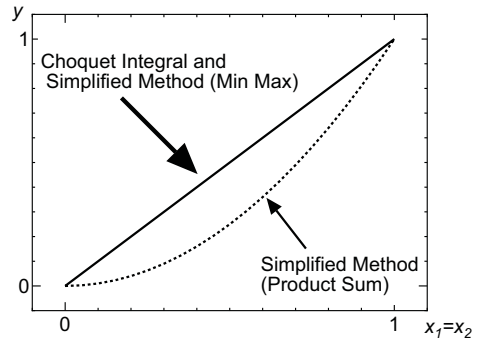

Figure 9: Comparison with product-sum-type method

Since $x_1 = x_2 = 0.5$ only satisfies half of the rule condition, it is expected that the output value is 0.5, but while the product-sum-type is 0.25. Moreover, if the number of inputs for the condition is increased, the output given by the product-sum method decreases. For example, if the number of inputs is 3 or 4, the product-sum output is $0.5^3 = 0.125$ or $0.5^4 = 0.0625$, respectively.

5.2 Min-max type Simplified Fuzzy Reasoning

In ordinal simplified fuzzy reasoning, product-sum calculation is performed, but it is possible to use min and max operators instead of product and sum operators.

Table 9: Monotone fuzzy rule table

Input 2 \ Input 1	Small	Big
Small	0.6 ($c(1,1)$)	0.7 ($c(2,1)$)
Big	0.8 ($c(1,2)$)	1.0 ($c(2,2)$)

Table 9 is represented by the fuzzy switching function

$$y = (c(1,1) \wedge x_1^1 \wedge x_2^1) \vee (c(2,1) \wedge x_1^2 \wedge x_2^1) \vee (c(1,2) \wedge x_1^1 \wedge x_2^2) \vee (c(2,2) \wedge x_1^2 \wedge x_2^2),$$

where $x_1^1 + x_1^2 = 1$ and $x_2^1 + x_2^2 = 1$. The equation does not satisfy the monotonicity property because fuzzy switching functions do not satisfy the complementary laws. For example, if $x_1^2 = 0.5$ and $x_2^2 = 1.0$, $y = 0.5$. However, if $x_1^2 = 0.4$ and $x_2^2 = 1.0$, $y = 0.6$.

Therefore, if fuzzy-value calculations are necessary, it is preferable to use Choquet-integral-based calculations.

6 Conclusions

This model is very useful for applications in social science, such as performance evaluation and educational evaluations. Since social science applications require strict validity of the output values, the global evaluation functions should not exhibit non-monotonicity and unexpected nonlinearity, such as that seen in figure 9. The Choquet integral models can be used to ensure the validity of the outputs. However, the attitude of evaluators might change according to the situation or the input values, and this might change the weights and the relationships among the evaluation parameters. The Choquet integral models keep those validities. Fuzzy rule tables can be used to represent these attitudes. Therefore, the proposed model inherits the merits of both the Choquet integral model and the fuzzy rule table.

Abstract— *This paper examines a short-time estimation problem of an origin-destination (OD) matrix, where each element is a volume of vehicle flow between one of the OD pair of zones of a signalised junction. The estimation is based on the use of traffic measurements provided by video sensors and on the knowledge of the traffic lights. This data is subject to redundancy, imprecision and uncertainty. The main purpose of this paper is to obtain the best estimates of the OD matrix by modelling the data imperfection, using a two-step method. First, relationships between the observed data are built in real-time using High-Level Petri Nets. Due to the imperfection of data the system obtained is underdetermined and inconsistent. Second, the fuzzy sets theory is used to model this imperfection and to overcome the inconsistency of the system.*

Keywords— Fuzzy least squares, Fuzzy linear programming, Fuzzy modelling, Origin-destination matrix

1 Introduction

Knowledge about origins and destinations (OD) of vehicles in a road network is important in most transport systems. In the case of a junction, its mathematical representation is OD matrix $\mathbf{B}$, each element b_{ij} of which is a proportion of the flow of vehicles that come from entrance (origin) i and go to exit (destination) j. Such a proportion is called the *OD flow rate*. Since the OD matrix changes in time following the changes in traffic demand, the estimation period of the OD matrix has to be as short as possible. In particular, the period should be equal to a traffic light cycle (duration of green-amber-red sequence) when we deal with a signalised junction. At INRETS/GRETIA we use such a short-time estimation of the OD matrix as part of a diagnostic system for signalised junctions [1]. This system compares the impacts of different traffic control strategies expressed in terms of CO_2 and pollutant emissions.

The OD matrix is generally deduced from vehicle counts made on each entrance and each exit of the junction during a given time interval. These counts are usually provided by magnetic loops embedded in the road surfaces and sensitive to metallic masses. The estimation can be obtained from a conservation law of vehicles which is a set of relationships between exit and entrance flow counts. In general, when loops are installed on every entrance and exit of the junction, the estimation problem is underdetermined. Thus a solution is not unique and additional information such as a *prior* OD matrix is used to choose the OD matrix which corresponds best to the actual matrix. Some of the existing methods are based on the information minimisation principle [2], on maximisation of likelihood [3] or on Bayesian inference [4]. Other methods propose a recursive estimation of the OD matrix [5, 6]. Furthermore, the estimation problem can be represented as a constraint optimisation problem [7, 8]. Methods which use traffic lights are described in [9, 10].

This paper considers the problem of reconstituting the origins and destinations of vehicle flows crossing a signalised junction, at each traffic light cycle. OD flow volumes are estimated using traffic lights and traffic measurements from video cameras installed at the junction. These measurements, provided every second, are the vehicle counts made on each entrance and exit of the junction and the number of vehicles stopped at each inner section of the junction. The data is subject to redundancy, uncertainty and inaccuracy. Such an imperfection is linked to the reliability of video sensors, measurement conditions, traffic characteristics and drivers' behaviour.

In order to take into account all available information it is necessary to consider the nature and possible interdependence of the data. None of the cited methods takes into account the lake of imprecision of vehicle counts, the possible physical complexity of the junction and the traffic lights at the same time. Moreover they cannot be applied to the problem because the period of estimation is quite short.

The main purpose of this paper is to obtain the best estimates of the OD matrix by modelling the data imperfection, using a two-stage method. First, a conservation law of vehicles, which is represented by an inconsistent and underdetermined system of equations, is built by High-Level Petri Nets at each traffic light cycle. Second, the fuzzy sets theory is used to overcome the inconsistency of the system and to model the data imperfection. Three different approaches have been analysed to solve this system of equations: ordinary least squares, fuzzy least squares and fuzzy linear programming. A numerical study of the proposed methods has been done using the data collected in a real experimental junction fitted out with video cameras and a traffic light controller.

The rest of the paper is organised as follows. Section 2

ISBN: 978-989-95079-6-8

presents the problem and describes the real data. Sections 3 and 4 introduce the fundamental principles of High-Level Petri Nets and show how they are applied to model the OD flows through the experimental site. Section 5 proposes three methods for OD matrix estimation and the paper concludes by proposing further lines of research.

2 The problem

The experimental site is an isolated signalised junction of two double-lane roads situated in the south suburb of Paris (Fig. 1). The main road B-D which connects the suburbs to Paris has a high traffic volume, whereas the road A-C has lower traffic volume. Traffic lights control four incoming links and four inner zones. Note that right-turning vehicles use special lanes and are not taken into account in this study. Only eight OD flows are statistically significant: $AC, AD, BD, BB, CB, DB, DC, DD$.

Eight video cameras are installed at the junction in order to capture all the entrance and exit links and the inner zones. The location, height and angle of each camera depend on the geometry of the junction and are chosen to favour the measurement of space traffic parameters such as queue length on incoming links. The camera views are analysed in real time using image processing techniques developed at INRETS [11]. They provide several measurements every second:

- $\mathcal{X}_i(\tau)$ vehicle counts measured at the end of an entrance i at second τ ($i = 1, \ldots, n$),
- $\mathcal{Y}_j(\tau)$ number of vehicles that have passed through the beginning of the exit j at second τ ($j = 1, \ldots, m$),
- $\mathcal{Z}_k(\tau)$ number of stopped vehicles at inner zone k at second τ ($k = 1, \ldots, p$),

where n, m and p are the numbers of entrances, exits and inner zones respectively. Here, a *traffic light cycle* is a period of time between two sequential onsets of the red light on the main road B-D .

Many phenomena influence the quality measurement of traffic parameters. Traffic conditions (peak or off-peak periods) are the reason for many traffic count errors. If the traffic flow is heavy, the gaps between vehicles are small and it is difficult to distinguish these gaps on the video images. Thus the number of vehicles measured is lower than the actual number.

The characteristics of vehicles are also a source of measurement errors. High vehicles passing in front of camera will hide the smaller vehicles or the whole camera field, i.e. they will produce a *masking effect*. Two-wheeled vehicles are only seldom counted because they are small. The heterogeneous colours of vehicle roofs also add to the problem of detection.

Meteorological conditions inevitably have an influence on all types of traffic measurements and the video are blurred: the wind shakes the posts the cameras are fixed to, the sun's rays cause the reflections on the vehicle surfaces and camera lenses, rain, snow and fog obscure a camera field. Changes in brightness caused by the position of the sun, clouds and headlights at night also determine the reliability of the measurements.

Let $x_i(c)$ be the flow volume at entrance i during a traffic light cycle c and $y_j(c)$ be the flow volume which entered the junction during cycle c and leaves it by exit j. *OD flow rate*

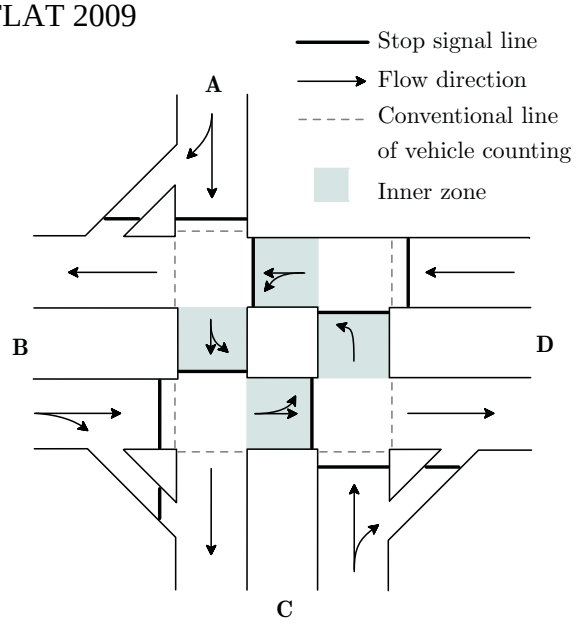

Figure 1: The experimental junction

b_{ij} is the proportion of the flow of vehicles that come from entrance i and go to exit j. The problem is to estimate OD flow rates b_{ij} ($\forall i \in [\![1, n]\!], \forall j \in [\![1, m]\!]$) at the end of each traffic light cycle c, such that

$$y_j(c) = \sum_{i=1}^{n} b_{ij}(c) x_i(c), \tag{1a}$$

$$x_i(c) b_{ij}(c) \geq z_{kij}(c) \quad \forall k \text{ s.t. } \delta_{kij} = 1, \tag{1b}$$

$$\sum_{j=1}^{m} b_{ij}(c) = 1, \tag{1c}$$

$$b_{ij}(c) \geq 0, \tag{1d}$$

where $z_{kij}(c)$ is the number of vehicles which cross the junction from i to j and stop at inner zone k during cycle c, $\delta_{kij} = 1$ if OD flow from i to j can pass through inner zone k and is 0 otherwise. For a given cycle c the value of variable $x_i(c)$ can be obtained from instantaneous vehicle counts

$$x_i(c) = \sum_{\tau=1}^{\mathcal{G}_i(c)} \mathcal{X}_i(\tau),$$

where $\mathcal{G}_i(c)$ is a duration of the green light of cycle c in entrance i. The values of $y_j(c)$ and $z_{kij}(c)$ cannot be obtained directly from traffic measurements, because it is impossible to know the period of time when the vehicle flow $x_i(c)$ leaves the junction or stops at inner zones.

This paper proposes a method to obtain the values of $y_j(c)$ and $z_{kij}(c)$ from $\mathcal{Y}_j(\tau)$ and $\mathcal{Z}_k(\tau)$ respectively and then to estimate the OD flow rates. First, a tool for vehicle flow segmentation is built via two High-Level Petri Nets (HLPN). The first net indicates the set of vehicle flows which may be present in each zone at any given second. It makes possible to associate these flows to the measurements taken in the corresponding zones and provides the beginnings of the flows. The second net provides the ends of the flows. For a given cycle we thus know the duration of the presence of the flows in each zone

ISBN: 978-989-95079-6-8

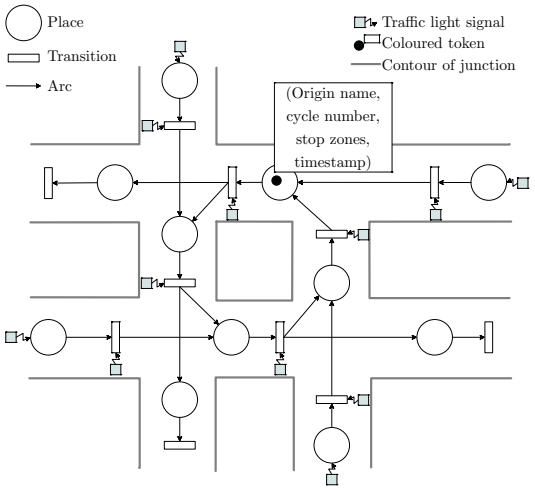

Figure 2: High Level Petri Net 1

and can collect the corresponding measurements. A consistent underdetermined system of equations, whose unknowns are the OD flow rates, can thus be built dynamically and solved at each traffic light cycle.

3 Fundamentals of High-Level Petri Nets

A High-Level Petri Net (HLPN) is a graphical and mathematical tool used to model discrete-event systems [12, 13]. In this paper, the HLPN is a classical Petri Net [14] complemented by the notions of time and colour. In graphic representation, an HLPN is a directed graph composed of two kinds of nodes: *places*, drawn by circles, and *transitions* represented as bars. The arcs connect either a place to a transition or, inversely, a transition to a place. A place may be *marked* by coloured *tokens* endowed with timestamps and characterises the system state. A transition represent an event that can change the state of the system modelled. The set of input and output places of a transition is also interpreted as a set of pre- and post-conditions of an event. When the event occurs the transition is *enabled* and the marking of input and output places changes. Thereby, the dynamic behaviour of the system is expressed by means of time-varying marking.

A 7-tuple $N = (\Sigma, \mathcal{P}, \mathcal{T}, \mathcal{A}, \mathcal{C}, \mathcal{W}, \mathcal{F})$ is a formal representation of HLPN, where:

- Σ is a finite non-empty colour set,
- $\mathcal{P}$ and $\mathcal{T}$ are the finite sets of places and transitions respectively, such that $\mathcal{P} \cap \mathcal{T} = \emptyset$ and $\mathcal{P} \cup \mathcal{T} \neq \emptyset$,
- $\mathcal{A} \subset (\mathcal{P} \times \mathcal{T}) \cup (\mathcal{T} \times \mathcal{P})$ is the finite set of arcs,
- $\mathcal{C} : \mathcal{P} \rightarrow 2^{\Sigma}$ is a *colour function* which associates a set of colours to a place,
- $\mathcal{W} : \mathcal{A} \rightarrow 2^{\Sigma}$ is an *arc function*.
- $\mathcal{F}$ is a delay associated to an arc.

A token is represented by a triple (p, s, θ), where $p \in \mathcal{P}$ is the place marked by the token, $s \subseteq \mathcal{C}(p)$ is a colour set which describes the system state in p, called *colour*, and θ is the time at which the token becomes available and the system state changes, called *timestamp*. Marking $\mathcal{M}(p, \tau)$ of place $p \in \mathcal{P}$ at time τ is a multiset represented by the pair $(S, \mathbf{n})$ where S is the set of colours of tokens arrived in p at $\tau = \theta$ and $\mathbf{n}$ is the vector every element of which is the number of occurrences of the token's colour s in set S.

Function $\mathcal{W}(p, t)$, corresponding to the arc from output place p to t, is a multiset of colours that are elements of the set $\mathcal{C}(p)$. The function $\mathcal{W}(t, p)$ is defined similarly.

Transition $t \in \mathcal{T}$ is enabled if $\mathcal{M}(p, \tau) \supseteq \mathcal{W}(p, t)$. It removes $\mathcal{W}(p, t)$ tokens from each of its input places p of t and adds $\mathcal{W}(t, p)$ tokens to its output places p with delay $\mathcal{F}(t, p)$ associated to an arc from t to p.

4 Modelling the traffic flows crossing a signalised junction

In this paper two HLPNs are used to model and segment the OD flows of vehicles crossing the junction in order to built the vehicle conservation law in a dynamic way. In the first net, a place stands for a zone of the experimental junction (Fig. 2). A token in a place is represented by a colour set $s = (s_1, s_2, s_3)$, where $s1 \in \{A, B, C, D\}$ is the name of flow origin, $s2 \in \mathbb{N}$ is a cycle number and $s3$ is a set of stop zones. In addition, it has a timestamp θ. A token in place p means the possible presence of a flow of origin $s1$ in the zone corresponding to p. Some transitions are related to the change of traffic lights in entrances and inner zones, other transitions represent the flow departures. An arc function $\mathcal{W}(t, p)$ is defined over a set of colours $s1$ representing the origins of the flows that pass through this arc. Delay $\mathcal{F}(t, p)$ is an average vehicle travel time between two successive zones of the junction corresponding to the input and output places of transition t.

The rules for changing colours of tokens, enabling transitions and marking places are defined as follows. During the green light at entrance i of the junction, the corresponding place is marked by one token with colour $s = (s1, s2, s3)$, $s_3 = \emptyset$, every second. Transition t associated to entrance i becomes enabled and the token is transmitted to output places of t. The transition associated with an inner traffic light is enabled if its input place contains at least one token and the corresponding traffic light is green. The enabled transition transmits the token downstream according to $\mathcal{W}(t, p)$ and $\mathcal{F}(t, p)$. If the light in inner zone k is red, tokens are stacked in the corresponding place. Their colours are changed by adding the name of inner zone k to the colour set s_3. At the beginning of the green light these tokens are shifted to the exit place p with predefined delay $\mathcal{F}(t, p)$. The transition related to the exit of junction is enabled when each of its input places contains at least one token.

Marking $\mathcal{M}(p, \tau)$ of place p characterizes a set of entrance flows that can be present at time τ in a junction zone corresponding to p. When the marking of p does not change during certain period of time $\Delta\tau$, all measurements taken at the corresponding zone during $\Delta\tau$ are associated to the set of flows. Thus, for a given cycle c, each exit flow $y_j(c)$ can be seg-

ISBN: 978-989-95079-6-8

mented into L_j vehicle platoons, such that

$$y_j^l(c) = \sum_{\tau \in \Delta\tau_l(c)} \mathcal{Y}_j(\tau) \qquad \forall l \in [\![1, L_j(c)]\!],$$

$$z_{kij}^l(c) = \max_{\tau \in \mathcal{R}_k(c)} \mathcal{Z}_k(\tau)\delta_{kij} \quad \begin{array}{l} \forall l \in [\![1, L_j(c)]\!], \\ \forall i \in \mathcal{M}(p, \Delta\tau_l), \\ \forall k \text{ s.t. } \delta_{kij} = 1, \end{array}$$

where $\Delta\tau_l(c)$ is a period of time during which platoon l has left the junction, $z_{kij}^l(c)$ is a maximum number of vehicles that belong to platoon l and have stopped at inner zone k, $\mathcal{R}_k(c)$ is a duration of red light in inner zone k, δ_{kij} indicates if zone k is situated between OD pair of zones (i, j), $\mathcal{M}(p, \Delta\tau_l)$ is a marking of place $p \in \mathcal{P}$ corresponding to exit j. The number of platoons $L_j(c)$ depends on the number of entrances of the junction, and on traffic volume and traffic light command.

Note that the first occurrence of token $(p, \{s1, s2, s3\}, \theta)$ denotes that the beginning of the flow with origin $s1$ crosses the zone corresponding to place p. The ends of the flows are provided by the second HLPN, which has the identical topology and the same representation of places and transitions as the first HLPN. However, the meaning of the tokens is different. A token stands for the end of a flow and is represented by a set of two colours without a timestamp: the name of flow origin $s1 \in \{A, B, C, D\}$ and a cycle number $s2 \in \mathbb{N}$.

The onsets of the beginning and the end of a flow in place p allow us to determine the duration of the flow presence in zone related to p. Thus we can collect the measurements made in this zone and, at each cycle c, can built the following set of equations

$$y_j^l = \sum_{i \in \mathcal{M}(p_j, \Delta\tau_l)} b_{ij}^l x_i \qquad \forall j \in [\![1, m]\!], \forall l \in [\![1, L_j]\!], \quad (2a)$$

$$x_i b_{ij}^l \geq z_{kij}^l \quad \begin{array}{l} \forall j \in [\![1, m]\!], \forall l \in [\![1, L_j]\!], \\ \forall i \in \mathcal{M}(p_j, \Delta\tau_l), \\ \forall k \text{ s.t. } \delta_{kij} = 1, \end{array}, \quad (2b)$$

$$\sum_{j,l} b_{ij}^l = 1 \qquad \forall i \in [\![1, n]\!], \quad (2c)$$

$$b_{ij}^l \geq 0 \quad \begin{array}{l} \forall j \in [\![1, m]\!], \forall l \in [\![1, L_j]\!], \\ i \in \mathcal{M}(p_j, \Delta\tau_l), \end{array} \quad (2d)$$

where the cycle c has been omitted to simplify the notations.

Let J and K be the numbers of constraints (2a) and (2b) respectively, and I be the number of unknowns b_{ij}^l, such that

$$\begin{aligned} J &= \sum_{j=1}^{m} jL_j, \\ K &= \sum_{j=1}^{m} \sum_{l=1}^{L_j} \sum_{i \in \mathcal{M}(p_j, \tau_l)} \sum_{k=1}^{p} \delta_{kij}, \\ I &= \sum_{j=1}^{m} \sum_{l=1}^{L_j} \sum_{i \in \mathcal{M}(p_j, \tau_l)} i. \end{aligned}$$

Since in general $I \geq J$ (in this paper $I \approx 10$), the obtained system of equations (2a) is underdetermined.

5 OD matrix estimation

The estimation problem of OD flow rates b_{ij}^l from the relationship (2a) can be viewed as an estimation of coefficients of the regression model

$$\mathbf{y} = \mathbf{X_1 b}, \quad (3)$$

where $\mathbf{y}$ is a vector composed of J output variables y_j^l, $\mathbf{b}$ is a vector containing the I unknowns b_{ij}^l, $\mathbf{X_1}$ is an $J \times I$ matrix rearranged in such a way that (2a) corresponds to (3).

The elements of model (3) must satisfy the constraints:

$$\mathbf{X_2 b} \geq \mathbf{z}, \quad (4a)$$

$$\mathbf{I b} = \mathbb{1}, \quad (4b)$$

$$\mathbf{b} \geq 0, \quad (4c)$$

where $\mathbf{z}$ is a vector composed of K variables z_{ijk}^l, $\mathbf{X_2}$ is an $K \times I$ matrix built so that (2b) is equal to (4a), $\mathbf{I}$ is an indicator $n \times I$ matrix organised in such a manner that (4b) is equivalent to (2c) and $\mathbb{1}$ is an identity n-vector.

Considering $\mathbf{b}$ to be an m-vector of crisp elements, three situations are studied in this section of the paper:

A) values of $\mathbf{X}_1$, $\mathbf{X}_2$, $\mathbf{y}$ and $\mathbf{z}$ are crisp

B) values of $\mathbf{X}_1$, $\mathbf{X}_2$, $\mathbf{y}$ and $\mathbf{z}$ are fuzzy

C) values of $\mathbf{X}_1$, $\mathbf{X}_2$, $\mathbf{y}$ and $\mathbf{z}$ are crisp, relationships (3) and (4a) are fuzzy, where the strict mathematical relations are replaced by fuzzy equivalents $\lessapprox$ and $\gtrapprox$ that are read "essentially smaller or equal to" and "essentially greater than or equal to".

In the first case, we use the least squares method to estimate the crisp regression coefficients $\mathbf{b}$. The fuzzy least squares (FLS) model based on commonly used Diamond ρ_2-metric [15] has been applied to the second situation. For the last case, we formulate a fuzzy linear programming problem (FLP) following the approach proposed by Zimmernann [16]. We present in the sequel the three methods and their results on our application.

5.1 Least squares method

Let the input and output variables $\mathbf{X}_1$ and $\mathbf{y}$ of the regression model (3) be non-negative crisp numbers. The unknown coefficients $\mathbf{b}$ of the model and the elements of $\mathbf{X}_2$ and $\mathbf{z}$ are also considered to be crisp. A first approach to estimate $\mathbf{b}$ is to use a least squares method. To insure the existence of feasible solutions, we introduce slack variables, e_i ($\forall i = 1, \ldots, K$), and we propose to solve the following problem:

$$\min_{\mathbf{b},\mathbf{e}} \| \mathbf{y} - \mathbf{X_1 b} \|^2 + \sum_{i=1}^{K} e_i \quad (5)$$

subject to

$$\begin{cases} \mathbf{X_2 b} + \mathbf{e} \geq \mathbf{z}, \\ \mathbf{I b} = \mathbb{1}, \\ \mathbf{b} \geq 0, \\ \mathbf{e} \geq 0. \end{cases} \quad (6)$$

5.2 Fuzzy least squares method

To take into account model errors and the inherent imprecision of data measurements, we choose to represent the input and output variables of the regression model (3) by triangular fuzzy numbers $\tilde{\mathbf{X}}_1 = (\underline{\mathbf{X}}_1, \mathbf{X}_1^m, \overline{\mathbf{X}}_1)$, $\tilde{\mathbf{y}} = (\underline{\mathbf{y}}, \mathbf{y}^m, \overline{\mathbf{y}})$ and

ISBN: 978-989-95079-6-8

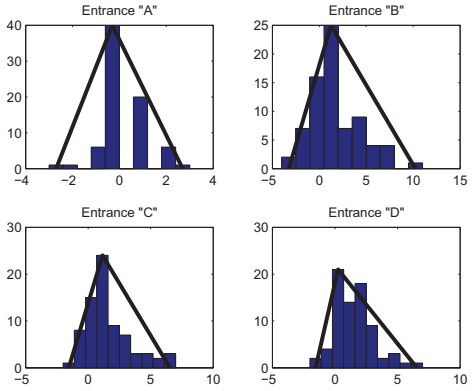

Figure 3: Empirical distributions of error counts for the entrances of the junction

$\tilde{\mathbf{z}} = (\underline{\mathbf{z}}, \mathbf{z}^m, \overline{\mathbf{z}})$, where $[\underline{a}, \overline{a}]$ is the support and a^m is the mode of fuzzy number $\tilde{a}$. The form of fuzzy numbers $\tilde{\mathbf{X}}_1$ was derived from empirical distributions of the error counts as shown in Fig. 3. In most cases, counts of vehicles at the entrances are smaller than the true value of $\mathbf{X}_1$. The fuzzy number $\tilde{\mathbf{X}}_2$ is determined similarly to $\tilde{\mathbf{X}}_1$. Since there is no available histograms of error counts for $\mathbf{y}$ and $\mathbf{z}$, the fuzzy numbers $\tilde{\mathbf{y}}$ and $\tilde{\mathbf{z}}$ are supposed to be symmetrical with the spreads chosen experimentally. Note that $\underline{\mathbf{X}}_1, \underline{\mathbf{X}}_2, \underline{\mathbf{y}}, \underline{\mathbf{z}} \in \mathbb{R}^+$ because of the nature of the data.

According to the fuzzy least squares (FLS) method proposed by Diamond [15, 17] and supposing the unknown coefficients $\mathbf{b}$ to be crisp, the following minimisation problem is written:

$$\min_{\mathbf{b}} \left(\| \underline{\mathbf{y}} - \underline{\mathbf{X}}_\mathbf{1}\mathbf{b} \|^2 + \| \mathbf{y}^m - \mathbf{X}_1^m\mathbf{b} \|^2 + \right. \\ \left. + \| \overline{\mathbf{y}} - \overline{\mathbf{X}}_\mathbf{1}\mathbf{b} \|^2 \right) \quad (7)$$

subject to

$$\begin{cases} \overline{\mathbf{X}}_\mathbf{2}\mathbf{b} \geq \underline{\mathbf{z}}, \\ \mathbf{I}\mathbf{b} = \mathbb{1}, \\ \mathbf{b} \geq 0. \end{cases} \quad (8)$$

Note that the first constraint in (8) is the least conservative translation of the strong relation (4a).

5.3 Fuzzy linear programming approach

Another approach to estimate the OD flow rates is to model the constraints (3) and (4a) by fuzzy sets. Assuming that the values of $\mathbf{X}_1$, $\mathbf{X}_2$, $\mathbf{y}$ and $\mathbf{z}$ are strict numbers, we consider the estimation problem of $\mathbf{b}$ that satisfies:

$$\mathbf{X_1 b} \gtrsim \mathbf{y} \quad -\mathbf{X_1 b} \gtrsim -\mathbf{y}, \quad (9a)$$
$$\mathbf{X_2 b} \gtrsim \mathbf{z}, \quad (9b)$$
$$\mathbf{I b} = \mathbb{1}, \quad (9c)$$
$$\mathbf{b} \geq 0, \quad (9d)$$

where the sign $\gtrsim$ means that we accept a small violation of the strict relation $\geq$ in a sense that is described below..

Denoting

$$\mathbf{H} = (-\mathbf{X}_1, \mathbf{X}_1, -\mathbf{X}_2)^\top,$$
$$\mathbf{h} = (-\mathbf{y}, \mathbf{y}, -\mathbf{z})^\top,$$

we write (9a)-(9b) as

$$\mathbf{H b} \lesssim \mathbf{h} \quad (10)$$

Each row i of (10) is assumed to be a fuzzy set with a membership function $\mu_i(\mathbf{b})$:

$$\mu_i(\mathbf{b}) = \begin{cases} 1 & H_i\mathbf{b} \leq h_i \\ 1 - \frac{H_i\mathbf{b} - h_i}{\xi_i} & h_i < H_i\mathbf{b} \leq h_i + \xi_i \\ 0 & H_i\mathbf{b} > h_i + \xi_i \end{cases} \quad (11)$$

where each $\xi_i > 0$ is a given constant reflecting an acceptable degree of constraint violation, $i = 1, \ldots, 2J + K$. Here $\mu_i(\mathbf{b})$ is defined as the degree to which $\mathbf{b}$ satisfies the relationship i.

With respect to Bellman-Zadeh decision-making rule for fuzzy sets [18], the membership function of the fuzzy decision set $\tilde{B}$ is defined as follows

$$\mu_{\tilde{B}}(\mathbf{b}) = \min_i \left(\mu_i(\mathbf{b})\right) = \min_i \left(1 - \frac{H_i\mathbf{b} - h_i}{\xi_i}\right), \\ \forall i = 1, \ldots, 2J + K. \quad (12)$$

According to the symmetric FLP method proposed by Zimmermann [16, 19], the crisp optimal solution can be given by

$$\max_{\mathbf{b} \geq 0, \mathbf{I}\mathbf{b} = \mathbb{1}} \mu_{\tilde{B}}(\mathbf{b}) \quad (13)$$

which can be obtained by solving the following problem of linear programming:

$$\max_{\lambda, \mathbf{b}} \lambda \quad (14)$$

subject to

$$\begin{cases} \lambda < 1 - \frac{H_i\mathbf{b} - h_i}{\xi_i} & \forall i = 1, \ldots, 2J + K, \\ \mathbf{I}\mathbf{b} = \mathbb{1}, \\ \mathbf{b} \geq 0. \end{cases} \quad (15)$$

5.4 Results

These methods have been tested using the *raw data* collected at the experimental junction. The estimation is made on 25 consecutive traffic light cycles, equivalent to 30 minutes. In addition, the actual values of OD flow rates b_i^* ($\forall i = 1, \ldots, 8$), derived manually from video images, are available for all cycles.

Since the measure of the number of stopped vehicles is more accurate than the measure of exit flow volume, the following parameters of the FLS method where chosen: $\mathbf{y}^m - \underline{\mathbf{y}} = \overline{\mathbf{y}} - \mathbf{y}^m = 3$, $\mathbf{z}^m - \underline{\mathbf{z}} = \overline{\mathbf{z}} - \mathbf{z}^m = 2$. The acceptable degree of constraint violation ξ_i ($\forall i = 1, \ldots, 2J + K$) in FLP method has been fixed to 5 for constraints (9a) and to 3 for constraints (9b).

The estimation error has been calculated for the OD flow rates (Fig. 4): $E = \mathbf{b}\mathbf{X}^* - \mathbf{b}^*\mathbf{X}^*$, where $\mathbf{X}^*$ is a vector of actual vehicle counts at the entrances of the experimental junction. The best results are obtained with the FLS method for which the median error is almost zero for all OD flows. The results of the least squares method are less accurate than those of the FLS method. Surprisingly, the FLP method, although it seems to be a more natural fuzzy translation of the crisp initial problem, does not provide very good results. Note that the estimation error E of all methods is higher, if the flow volume is lower, like for the OD flows "AD" and "BB".

6 Conclusion and future lines of research

In this paper we have proposed a new short-time estimation method of the OD matrix for a signalised junction. We have built a model of the segmentation of traffic flows crossing the junction in order to draw up a vehicle conservation law, represented by a underdetermined system of equations, for each traffic light cycle. The model, made using High-Level Petri Nets, is based on the use of traffic lights.

Real traffic measurements collected at the real experimental junction are used to estimate the OD flow rates. The experimental comparison shows that a small gain is obtained when the data imprecision and uncertainty is taken into account using a fuzzy modelling. Among the two proposed fuzzy approaches, the fuzzy least squares yields the most accurate results. In spite of the important imprecision of the real data, the first results are very encouraging to continue the research on improvement of the estimation accuracy.

The main future line of research is to fuzzify the token timestamps of the first HLPN in order to model the temporal imprecision of data measurements. The application of our method should be also extended to a sequence of junctions.

Classification with reject options in a logical framework: a fuzzy residual implication approach

Hoel Le Capitaine Carl Frélicot

MIA Laboratory, University of La Rochelle
La Rochelle, France
Emails: {hoel.le_capitaine, carl.frelicot}@univ-lr.fr

Abstract— *In many classification problems, overlapping classes and outliers can significantly decrease a classifier performance. In this paper, we introduce the possibility of a given classifier to reject patterns either for ambiguity or for distance. From a set of typicality degrees for a pattern to be classified, we propose to use fuzzy implications to quantify the similarity of the degrees. A class-selective scheme based on this new family is presented, and experimental results showing the efficiency of the proposed algorithm are given.*

Keywords— Ambiguity measures, Dombi and Hamacher implications, fuzzy r-implications, pattern classification, reject options

1 Introduction

Usual classification of objects, or patterns, consists in assigning incoming samples to one class belonging to a set of known ones. Since classes may overlap in the feature space and all of them do not appear during the learning step of most real classification problems, some samples may have to be not classified but rejected. In practice, two situations can lead to rejection, either the incoming sample could belong to unknown class(es) (*distance rejection*) or it should be assigned to several classes (*ambiguity rejection*) [1]. In this paper, we focus our attention on this latter situation. Initially introduced by Chow [2], it consists in rejecting the most unreliable patterns that have a low posterior probability, or more generally a low membership degree value, to its closest class. Such a reject classification rule is optimal if posterior probabilities are estimated without error, unfortunately this is not the case in practice.

We investigate some new measures that aim at quantifying to what extent such a pattern is ambiguous from its membership degrees, or more generally from its multi-class classifier soft outputs, using fuzzy implications. These measures assess the relationships between membership values with various combination of triangular norm operators (t-norms for short, see [3] for an overview).

The remainder of this paper is organized as follows. In section 2, we start by presenting distance-based class models that we will use in the sequel, and then discuss about standard approaches to pattern rejection. Next, we give a brief recall on some basic definitions of triangular norms and fuzzy residual implications, as well as some new parametrical implications (section 3). Section 4 is devoted to the proposal of using implications as ambiguity measures. In section 5, an experimental evaluation and comparisons to well known class-selective pattern recognition schemes are provided. We finally conclude and give some perspectives in section 6.

2 Classification with reject options

2.1 Classification

Let $\mathbf{x}$ be a pattern described by a p (real) features and let $\Omega = \{\omega_1, \cdots, \omega_c\}$ be a set of classes of cardinality c. The objective of classification is to assign any pattern $\mathbf{x} \in \mathbb{R}^p$ to one of the c classes of Ω. It generally consists of two steps L (*labeling*) and H (*hardening*):

- $L : \mathbf{x} \mapsto \mathbf{u}(\mathbf{x}) = {}^t(u_1(\mathbf{x}), \ldots, u_c(\mathbf{x})) \in \mathcal{L}_{\bullet c}$
- $H : \mathbf{u}(\mathbf{x}) \mapsto \mathbf{h}(\mathbf{x}) = {}^t(h_1(\mathbf{x}), \ldots, h_c(\mathbf{x})) \in \mathcal{L}_{hc}$.

where $\mathcal{L}_{hc} = \{\mathbf{h}(\mathbf{x}) \in \mathcal{L}_{fc} : h_i(\mathbf{x}) \in \{0,1\}\}$ and $\mathcal{L}_{\bullet c}$ depends on the mathematical framework the classifier relies on, e.g. $\mathcal{L}_{pc} = [0,1]^c$ for degrees of typicality or $\mathcal{L}_{fc} = \{\mathbf{u}(\mathbf{x}) \in \mathcal{L}_{pc} : \sum_{i=1}^{c} u_i(\mathbf{x}) = 1\}$ for posterior probabilities and membership degrees. Posterior probabilities can be obtained either from (known) class-conditional densities whose parameters are estimated using a learning set X of patterns, i.e. patterns for which the assignment is known, or from class-density estimates using the classes of their neighbors in X. However, for high dimensional feature spaces, many patterns are required to perform good class-density estimates (curse of dimensionality). When the learning set is small, distances to prototypes of each class are used, e.g.

$$d^2(\mathbf{x}, \mathbf{v}_i) = (\mathbf{x} - \mathbf{v}_i)^t \Sigma_i^{-1} (\mathbf{x} - \mathbf{v}_i) \tag{1}$$

where $\mathbf{v}_i$ and Σ_i are the mean vector and covariance matrix of the class ω_i estimated from X. In order to have a common scaling, label values are often obtained in the unit interval, e.g.

$$u_i(\mathbf{x}) = \frac{\alpha_i}{\alpha_i + d^2(\mathbf{x}, \mathbf{v}_i)} \tag{2}$$

where α_i are user-defined parameters.

We focus on the $H-$step because it is in charge of the classification. This step often reduces to the class of maximum label value selection, resulting in an exclusive classification rule which is not efficient in practice because it supposes that Ω is exhaustively defined (closed-world assumption) and classes do not overlap (separability assumption). Such untrue assumptions can lead to very undesired decisions. In many real applications, it is more convenient to with-hold making a decision than making a wrong assignment, e.g. in medical diagnosis where a false negative outcome can be much more costly than a false positive. Reject options have been proposed to overcome these difficulties and to reduce misclassification risk. The first one, called *distance rejection* [1], is dedicated

ISBN: 978-989-95079-6-8

to outlying patterns. If $\mathbf{x}$ is far from all the class prototypes, this option allows to assign it to no class. The second one, called *ambiguity rejection*, allows to assign inlying patterns to several or all classes [2, 4]. If $\mathbf{x}$ is close to two or more class prototypes, it is associated with the corresponding classes. Including reject options leads to partition the feature space into as many regions as subsets of classes, i.e. at most 2^c ones, to which a pattern can be assigned. Formally, it consists in modifying H such that $\mathbf{h}(\mathbf{x})$ can take values in the set of vertices of the unit hypercube $\mathcal{L}_{hc}^c = \{0,1\}^c$ instead of the exclusive subset $\mathcal{L}_{hc} \subset \mathcal{L}_{hc}^c$. Different strategies can be adopted to handle these options at hand, but they all lead to a three types decision system: distance rejection when $\mathbf{h}(\mathbf{x}) = {}^t(0,\ldots,0) = \underline{0}$, exclusive classification when $\mathbf{h}(\mathbf{x}) \in \mathcal{L}_{hc}$, ambiguity rejection when $\mathbf{h}(\mathbf{x}) \in \mathcal{L}_{hc}^c \backslash \{\mathcal{L}_{hc} \cup \underline{0}\}$. The resulting classification rule is then a matter of selecting the appropriate number of classes varying from zero (distance rejection) to c (total ambiguity rejection).

2.2 Usual reject schemes

Since the work by Chow [2], many rejection schemes have been proposed. In its general form, a class-selective procedure is defined by

$$n^\star(\mathbf{x},t) = \min_{k\in[1,c]} \{k : \mathcal{A}_k(\mathbf{x}) \leq t\} \tag{3}$$

where $\mathcal{A}_k$ is a given ambiguity measure on membership degrees, $n^\star(\mathbf{x},t)$ is the number of selected classes for the pattern $\mathbf{x}$ to be classified, and t is a user-defined threshold which can be class dependent (e.g. t_k). This threshold can be set conditionally to cost functions relative to error, reject and correct classification rates. Propositions from the literature mainly consist in new definitions of ambiguity measures $\mathcal{A}_k$. For Chow, $\mathcal{A}_k$ was one minus the maximum value of the membership degrees. In the paper by Ha [4], the second highest value was tested to decide wether one or several classes are selected. Since this scheme is leading to unnatural decisions, Horiuchi [5] proposed a new measure defined by the difference of the membership degrees which is actually a disambiguity measure. In [6], Frélicot proposed to use the ratio of membership degrees. As usual, we use the convention that if $\mathcal{A}_k(x) > t$ for all k, then we set $n^\star(\mathbf{x},t) = c$. Table 1 summarizes the existing ambiguity measures used for pattern rejection, where the membership degrees are assumed to be sorted in decreasing order for writing convenience, i.e. $u_1(\mathbf{x}) \geq \cdots \geq u_c(\mathbf{x})$.

Table 1: Existing ambiguity measures related to Eq. (3).

Scheme	**Ambiguity Measure** $\mathcal{A}_k(\mathbf{x})$
Chow [2]	$1 - u_1(\mathbf{x})$
Ha [4]	$u_{k+1}(\mathbf{x})$
Horiuchi [5]	$1 - (u_k(\mathbf{x}) - u_{k+1}(\mathbf{x}))$
Frélicot [6]	$u_{k+1}(\mathbf{x})/u_k(\mathbf{x})$

3 Fuzzy residual implications

3.1 Basic definitions

Let us recall basic definitions of fuzzy operators that will be used to combine the values of interest, i.e. the pattern class-degrees of typicality. Depending on properties, aggregation functions can be classified into several categories: conjunctive, disjunctive, compensatory, and so on. We restrict on conjunctive and disjunctive functions. By definition, the output of a conjunctive operator is lower or equal than the minimum value, whereas the output of a disjunctive operator is greater or equal than the maximum value. Beyond these operators, we choose to use the triangular norms because of their ability to generalize the logical AND and OR crisp operators to fuzzy sets, see [3] for a survey. Briefly, a triangular norm (or t-norm) is a binary operation on the unit interval $\top : [0,1]^2 \to [0,1]$ which is commutative, associative, non decreasing and has 1 for neutral element. Thus, a t-norm $\top$ is conjunctive and the minimum operator $\wedge$ is the greatest t-norm. Alternatively, a triangular conorm (or t-conorm) is the dual binary operation $\perp : [0,1]^2 \to [0,1]$ having the same properties except that its neutral element is 0. Thus, a t-conorm $\perp$ is disjunctive and the maximum operator $\vee$ is the lowest t-conorm. Typical examples of dual couples (t-norm, t-conorm) that will be used in the sequel are given in Table 2.

Table 2: Examples of dual couples, including parametrical ones.

Standard	$a\top_S b = \min(a,b)$ $a\perp_S b = \max(a,b)$
Algebraic	$a\top_A b = a\,b$ $a\perp_A b = a + b - a\,b$
Łukasiewicz	$a\top_L b = \max(a+b-1,0)$ $a\perp_L b = \min(a+b,1)$
Hamacher	$a\top_{H_\gamma} b = \frac{a\,b}{\gamma+(1-\gamma)\,(a+b-a\,b)}$ $a\perp_{H_\gamma} b = \frac{a+b+(\gamma-2)\,a\,b}{1+(\gamma-1)\,a\,b}$
Dombi	$a\top_{D_\gamma} b = \left(1+\left(\left(\frac{1-a}{a}\right)^\gamma + \left(\frac{1-b}{b}\right)^\gamma\right)^{1/\gamma}\right)^{-1}$ $a\perp_{D_\gamma} b = 1-\left(1+\left(\left(\frac{a}{1-a}\right)^\gamma + \left(\frac{b}{1-b}\right)^\gamma\right)^{1/\gamma}\right)^{-1}$

A fuzzy residual implication, denoted R-implication (or $\rightarrow$) is defined by:

$$I(a,b) = \sup_t \{t \in [0,1] : \top(a,t) \leq b\} \tag{4}$$

Note that if $\top$ is a left-continuous t-norm, the supremum operation can be substituted by maximum. If we use additive generating functions, i.e. a strictly decreasing function $f : [0,1] \to [0,+\infty]$ with $f(1) = 0$, and admitting an inverse (or pseudo-inverse) function f^{-1}, Eq. (4) can be written as

$$I(a,b) = \max(f^{-1}(f(b) - f(a)), 0) \tag{5}$$

because f is strictly monotonic. We generally speak about an implication function if I is non-increasing in the first variable, non-decreasing in the second variable and $I(0,0) = I(1,1) = 1$, and $I(1,0) = 0$, see [7] for a large survey on fuzzy implication functions. Within theses implications, the well-known *Gödel* and *Goguen* ones are respectively given by

$$I(a,b) = \begin{cases} 1 & \text{if } b \geq a \\ b & \text{if } b < a \end{cases} \tag{6}$$

and

$$I(a,b) = \begin{cases} 1 & \text{if } b \geq a \\ \frac{b}{a} & \text{if } b \leq a \end{cases} \tag{7}$$

ISBN: 978-989-95079-6-8

which are obtained with the minimum and algebraic (or product) triangular norms, respectively. In the sequel, we will assume for writing convenience that the fuzzy values are sorted in decreasing order, e.g. $a \geq b$.

3.2 Parametrical implications

Proposition 1. *Let $(\top_{H_\gamma})$, $\gamma \in [0, +\infty[$, be the family of Hamacher t-norms. The residual Hamacher implication is given by*

$$I_{H_\gamma}(a,b) = \begin{cases} 1 & \text{if } b \geq a \\ \frac{b\,(\gamma+a-\gamma a)}{b\,(\gamma+a-\gamma a)+a-b} & \text{if } b \leq a \end{cases} \tag{8}$$

Proof. By definition of R-implications (4), we can write $I_{H_\gamma}(a,b) = \sup_t\{t \in [0,1] : \top_{H_\gamma}(a,t) \leq b\}$. We also have $I_{H_\gamma}(a,b) = \max_t\{t \in [0,1] : \top_{H_\gamma}(a,t) \leq b\}$ because $\top_{H_\gamma}$ is a left-continuous t-norm. Then, solving

$$\frac{a\,t}{\gamma + (1-\gamma)\,(a+t-a\,t)} \leq b \tag{9}$$

gives

$$t \leq \frac{b\,(\gamma+a-\gamma a)}{b\,(\gamma+a-\gamma a)+a-b}. \tag{10}$$

Since $a \geq b$, it is easy to show that the right part of Eq. (10) is in $[0,1]$, hence we obtain Eq.(8). □

Proposition 2. *Let $(\top_{D_\gamma})$, $\gamma \in]0, +\infty[$, be the family of Dombi t-norms. The residual Dombi implication is given by*

$$I_{D_\gamma}(a,b) = \begin{cases} 1 & \text{if } b \geq a \\ \left(1 + \left(\left(\frac{1-b}{b}\right)^\gamma - \left(\frac{1-a}{a}\right)^\gamma\right)^{1/\gamma}\right)^{-1} & \text{if } b < a \end{cases} \tag{11}$$

Proof. $I_{D_\gamma}(a,b) = \sup_t\{t \in [0,1] : \top_{H_\gamma}(a,t) \leq b\}$ by (4). Since $\top_{D_\gamma}$ is a left-continuous t-norm, we can write $I_{D_\gamma}(a,b) = \max_t\{t \in [0,1] : \top_{D_\gamma}(a,t) \leq b\}$. Then, solving

$$\left(1 + \left(\left(\frac{1-a}{a}\right)^\gamma + \left(\frac{1-t}{t}\right)^\gamma\right)^{1/\gamma}\right)^{-1} \leq b \tag{12}$$

gives

$$t \leq \left(1 + \left(\left(\frac{1-b}{b}\right)^\gamma - \left(\frac{1-a}{a}\right)^\gamma\right)^{1/\gamma}\right)^{-1}. \tag{13}$$

Since, $a \geq b$, it is easy to show that $\left(\left(\frac{1-b}{b}\right)^\gamma - \left(\frac{1-a}{a}\right)^\gamma\right)^{1/\gamma} \geq 0$, hence the right part of Eq. (13) is in $[0,1]$ and (11) is obtained. □

Note that R-implications are mostly used in fuzzy inference systems, see [8] for a large overview on the use of parametrical R-implications in fuzzy rule based systems.

4 Some parametrical measures of ambiguity

In this section, the concept of similarity measure and its relationship with ambiguity measures are described. Then we propose to use fuzzy parametrical implications as new families of ambiguity measures to be used for pattern classification with reject options. The resulting class-selection algorithm (H-step) is presented and we finally discuss the choice of the parameter for parametrical implications with the help of numerical examples.

4.1 Proposition and properties

A similarity measure $\mathcal{S}$ generally satisfies the following properties:

(P1) $\mathcal{S}(a,b) = \mathcal{S}(b,a)$, *(symmetry)*

(P2) $\mathcal{S}(a,a) \geq \mathcal{S}(a,b)$, *(minimality)*

(P3) $\mathcal{S}(a,b) = 1 \Leftrightarrow a = b$, *(identity)*

However, the symmetry property (P1) is still subject to experimental investigation: if $\mathcal{S}(a,b)$ is the answer to the question *how is a similar to b?*, then, when making comparisons, subjects focus more on the feature a than on b. This corresponds to the notion of *saliency of a and b* [9]: if b is more salient than a, then a is more similar to b than vice versa, which is experimentally confirmed. Property (P2) is also open because it can be violated experimentally, see [9] for details.

There are several ways to deal with the comparison of fuzzy values, or fuzzy quantities. The first one is based on a broad class of measures of equality based on a distance measure which is specified for membership functions of fuzzy sets. This approach takes its roots from studies on how to measure the distance between two real functions and do not refer to any specific interpretation. The general form of a Minkowski r-metric is usually taken and leads to well known distance functions (Hamming, Euclidean, Chebyshev). A second way to compare fuzzy values comes from some basic set-theoretic considerations where union, intersection and complement are defined for fuzzy sets. Cardinal and possibility based measures belong to this category. In this paper, we focus on the third way to deal with fuzzy values comparison: the logical framework. Accordingly to [10], for a certain universe of discourse $\mathcal{D}$, the degree of equality of two fuzzy elements a and b can be defined by implications as follows:

$$(a \equiv b) = \frac{1}{2}\big((a \to b) \wedge (b \to a) + (\bar{a} \to \bar{b}) \wedge (\bar{b} \to \bar{a})\big) \tag{14}$$

where $\wedge$ stands for minimum, $\to$ is an implication and $\bar{a}$ is the strict negation $\bar{a} = 1 - a$.

Since 1 is the neutral element of t-norms, applying Eq. (4) with $a \geq b$ gives

$$(a \equiv b) = \frac{1}{2}\big((a \to b) + (\bar{b} \to \bar{a})\big). \tag{15}$$

A convenient way to define an ambiguity measure is to quantify to which extent two fuzzy membership degrees are similar, so that it is closely related to the problem of matching fuzzy quantities, or fuzzy sets similarity. So we propose to use fuzzy R-implications as generalized ambiguity measures.

ISBN: 978-989-95079-6-8

Given a set of c truth values assumed to be sorted in decreasing order, i.e. $u_1(\mathbf{x}) \geq \cdots \geq u_c(\mathbf{x})$, with no loss of generality, let us have two predicates ($\mathbf{x}$ *is* ω_i), with the truth value $u_i(\mathbf{x})$, and ($\mathbf{x}$ *is* ω_k), with the truth value $u_k(\mathbf{x})$. The truth value of the implication *if the pattern* $\mathbf{x}$ *is* ω_i*, then the pattern* $\mathbf{x}$ *is also* ω_j*,* $\forall j$ *varying from* $i+1$ *to* k is an ambiguity measure given by $I(u_i(\mathbf{x}), u_k(\mathbf{x}))$. By convention, we assume that the assignment of $\mathbf{x}$ to ω_i is more probable than the assignment of $\mathbf{x}$ to ω_k when using this implication because $u_i(\mathbf{x}) \geq u_k(\mathbf{x})$ and obviously we have $I(u_i(\mathbf{x}), u_{i+1}(\mathbf{x})) \geq I(u_i(\mathbf{x}), u_{k>i+1}(\mathbf{x}))$.

Proposition 3. *Given* $t \in [0,1]$*, the optimum cardinality of the generalized class-selective rejection rule is given by*

$$n^\star(\mathbf{x}, t) = \min_{k \in [1,c]} \left\{ k : I\Big(u_k(\mathbf{x}), u_{k+1}(\mathbf{x})\Big) \leq t \right\} \qquad (16)$$

with $u_1(\mathbf{x}) \geq \cdots \geq u_c(\mathbf{x})$*, and the convention* $u_{c+1}(\mathbf{x}) = 0$*.*

Since $I(a,0) = 0$ if $a \neq 0$, c classes will be selected if none were previously selected.

Property 1. *If we use the Standard triangular norm* min*, we obtain the Ha class-selective rejection scheme [4].*

Property 2. *If we use the Łukasiewicz triangular norm, we obtain the Horiuchi class-selective rejection scheme [5].*

Property 3. *If we use the Algebraic triangular norm, we obtain the Frélicot class-selective rejection scheme [6].*

Proofs are straightforward and will be given in a longer forthcoming paper. Note that modifying Eq.(16) such as

$$n^\star(\mathbf{x}, t) = \min_{k \in [0,c]} \left\{ k : I\Big(u_k(\mathbf{x}), u_{k+1}(\mathbf{x})\Big) \leq t \right\} \qquad (17)$$

with the convention $u_0(\mathbf{x}) = 1$ allows to select none of the classes, i.e. to proceed to distance rejection, since $I(1,a) = a$ whatever the triangular norm.
The resulting generalized pattern classification rule with reject options ($H-$step) is presented in Algorithm 1. It can be used to compare various schemes, depending on the choice of the triangular norm.

Algorithm 1: $H-$step classification algorithm.

Data: a vector of soft class-labels $\mathbf{u}(\mathbf{x}) \in \mathcal{L}_{pc}$ and a reject threshold t
Result: a vector of class-selective assignments $\mathbf{h}(\mathbf{x}) \in \mathcal{L}_{hc}^c$
begin
  set $\mathbf{h}(\mathbf{x})$ to $\underline{0}$
  find $n^\star(\mathbf{x}, t)$ − Eq.(16) or Eq.(17)
  foreach $j = 1 : n^\star(\mathbf{x}, t)$
  in decreasing order of $u_j(\mathbf{x})'s$ **do**
    set $h_j(\mathbf{x}) = 1$
  end
end

4.2 Discussion and examples

One of the main difficulties when using t-norms is to choose the dual couple and if needed to set the parameter value. Let us study how the choice of γ for Hamacher and Dombi implications modifies the resulting implication strength.
• *Hamacher*: increasing the value of γ will make two fuzzy values more similar because $I_{H_\gamma}(a,b) = ab/(a-b+ab)$ if $\gamma = 0$ while $\lim_{\gamma \to +\infty} I_{H_\gamma}(a,b) = 1$ whatever $(a,b) \in [0,1]^2$. Indeed, I_{H_γ} is non-decreasing with γ since

$$\frac{\partial I_{H_\gamma}}{\partial \gamma} = \frac{(b-ab)(a-b)}{(b(\gamma + a - \gamma a) + a - b)^2} \geq 0.$$

The influence of γ is much more significant for low values of a and b than for high ones because $b(\gamma + a - \gamma a)$ appears to be of order $b\,a$ (respectively $b\,(\gamma + a)$) for high (respectively low) values of a and b. It follows that if $\gamma_1 >> \gamma_2$, we have $\frac{\gamma_1}{\gamma_1+\varepsilon} >> \frac{\gamma_2}{\gamma_2+\varepsilon}$, so that large values of γ associated to low values of (a,b) will result in a high value of I_{H_γ}, see Table 3 for examples.

Table 3: Hamacher implications examples for $a = 0.9$, $b = 0.8$, $c = 0.1$ and $d = 0.05$.

γ	0	2	10
$I_{H_\gamma}(a,b)$	0.87	0.89	0.93
$I_{H_\gamma}(a,c)$	0.10	0.12	0.19
$I_{H_\gamma}(c,d)$	0.09	0.65	0.90

• *Dombi*: decreasing the value of γ will make two fuzzy values more similar because $\lim_{\gamma \to +\infty} I_{D_\gamma}(a,b) = b$ while $\lim_{\gamma \to 0} I_{D_\gamma}(a,b) = 1$ whatever $(a,b) \in [0,1]^2$. Analogously to Hamacher family, I_{D_γ} is non-increasing with γ since

$$\frac{\partial I_{D_\gamma}}{\partial \gamma} \leq 0.$$

Thus, decreasing γ for the Dombi family has the same impact as increasing γ for the Hamacher family, so that we expect the opposite tendency, see Table 4 for examples. The appropriate tuning of γ can be achieved using a gradient procedure, as in [11].

Table 4: Dombi implications examples for $a = 0.9$, $b = 0.8$, $c = 0.1$ and $d = 0.05$.

γ	0.5	2	10
$I_{D_\gamma}(a,b)$	0.97	0.81	0.80
$I_{D_\gamma}(a,c)$	0.12	0.10	0.10
$I_{D_\gamma}(c,d)$	0.35	0.06	0.05

The simple graphical example shown in Fig.1 illustrates how the different implications behave. The top-plot shows a one-dimensional dataset composed of two classes (□ and ×) described by a distance-based model (Eqs.(1-2)) with $\alpha_i = 1$ ($\forall i = 1, c$). In the middle, implication truth values for the standard, algebraic, and Łukasiewicz triangular norms, corresponding to Ha, Frélicot and Horiuchi class-selective schemes respectively, as well as Chow's scheme are shown. Truth values when using parametrical implications are shown in the bottom-plot. Observing the data points in the top-plot allows to obtain the bounds of intervals of x values where the classes do not overlap, therefore for which no misclassification should

ISBN: 978-989-95079-6-8

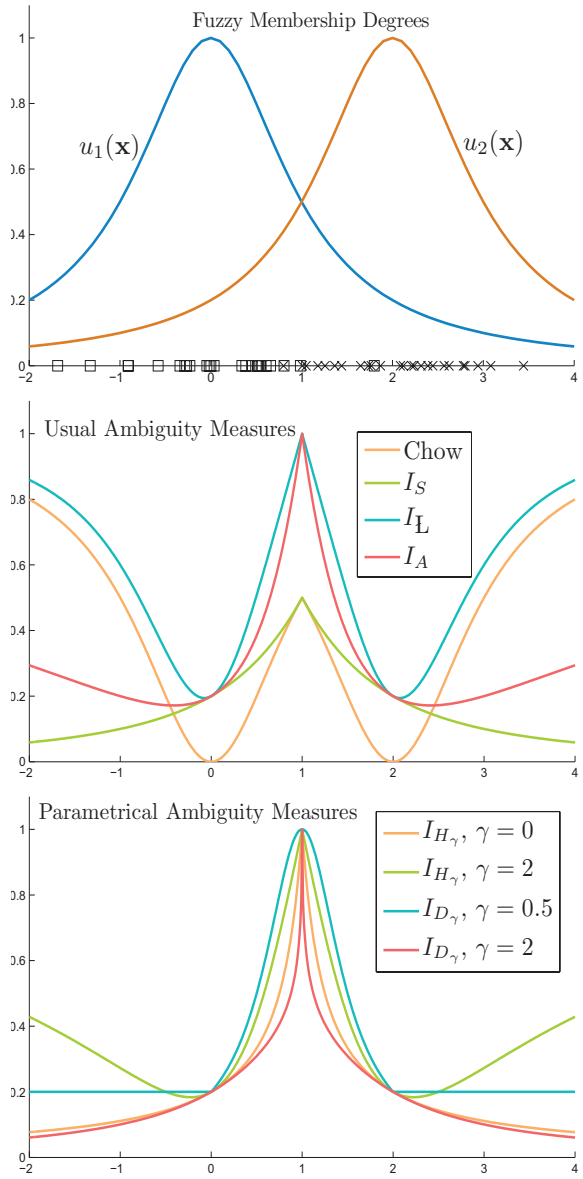

Figure 1: Original outputs using Eqs.(1-2) for two classes with normal distributions (*top*), implication truth values with usual triangular norms (*middle*) and implication truth values with Hamacher and Dombi families (*bottom*).

happen, here $\mathbf{x}_{low} \approx 0.8$ and $\mathbf{x}_{up} \approx 1.9$. Then, the corresponding $u_1(\mathbf{x}_{low})$ and $u_2(\mathbf{x}_{up})$ ordinate values can be used to set the classification threshold t. Then, referring to measures of ambiguity in the middle - and bottom - plots, the behaviour of the different schemes can be analyzed. In such a situation, Chow's and Horiuchi's (Łukasiewicz implication) schemes would lead to reject too many points in low density areas, while other schemes do not show these drawbacks. On the other hand, Ha's scheme (standard implication) would not allow to reject simultaneously highly ambiguous and outlying patterns, whereas schemes based on algebraic or parametrical implications do (provided an appropriate value for the parameter), so a better classification performance can be expected. One can also see in the bottom-plot that tuning the parameter allows to reject patterns for ambiguity as well as for distance (a higher value of γ for the Hamacher family and a lower value for the Dombi family) as pointed out in the discussion.

5 Experimental results

In this section, we report experiments carried out on both artificial and real benchmark datasets for which it is beneficial to introduce the ambiguity reject option because the classes overlap in the feature space. The proposed class-selective rejection scheme is compared to the usual rejection schemes presented in section 2. For additional comparison, results obtained using the two very recent classification rules proposed by Tax and Duin [12] called *Outlier-norm* and *Target-norm* are given, the former being especially designed for distance rejection. Note we did not detailed these (not usual) rules here because they do not rely on an ambiguity measure, therefore they cannot be derived using fuzzy R-implications, by contrast to the previous ones. In all cases, the $L-$step was performed using Eqs.(1-2) with $\alpha_i = 1$ $(\forall i = 1, c)$.

5.1 The datasets

Two synthetic datasets are used: D which contains 2000 points drawn from two normal seven-dimensional distributions of 1000 points each with means $\mathbf{v}_1 = {}^t(1 \;\; 0 \;\cdots\; 0)$ and $\mathbf{v}_2 = {}^t(-1 \;\; 0 \;\cdots\; 0)$, and equal covariance matrices $\Sigma_1 = \Sigma_2 = I$, and DH which consists of two overlapping gaussian classes with different covariance matrices according to the Highleyman distribution, each composed of 800 observations in $\mathbb{R}^2$, see [13]. Real datasets are taken from the UCI Machine Learning Repository [14]. The characteristics (number n of patterns, number p of features, number c of classes, degree of overlap) are reported in Table 5.

Table 5: The datasets and their characteristics.

Dataset	n	p	c	**Overlap**
D	2000	7	2	slight
DH	1600	2	2	very slight
Ionosphere	351	34	2	very strong
Forest	495411	10	2	moderate
Vowel	528	10	11	very slight
Digits	10992	16	10	very slight
Thyroid	215	5	3	very slight
Pima	768	9	2	strong
Statlog	6435	36	6	slight
Glass	214	9	6	moderate

5.2 Results

Table 6 shows the classification performance of the different rejection schemes obtained by a 10-fold cross-validation procedure on the different datasets. In all cases, the threshold t was set to reject 10% of the data, so that 90% is the best achievable correct classification rate performance, then the error rate is $(90 - \text{correct})\%$. The best results are indicated in bold. Note that there are no outliers in the datasets, so that a part of the rejected points are considered as outliers whereas they belong to classes.

It appears from these results that parametrical implications generally outperform usual rejection schemes as well as non usual ones (Outlier-norm, Target-norm), e.g. $I_{H_{\gamma=2}}$ and $I_{D_{\gamma=0.5}}$. As expected in the previous section, these schemes enable to reject both ambiguous and outlying patterns. Furthermore, the tradeoff to be found between a scheme which

does not reject outliers (Ha) and others which reject too much patterns (Chow, Horuichi) appears to favour the choice of implications based on a t-norm which is lower than $\top_S$ (the highest t-norm) and greater than $\top_L$, e.g. the algebraic or the parametrical implications (provided an appropriate value for γ). More generally, rejection schemes that take into account relationship between fuzzy membership degrees (Horiuchi, Frélicot, Hamacher, Dombi) perform better than all the others schemes we tested. Looking at the degrees of overlap, $I_{D_{\gamma=0.5}}$ (respectively $I_{H_{\gamma=2}}$) is more efficient for datasets presenting a slight/very slight (respectively strong/very strong) overlap.

6 Conclusion and perspectives

In this paper, a generalized class-selective rejection scheme based on a logical approach to pattern assignation is presented allowing to either reject only ambiguous patterns or ambiguous and outlying patterns. For this purpose, we propose to design a family of ambiguity measures based on fuzzy residual implication functions, which indicate to which extent a pattern should be assigned to $n^\star$ classes depending on its membership degrees from the truth value of the implication. These measures assess the relationships between membership values with various combination of triangular norm operators, including parametrical families. It is shown that the proposed scheme generalizes well-known ones of the literature on pattern classification with reject options. It appears from experiments on both synthetic and real datasets that using, as the basis for residual implication computation, triangular norms greater than the Łukasiewicz triangular norm and lower than the standard one, gives better classification performance. Furthermore, measures taking in consideration several membership degrees, so that interactions between classes are taken into account, also give better results.

A future work will consist in defining new class-selective rejection schemes based on other parametrical triangular families (Sklar, Frank, Yager and so on) and compare their classification performance. We also think that, depending on the context of the pattern recognition problem, other implications functions than the residual implication ones would be suitable. We plan to make an extensive study on the behavior of *S-implications* which are an immediate generalization of the usual boolean implication, *QL-implications* coming from quantum mechanic logic, and *D-implications* which are the contraposition with respect to a negation of QL-implications, see [7] for definitions.

Abstract— *This paper presents a new clustering algorithm ,which is based on fuzzy c-lines, can treat data with some errors. First, the tolerance is formulated and introduce into optimization problem of clustering. Next, the problem is solved using Karush-Kuhn-Tucker conditions. Last, the algorithm is constructed based on the results of solving the problem. Some numerical examples for the proposed method are shown.*

Keywords— Data with Tolerance, Fuzzy c-Lines, Fuzzy Clustering

1 Introduction

Fuzzy c-means (FCM) [1] is one of the well-known fuzzy clustering and many FCM variants have been proposed after FCM. In these variants, an algorithm allowing cluster prototypes to be linear varieties instead of points has been proposed [1]. This algorithm is called fuzzy c-varieties (FCV) and regarded as the combination of clustering and principal component analysis. If linear varieties of the prototypes are limited to one dimensional, FCV is called fuzzy c-lines(FCL).

In general, any data that is represented by numeric have some errors. In order to classify such data, an algorithm has been proposed by some of the authors [2]. This algorithm is called the FCM for data with tolerance (FCM-T). In FCM-T, the tolerance is regarded as another decision variable composing the optimization problem like membership grades and the cluster centers, and is determined as minimizing the objective function.

In this paper, on the analogy of the story from FCM to FCM-T, we propose fuzzy c-lines for data with tolerance (FCL-T).

The contents of this paper are the followings. In the second section, we define some notations and introduce FCM-T and FCL. In the third section, we propose FCL-T. In the fourth section, some numerical examples are shown. In the last section, we conclude this paper.

2 Preliminaries

In this section, we define some notations, introduce fuzzy c-lines (FCL), and also introduce fuzzy c-means with tolerance (FCM-T) derived from conventional fuzzy c-means (FCM). In the first subsection, we define some notations which are the data for clustering, the membership by which the each data belongs to the each cluster, the cluster prototypes of one dimensional linear manifold. In the second subsection, we introduce FCL, whose prototypes are one dimensional linear manifolds. In the third subsection, we define the tolerance for the data and the maximum tolerance for the data, and introduce FCM-T, which is the story that clustering algorithms were oriented for data with some errors.

2.1 Notations

In this subsection, we define some notations which are the data for clustering, the membership by which the each data belongs to the each cluster, the cluster prototypes of one dimensional linear manifold.

The data set $x = \{x_i \mid x_i \in \mathbf{R}^p, i \in \{1, \ldots, N\}\}$ is given. The membership by which x_i belongs to the j-th cluster is denoted by $u_{i,j}$ $(i \in \{1, \cdots, N\}, j \in \{1, \cdots, C\})$ and the set of $u_{i,j}$ is denoted by $u \in \mathbf{R}^{N \times C}$ called the partition matrix. The constraint for u is

$$\sum_{j=1}^{C} u_{i,j} = 1 \quad (0 \leq u_{i,j} \leq 1).$$

The cluster prototype set is denoted by $V = \{V_1, \cdots, V_C\}$, where

$$V_j = \{y_j \in \mathbf{R}^p \mid y_j = v_j + t_j s_j, t_j \in \mathbf{R}\}$$

with $v = \{v_j \mid v_j \in \mathbf{R}^p, j \in \{1, \ldots, C\}\}$ and $s = \{s_j \in \mathbf{R}^p \mid \|s_j\| = 1, j \in \{1, \cdots, C\}\}$.

2.2 Fuzzy c-Lines

In this subsection, we introduce FCL (FCV), whose prototypes are one dimensional linear manifolds.

FCL is the algorithm obtained by solving the following optimization problem:

$$\underset{u,v,s}{\text{minimize}}\, J_\ell(u, v, s) \tag{1}$$

$$\text{subject to} \sum_{j=1}^{C} u_{i,j} = 1, \quad \|s_j\| = 1, \tag{2}$$

where

$$J_\ell(u, v, s) = \sum_{i=1}^{N} \sum_{j=1}^{C} u_{i,j}^m \left(\|x_i - v_j\|^2 - ((x_i - v_j) s_{j,\ell})^2 \right). \tag{3}$$

The optimal solutions u, v and s are obtained by the following algorithm.

Algorithm 1 (FCL)

Step 1 *Give the number of clusters C and the fuzzifier parameter m. Set the initial values of v and s.*

Step 2 *Calculate u such that*

$$u_{i,j} = 1 / \sum_{k=1}^{C} \left(\frac{d_{i,j}}{d_{i,k}} \right)^{1/(m-1)}, \tag{4}$$

where

$$d_{i,j} = \|x_i - v_j\|^2 - ((x_i - v_j) s_{j,\ell})^2. \tag{5}$$

ISBN: 978-989-95079-6-8

Step 3 *Calculate v such that*

$$v_j = U_j^{-1} \sum_{i=1}^{N} u_{i,j}^m x_i, \tag{6}$$

where

$$U_j = \sum_{i=1}^{N} u_{i,j}^m. \tag{7}$$

Step 4 *Calculate s as the eigenvector corresponding to the maximal eigenvalue of the following matrix:*

$$\sum_{i=1}^{N} u_{i,j}^m (x_i - v_j)(x_i - v_j)^{\mathrm{T}}. \tag{8}$$

Step 5 *Check the stopping criterion for (u, v, s). If the criterion is not satisfied, go back to* Step 2.

2.3 Fuzzy c-Means for Data with Tolerance

In this subsection, we define the tolerance for the data and the maximum tolerance for the data, and introduce fuzzy c-means for data with tolerance (FCM-T) [2]. This algorithm is oriented toward data with error. The tolerance for the data x is denoted by $\varepsilon = \{\varepsilon_i \mid \varepsilon_i \in \mathbf{R}^p, i \in \{1, \ldots, N\}\}$. The maximum tolerance is denoted by $\kappa = \{\kappa_i \mid \kappa_i \in \mathbf{R}_+, i \in \{1, \ldots, N\}\}$.

FCM-T is the algorithm obtained by solving the following optimization problem:

$$\underset{u,\varepsilon,v}{\text{minimize}}\, J_{\mathrm{t}}(u, \varepsilon, v)$$

$$\text{subject to} \quad \begin{cases} \displaystyle\sum_{j=1}^{C} u_{i,j} = 1, \\ \|\varepsilon_i\|^2 \le \kappa_i^2 \quad (\kappa_i > 0), \end{cases}$$

where

$$J_{\mathrm{t}}(u, \varepsilon, v) = \sum_{i=1}^{N} \sum_{j=1}^{C} u_{i,j}^m \|x_i + \varepsilon_i - v_j\|^2. \tag{9}$$

The optimal solutions u, ε and v are obtained by the following algorithm.

Algorithm 2 (FCM-T)

Step 1 *Give the number of clusters C, the fuzzifier parameter m and the maximum tolerance set κ for data x. Set the initial values of ε and v.*

Step 2 *Calculate u such that*

$$u_{i,j} = 1 / \sum_{k=1}^{C} \left(\frac{d_{i,j}}{d_{i,k}} \right)^{1/(m-1)}, \tag{10}$$

where

$$d_{i,j} = \|x_i + \varepsilon_i - v_j\|^2. \tag{11}$$

Step 3 *Calculate ε such that*

$$\varepsilon_i = -\alpha_i \left(x_i - \sum_{j=1}^{C} u_{i,j}^m v_j \right), \tag{12}$$

where

$$\alpha_i = \min \left\{ \kappa_i \left\| x_i - \sum_{j=1}^{C} u_{i,j}^m v_j \right\|^{-1}, \left(\sum_{j=1}^{C} u_{i,j}^m \right)^{-1} \right\}. \tag{13}$$

Step 4 *Calculate v such that*

$$v_j = U_j^{-1} \sum_{i=1}^{N} u_{i,j}^m (x_i + \varepsilon_i), \tag{14}$$

where

$$U_j = \sum_{i=1}^{N} u_{i,j}^m. \tag{15}$$

Step 5 *Check the stopping criterion for (u, ε, v). If the criterion is not satisfied, go back to* Step 2.

If the maximal tolerance κ_i is set to zero, this algorithm is coincides with FCM without tolerance. This algorithm is executing FCM without tolerance for data moving within a region as shown in Fig. 1.

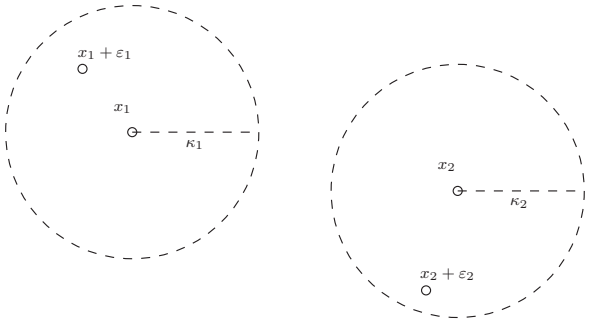

Figure 1: Data with Tolerance

3 Fuzzy c-Lines for Data with Tolerance

In this section, fuzzy c-lines for data with tolerance (FCL-T) is proposed. First, the tolerance is formulated and introduce into optimization problem of FCL. Next, the problem is solved using Karush-Kuhn-Tucker conditions. Last, the algorithm is constructed based on the results of solving the problem.

3.1 Optimization Problem and Its KKT conditions

In this subsection, a new optimization problem is proposed such that the tolerance is formulated and introduce into optimization problem of FCL, and its Karush-Kuhn-Tucker conditions are considered.

Let us consider the following optimization problem:

$$\underset{u,\varepsilon,v,s}{\text{minimize}}\, J_{\ell,\mathrm{t}}(u, \varepsilon, v, s)$$

$$\text{subject to} \quad \begin{cases} \displaystyle\sum_{j=1}^{C} u_{i,j} = 1, \\ \|s_j\| = 1, \\ \|\varepsilon_i\|^2 \le \kappa_i^2, \end{cases} \tag{16}$$

ISBN: 978-989-95079-6-8

where

$$J_{\ell,\mathrm{t}}(u,\varepsilon,v,s) = \sum_{i=1}^{N}\sum_{j=1}^{C} u_{i,j}^{m}\left(\|x_i+\varepsilon_i-v_j\|^2-((x_i+\varepsilon_i-v_j)s_j)^2\right). \tag{17}$$

Lagrange function of this problem $L_{\ell,\mathrm{t}}(u,\varepsilon,v,s)$ is described as below:

$$\begin{aligned} L_{\ell,\mathrm{t}}(u,\varepsilon,v,s) =& J_{\mathrm{s},\ell,\mathrm{t}}(u,\varepsilon,v,s) + \sum_{i=1}^{N}\gamma_i\left(\sum_{j=1}^{} u_{i,j}-1\right) \\ &+\sum_{j=1}^{C}\xi_j\left(s_j^{\mathrm{T}}s_j-1\right) \\ &+\sum_{i=1}^{N}\delta_i\left(\|\varepsilon_i\|^2-\kappa_i^2\right). \end{aligned} \tag{18}$$

where $\gamma = (\gamma_1,\cdots,\gamma_N)$, $\xi = (\xi_1,\cdots,\xi_C)$ and $\delta = (\delta_1,\cdots,\delta_N)$ are Karush-Kuhn-Tucker vectors. Karush-Kuhn-Tucker (KKT) conditions are described as below:

$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial u_{i,j}} =0, \tag{19}$$
$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial v_j} =0, \tag{20}$$
$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial s_j} =0, \tag{21}$$
$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial \varepsilon_i} =0, \tag{22}$$
$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial \gamma_i} =0, \tag{23}$$
$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial \xi_j} =0, \tag{24}$$
$$\frac{\partial L_{\ell,\mathrm{t}}}{\partial \delta_i} =0, \tag{25}$$
$$\delta_i\frac{\partial L_{\ell,\mathrm{t}}}{\partial \delta_i} =0, \tag{26}$$
$$\delta_i \geq 0. \tag{27}$$

3.2 Optimal Solution of $u_{i,j}$, v_j and s_j

In this subsection, we derive the optimal solution of $u_{i,j}$, v_j and s_j from the above KKT conditions, and we show that these solutions are just substituting $x_i+\varepsilon_i$ to x_i in FCL (Algorithm 1).

From KKT conditions (19) and (23), we have the optimal solution of $u_{i,j}$ as

$$u_{i,j} = 1/\sum_{k=1}\left(\frac{d_{i,j}}{d_{i,k}}\right)^{1/(m-1)}, \tag{28}$$

where

$$d_{i,j} = \|x_i+\varepsilon-v_j\|^2-(s_j^{\mathrm{T}}(x_i+\varepsilon_i-v_j))^2. \tag{29}$$

From KKT conditions (20), we have

$$(E-s_js_j^{\mathrm{T}})\sum_{i=1}^{N}u_{i,j}^{m}(x_i+\varepsilon_i-v_j)=0, \tag{30}$$

where E is the p-dimensional unit matrix. The null space of the matrix $E-s_js_j^{\mathrm{T}}$ include s_j since

$$(E-s_js_j^{\mathrm{T}})s_j = s_j-(s_j^{\mathrm{T}}s_j)s_j=0. \tag{31}$$

For the p-dimensional vector w such as $w^{\mathrm{T}}s_j=0$ and as $w^{\mathrm{T}}w=1$ and for a scalar value α, we have

$$\begin{aligned}(E-s_js_j^{\mathrm{T}})(\alpha w) =& \alpha(w-(s^{\mathrm{T}}w)s_j)\\ =&\alpha w,\end{aligned} \tag{32}$$

which is equal to 0 if and only if $\alpha=0$, hence, the null space of $E-s_js_j^{\mathrm{T}}$ is just s_j. Therefore, Eq.(30) indicates that

$$\sum_{i=1}^{N}u_{i,j}^{m}(x_i+\varepsilon_i-v_j)=as_j \tag{33}$$

for an arbitrary value of a. From the above, we have the optimal solution of v_j as

$$v_j=\frac{\sum_{i=1}^{N}u_{i,j}^{m}(x_i+\varepsilon_i)-as_j}{\sum_{i=1}^{N}u_{i,j}^{m}}, \tag{34}$$

in which we may set $a=0$ and have

$$v_j=\frac{\sum_{i=1}^{N}u_{i,j}^{m}(x_i+\varepsilon_i)}{\sum_{i=1}^{N}u_{i,j}^{m}}. \tag{35}$$

From KKT conditions (21) and (24), we have

$$\sum_{i=1}^{N}u_{i,j}^{m}(x_i+\varepsilon_i-v_j)(x_i+\varepsilon_i-v_j)^{\mathrm{T}}s_j=-\xi_js_j, \tag{36}$$

from which we can obtain the optimal solution of s_j as the eigenvector for the maximal eigenvalue of the matrix

$$\sum_{i=1}^{N}u_{i,j}^{m}(x_i+\varepsilon_i-v_j)(x_i+\varepsilon_i-v_j)^{\mathrm{T}}. \tag{37}$$

Comparing between Eq. (28) and (4), Eq. (29) and (5), Eq. (35) and (6), and Eq. (37) and (8), we can see that optimal solutions in FCL-T is obtained just by substituting $x_i+\varepsilon_i$ to x_i in FCL (Algorithm 1).

3.3 Optimal Solution of ε_i

In this subsection, we obtain the optimal solution of ε_i from the KKT conditions.

From KKT conditions (22), (25), (26) and (27), we have

$$\left(\delta_iE+\sum_{j=1}^{C}u_{i,j}^{m}(E-s_js_j^{\mathrm{T}})\right)\varepsilon_i+ \sum_{j=1}^{C}u_{i,j}^{m}(E-s_js_j^{\mathrm{T}})(x_i-v_j)=0, \tag{38}$$

$$\delta_i(\|\varepsilon_i\|^2-\kappa_i^2)=0. \tag{39}$$

ISBN: 978-989-95079-6-8

In order to solve this equation, we discuss in each case that the matrix $\left(\sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})\right)$ is invertible or not as the followings.

The matrix $\left(\sum_{j=1}^{C} u_{i,j}^m \left(E - s_j s_j^{\mathrm{T}}\right)\right)$ is not invertible if $s_j = s_{\tilde{j}}$ for any $j \neq \tilde{j}$ or if there exists j^* such as $u_{i,j^*} = 1$, though the proof is omitted because of the sake of the pages. Here, we write $s = s_j$ in the case of $s_j = s_{\tilde{j}}$ for any $j \neq \tilde{j}$ and also write $s = s_{j^*}$ in the case that there exists j^* such as $u_{i,j^*} = 1$. In these cases, Eq. (38) is rewritten by setting $\varepsilon_i = \alpha s + \beta w$ with certain values α and β, and a p-dimensional vector w such as $s^{\mathrm{T}} w = 0$ and as $w^{\mathrm{T}} w = 1$, as

$$\beta(\sum_{j=1}^{C} u_{i,j}^m) w + \delta_i(\alpha s + \beta w) + (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j) = 0. \quad (40)$$

Multiplying s^{T} to Eq.(40), we have $\delta_i \alpha = 0$, which indicates $\delta_i = 0$ or $\alpha = 0$. $\alpha = 0$ means that ε_i is orthogonal to s. In the case of $\delta_i = 0$, we have

$$(E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i + \varepsilon_i - v_j) = 0. \quad (41)$$

which implies

$$\sum_{j=1}^{C} u_{i,j}^m (x_i + \varepsilon_i - v_j) = as \quad (42)$$

with an arbitrary value a. Hence, we have the optimal solution of ε_i in the case that $\left(\sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})\right)$ is not invertible with $\delta_i = 0$, as

$$\varepsilon_i = \frac{as - \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j)}{\sum_{j=1}^{C} u_{i,j}}. \quad (43)$$

If we set a such that ε_i is orthogonal to s, we can discuss both the case of $\delta_i \alpha = 0$ and the base of $\alpha = 0$ as the followings. Since $s^{\mathrm{T}} \varepsilon_i = 0$, Eq.(38) is rewritten as

$$\left(\sum_{j=1}^{C} u_{i,j}^m\right) \varepsilon_i + \delta_i \varepsilon_i + (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j) = 0, \quad (44)$$

from which we have

$$\varepsilon_i = -\frac{(E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j)}{\sum_{j=1}^{C} u_{i,j}^m + \delta_i}. \quad (45)$$

If $\delta_i = 0$, we have

$$\varepsilon_i = -\frac{(E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j)}{\sum_{j=1}^{C} u_{i,j}^m}. \quad (46)$$

If $\delta_i \neq 0$, then $\|\varepsilon_i\| = \kappa_i^2$ from Eq. (39), by which we have

$$\|\varepsilon_i\|^2 = \left\| \frac{(E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j)}{\sum_{j=1}^{C} u_{i,j}^m + \delta_i} \right\|^2 = \kappa_i^2. \quad (47)$$

By solving Eq.(47) as

$$\sum_{j=1}^{C} u_{i,j}^m + \delta_i = \frac{\left\| (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j) \right\|}{\kappa_i}, \quad (48)$$

we have

$$\varepsilon_i = -\kappa_i \left\| (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j) \right\|^{-1} \cdot (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j). \quad (49)$$

Getting Eq.(46) and (49) together, we have the optimal solution of ε_i in the case that the matrix $\left(\sum_{j=1}^{C} u_{i,j}^m \left(E - s_j s_j^{\mathrm{T}}\right)\right)$ is not invertible

$$\varepsilon_i = -\min \left\{ \kappa_i \left\| (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j) \right\|^{-1}, \left(\sum_{j=1}^{C} u_{i,j}^m\right)^{-1} \right\} (E - ss^{\mathrm{T}}) \sum_{j=1}^{C} u_{i,j}^m (x_i - v_j). \quad (50)$$

In the case that $\left(\sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})\right)$ is invertible, we cannot obtain the explicit form of the optimal solution ε_i, so, we apply some numerical method for Eq. (38) and (39) as the followings. First, we set $\delta_i = 0$ and solve Eq. (38) as

$$\varepsilon_i = -\left(\sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})\right)^{-1} \cdot \sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})(x_i - v_j). \quad (51)$$

If the obtained value of ε_i satisfies $\|\varepsilon_i\|^2 \leq \kappa_i^2$, we adopt this value as the optimal solution of ε_i. Otherwise, we solve Eq. (38) with $\|\varepsilon_i\|^2 = \kappa_i^2$ numerically.

3.4 Algorithm

In this subsection, we propose an iterative algorithm of fuzzy c-lines for data with tolerance from the above discussion.

Algorithm 3 (FCL-T)

Step 1 *Give the values of the fuzzifier parameter m and the maximal tolerance set κ. Set the initial cluster center v, s and ε.*

Step 2 *Calculate $u_{i,j}$ such that*

$$u_{i,j} = 1/\sum_{k=1}^{C}\left(\frac{d_{i,j}}{d_{i,k}}\right)^{1/(m-1)}, \tag{52}$$

where

$$d_{i,j} = \|x_i + \varepsilon - v_j\|^2 - (s_j^{\mathrm{T}}(x_i + \varepsilon_i - v_j))^2. \tag{53}$$

Step 3 *Calculate v_j such that*

$$v_j = \frac{\sum_{i=1}^{N} u_{i,j}^m (x_i + \varepsilon_i)}{\sum_{i=1}^{N} u_{i,j}^m}. \tag{54}$$

Step 4 *Obtain s_j as the eigenvector with the maximal eigenvalue of the matrix*

$$\sum_{i=1}^{N} u_{i,j}^m (x_i + \varepsilon_i - v_j)(x_i + \varepsilon_i - v_j)^{\mathrm{T}}. \tag{55}$$

Step 5 *If $s_j = s_{\tilde{j}}$ for any $j \neq \tilde{j}$ or if there exists j such that $u_{i,j} = 1$, obtain ε_i as*

$$\varepsilon_i = -\min\left\{\kappa_i \left\|(E - ss^{\mathrm{T}})\sum_{j=1}^{C} u_{i,j}^m (x_i - v_j)\right\|^{-1}, \left(\sum_{j=1}^{C} u_{i,j}^m\right)^{-1}\right\}(E - ss^{\mathrm{T}})\sum_{j=1}^{C} u_{i,j}^m (x_i - v_j), \tag{56}$$

where

$$s = \begin{cases} s_j & \text{for} s_j = s_{\tilde{j}} \quad (j \neq \tilde{j}), \\ s_{j^*} & \text{for } u_{i,j^*} = 1, \end{cases} \tag{57}$$

and go to Step 7. *Otherwise, go to* Step 6.

Step 6 *Calculate*

$$\varepsilon_i = -\left(\sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})\right)^{-1} \cdot \sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})(x_i - v_j). \tag{58}$$

If $\|\varepsilon_i\|^2 \leq \kappa_i^2$ holds, adopt this ε_i and go to Step 7. *Otherwise, solve the equation*

$$\left(\delta_i E + \sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})\right)\varepsilon_i + \sum_{j=1}^{C} u_{i,j}^m (E - s_j s_j^{\mathrm{T}})(x_i - v_j) = 0, \tag{59}$$

$$\|\varepsilon_i\|^2 = \kappa_i^2 \tag{60}$$

Step 7 *Check the stopping criterion. If the criterion is not satisfied, go back to* Step 2.

If the maximal tolerance κ_i is set to zero, this algorithm is coincides with FCL without tolerance (Algorithm 1). Remark that Eq. (56) in Algorithm 3 and Eq. (13) for obtaining the tolerance in Algorithm 2 are essentially the same with each other, because Eq. (56) means that the tolerance is obtaining in the orthogonal complementary space of s in the pattern space. Remark also that there is the quite similarity between Eq. (58) in Algorithm 3 and Eq. (9.29) in [3] for dealing with the missing data in linear fuzzy clustering followed by the optimal completion strategy [4], because Eq. (58) means that the optimal solution of the tolerance in a certain condition is not affected by the constraint of the tolerance $\|\varepsilon_i\| \leq \kappa_i^2$, while Eq. (9.29) in [3] does not consider the constraint for missing component of data from the beginning.

4 Numerical Example

In this section, we show some examples of classification by fuzzy c-lines for data with tolerance (Algorithm 3). In each example, 100 trials for Algorithm 3 with different initial cluster centers are tested and the solution with the minimal objective function value is selected as the final result. The classified dataset is Gustaffson's cross [5] shown in Fig. 2. This dataset consists of 20 points ($N = 20$) in $\mathbf{R}^2$ and forms two visually apparent linear clusters with the crossing shape.

We fix $m = 2$ and test four different values of $\kappa_i \in \{0, 0.016, 0.032, 0.064\}$. All cases of κ_i produce the correctly classified results shown in Fig. 3, 4 and 5, respectively. Especially, the cases of $\kappa_i \in \{0.032, 0.064\}$ produce the same results shown in Fig. 5. From Fig. 4, we can see that each data moves to the direction of its own prototype. From Fig. 5, we can see that each data moves just on its own prototype.

From these results, we consider the following hypothesis: if Gustaffson's cross is generated by adding error followed by uniform distribution with a width after sampling from the two crossing exactly linear shaped population, FCL-T (Algorithm 3) produces the shape of the original population by $v_j + ts_j$ and also produces the width of the uniform distribution by κ_i, though we have not proved it yet.

5 Conclusion

In this paper, we proposed fuzzy c-lines for data with tolerance. The proposed method is obtained by introducing the idea of tolerance, which means that each datum moves within a region, into fuzzy c-lines. This is the analogy with that fuzzy c-means for data with tolerance is obtained by introducing the idea of tolerance into fuzzy c-means. In the numerical examples, we can see that each data moves to the direction of its own prototype in setting the positive maximal tolerance, and that each data moves on its own prototype in setting larger maximal tolerance.

ISBN: 978-989-95079-6-8

From this feature of the proposed method, we consider the following hypothesis: if dataset is generated by adding error followed by uniform distribution with a width after sampling from the exactly linear shaped population, FCL-T (Algorithm 3) produces the shape of the original population and also produces the width of the uniform distribution. But we must investigate the proposed method theoretically and through many numerical experiments, which is the first future work.

As another future works, (1) entropy regularlized fuzzy c-means [6] for data with tolerance will be proposed by the similar discussion, (2) the cases of error followed by other probabilistic distribution will be considered, e.g., the case of error followed by normal distribution can be considered by adding the penalty term of squared tolerance, and Laplace one by the penalty term of absolute value of tolerance.

Abstract— *A Geographic Information Retrieval (GIR) model is defined and the architecture of a GIR system, named Geo-Finder, is described. The GIR system is constituted by two main modules. The geo-indexing module applies bipolar criteria to automatically identify the geo-reference focus (footprint) of textual documents. The geo-retrieval module applies a context dependent matching function to evaluate queries consisting of two orthogonal constraints, a content constraint and a spatial constraint; the spatial constraint is defined by modeling the user's perception of geographic "closeness" between the documents' footprint and the query footprint. For each retrieved document, two relevance scores are computed with respect to the two query conditions, that can be combined to generate an overall ranked list of documents in a flexible way, by allowing users to specify a trade off between them.*

Keywords— bipolar criteria evaluation, geo-footprint, geo-indexing, geographic information retrieval, perception distance, spatial query evaluation.

1 Introduction

The representation and management of Geographic Information is becoming a hot topic in the research area of information retrieval [9]. Given that about 15% of the queries submitted to search engines contain geographic names [20], the effective indexing and retrieval of geographical information poses new challenges to the design of *location-based search services* [18].

Location based search services allow users to search into specialized repositories, and more generally on the Internet, documents describing both resources and specific contents in the *neighbourhood of the user location*, or in the *neighbourhood of a geographic location* that is explicitly specified in the request. "*In the neighbourhood of a location*" specifies a spatial constraint on the geographic content of the retrieved documents, typically a constraint on the geographic distance from the desired location, like in the request "*find Indian restaurants near Bergamo university*".

Nevertheless, actual search engines do not enhance the influence of the geographical information content in evaluating requests containing geographic names. For example, the previous request submitted to *Google* retrieves as first ranked web page "*hotels near Indiana University East*" that does not satisfy the spatial constraint to be close to Bergamo. Generally, search engines are able to find specific resources such as hotels, restaurants, hospitals, in the neighbourhood of a locality, e.g. "*find hospital near Milan*", but this works only for specific resources, and moreover the ranking does not depend on the distance from the specified locality.

Furthermore, the indexing process does not extract most of these places automatically; consequently many web pages related to the query are not displayed as a result. In fact, many of the results obtained by a Google search are relative to resources that have directly informed Google of their geographical position. More specialized services has been developed for automatically mapping documents. For example, *MetaCarta* [11] is a system that geo-tags news, and allows searches in which one can distinctly specify the content constraint and the location of the news. However, this system is unable to retrieve news in the neighbourhood of a desired locality.

The identification of the geographic names, and successively the selection of the *geographic reference focus* (footprint) of web pages have been dealt with in several papers [1][2] [8][15]. Other papers considered the problem of spatial query evaluation [3][13][23]. In [15] the problem of implicit location identification is considered.

In this paper, after introducing the main problems involved in the design of a GIR system, we describe our GIR model and the system, named *Geo-Finder*, implementing it.

The main characteristics of the proposed geo-indexing model is the integration of multiple bipolar criteria satisfaction degrees [4][6][12][17][25], computed based on context dependent rules. Some criteria have a positive influence on the selection of the geographic names as footprints of the document; others have a negative influence. The positive and the negative constraints are heterogeneous and express pieces of information of a different nature [4]. The footprint of a document is represented as a fuzzy set of geographic coordinates (i.e., latitude and longitude, identifying the location and extent on the Earth surface of the geographic names occurring in the document) with membership degrees expressing their strength in defining the document footprint.

Second, we propose a distance measure to model the evaluation of the spatial query constraint, named "user's perception" distance. This distance measure depends on several aspects modelling the user context, such as the *spatial scope* of the query.

Finally, the system user interface maps the bi-dimensional relevance of retrieved documents in a Cartesian plane. The axes correspond to two orthogonal criteria

ISBN: 978-989-95079-6-8

(content constraint, geographic constraint), and the distance from the origin is inversely proportional to the global relevance of the documents. The user can also obtain a unique ranked list by choosing a trade-off of the two criteria satisfaction degrees based on their linear combination.

2 Why Geographic Information Retrieval is difficult

Geographic Information Retrieval (GIR) can be considered a specialized area of Information Retrieval, with an emphasis on the geographic indexing and geographic retrieval. GIR deals with any kind of information, i.e., not just maps or images but also texts, that have some relation to one or more locations on the Earth's surface, i.e., geo-referenced information [22]. Most of the information available on the Internet and in digital libraries is implicitly geo-referenced.

Often the link to the place (geographic footprint) is encoded by a geographic name. Geographic indexing implies the identification of the geographic names in a text and their translation into footprints, which are two operations that imply the management of imprecision, ambiguity, and incompleteness.

Often geographic names are ambiguous [14][21], some of them are homonymous of general terms (e.g. "*Los Angeles"*), some others identify distinct places on the Earth (e.g."*Rome*") or are temporal (e.g."*Leningrad*", "*Petersburg*", "*St Petersburg*"), or even are local names whose recognition relies on the knowledge of the local language.

Further, some pseudo-names are imprecise (e.g. "*around Milan*") or implicitly mentioned (e.g. "*the capital of Italy*"), or depending on the context (e.g. "*highest peak*" implicitly identifies "*Mont Blanc*" in a text describing the Alps). In [19] it has been argued that, given all these characteristics, geographic indexing can be feasibly faced by considering large corpora of geographic knowledge and heuristic rules.

On the other side, geographic retrieval implies being able to retrieve documents whose geographic focus satisfies a spatial constraint specified in a query. Generally, the spatial constraint demands the document footprint to be "*in the neighbourhood of a place*", i.e., it is a constraint on the distance. However, in this context the geographic distance is not merely Euclidean, but is related to the user's spatial context of interest, that can be related to the human perception of the time needed to cover it [5].

When a user searches resources or documents on the internet that are close to his/her current location, the judgment on the distance is related to his/her perception, depending on the fact that he/she is walking, driving or flying. Then, the constraint on the distance depends on the request and users' context.

Besides distance, other topological constraints could be defined, e.g., inclusion, overlapping, at the south/north of a specific region. Also these constraints must be interpreted in a tolerant, approximate way.

Then, geographic retrieval can draw benefits by defining the spatial constraints as soft, context dependent constraints, admitting degrees of satisfaction.

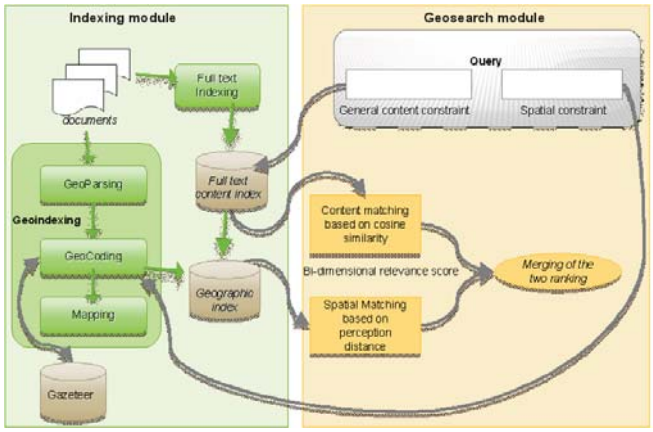

Figure1. Architecture of the Geographic Information Retrieval system *Geo-Finder*

3 The Architecture of the Geographic Information Retrieval System *Geo-Finder*

In this section we present the general architecture of the GIR system named *Geo-Finder*, that we designed and implemented. The architecture is depicted in Figure 1.

The system has the typical structure of an IRS, consisting of two main components: the *Indexing Module* and the *Retrieval Module* (named *GeoSearch*).

The Indexing Module has two main sub-modules: the *Full-Text Indexing sub-module* performs the full text indexing of the documents to represent their generic content, and generates the textual inverted index.

The *GeoIndexing sub-module* is the novel component, specialized in the identification of the footprints of documents, representing their geographic focus. This sub-module makes use of a *gazetteer* stored into a PostgreSQL database, containing the names of geographic entities (both administrative and physical entities) of all over the world, in English language and local languages (*GeoNames*) [10].

Once the *GeoIndexing* module has identified the footprints, it also stores them into the geographic index, that is a posting file containing the documents' identifiers and their footprints.

On the other side, the *GeoSearch* module interprets queries composed of two conditions. On the left hand side of the *GeoSearch* box in Figure 1, the generic content condition can be specified as a set of keywords, which define the *generic content constraint* on the documents' full text content representation. On the right hand side, the spatial condition can be specified as a geographic name, which is used to define the *spatial constraint* on the documents' footprints.

The *GeoIndexing* module parses the terms in the spatial condition to identify their footprint. These two conditions are evaluated by the sub-modules named *Content Matching module* (based on the *Lucene* library) and *Spatial Matching module*, based on perception distance (that is based on the original geo-retrieval model introduced in the next section), respectively.

In order to be retrieved, a document must satisfy, at least a little, the first content based condition (necessary condition), while the spatial condition is used for conditioning the ranking of the documents (optional

ISBN: 978-989-95079-6-8

condition). Then, the two conditions are *merged* by an "*and possibly*" aggregator, applied by the *Merging* sub-module that combines the satisfaction degrees of the two constraints, in order to obtain a unique value that performs the global ranking of documents. In the combination, one can give more preference to one of the two conditions, in order to emphasize the influence on the global ranking of either the document content or the document footprint.

4 The Geo-Retrieval Model

In this section, we describe the geo-retrieval model at the basis of the system implementation. In the first subsection the *GeoIndexing* model is described. In the second subsection, we introduce the geo-retrieval model at the basis of the *GeoSearch* component.

4.1 The GeoIndexing model

The GeoIndexing model is defined to identify for each document its footprint. A footprint of a document *d*, *Foot(d)*, is as a fuzzy set of geographic coordinates gc=(*lat,lon*), *lat*=latitude *lon*=longitude, expressed in degrees, with a membership degree $\mu_{Foot(d)}(gc)=GeoRef(gc) \in [0,1]$ representing the strength by which the geographic location gc, named gw, belongs to the footprint of the document d.

$$Foot(d)=\{GeoRef(gc_1)/gc_1,...,GeoRef(gc_n)/gc_n\}$$

A document is represented as a stream of tokens <*t*>. Some terms *t* have been selected as content indexes and thus are in the dictionary. For each of them, the frequency in the collection is known, while in the posting list we enter the documents in which they appear with their significance degrees *F(d,t)*. The significance degree is usually defined based on statistic analysis of the document text [16].

Besides this information, in the posting list we can also find the positions of the occurrences of the index terms in the document text, $occ_k(t_i,d)$, the k-th occurrence of t_i in *d*.

The identification of the document footprint is achieved in three steps, where distinct sets of heuristic rules are evaluated. Each set of rules acts as a filter on the input terms, so that only those terms whose global satisfaction degree of the set of rules is above a threshold are selected as input to the second step.

The *GeoIndexing* module implements this geoindexing model. It operates in two subsequent phases: first, it performs a G*eoParsing* that applies the first two sets of rules to detect the candidate geographic names (gw). Then, the *GeoCoding* sub-module identifies the document footprint *Foot(d)* and stores it in a file with the document unique identifier *d*.

The first set of rules consists of Name Entity Recognition (NER) rules, aimed at reducing the set of terms among which to successively select the candidate geographic names e.g.:

```
if Language(d)="English"∧
   FirstChar(t)=Capital then return(t).
```

The second set of rules receives, in input, a stream of previously selected terms, hereafter indicated by gw, and filters the candidate geographic names, a subset of the input terms. It applies bipolar [4] context dependent rules (r_i) exploiting a *gazetteer* [10] and computing independently a satisfaction degree *s(gw)* and a dissatisfaction degree *d(gw)* that denote to what extent gw is a geo-name and is not a geo-name, respectively.

The aggregation of the positive (negative) rules is done based on a Generalized Conjunction Disjunction function (GCD) [12], that, for distinct values of the parameter *p*, can model aggregations from completely compensative (or), where each rule can replace any other, to completely not compensative (and), where all rule must be satisfied simultaneously [6]:

$$s(gw)=\left(\sum_{i=1}^{m}\lambda_i*\left(r_i(gw)\right)^{ps}\right)^{1/ps}$$
$$d(gw)=\left(\sum_{j=1}^{n}\overline{\lambda}_j*\left(\overline{r}_j(gw)\right)^{pd}\right)^{1/pd} \quad (1)$$

The rules r_i and $\overline{r}_j$ assume a value in [0,1]. *ps* and *pd* are set so as to define (partially) compensative aggregations. In our experiment we used *ps=pd*=20, i.e., towards or like aggregation [6].

$\lambda_i,\overline{\lambda}_j \in [0,1]$ with $\sum_{i=1}^{m}\lambda_i=1, \sum_{i=1}^{n}\overline{\lambda}_j=1$ are the weights of the rules, i.e. their importance degrees in the aggregation, and are determined based on statistical analysis on a sample set of documents of a collection, and are set in a configuration file that is read by the *GeoParsing* sub-module during index generation. This way, the geoindexing can be suited to the characteristics of a collection.

The satisfaction of a rule r_i with *i=1,m* is interpreted as a hint of evidence that gw is a geographic name; thus the first *m* rules have a positive influence on the recognition of gw as a candidate geoname, like, e.g., the following two rules:

$$\text{If } gw \in gazetteer \wedge \exists gw_k \in d$$
$$\wedge\ gw_k = administrative\_distr(gw) \Rightarrow r_2(gw)=0.5$$
$$\wedge\ |occ_i(gw,d)-occ_j(gw_k,d)|<\Delta \Rightarrow r_2(gw)=r_2(gw)+0.5$$

E.g. if gw="*San Francisco*" and gw_k="*California*", its administrative district, occurs in the same document *d* at a maximum distance $\Delta=3$ words, then $r_2(gw)=1$, otherwise if the occurrences are at a greater distance than Δ the rule is only partially satisfied, i.e., $r_2(gw)=0.5$.

Another rule is the following:

$$\text{If } gw \in gazetteer \wedge gw_{-1} \in prefix \Rightarrow r_3(gw)=1$$

e.g. if gw="*Blanc*" is preceded by gw_{-1}="*Mount*" that belongs to the set prefix of prefixes of geographic names such as *Mount*, *lake*, *city*, *river*, then $r_3(gw)=1$.

Conversely, the satisfaction of a rule $\overline{r}_j$ with *j=1,n* is interpreted as a hint of evidence that gw is not a geographic name. Thus, these rules have a negative influence, like the following one:

$$\text{If } gw \in gazetteer \wedge gw \in Stopwords \Rightarrow \overline{r}_4(gw)=1$$

ISBN: 978-989-95079-6-8

e.g. gw ="Nice" is a stop-word too.

For each input gw, a geo-score *GeoScore*(gw)∈[0,1] is computed based on the values of *s*(gw) and *d*(gw) as follows:

$$GeoScore(\mathtt{gw}) = \begin{cases} s(\mathtt{gw}) - d(\mathtt{gw}) & if\ s(\mathtt{gw}) > d(\mathtt{gw}) \\ 0 & if\ otherwise \end{cases}$$

We select the gw with *GeoScore*(gw)$>\tau>0$ as reliable geographic names. This threshold allows restricting the footprint of a document to reduce the possibility of identifying false positives. τ must be set based on experimentations, and is also specified in the configuration file. The greater it is, the smaller is the possibility of selecting false geo-names. Generally, it is better to lose some true geo-names than to select false ones.

The third set of rules, used in the third step by the *GeoCoding* sub-module, is aimed at identifying, from the reliable geographic names, the geographic locations that belong to the document footprint (i.e., the fuzzy set *Foot*(*d*) of pairs of geographic coordinates).

For each of the selected geo-names, gw, a (set) of pair(s) of geographic coordinates $GC_{gw}=\{gc_1,\ldots,gc_n\}$, with gc=(lat,lon), is retrieved from the gazetteer. Each pair gc is a geocode of gw, uniquely identifying a geographic place on the geographic domain. Notice that homonymous geo-names have the same name but distinct gc pairs.

For each geocode associated with a selected gw, a *geo-reference score (GeoRef*(gc)) ∈[0,1] is computed, that expresses the strength by which gw, located in gc, belongs to the document footprint (i.e. it is marginal or central in defining the geographic focus of the document).

A true geographic name can be correctly identified in a document, but it can be meaningless in defining the geographic focus of the document itself. Let us consider, for example, the geographic names that are often present at the very end of web pages or in their footnotes: they generally have nothing to do with the document content, but are related with the affiliation of the web master, and thus must not define the document footprint.

Also these rules have a satisfaction degree $r'_1(gc)\in$ [0,1] that is dependent on some variable. For example, the frequency F(*d*,gw) of a geoname gw in a document *d*, increases the strength of its geocodes in the footprint proportionally to the degree by which the geoname was recognized as a candidate geo-name *s*(gw), and inversely proportional to the degree by which it was recognized as not being a geo-name *d*(gw). This is represented by the following rule:

$$r'_1(gc) = \mu_{significant}(F(d,gw) * GeoScore(gw))$$

with $gc\in GC_{gw}$ and $\mu_{significant}$ is a monotonic non-decreasing membership function.

Another rule evaluates the presence of another geoname gw_k in *d*, whose geo-code is geographically near to that of gw (at a maximum geographic distance *dist* equal top *Δ*). When this occurs, it increases *GeoRef*(gc). That is:

$$r'_2(gc) = max(0, \Delta - dist(gc, gc_k))$$

with $gc\in GC_{gw}$, $gc_k\in GC_{gwk}$ and $gw_k \in d$.

The population attribute of an administrative name gw, that has multiple geocodes, indicated by *population*(gc), is used to favour the influence of big cities w.r.t. small ones having the same geoname in the footprint:

$$r'_3(gc) = (population(gc))/max_k(population(gc_k))$$

$gw \in gazetteer,\ gc, gc_k \in GC_{gw}$

This rule allows us to resolve ambiguities, generated by homonymous geographic names, that is, to favour the geographic coordinates (geo-codes) that most likely belong to the document footprint.

These rules are aggregated based on a GCD aggregation, in which each rule has a weight $\lambda'_i\in[0,1]$, with $\sum_{i=1}^{m}\lambda'_i = 1$, determined based on statistical analysis and the parameter *p*=1, neutral aggregation (all configurable):

$$GeoRef(gc) = \left(\sum_{i=1}^{m}\lambda'_i\left(r'_i(gc)\right)^p\right)^{1/p} \quad (2)$$

A minimum threshold *Φ*>0 on *GeoRef*(gc) (configurable) restricts the footprint of a document to reduce its extent. Therefore, at the end of this model, for each geoname we have two different scores: *GeoScore*(gw)$>\tau>0$ and *GeoRef*(gc)$>\Phi>0$. Figure 2 shows the geonames extracted from a sample paper. The map was generated by the *Mapping module*: this module creates distinct graphic metafiles for each document to map the footprint in distinct graphic environments, such as Gmaps for Google maps (see figure 2), KML for Google Earth, and GPX for GPS data format environments .

Score	GeoLocation	Name	Latitude	Longitude	Country code	Population
0,54	Milano	Milan	45.461216	9.187832	IT	1306661
1,00	Italy	Italian Republic	42.833332	12.833333	IT	58103033

The hue of the red pins represents the degree of the *geo-Reference* scores of the localities in the document footprint. A table with the geographic coordinates in the footprint and their country code and population attribute is also reported.

ISBN: 978-989-95079-6-8

4.2 The GeoRetrieval model

The GeoRetrieval model takes the footprint (*Foot(q)*) of the spatial query condition *q*, that consists of a single or a set of geographic names. The footprint *Foot(q),* if not directly found in the geographic index, is identified by applying the *GeoParsing* and *GeoCoding* rules described in the previous subsection.

For each document d that has been retrieved by the *Content-based Matching* module, we match its footprint, *Foot(d)* w.r.t. the query Footprint *Foot(q)* by applying formula (3). This matching function defines the semantics of the soft spatial constraint "*close*" that computes a degree of satisfaction $GRS(d) \in [0,1]$ (*GeoRelevanceScore*) as follows:

$$GRS(d) = \mu_{close}\left(Foot(d), Foot(q)\right) \tag{3}$$

$$\mu_{close}(Foot(d), Foot(q)) =$$

$$= \max_{i,j}\left[\mu_{Foot(d)}[i] * \mu_{Foot(q)}[j] * \left(1 - \frac{qscope(dist(i,j))}{Maxdist(Foot(d) \cup Food(q))}\right)\right]$$

with

$$\mu_{Foot(e)}[i] = GeoRef(gc_i) > 0$$

and

$$qscope(x) = \begin{cases} x & if \quad x \le \delta + k * Maxdist(Foot(q)) \\ & with \qquad \delta \ge 0 \quad k > 0 \\ 0 & otherwise \end{cases}$$

and *Maxdist(X)* is the maximum geographic distance (*dist*) of any two elements in the footprint *X*.

i and *j* represent the i-th and j-th pairs of geographic coordinates *latitude* and *longitude* in the footprints of the document *d,* with membership degrees *GeoRef*(*i*), and of the query *q*, with membership degrees *GeoRef*(*j*) that is assumed equal to 1.

The *qscope* function models the "user perception" distance measure, where *Maxdist(Foot(q))* is the query footprint maximum dispersion. δ and k are constant values that define the query scope and are set without user explicit input.

We consider four main query scopes, a *full* scope considering the whole globe, a *large* scope, considering an area covered by a continent or a big country like Russia, a *meso* scope considering an area of a nation or a big region, and a *small* scope considering a city and its surroundings. Each scope has specific values for the parameters (e.g. *k=3, δ=10km* is associated with a small scope, *k=30*, *δ=100km* with a *meso* scope).

δ is the query *range*, and is useful in the case of a query footprint consisting of a single geographic coordinate pair in order to retrieve also documents with footprint in the surrounding places. Distinct δ can adapt the evaluation of the spatial constraint "*close*" to the user perception; thus, modelling strict or relaxed interpretations of the *close* surrounding of a point. *k* allows to model a tolerance on the geographic distance between a document footprint and the query footprint that is equal to *k* times the query maximum dispersion, i.e., *Maxdist(Foot(q))*. This allows enlarging or reducing the query scope. This parameter can be related to the scale of the map needed to represent the minimum bounding box of the Minkowski sum of *Foot(q)* and a circle of radius *k* [7].

For example, if one specifies the two geonames *Bergamo*, *Como* (*Como* being at about 40km from Bergamo*)* as spatial condition, and the query scope is *small* (i.e. *k=3* and *δ=10km*) documents with footprints at a maximum distance of 130 km from the query footprint are retrieved (e.g. both documents in *Milano* and *Lugano* are retrieved while a document with a footprint in *Rome* is not).

On the other side, a query with footprint in *Bergamo, Dalmine* (10 *km* from *Bergamo* in *Milano* direction) will retrieve documents at a maximum distance from the query footprint of 40 km, (e.g. it will retrieve just the document in "*Milano*" and not the one in "*Lugano*").

Figure 3 depicts the *GeoSearch* user interface of the GIR system. At the top, there are two text forms for submitting the content (left) and spatial (right) query condition.

Bottom, on the right panel the bi-dimensional relevance domain is depicted, in with each point corresponds to a retrieved document. The origin identifies the query. The document's X coordinate (Y coordinate) is its relevance degree w.r.t. spatial (general content) query constraint. The closest the document is to the origin, the most relevant it is with respect to at least one query constraint.

On the left panel, the ordered list of retrieved documents is reported corresponding with a merging of the two relevance degrees giving equal importance to the two conditions. By moving the sliding bar at the top of this panel, it is possible to modify the preference between the two conditions and thus to re-rank the documents accordingly. This is achieved by a linear combination of the relevance rankings.

5 Conclusions

The system has undergone a first evaluation based on a collection of 1100 documents in *Italian* and *English* with an average length of 800 words. The collection comprehends research papers on geological studies carried out at IDPA CNR, Reuters news of the RCV1 collection, and web pages of the Open Directory Project.

This first evaluation was aimed at estimating the ability of the *GeoParser* to identify the correct geonames in documents text. For each document, we classified its geo-names and we compared the classification with respect to the footprints of the documents. We achieved a recall of 91% and a precision of 93%. Nevertheless, these results are preliminary, and further tests are needed to complete the evaluation.

The contributions of this proposal with respect to current practice are several: first of all, the computation of a fuzzy footprint to represent the geo-reference focus of a textual document, based on a bipolar criteria decision process; second, the use of a user's perception based distance measure at the basis of the computation of the degree of satisfaction of the spatial query constraint; third, the evaluation of a bi-dimensional relevance score, and the possibility to flexibly merge the two rankings into a single one by specifying a relative importance weight of the two query constraints.

Toyonaka, Osaka, Japan
Email: inuiguti@sys.es.osaka-u.ac.jp

Abstract— *In this paper, possibilistic linear programming problems are investigated. After reviewing relations among conjunction and implication functions, necessity fractile optimization models with various implication functions are applied to the possibilistic linear problems. We show that the necessity fractile optimization models are reduced to semi-infinite linear programming problems. A simple numerical example is given to demonstrate the correctness of the result. The paper is concluded with some remarks for further developments.*

Keywords— Possibilistic linear programming, semi-infinite linear programming, necessity measure, implication function, conjunction function

1 Introduction

Fuzzy and possibilistic programming approaches are proposed to mathematical programming problems with ambiguity and vagueness [1, 2, 3]. By those approaches, we obtain reasonable solutions under conflicting soft constraints and goals, robust solutions under hard and soft constraints, hopeful solutions of attaining high-level goals, and so on. In possibilistic programming approaches, possibility and necessity measures are used to reduce the problems to the conventional programming problems. Many results demonstrate that possibilistic linear programming problems preserve the linearity in the reduced problems when possibility and necessity measures are defined by minimum operation and Dienes implication function. However, cases with the other conjunction and implication functions have not yet considerably investigated while several alternative approaches [4, 5] have been proposed in calculation of linear functions with fuzzy coefficients.

In this paper, we treat necessity fractile optimization model of possibilistic linear programming problems with soft constraints. We note that soft constraints include hard constraints as a special case. Then the problems are more general than problems with hard constraints. To construct necessity measures, we allow arbitrary implication satisfying weak requirements. Moreover, implication functions can be different among constraints. By the properties of implication functions, we show that necessity fractile optimization problems are reduced to a semi-infinite linear programming problems. Therefore the problems can be approximated by linear programming problems or the solutions can be obtained by a relaxation procedure together with the simplex method.

In next section, we briefly review the closure of generation procedures among conjunction and implication functions. Moreover, we introduce possibility and necessity measures. Possibilistic linear programming problems with soft constraints are given and reduced to the conventional programming problems through necessity fractile optimization models in Section 3. The main results are shown together with a conceivable solution procedure. in Section 4. In Section 5, a simple numerical example is given to demonstrate the correctness of the main result.

2 Conjunction and Implication Functions

2.1 Definitions

In this paper, a conjunction function is defined as a two-place function $T : [0,1] \times [0,1] \to [0,1]$ satisfying

(T0) T is lower semi-continuous, (semi-continuity)
(T1) $T(0,0) = T(0,1) = T(1,0) = 0$ and $T(1,1) = 1$, (boundary condition)
(T2) $T(a,b) \le T(c,d)$ if $0 \le a \le c \le 1$ and $0 \le b \le d \le 1$. (monotonicity)

A conjunction function T satisfies the following properties (t1) $T(a,1) = T(1,a) = a$ for any $a \in [0,1]$, (T3) $T(a,b) = T(b,a)$ for any $a, b \in [0,1]$ (commutativity) and (T4) $T(a,T(b,c)) = T(T(a,b),c)$ for any $a, b, c \in [0,1]$ (associativity) is known as a triangular norm.

In this paper, an implication function is a two-place function $I : [0,1] \times [0,1] \to [0,1]$ satisfying

(I0) I is upper semi-continuous, (semi-continuity)
(I1) $I(0,0) = I(0,1) = I(1,1) = 1$ and $I(1,0) = 0$, (boundary condition)
(I2) $I(a,b) \le I(c,d)$ if $0 \le c \le a \le 1$ and $0 \le b \le d \le 1$. (monotonicity)

Given a conjunction function and/or a strong negation n, an implication function can be generated through a transformation. The following three transformations are frequently adopted in the literature for implication generators:

$$I^{\mathrm{R}}[T](a,b) = \sup\{s \in [0,1] \mid T(a,s) \le b\}, \quad (1)$$

$$I^{\mathrm{S}}[T](a,b) = n(T(a,n(b))), \quad (2)$$

$$I^{\mathrm{r-R}}[T](a,b) = \sup\{s \in [0,1] \mid T(n(b),s) \le n(a)\}. \quad (3)$$

The first one, I^{R}, is encountered in the maximum solution of a fuzzy relation equation [6] and adopted in view of modus ponens. The second one, I^{S}, is introduced in analogy to Boolean logic. The last one, $I^{\mathrm{r-R}}$ is reciprocal to the first one which is obtained by taking a contraposition of the first one. When T is a t-norm, $I^{\mathrm{R}}[T]$, $I^{\mathrm{S}}[T]$ and $I^{\mathrm{r-R}}[T]$ are called R-implication (residual implication), S-implication and reciprocal R-implication, respectively. Whereas I^{S} produces an implication function from an arbitrary conjunction function T,

ISBN: 978-989-95079-6-8

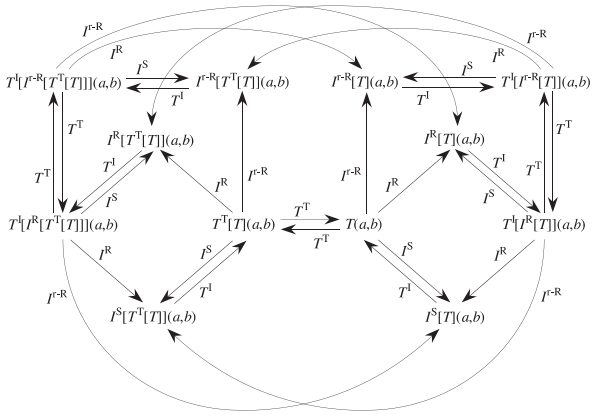

Figure 1: Conjunction and implication generation

I^{R} and $I^{\mathrm{r-R}}$ produce an implication function from a conjunction function which satisfies

$$T(1,a) > 0 \text{ for any } a > 0. \tag{4}$$

On the other hand, a conjunction function can be generated from an implication function through a transformation,

$$T^{\mathrm{I}}[I](a,b) = n(I(a,n(b))). \tag{5}$$

This transformation is symmetrical to I^{S}. From an implication function, a conjunction function is produced through T^{I}.

A conjunction function in this paper is not commutative. Thus, a new conjunction function may be generated from a conjunction function through

$$T^{\mathrm{T}}[T](a,b) = T(b,a). \tag{6}$$

2.2 Closure of generation processes

For the transformations (1)–(3), (5) and (6), the following equalities can be easily shown:

$$T^{\mathrm{I}} \circ I^{\mathrm{S}} = \mathrm{id.},\ I^{\mathrm{S}} \circ T^{\mathrm{I}} = \mathrm{id.},\ T^{\mathrm{T}} \circ T^{\mathrm{T}} = \mathrm{id.}, \tag{7}$$

$$I^{\mathrm{S}} \circ T^{\mathrm{T}} \circ T^{\mathrm{I}} \circ I^{\mathrm{R}} = I^{\mathrm{r-R}}, \tag{8}$$

where '$\circ$' denotes a composition, for example, $T^{\mathrm{I}} \circ I^{\mathrm{R}}$ is a composite transformation of I^{R} and T^{I}, i.e.,

$$T^{\mathrm{I}} \circ I^{\mathrm{R}}[T](a,b) = T^{\mathrm{I}}[I^{\mathrm{R}}[T]](a,b).$$

The notation 'id.' stands for the identical transformation.

From (T0), we have the following equalities [7]:

$$I^{\mathrm{R}} \circ T^{\mathrm{I}} \circ I^{\mathrm{R}}[T] = I^{\mathrm{S}}[T], \tag{9}$$

$$I^{\mathrm{r-R}} \circ T^{\mathrm{I}} \circ I^{\mathrm{R}} \circ T^{\mathrm{T}}[T] = I^{\mathrm{S}}[T], \tag{10}$$

$$I^{\mathrm{R}} \circ T^{\mathrm{I}} \circ I^{\mathrm{r-R}} \circ T^{\mathrm{T}}[T] = I^{\mathrm{r-R}}[T], \tag{11}$$

$$I^{\mathrm{r-R}} \circ T^{\mathrm{I}} \circ I^{\mathrm{r-R}} \circ T^{\mathrm{T}}[T] = I^{R}[T], \tag{12}$$

Equations (7)–(12) are summed up by Figure 1. As shown in Figure 1, the generation processes from a lower semi-continuous conjunction function as well as from an upper semi-continuous implication function are closed. This result is given by Inuiguchi and Sakawa [7] as the generalization of the result by Dubois and Prade [8]. Note that the semi-continuity is preserved through the generation processes [7].

As shown in Figure 1, we have six conjunction functions and six implication functions. The mappings among those twelve functions are given in Table 1. The inverse mappings are also indicated in Table 1. Some of those functions often appear in literatures on fuzzy relation equations, fuzzy logic, approximate reasoning and so on.

2.3 Possibility and necessity measures

Given a possible range V, the possibility and necessity measures $\Pi_V(S)$ and $N_V(S)$ of a fuzzy event S are defined by

$$\Pi_V(S) = \sup_{u \in U} T(\mu_V(u), \mu_S(u)), \tag{13}$$

$$N_V(S) = \inf_{u \in U} I(\mu_V(u), \mu_S(u)), \tag{14}$$

where μ_V and μ_S are membership functions of fuzzy sets V and S, respectively. U is the universal set. $\Pi_V(S)$ indicates the degree to what extent S is possible under possible range V, while $N_V(S)$ indicates the degree to what extent S is certain under possible range V.

Neither possibility measure nor necessity measure is unique. Therefore, we need to select possibility and necessity measures suitable for the given problem. By their definitions, selections of possibility and necessity measures are equivalent to selections of conjunction and implication functions. In the literature, minimum operation, i.e., $T(a,b) = \min(a,b)$ and Dienes implication, i.e., $I(a,b) = \max(1-a,b)$ are often used because they are simple and used in the original definitions of possibility and necessity measures [9, 10]. However, there is no guarantee that those possibility and necessity measures represent the decision maker's preferences well. Considering the variety of decision maker's preferences, the original possibility and necessity measures are not sufficiently flexible. Then the selections of possibility and necessity measures are important issues.

A conceivable approach to their selections are proposed by Inuiguchi and Tanino [11] and by Inuiguchi et al. [12]. The approach is based on the images of relations between two fuzzy sets represented by two modifier functions. Because of space limitations, we do not introduce this approach but we treat various kinds of necessity measures in the framework of possibilistic linear programming problems.

3 Linear Program with Necessity Measures

We consider a possibilistic linear programming problem,

$$\begin{array}{ll} \text{maximize} & \mathbf{c}^{\mathrm{T}}\mathbf{x}, \\ \text{subject to} & \mathbf{a}_i^{\mathrm{T}}\mathbf{x} \lesssim_i b_i,\ i = 1,2,\ldots,m, \\ & \mathbf{x} \geq \mathbf{0}, \end{array} \tag{15}$$

where $\mathbf{x} = (x_1, x_2, \ldots, x_n)^{\mathrm{T}}$ is a decision vector. b_i, $i = 1,2,\ldots,m$ are constants. Components c_j and a_{ij} of $\mathbf{c}$ and $\mathbf{a}_i$ are not known exactly but the possible ranges of those values are known as fuzzy numbers C_j and A_{ij}, respectively. A fuzzy number is a normal, convex and bounded fuzzy set on the real line whose membership function is upper semi-continuous. The notation $\lesssim_i$ is a fuzzified inequality so that $\lesssim_i\ b_i$ corresponds to a fuzzy set B_i with verbal expression 'a set of real numbers which are roughly smaller than b_i'. We assume that the membership function μ_{B_i} of B_i is non-increasing and upper semi-continuous and satisfies $\mu_{B_i}(b_i) = 1$.

$I^{\mathrm{r-R}}[T^{\mathrm{T}}[T^{\mathrm{I}}[I]]]$	$\sup\{s\in[0,1] \mid I(s,b)\ge a\}$	$I^{\mathrm{r-R}}[T^{\mathrm{T}}[T^{\mathrm{I}}[I]]]$

By the extension principle, the possible ranges of $\mathbf{c}^{\mathrm{T}}\mathbf{x}$ and $\mathbf{a}_i^{\mathrm{T}}\mathbf{x}$ are obtained as fuzzy sets $\mathbf{C}^{\mathrm{T}}\mathbf{x}$ and $\mathbf{A}_i^{\mathrm{T}}\mathbf{x}$, respectively, defined by the following membership functions:

$$\mu_{\boldsymbol{C}^{\mathrm{T}}\boldsymbol{x}}(y)=\sup_{\substack{r_1,\ldots,r_n\\ \boldsymbol{r}^{\mathrm{T}}\boldsymbol{x}=y}}\min\left(\mu_{C_1}(r_1),\ldots,\mu_{C_n}(r_n)\right), \quad (16)$$

$$\mu_{\boldsymbol{A}_i^{\mathrm{T}}\boldsymbol{x}}(y)=\sup_{\substack{r_1,\ldots,r_n\\ \boldsymbol{r}^{\mathrm{T}}\boldsymbol{x}=y}}\min\left(\mu_{A_{i1}}(r_1),\ldots,\mu_{A_{in}}(r_n)\right), \quad (17)$$

where $\mathbf{r}=(r_1,\ldots,r_n)^{\mathrm{T}}$.

Using a necessity measure N^i defined by an upper semi-continuous implication function I^i, in this paper, we formulate Problem (15) as a necessity fractile optimization model (see Inuiguchi and Ramík [3]):

$$\begin{array}{ll}\text{maximize} & q,\\ \text{subject to} & N^0_{\boldsymbol{C}^{\mathrm{T}}\boldsymbol{x}}([q,+\infty))\ge h^0,\\ & N^i_{\boldsymbol{A}_i^{\mathrm{T}}\boldsymbol{x}}(B_i)\ge h^i,\ i=1,2,\ldots,m,\\ & \mathbf{x}\ge\mathbf{0},\end{array} \quad (18)$$

where q is an auxiliary variable. $h^0\in(0,1]$ and $h^i\in(0,1]$, $i=1,2,\ldots,m$ are certainty levels of goal achievement and constraint satisfactions specified by the decision maker. Note that we obtain

$$N^0_{\boldsymbol{C}^{\mathrm{T}}\boldsymbol{x}}([q,+\infty))=\inf_{r<q}I^0(\mu_{\boldsymbol{C}^{\mathrm{T}}\boldsymbol{x}}(r),0), \quad (19)$$

$$N^i_{\boldsymbol{A}_i^{\mathrm{T}}\boldsymbol{x}}(B_i)=\inf_{r}I^i(\mu_{\boldsymbol{A}_i^{\mathrm{T}}\boldsymbol{x}}(r),\mu_{B_i}(r)). \quad (20)$$

The selections of necessity measures and certainty levels depend on the required robustness of goal achievement/constraint satisfactions, the meanings of total goal achievement/constraint satisfactions, the estimation of fuzzy coefficients and so on. The method proposed by Inuiguchi and Tanino [11] and by Inuiguchi et al. [12] would be useful for selecting suitable necessity measures.

Let $[S]_h$ be a h-level set of a fuzzy set S, i.e., $[S]_h=\{u\in U \mid \mu_S(u)\ge h\}$. Then, because fuzzy numbers C_i and A_{ij} are bounded and have upper semi-continuous mem-

ISBN: 978-989-95079-6-8

bership functions, we have (see Dubois and Prade [13])

$$[\mathbf{C}^{\mathrm{T}}\mathbf{x}]_h = \sum_{j=1}^{n} [C_j]_h x_j, \tag{21}$$

$$[\mathbf{A}_i^{\mathrm{T}}\mathbf{x}]_h = \sum_{j=1}^{n} [A_{ij}]_h x_j. \tag{22}$$

Let $c_j^{\mathrm{L}}(h) = \inf[C_j]_h$, $c_j^{\mathrm{R}}(h) = \sup[C_j]_h$, $a_{ij}^{\mathrm{L}}(h) = \inf[A_{ij}]_h$ and $a_{ij}^{\mathrm{R}}(h) = \sup[A_{ij}]_h$. Then, considering the non-negativity of $\mathbf{x}$, we have

$$[\mathbf{C}^{\mathrm{T}}\mathbf{x}]_h = \left[\sum_{j=1}^{n} c_j^{\mathrm{L}}(h)x_j, \sum_{j=1}^{n} c_j^{\mathrm{R}}(h)x_j \right], \tag{23}$$

$$[\mathbf{A}_i^{\mathrm{T}}\mathbf{x}]_h = \left[\sum_{j=1}^{n} a_{ij}^{\mathrm{L}}(h)x_j, \sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(h)x_j \right]. \tag{24}$$

To reduce Problem (18), the following theorem is useful.

Theorem 1. *Let N^i be a necessity measure defined by an implication function I^i. Then for any fuzzy sets V and S of a universal set U, we have*

$$\begin{aligned} & N_V^i(S) \geq h \\ & \Leftrightarrow \forall u \in U,\ \forall k \in [0,1]; \\ & \quad \mu_V(u) \geq k \text{ implies } \mu_S(u) \geq T^{\mathrm{I}}[I^{\mathrm{R}}[T^{\mathrm{I}}[I^i]]](k,h), \\ & \Leftrightarrow \forall k \in [0,1];\ [V]_k \subseteq [S]_{f^i(k,h)}, \end{aligned} \tag{25}$$

where $f^i(k,h) = T^{\mathrm{I}}[I^{\mathrm{R}}[T^{\mathrm{I}}[I^i]]](k,h)$.

(**Proof**) Because of the upper semi-continuity of I^i, Figure 1 and Table 1, we have

$$\begin{aligned} & N_V^i(S) = \inf_{u\in U} I^i(\mu_V(u), \mu_S(u)) \geq h \\ & \Leftrightarrow \forall u \in U;\ I^i(\mu_V(u), \mu_S(u)) \geq h \\ & \Leftrightarrow \forall u \in U;\ \mu_V(u) \leq \sup\{s \in [0,1] \mid I^i(s, \mu_S(u)) \geq h\} \\ & \Leftrightarrow \forall u \in U;\ \mu_V(u) \leq I^{\mathrm{r-R}}[T^{\mathrm{T}}[T^{\mathrm{I}}[I^i]]](h, \mu_S(u)) \\ & \Leftrightarrow \forall u \in U,\ \forall k \in [0,1]; \\ & \quad \mu_V(u) \geq k \text{ implies } I^{\mathrm{r-R}}[T^{\mathrm{T}}[T^{\mathrm{I}}[I^i]]](h, \mu_S(u)) \geq k \\ & \Leftrightarrow \forall u \in U,\ \forall k \in [0,1];\ \mu_V(u) \geq k \text{ implies} \\ & \quad \mu_S(u) \geq \inf\{s \in [0,1] \mid I^{\mathrm{r-R}}[T^{\mathrm{T}}[T^{\mathrm{I}}[I^i]]](h,s) \geq k\} \\ & \Leftrightarrow \forall u \in U,\ \forall k \in [0,1];\ \mu_V(u) \geq k \text{ implies} \\ & \quad \mu_S(u) \geq T^{\mathrm{I}}[I^{\mathrm{r-R}}[T^{\mathrm{I}}[I^{\mathrm{r-R}}[T^{\mathrm{T}}[T^{\mathrm{I}}[I^i]]]]]](k,h) \\ & \Leftrightarrow \forall u \in U,\ \forall k \in [0,1];\ \mu_V(u) \geq k \text{ implies} \\ & \quad \mu_S(u) \geq T^{\mathrm{I}}[I^{\mathrm{R}}[T^{\mathrm{I}}[I^i]]](k,h). \end{aligned}$$

(Q.E.D.)

From the assumptions of B_i, we have $[B_i]_k = (-\infty, \bar{b}_i(k)]$, where $\bar{b}_i : [0,1] \to [0,+\infty)$ is defined by $\bar{b}_i(k) = \sup\{r \mid \mu_{B_i}(r) \geq k\}$. From (23), (24) and Theorem 1, Problem (18) is reduced to the following linear semi-infinite programming problem:

$$\begin{aligned} \text{maximize} \quad & q, \\ \text{subject to} \quad & \sum_{j=1}^{n} c_j^{\mathrm{L}}(k)x_j \geq \bar{q}(f^0(k,h^0)),\ \forall k \in [0,1], \\ & \sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(k)x_j \leq b_i(f^i(k,h^i)),\ \forall k \in [0,1], \\ & \qquad\qquad i = 1,2,\ldots,m, \\ & \mathbf{x} \geq \mathbf{0}, \end{aligned} \tag{26}$$

where $\bar{q} : [0,1] \to \{-\infty, q\}$ is defined by

$$\bar{q}(k) = \begin{cases} q, & \text{if } k > 0, \\ -\infty, & \text{if } k = 0. \end{cases} \tag{27}$$

We showed that fractile optimization models based on necessity measures defined by any implication functions of possibilistic linear programming problems are reduced to linear semi-infinite programming problems. Thus, we can solve the problems by using linear semi-infinite programming techniques [14]. For example, let $\varepsilon > 0$ be a sufficiently small number and let $k_v = (v-1)(1-\varepsilon)/(l-1)+\varepsilon$, $v = 1,2,\ldots,l$. Then Problem (26) can be approximated by the following linear programming problem:

$$\begin{aligned} \text{maximize} \quad & q, \\ \text{subject to} \quad & \sum_{j=1}^{n} c_j^{\mathrm{L}}(k_v)x_j \geq \bar{q}(f^0(k_v,h^0)),\ v = 1,\ldots,l, \\ & \sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(k_v)x_j \leq b_i(f^i(k_v,h^i)), \\ & \qquad\qquad v = 1,\ldots,l,\ i = 1,\ldots,m, \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned} \tag{28}$$

Let $M = \{1,2,\ldots,m\}$. As another approach to computation of an approximate solution to Problem (26), the following algorithm based on a relaxation procedure is conceivable:

Algorithm

S1. Let $z = 0$ and $\varepsilon > 0$ be a sufficiently small positive number. Solve the following linear programming problem:

$$\begin{aligned} & \text{maximize } q, \\ & \text{subject to} \\ & \sum_{j=1}^{n} c_j^{\mathrm{L}}(k_0)x_j \geq \bar{q}(f^0(k_0,h^0)), k_0 = \varepsilon, 1, \\ & \sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(k_i)x_j \leq b_i(f^i(k_i,h^i)),\ k_i = \varepsilon, 1,\ i \in M, \\ & \mathbf{x} \geq \mathbf{0}. \end{aligned}$$

Let $\mathbf{x}^z = (x_1^z,\ldots,x_n^z)^{\mathrm{T}}$ be the obtained optimal solution and q^z be the optimal value.

S2. Calculate $d_0 = \inf_{r\in[0,1]} \sum_{j=1}^{n} c_j^{\mathrm{L}}(r)x_j^z - \bar{q}(f^0(r,h^0))$. If $d_0 < 0$, we define $k_0^z = \arg\inf_{r\in[0,1]} \sum_{j=1}^{n} c_j^{\mathrm{L}}(r)x_j^z - \bar{q}(f^0(r,h^0))$ and otherwise, $k_0^z = 0$.

S3. For $i = 1,2,\ldots,m$, the following processes (a) and (b) are applied. (a) calculate $d_i = \sup_{r\in[0,1]} \sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(r)x_j^z - b_i(f^i(r,h^i))$. (b) If $d_0 > 0$, we define $k_0^z = \arg\sup_{r\in[0,1]} \sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(r)x_j^z - b_i(f^i(r,h^i))$ and otherwise, $k_i^z = 0$.

Table 2: Fuzzy numbers and constraints

$C_1 = \langle 5, 1\rangle$	$C_2 = \langle 7, 0.7\rangle$	
$A_{11} = \langle 2, 0.7\rangle$	$A_{12} = \langle 3, 0.5\rangle$	$B_1 = (230, 60\rangle$
$A_{21} = \langle 4, 1.5\rangle$	$A_{22} = \langle 2, 0.3\rangle$	$B_2 = (370, 100\rangle$
$A_{31} = \langle 1, 0.5\rangle$	$A_{32} = \langle 3, 0.3\rangle$	$B_3 = (140, 90\rangle$

S4. If $\sum_{i=0}^{m} k_i^z = 0$, terminate the algorithm. An approximate solution is obtained as $\mathbf{x}^z$ and q^z.

S5. Let $z = z + 1$. Solve the following linear programming problem:

$$
\begin{aligned}
&\text{maximize } q,\\
&\text{subject to}\\
&\sum_{j=1}^{n} c_j^{\mathrm{L}}(k_0)x_j \geq \bar{q}(f^0(k_0, h^0)), k_0 = \varepsilon, 1,\\
&\sum_{j=1}^{n} c_j^{\mathrm{L}}(k_0^w)x_j \geq \bar{q}(f^0(k_0^w, h^0)), w = 1, \ldots, z\\
&\sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(k_i)x_j \leq b_i(f^i(k_i, h^i)),\ k_i = \varepsilon, 1,\ i \in M,\\
&\sum_{j=1}^{n} a_{ij}^{\mathrm{R}}(k_i^w)x_j \leq b_i(f^i(k_i^w, h^i)),\ w = 1, \ldots, z,\ i \in M,\\
&\mathbf{x} \geq \mathbf{0}.
\end{aligned}
$$

Let $\mathbf{x}^z = (x_1^z, \ldots, x_n^z)^{\mathrm{T}}$ be the obtained optimal solution and q^z be the optimal value. Go to S2.

4 A Numerical Example

In order to demonstrate that Problem (26) is equivalent to Problem (18), in other words, an optimal solution to Problem (28) is an approximate solution to Problem (18), we consider the possibilistic linear programming problem (15) with $m = 3$. Fuzzy numbers C_j and A_{ij} are given by symmetric triangular fuzzy numbers whose center values and spreads are shown in Table 2, where a symmetric triangular fuzzy number Q=$\langle q^{\mathrm{C}}, q^{\mathrm{S}}\rangle$ ($q^{\mathrm{S}} > 0$) is characterized by a membership function,

$$
\mu_Q(r) = \begin{cases} 1 - \dfrac{|r - q^{\mathrm{C}}|}{q^{\mathrm{S}}} & \text{if } r \in [q^{\mathrm{C}} - q^{\mathrm{S}}, q^{\mathrm{C}} + q^{\mathrm{S}}],\\ 0 & \text{otherwise.}\end{cases} \tag{29}
$$

As shown in Table 2, fuzzy constraints B_i are defined by fuzzy sets $B_i = (b_i^{\mathrm{C}}, b_i^{\mathrm{S}}\rangle$ with a linear membership function,

$$
\mu_{B_i}(r) = \begin{cases} 1 & \text{if } r < b_i^{\mathrm{C}},\\ 1 - \dfrac{r - b_i^{\mathrm{C}}|}{b_i^{\mathrm{S}}} & \text{if } r \in [b_i^{\mathrm{C}}, b_i^{\mathrm{C}} + b_i^{\mathrm{S}}],\\ 0 & \text{otherwise.}\end{cases} \tag{30}
$$

We apply Problem (18) with reciprocal Goguen implication $I^0(a, b) = \min(1, (1-a)/(1-b))$ with definition $(1-a)/0 = +\infty$ for any $a \leq 1$, Lukasiewicz implication $I^1(a, b) = \min(1, 1-a+b)$, Reichenbach implication $I^2(a, b) = 1-a+ab$ and Goguen implication $I^3(a, b) = \min(1, b/a)$ with definition $b/0 = +\infty$ for any $b \geq 0$. Then, for $h > 0$ and $k > 0$, we obtain $f_0(k, h) = \max(0, 1 - (1 - k)/h)$, $f_1(k, h) = \max(0, k + h - 1)$, $f_2(k, h) = \max(0, (k + h - 1)/k)$ and $f_3(k, h) = kh$. Moreover, we set $h^0 = 0.5$, $h^1 = 0.5$, $h^2 = 0.62$ and $h^3 = 0.62$.

Let $\varepsilon = 0.0000001$ and $l = 20$, we solve Problem (28), i.e.,

$$
\begin{aligned}
&\text{maximize } q,\\
&\text{subject to}\\
&4.500x_1 + 6.650x_2 \geq q, && 4.550x_1 + 6.685x_2 \geq q,\\
&4.600x_1 + 6.720x_2 \geq q, && 4.650x_1 + 6.755x_2 \geq q,\\
&4.700x_1 + 6.790x_2 \geq q, && 4.750x_1 + 6.825x_2 \geq q,\\
&4.800x_1 + 6.860x_2 \geq q, && 4.850x_1 + 6.895x_2 \geq q,\\
&4.900x_1 + 6.930x_2 \geq q, && 4.950x_1 + 6.965x_2 \geq q,\\
&5x_1 + 7x_2 \geq q, && 2.350x_1 + 3.250x_2 \leq 290.00,\\
&2.315x_1 + 3.225x_2 \leq 287.00, && 2.280x_1 + 3.200x_2 \leq 284.00,\\
&2.245x_1 + 3.175x_2 \leq 281.00, && 2.210x_1 + 3.150x_2 \leq 278.00,\\
&2.175x_1 + 3.125x_2 \leq 275.00, && 2.140x_1 + 3.100x_2 \leq 272.00,\\

&x_1 \geq 0,\ x_2 \geq 0.
\end{aligned}
\tag{31}
$$

Solving this problem, we obtain an optimal solution $\mathbf{x}^* = (x_1^*, x_2^*) = (79.508, 31.564)$ with the optimal value $q^* = 567.69$. As shown in Figures 2∼5, we can observe that the obtained solution approximately satisfies constraints, $N^0_{\boldsymbol{C}^{\mathrm{T}}\boldsymbol{x}}([q^*, +\infty)) \geq 0,5$ and $N^i_{\boldsymbol{A}_i^{\mathrm{T}}\mathbf{x}}(B_i) \geq h^i$, $i = 1, 2, 3$.

5 Concluding Remarks

Utilizing the closure of generation processes of conjunction and implication functions, we have shown that necessity fractile optimization models of possibilistic linear programming problems are reduced to semi-infinite linear programming problems. Therefore, we can solve the problems approximately by linear programming techniques. As a solution procedure for the reduced semi-infinite linear programming problem, we have described a relaxation procedure. In order to demonstrate the main result, we have given a simple numerical example. In the example, the reduced semi-infinite linear programming problem is approximated by a linear programming problem having coarsely-sampled constraints. It has been confirmed that the obtained solution approximately satisfies the required constraints on necessity measures by figures.

The investigation on possibilistic linear programming problems with necessity measures is important to have flexible

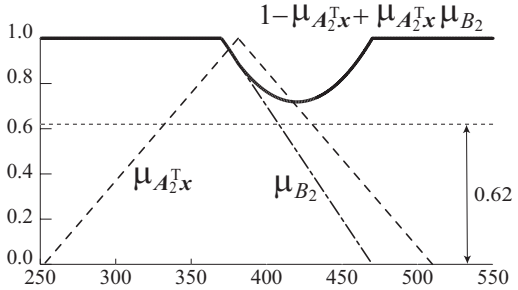

Figure 4: The satisfaction of $N^2_{\boldsymbol{A}_2^{\mathrm{T}}\mathbf{x}}(B_2) \geq 0.62$

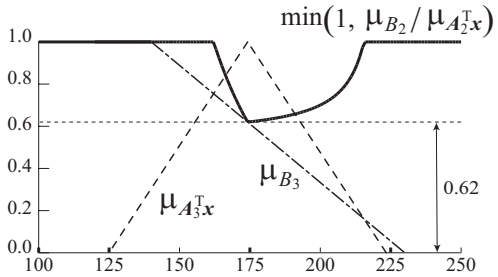

Figure 5: The satisfaction of $N^3_{\boldsymbol{A}_3^{\mathrm{T}}\mathbf{x}}(B_3) \geq 0.62$

models of robust optimization reflecting decision makers' various attitudes toward the uncertainty. Fortunately, models with necessity measures are often easier than models with possibility measures. Analyzing some special implication functions defining necessity measures and special shapes of fuzzy coefficients, the reduced semi-infinite constraints can further reduced to finite constraints. Moreover, we may solve necessity measure optimization models of possibilistic linear programming problems by the simplex method together with the bisection method. These would be future topics in our studies.

Abstract— *By interpreting* 'p *is* impossible' *by* 'p *is* self-contradictory'*, and* 'p *is* always' *by* 'not p *is* self-contradictory'*, this paper studies which of the three-valued systems of Łucasiewicz, Gödel, Kleene, Bochvar, and Post, do verify the Aristotle's principles of Non-Contradiction (NC), and Excluded-Middle (EM).*

Keywords— Systems of three-valued logic, Non-Contradiction, Excluded-Middle.

1 Introduction

As it is well known, the systems of multiple-valued logic do not verify the *principles of non-contradiction* and *excluded-middle*, once presented in the forms (see [5])

$$a \cdot a' = 0,\ a + a' = 1.$$

Nevertheless, in [7] a different way of looking at these two principles, and based on the concept of self-contradiction, respectively $a \cdot a' \leq (a \cdot a')'$, and $(a + a')' \leq ((a + a')')'$, for all a, b, was introduced. These expressions, that are even in more agreement with the original formulation given by Aristotle (see [1]), allow the verification of the two principles for a wide class of structures that include all algebras of fuzzy sets, as well as De Morgan algebras (see [5]). All that meant some progress for what concerns the verification of the two principles.

This paper tries to study the verification of the two Aristotle's principles once interpreted as in [7] , by some of the most well known systems of three-valued logic, namely, by those of the Łukasiewicz, Gödel, Kleene, Bochvar and Post. It is first shown that in Łukasiewicz, Gödel and Kleene cases the two principles are verified, that in the case of Bochvar only one of them is verified, and that in the case of Post no one is verified. Everything is done in agreement with the implication's semantics, as given at each case by its truth-table. At the end, although far from the semantical interpretation at each case, it is shown how the five systems could verify the two principles in the sense introduced in [7].

2 Systems of MV logic

2.1

Let Ω be a set consisting of propositions $p, q, r, \ldots$ and such that,

- If $p \in \Omega$, then '*not p*'$\in \Omega$
- If $p, q \in \Omega$, then '*p and q*', '*p or q*', and '*If p, then q*', are in Ω

2.2

Let L be a set with at least three elements, and endowed with a unary operation $' : L \to L$, and three binary operations $\cdot, +, \to: L \times L \to L$. Suppose there exists 0, 1 in L such that $0 \neq 1$, and $0' = 1$.

2.3

(Ω, L, t) is a *system of multiple-valued logic*, if $t : \Omega \to L$ (truth-function) verifies:

- $t(\text{not } p) = t(p)'$
- $t(p \text{ and } q) = t(p) \cdot t(q)$
- $t(p \text{ or } q) = t(p) + t(q)$
- $t(\text{if } p, \text{ then } q) = t(p) \to t(q)$

for all p, q in Ω. If L is with n elements, the system is an *n-valued* one.

2.4

Two systems of multiple-valued logic, (Ω_1, L_1, t_1) and (Ω_2, L_2, t_2), are *isomorphic* if there exist a pair of bijections (Φ, φ) such that

- $\Phi : \Omega_1 \to \Omega_2, \quad \varphi : L_1 \to L_2$
- $\varphi(a') = \varphi(a)', \varphi(a \cdot b) = \varphi(a) \cdot \varphi(b), \varphi(a + b) = \varphi(a) + \varphi(b), \varphi(a \to b) = \varphi(a) \to \varphi(b)$ with the corresponding operations in L_1, L_2
- $t_1 = \varphi^{-1} \circ t_2 \circ \Phi$, or $t_2(\Phi(p)) = \varphi(t_1(p))$ for all $p \in \Omega_1$.

Example.
The three-valued system of Łukasiewicz, Ł$_3$, (see [5]) is obtained with $L = \{T, F, I\}$ and the four operations given by the following tables:

	$'$
T	F
I	I
F	T

$\bullet$	T	I	F
T	T	I	F
I	I	I	F
F	F	F	F

$+$	T	I	F
T	T	T	T
I	T	I	I
F	T	I	F

$\to$	T	I	F
T	T	I	F
I	T	T	I
F	T	T	T

*This work has been partially supported by the Foundation for the Advancement of Soft Computing (Asturias, Spain), and CICYT (Spain) under project TIN2008-06890-C02-01

†Corresponding author.

ISBN: 978-989-95079-6-8

where $T, I, F \in L, T \neq F$, and $F' = T$.

With $L_0 = \{1, \frac{1}{2}, 0\}$, and $\varphi : L \to L_0$ given by $\varphi(T) = 1, \varphi(I) = \frac{1}{2}, \varphi(F) = 0$, the tables are translated into,

$'$	
1	0
$\frac{1}{2}$	$\frac{1}{2}$
0	1

$\bullet$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	0
0	0	0	0

$+$	1	$\frac{1}{2}$	0
1	1	1	1
1	1	$\frac{1}{2}$	$\frac{1}{2}$
0	1	$\frac{1}{2}$	0

$\to$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	1	1	$\frac{1}{2}$
0	1	1	1

Then, *any system* $Ł_3(\Omega, L, t)$ *is isomorphic to* (Ω, L_0, t^*), with $t^*(p) = \varphi(t(p))$, for all $p \in \Omega$.

Notice that it is,
$a' = 1 - a, a \cdot b = \min(a, b), a + b = \max(a, b)$,
$a \to b = \min(1, 1 - a + b)$, for all $a, b \in L_0$.
Hence,
$t(\text{not } p) = 1 - t(p), t(p \text{ and } q) = \min(t(p), t(q))$,
$t(p \text{ or } q) = \max(t(p), t(q))$,
$t(\text{If } p, \text{ then } q) = \min(1, 1 - t(p) + t(q))$,
for all $p, q \in \Omega$.
Notice that $(a')' = a'' = a$.

3 The other L_0 three-valued systems

Analogously, we can obtain the corresponding systems of Gödel, Bochvar, Kleene and Post (see [5], [2]), by their isomorphic images with $\varphi : L \to L_0$ given by $\varphi(T) = 1, \varphi(I) = \frac{1}{2}, \varphi(F) = 0$.

3.1

Gödel (G_3), is translated into L_0 by

$'$	
1	0
$\frac{1}{2}$	0
0	1

$\bullet$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	0
0	0	0	0

$+$	1	$\frac{1}{2}$	0
1	1	1	1
$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{2}$
0	1	$\frac{1}{2}$	0

$\to$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	1	1	0
0	1	1	1

or, for all $a \in L_0$,

$$a' = \begin{cases} 1, & \text{if } a = 0 \\ 0, & \text{if } a \neq 0 \end{cases}$$

$a \cdot b = \min(a, b)$
$a + b = \max(a, b)$

$$a \to b = \begin{cases} 1, & \text{if } a \leq b \\ b, & \text{if } a > b \end{cases}$$

Notice that, the negation $'$ is not strong, since $(\frac{1}{2}')' = 0' = 1$.

3.2

Kleene (K_3), is translated into L_0 by

$'$	
1	0
$\frac{1}{2}$	$\frac{1}{2}$
0	1

$\bullet$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	0
0	0	0	0

$+$	1	$\frac{1}{2}$	0
1	1	1	1
$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{2}$
0	1	$\frac{1}{2}$	0

$\to$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{2}$
0	1	1	1

or, for all $a \in L_0$,
$a' = 1 - a$,
$a \cdot b = \min(a, b)$,
$a + b = \max(a, b)$,
$a \to b = \max(1 - a, b)$.

Notice that $(a')' = a'' = a$, for all $a \in L_0$ (the negation is strong).

3.3

Bochvar (B_3) is translated into L_0 by

$'$	
1	0
$\frac{1}{2}$	$\frac{1}{2}$
0	1

$\bullet$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
0	0	$\frac{1}{2}$	0

$+$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	1
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
0	1	$\frac{1}{2}$	0

$\to$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
0	1	$\frac{1}{2}$	1

or,
$a' = 1 - a$,

$$a \cdot b = \begin{cases} \frac{1}{2}, & \text{if } (a, b) \in \{(\frac{1}{2}, 0), (0, \frac{1}{2})\} \\ \min(a, b), & \text{otherwise} \end{cases},$$

$$a + b = \begin{cases} \frac{1}{2}, & \text{if } (a, b) \in \{(1, \frac{1}{2}), (\frac{1}{2}, 1)\} \\ \max(a, b), & \text{otherwise} \end{cases},$$

$a \to b = a' + b$.

Notice that $(a')' = a'' = a$, for all $a \in L_0$ (the negation is strong).

3.4

Post (P_3), is translated into L_0 by

$'$	
1	$\frac{1}{2}$
$\frac{1}{2}$	0
0	1

$\bullet$	1	$\frac{1}{2}$	0
1	0	0	$\frac{1}{2}$
$\frac{1}{2}$	0	1	$\frac{1}{2}$
0	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$

$+$	1	$\frac{1}{2}$	0
1	1	1	1
$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{2}$
0	1	$\frac{1}{2}$	0

$\to$	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	$\frac{1}{2}$
$\frac{1}{2}$	1	$\frac{1}{2}$	0
0	1	1	1

or,

$$a' = \begin{cases} 1, & \text{if } a = 0 \\ |\frac{1}{2} - a|, & \text{if } a \neq 0 \end{cases},$$

$a \cdot b = (a' + b')'$,
$a + b = \max(a, b)$,
$a \to b = a' + b$.

Notice that, for all $a \in L_0$, is $(a')' = a'' \neq a$ (the negation is not strong).

Remark. 3.1. In the systems $Ł_3, K_3, G_3, B_3$ but not in P_3, holds the following:

- $0 \cdot 1 = 1 \cdot 0 = 0 \cdot 0 = 0, 1 \cdot 1 = 1$
- $0 + 1 = 1 + 0 = 1 + 1 = 1, 0 + 0 = 0$
- $0' = 1, 1' = 0$

ISBN: 978-989-95079-6-8

- $1 \to 1 = 0 \to 1 = 0 \to 0 = 1, 1 \to 0 = 0$

Then, these four three-valued systems do contain the classical system of two-valued logic based on the values $\{0, 1\}$ that, notwithstanding, is not contained in P_3, a system in which only the operation + preserves such classical case.

4 The two principles

4.1

Triplets $(L, \vDash, ')$ consisting of a non-empty set L, a transitive relation $\vDash \subset L \times L$, and a mapping $' : L \to L$ reversing $\vDash$: if $a \vDash b$, then $b' \vDash a'$, are called *transitive reversing systems* (TRS for short) (see [7])

4.2

An operation $\cdot : L \times L \to L$, is a *type-1 operation* in $(L, \vDash, ')$, provided $a \cdot a' \vDash a$ and $a \cdot a' \vDash a'$, for all $a \in L$.

An operation $+ : L \times L \to L$, is a *type-2 operation* in $(L, \vDash, ')$, provided $a \vDash a + a'$ and $a' \vDash a + a'$, for all $a \in L$.

Theorem 4.1. *(ANC, for Aristotle's Non-contradiction). If $(L, \vDash, ')$ is a TRS, and $\cdot$ is a type-1 operation, it holds*

$$a \cdot a' \vDash (a \cdot a')' \tag{1}$$

for all $a \in L$ (see [7])

Theorem 4.2. *(AEM, for Aristotle's Excluded-middle). If $(L, \vDash, ')$ is a TRS, and $+$ is a type-2 operation, it holds*

$$(a + a')' \vDash ((a + a')')' \tag{2}$$

for all $a \in L$ (see [7])

Remark. 4.3. By defining 'a is selfcontradictory' as $a \vDash a'$, and by taking $'$ representing 'not', $\cdot$ representing 'and', it is clear that (1) can be read

'a and not a, is self-contradictory'.

Hence, interpreting 'impossible' by 'self-contradictory' (1) represents 'a and not a, is impossible'. That is, (1) can be read as an algebraic translation of the Aristotle's Non-contradiction principle.

Remark. 4.4. Like in the previous remark, and taking + representing 'or', (2) can be read as 'not (a or not a) is self - contradictory', or 'not (a or not a) is impossible', an algebraic translation of the Aristotle's Excluded-middle principle usually stated as 'a or not a is always'.

4.3

Theorem 4.5. *Given a triplet $(L, \cdot, ')$, with $L \neq \emptyset$, $\cdot : L \times L \to L$, and $' : L \to L$, the relation $\vDash_{NC} \subset L \times L$, given by the set of pairs*

$$\vDash_{NC} = \{(a \cdot a', (a \cdot a')'); a \in L\},$$

assures the verification of the principle ANC.

Proof. Obviously, $a \cdot a' \vDash_{NC} (a \cdot a')'$, for all $a \in L$. □

Theorem 4.6. *Given a triplet $(L, +, ')$, with $L \neq \emptyset$, $+ : L \times L \to L$, and $' : L \to L$, the relation $\vDash_{EM} \subset L \times L$, given by the set of pairs*

$$\vDash_{EM} = \{((a + a')', ((a + a')')'); a \in L\},$$

assures the verification of the principle AEM

Proof. Obviously, $(a + a')' \vDash_{NC} (a + a')')'$, for all $a \in L$. □

Theorem 4.7. *Given a quadruplet $(L, \cdot, +, ')$, with $L \neq \emptyset$,$\cdot : L \times L \to L$, $+ : L \times L \to L$, and $' : L \to L$, the relation*

$$\vDash = \vDash_{NC} \cup \vDash_{EM} \subset L \times L$$

assures the verification of the two principles ANC and AEM.

Proof. Obviously, for all $a \in L$, is

- $a \cdot a' \vDash_{NC} (a \cdot a')'$ and $a \cdot a' \vDash (a \cdot a')'$
- $(a + a')' \vDash_{EM} ((a + a')')'$, and $(a + a')' \vDash ((a + a')')'$. □

It is to be noticed that *when $'$ verifies $(a')' = a'' = a$, ($'$ is strong), the triplets $(L, \vDash_{NC}, ')$* and $(L, \vDash_{EM}, ')$ are TRS, since:

- $a \cdot a' \vDash_{NC} (a \cdot a')'$, and $(a \cdot a')'' = a \cdot a'$
- $(a+a')' \vDash_{EM} ((a+a')')'$ is equivalent to $(a+a')' \vDash_{EM} a + a'$

Of course, *this does not mean that those triplets are TRS only when $'$ is strong*.

Remark. 4.8. It is obvious that the set of relations $\vDash$ for which $(L, \cdot, +, ')$ verifies, respectively, the principle ANC or the principle AEM, is not empty. If $\vDash$ allows to verify ANC, it is $\vDash_{NC} \subset \vDash$, if $\vDash$ allows to verify AEM is $\vDash_{EM} \subset \vDash$, and if $\vDash$ allows both principles is $\vDash_{NC} \cup \vDash_{EM} \subset \vDash$

Remark. 4.9. It should be pointed out that the last theorems ignore what follows. *The unary operation $'$ should represent 'not', and the relation $a \vDash b$ should represent* '*If a, then b*'. Otherwise, the interpretation of 'If a, then not a' by means of $a \vDash a'$ (a is self-contradictory) has no sense at all. Hence, *and provided $a \cdot b$ does represent* 'a and b', *those representations are crucial for asserting that $a \cdot a' \vDash (a \cdot a')'$ is an interpretation of* "'a and not a' is a self-contradictory statement". And analogously with $(a + a')' \vDash ((a + a')')'$.

4.4

Let us call *Modern Non-contradiction Principle* (MNC, for short), the statement '$a \cdot a' = 0$ for all $a \in L$', and *Modern Excluded-middle Principle* (MEM, for short), '$a + a' = 1$ for all $a \in L$'

Theorem 4.10. *Given a triplet $(L, \vDash, ')$, an operation $\cdot : L \times L \to L$, and $0 \in L$, such that*

- $0 \vDash 0'$
- $a \cdot a' = 0$ *(MNC)*

then, it holds ANC.

ISBN: 978-989-95079-6-8

Proof. $a \cdot a' = 0 \vDash 0' = (a \cdot a')'$. $\square$

Theorem 4.11. *Given a triplet* $(L, \vDash, ')$*, an operation* $+ : L \times L \to L$*, and* $1 \in L$*, such that*

- $1' \vDash (1')'$
- $a + a' = 1$ *(MEM)*

then, it holds AEM.

Proof. $(a + a')' = 1' \vDash (1')' = ((a + a')')'$. $\square$

Remark. 4.12. If $1' = 0$, then $1' \vDash (1')'$ is equivalent to $0 \vDash 0'$

Remark. 4.13. In the sense of theorems 4.10 and 4.11, MNC and MEM are particular cases of ANC and AEM, respectively.

Remark. 4.14. Apart of the three operations $(\cdot, +, ')$, the principles ANC and AEM only involve the relation $\vDash$, but the principles MNC and MEM do involve the relation =, and the 'singular' elements 0,1.

4.5

In what follows this paper is devoted to study if the three-valued systems $Ł_3, G_3, K_3, B_3$, and P_3, do verify the principles ANC or AEM once expressed in the above algebraic terms.

5 Posing the problem for the five three-valued systems

Given a MVL system (Ω, L_0, t), consider its 'values' part $(L_0, ', \cdot, +, \to)$, and the binary relations $\leq$ and $\vDash$ given, respectively, by

$a \vDash b \Leftrightarrow a \to b = 1$, and $\leq$ is the linear order in $L_0 = \{1, \frac{1}{2}, 0\}$, inherited from $\mathbb{R}$.

- *Case* $Ł_3$.

  It is $a \to b = 1 \Leftrightarrow \min(1, 1 - a + b) = 1 \Leftrightarrow a \leq b$. That is, $\vDash_{Ł} = \leq$.

  Since $a' = 1 - a$ implies "$a \leq b \Leftrightarrow b' \leq a'$", $(L_0, \leq, ')$ is a TRS in which, obviously, the operation $\cdot = \min$ is one of type-1, and $+ = \max$ is one of type-2. Hence, it holds

  $$a \cdot a' \leq (a \cdot a')', \ (a + a')' \leq ((a + a')')',$$

  for all $a \in L_0$.

- *Case* G_3.

  It is $a \to b = 1 \Leftrightarrow a \leq b$. That is, $\vDash_G = \leq$, like in the case $Ł_3$. Since it is also $\cdot = \min$, $+ = \max$, it also holds

  $$a \cdot a' \leq (a \cdot a')', \ (a + a')' \leq ((a + a')')',$$

  for all $a \in L_0$.

- *Case* K_3.

  Since, $\vDash_K = \{(1,1), (\frac{1}{2}, 1), (0,1), (0, \frac{1}{2}), (0,0)\} \subset \leq$, and $\vDash'_K = \{(0,0), (0, \frac{1}{2}), (0,1), (\frac{1}{2}, 1), (1,1)\} = \vDash_K$, it means that $(L_0, \vDash_K, ')$ is a TRS. Since, $a' = 1 - a$, it is also $(L_0, \leq, ')$ a TRS.

  From $\frac{1}{2} \cdot \frac{1}{2}' = \frac{1}{2}$, $(\frac{1}{2} \cdot \frac{1}{2}')' = \frac{1}{2}$, and $(\frac{1}{2}, \frac{1}{2}) \notin \vDash_K$, follows that it is not $a \cdot a' \vDash (a \cdot a')'$, for all $a \in L_0$.

  Analogously, $(\frac{1}{2} + \frac{1}{2}')' = \frac{1}{2}$, $(\frac{1}{2} + \frac{1}{2})'' = \frac{1}{2}$, shows that it is not $(a + a')' \vDash ((a \cdot a')')$, for all $a \in L_0$.

  Nevertheless, since $\cdot$ denoting $\min$ is a type-1 operation in $(L_0, \leq, ')$, and $+$ denoting $\max$ is a type-2 operation in $(L_0, \leq, ')$, it follows

  $$a \cdot a' \leq (a \cdot a')', \ (a + a')' \leq ((a + a')')',$$

  for all $a \in L_0$.

- *Case* B_3.

  It is $\vDash_B = \{(1,1), (0,1), (0,0)\} \subset \leq$, and $\vDash'_B = \{(b', a'); (a, b) \in \vDash_B\} = \{(0,0), (0,1), (1,1)\} = \vDash_B$. That is, $(L_0, \vDash_B, ')$ and $(L_0, \leq, ')$ are TRSs.

  Since, $\frac{1}{2} \cdot \frac{1}{2}' = \frac{1}{2}$ and $(\frac{1}{2} \cdot \frac{1}{2}')' = \frac{1}{2}$, but $(\frac{1}{2}, \frac{1}{2}) \notin \vDash_B$, it is not $a \cdot a' \vDash_B (a \cdot a')'$, for all $a \in L_0$.

  Since, $(\frac{1}{2} + \frac{1}{2}')' = \frac{1}{2}' = \frac{1}{2}$ and $((\frac{1}{2} + \frac{1}{2}')')' = \frac{1}{2}$, it is not $(a + a')' \vDash_B ((a + a')')'$, for all $a \in L_0$.

  Notwithstanding,

  $$\left.\begin{array}{lcl} 1 \cdot 1' = 0, (1 \cdot 1')' = 0' = 1 & \Rightarrow & 0 \leq 1 \\ \frac{1}{2} \cdot \frac{1}{2}' = \frac{1}{2}, (\frac{1}{2} \cdot \frac{1}{2}')' = \frac{1}{2} & \Rightarrow & \frac{1}{2} \leq \frac{1}{2} \\ 0 \cdot 0' = 0, (0 \cdot 0')' = 0' = 1 & \Rightarrow & 0 \leq 1 \end{array}\right\} \Rightarrow$$

  $a \cdot a' \leq (a \cdot a')'$, for all $a \in L_0$.

  Analogously,

  $$\left.\begin{array}{lcl} (1 + 1')' = 1, ((1 + 1')')' = 1' + 1 = 1 & \Rightarrow & 1 \leq 1 \\ (\frac{1}{2} + \frac{1}{2}')' = \frac{1}{2}, ((\frac{1}{2} + \frac{1}{2}')')' = \frac{1}{2} & \Rightarrow & \frac{1}{2} \leq \frac{1}{2} \\ (0 + 0')' = 0, ((0 + 0')')' = 0 + 0' = 1 & \Rightarrow & 0 \leq 1 \end{array}\right\} \Rightarrow$$

  $(a + a')' \leq ((a + a')')'$, for all $a \in L_0$.

- *Case* P_3.

  It is $\vDash_P = \{(1,1), (\frac{1}{2}, 1), (0,1), (0, \frac{1}{2}), (0,0)\} \subset \leq$, but since $(\frac{1}{2}, \frac{1}{2}) \in \vDash'_P$ it is not $\vDash'_P \subset \vDash_P$, and $(L_0, \vDash_P, ')$ is not a TRS. In addition, also $(L_0, \leq_P, ')$ it is not a TRS, since $\frac{1}{2} \leq 1$, but $1' = \frac{1}{2} \not\leq 0 = \frac{1}{2}'$.

  From, $0 \cdot 0' = 0 \cdot 1 = \frac{1}{2}, (0 \cdot 0')' = \frac{1}{2}' = 0$, and neither $(\frac{1}{2}, 0) \vDash 0$, nor $\frac{1}{2} \leq 0$, it follows that it is not $a \cdot a' \vDash_P (a \cdot a')'$, nor $a \cdot a' \leq (a \cdot a')'$, for all $a \in L_0$.

  From, $(0 + 0')' = \frac{1}{2}, ((0 + 0')')' = 0$, it follows that it is neither $(a + a')' \vDash_P ((a + a')')'$, nor $(a + a')' \leq ((a + a')')'$, for all $a \in L_0$.

6 The solutions to the problem

6.1

Given a multiple-valued system (Ω, L_0, t), consider the two relations:

$$p \vDash q \Leftrightarrow t(p) \vDash t(q), \text{ and } p \leq q \Leftrightarrow t(p) \leq t(q),$$

and define:

ISBN: 978-989-95079-6-8

- The MV-system (Ω, L_0, t) verifies the principle ANC respect to $\vDash, \leq$, respectively, whenever

  p *and not* $p \vDash$ *not* (p *and not* p),
  or, p *and not* $p \leq$ *not* (p *and not* p)

- The MV-system (Ω, L_0, t) verifies the principle AEM respect to $\vDash, \leq$, respectively, whenever

  not (p *or not* p) $\vDash$ *not*(*not* (p *or not* p)),
  or, *not*(p *or not* p) $\leq$ *not*(*not* (p *or not* p)),

  for all $p \in \Omega$.

6.2

Hence, from the results in section 5, follows:

1. Three-valued *Łukasiewicz* systems *do verify* ANC *and* AEM, *with respect to* $\vDash_{\mathbf{Ł}} = \leq$
2. Three-valued *Gödel* systems *do verify* ANC *and* AEM, *with respect to* $\vDash_G = \leq$
3. Three-valued *Kleene* systems *verify neither* ANC *,nor* AEM, *with respect to* $\vDash_K \subset \leq$
4. Three-valued *Kleene* systems *do verify* ANC *and* AEM, *with respect to* $\leq$
5. Three-valued *Bochvar* systems *verify neither* ANC, *nor* AEM, *with respect to* $\vDash_B \subset \vDash_K \subset \leq$
6. Three-valued *Bochvar* systems *do verify* ANC *and* AEM, *with respect to* $\leq$
7. Three-valued *Post* systems *verify neither* ANC, *nor* AEM, *with respect to* $\vDash_P = \vDash_K \subset \leq$
8. Three-valued *Post* systems *verify neither* ANC, *nor* AEM, *with respect to* $\leq$.

Anyway, and in the line of theorems in section 4.2, it is possible to go further for what concerns points 3, 5, 7 and 8.

6.3

Obviously, *the most surprising case is* P_3. By just adding $(\frac{1}{2}, 0)$ to $\vDash_P$, that is, with the relation

$$\vDash^*_P = \vDash \cup \{(\tfrac{1}{2}, 0)\},$$

it is easy to prove that *both* ANC *and* AEM *hold with respect to* $\vDash^*_P$. But the triplet $(L_=, \vDash^*_P, ')$ is not a TRS, since $(1,1) \in \vDash^*_P$ but $(1', 1') = (\frac{1}{2}, \frac{1}{2}) \notin \vDash^*_P$.

Taking $\vDash^{**}_P = \vDash^*_P \cup \{(\frac{1}{2}, \frac{1}{2})\} = \{(\frac{1}{2}, 0), (0, \frac{1}{2}), (0,0), (1,1), (\frac{1}{2}, 1), (0,1), (\frac{1}{2}, \frac{1}{2})\}$, it is obtained the TRS $(L_0, \vDash^{**}_P, ')$, and *it also holds* ANC *and* AEN *with respect to* $\vDash^{**}_P$. In addition, and as it is easy to check, *the operation* $\cdot$ *in* P_3 *is a type-1 operation in* $(L_0, \vDash^{**}_P, ')$, and *the operation* + in P_3 *is a type-2 operation in* $(L_0, \vDash^{**}_P, ')$.

It should be pointed out that neither $\cdot$ is a type-1 operation in $(L_0, \vDash^*_P, ')$, nor + is a type-2 operation in $(L_0, \vDash^*_P, ')$. The reasons are, respectively, that $\frac{1}{2} \cdot \frac{1}{2}' = \frac{1}{2}$, and $\frac{1}{2} + \frac{1}{2}' = \frac{1}{2}$, but $(\frac{1}{2} \cdot \frac{1}{2}) \notin \vDash^*_P$.

6.4

In the case K_3, taking $\vDash^*_K = \vDash_K \cup \{(\frac{1}{2}, \frac{1}{2})\} = \leq$, the triplet $(L_0, \vDash^*_K, ')$ is a TRS in which the operation $\cdot$ denoting min is a type-1 operation, and the operation + is a type-2 operation. Hence, *it holds ANC with respect to* $\vDash^*_K$ *, and also AEM with respect to the same* $\vDash^*_K$.

6.5

Concerning the case B_3, with $\vDash^*_B = \vDash_B \cup \{(\frac{1}{2}, \frac{1}{2})\}$, the TRS $(L_0, \vDash^*_B, ')$ is reached in which *it holds neither ANC, nor AEM, since*

$$(1+1')' = 1, ((1+1')')' = 1' = 0, \text{ but } (1,0) \notin \vDash^*_B .$$

Anyway, with $\vDash^{**}_B = \vDash^*_B \cup \{(1,0)\} = \{(1,1), (0,1), (0,0), (\frac{1}{2}, \frac{1}{2}), (1,0)\}$, it is obtained the TRS $(L_0, \vDash^{**}_B, ')$, *in which the two principles ANC and AEM obviously do hold.*

6.6

At the end, in the five cases there exist a TRS $(L_0, \vDash, ')$ for which the two principles ANC and AEM do hold. In the cases Ł$_3$ and G_3, it is $\vDash = \leq$ with $\leq$ the lineal order of the real line. In the case K_3, there is a solution with $\leq$, but also with $\vDash^*_K$ that, nevertheless, is again a part of the order $\leq$.

What is different are the cases of Bochvar and Post, where $\vDash^{**}_B$ is not a part of $\leq$, and $\vDash^{**}_P$ is not a part of $\leq$, but on the contrary, it is $\leq \subset \vDash^{**}_P$.

This fact, of not being a part of $\leq$, seems to be the red line between the three system Ł$_3, G_3, K_3$ and the two systems B_3, P_3. The trick to reach the principles ANC and AEM seems to be based on the identification of some pairs $(a, b) \in L_0 \times L_0$ that, added to $\vDash$ in the line of section 4.2, give a new relation for which (without altering the original negation) the two principles do hold.

6.7

Form Remark 4.8, it follows that the relation considered from 6.2 to 6.5 are larger than $\vDash_{NC}$, and $\vDash_{EM}$. As it is easy to check,

- In Ł$_3$, $\vDash_{NC} = \vDash_{EM} = \{(0,1), (\frac{1}{2}, \frac{1}{2})\} \subset \vDash_{\mathbf{Ł}} = \leq$
- In G_3, $\vDash_{NC} = \vDash_{EM} = \{(0,1)\} \subset \vDash_G = \leq$
- In K_3, $\vDash_{NC} = \vDash_{EM} = \{(0,1), (\frac{1}{2}, \frac{1}{2})\} \subset \leq$, but $\vDash_{NC} \nsubseteq \vDash_K$, and $\vDash_{NC} \nsubseteq \vDash^*_K$
- In B_3, $\vDash_{NC} = \vDash_{EM} = \{(0,1), (\frac{1}{2}, \frac{1}{2})\} \subset \leq$, but $\vDash_{NC} \nsubseteq \vDash_B$, and $\vDash_{NC} \nsubseteq \vDash^*_B$
- In P_3, $\vDash_{NC} = \vDash_{EM} = \{(0,1), (\frac{1}{2}, 0)\} \subset \vDash^*_P$, but $\vDash_{NC} \nsubseteq \leq$, and $\vDash_{NC} \nsubseteq \vDash_P$.

Remark. 6.1. An element $a \in L$ is $\vDash$-self-contradictory, if $a \vDash a'$.

In Ł$_3$, since $\vDash_{\mathbf{Ł}_3} = \leq$ and $a' = 1 - a$, it is $a \leq a'$ whenever $a \leq \frac{1}{2}$, that is, the self-contradictory elements are 0 and $\frac{1}{2}$. In G_3, with $\vDash_G = \leq$, the only element that is self-contradictory is 0.

In K_3, with $\vDash_K \subset \leq$, the only self-contradictory is 0, but with $\vDash^*_K$ also $\frac{1}{2}$ is self-contradictory.

ISBN: 978-989-95079-6-8

In B_3, with $\vDash_B \subset \leq$, the only element that is self-contradictory is 0, but with $\vDash_B^*$ and $\vDash_B^{**}$ also $\frac{1}{2}$ is self-contradictory.

In P_3, with $\vDash_P$, the only element that is self-contradictory is 0, but with $\vDash_P^*$ and $\vDash_P^{**}$ also $\frac{1}{2}$ is self-contradictory.

7 Conclusion

7.1

When the principles NC and EM are interpreted in the usual 'modern' forms,

$$a \cdot a' = 0,\ a + a' = 1$$

for all $a \in L_0$, neither Ł$_3$ nor G_3, K_3, B_3, P_3 do verify one of them. For example

- in Ł$_3, G_3, K_3, B_3$: $\frac{1}{2} \cdot \frac{1}{2}' = \frac{1}{2} \neq 0, \frac{1}{2} + \frac{1}{2}' = \frac{1}{2} \neq 1$
- in $P_3 : 0 \cdot 0' = \frac{1}{2} \neq 0, \frac{1}{2} + \frac{1}{2}' = \frac{1}{2} \neq 1$.

Hence, the results presented in this paper mean some progress in what concerns, jointly with what is in [7] and [6], the general verification of the non-contradiction and excluded-middle principles. If they can fail at the just mentioned 'modern' level, it seems to exist at least another level (that of self-contradiction) at which they do not fail.

7.2

Nevertheless, right now the authors are not yet able to completely answer the question of *why the systems Ł$_3, G_3, K_3$ do have solution in $\leq$, but the systems B_3, P_3 do have to exit from $\leq$ to reach a solution, and the system K_3 also admits a second solution in $\leq$*. In all these cases, the pairs that are to be added to the initial relation given by $a \to b = 1$, verify $a \to b \neq 1$. For example,

- In K_3, the added pair $(\frac{1}{2}, \frac{1}{2})$, verifies $\frac{1}{2} \to \frac{1}{2} = \frac{1}{2} \neq 1$
- In B_3, the added pairs $(\frac{1}{2}, \frac{1}{2})$ and $(1, 0)$, verify $\frac{1}{2} \to \frac{1}{2} = \frac{1}{2} \neq 1, 1 \to 0 = 0 \neq 1$
- In P_3, the added pairs $(\frac{1}{2}, 0)$ and $(\frac{1}{2}, \frac{1}{2})$, verify $\frac{1}{2} \to 0 = 0 \neq 1, \frac{1}{2} \to \frac{1}{2} = \frac{1}{2} \neq 1$

Notice that in the cases Ł$_3$ and G_3 it is $a \to b = 1 \Leftrightarrow a \leq b$. Instead, in K_3 it is only $a \to b = \max(1-a, b) = 1 \Rightarrow a = 0$, or $b = 1 \Rightarrow a \leq b$, but not reciprocally. It seems that the relation 'If a, then b' given by $a \to b = 1$, needs to be enlarged to reach both principles but without an agreement with the truth table of $\to$. The case K_3, with the change of $\frac{1}{2} \to \frac{1}{2} = \frac{1}{2}$ by $\frac{1}{2} \to \frac{1}{2} = 1$, results to be coincidental with Ł$_3$. This is a subject that, related to the semantics of the system, deserves more thinking.

7.3

Another consideration about the operators $\to$ drives us to see into its conditional behaviour related to the $\leq$ or $\vDash$ relations. That is [4], whether or not the *Modus Ponens* rule of inference, $a \cdot (a \to b) \leq b$, or $a \cdot (a \to b) \vDash b$, do hold.

Only the Gödel system, G_3, verifies them, as is easy to prove. For the rest of the cases the following counter-examples answer the question.

1. Ł$_3$, with respect to $\vDash_{Ł} = \leq$. It is $\frac{1}{2} \cdot (\frac{1}{2} \to 0) = \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{2} \not\leq 0$, that is $(\frac{1}{2}, 0) \notin \leq$.
2. K_3 , with respect to $\vDash_K$, and $\vDash_K^* = \leq$. It is $\frac{1}{2} \cdot (\frac{1}{2} \to 0) = \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{2}$, and $(\frac{1}{2}, 0) \notin \leq = \vDash_K^*$ and $(\frac{1}{2}, 0) \notin \vDash_K$ too.
3. B_3 , with respect to $\vDash_B, \vDash_B^*, \vDash_B^{**}$, and $\leq$. It is $\frac{1}{2} \cdot (\frac{1}{2} \to 0) = \frac{1}{2} \cdot \frac{1}{2} = \frac{1}{2}$, and $(\frac{1}{2}, 0) \notin \leq$, $(\frac{1}{2}, 0) \notin \vDash_B$, $(\frac{1}{2}, 0) \notin \vDash_B^*$ and $(\frac{1}{2}, 0) \notin \vDash_B^{**}$ too.
4. P_3 , with respect to both $\vDash_P$ and $\leq$. It is $\frac{1}{2} \cdot (\frac{1}{2} \to 0) = \frac{1}{2} \cdot 0 = \frac{1}{2}$, and $(\frac{1}{2}, 0) \notin \leq$, $(\frac{1}{2}, 0) \notin \vDash_P$. With respect to both $\vDash_P^*$ and $\vDash_P^{**}$. It is $\frac{1}{2} \cdot (\frac{1}{2} \to \frac{1}{2}) = \frac{1}{2} \cdot \frac{1}{2} = 1$, and $(1, \frac{1}{2}) \notin \vDash_P^*$, $(1, \frac{1}{2}) \notin \vDash_P^{**}$.

Hence, it is difficult to see the interest of such systems from the point of view of inference.

7.4

Last, but not least significant, is to notice how the different operators $\to$ verify the five properties characterizing implication functions [3], namely, i) $0 \to y = 1$, ii) $1 \to y = y$, iii) $x \to (y \to z) = y \to (x \to z)$, iv) $\to$ is decreasing in the first variable, and v) $\to$ is increasing in the second variable.

A simple calculation shows that in Ł$_3$, G_3, and K_3 the operation $\to$ verifies the five properties, therefore in these systems $\to$ is an implication function. On the contrary, B_3 does verify only properties ii and iii, and P_3 only i, iii, and iv. Hence, neither in B_3, nor in P_3, $\to$ is an implication function.

In the same vein, since in P_3 it is $1' = \frac{1}{2}$, but not $1' = 0$, operation $'$ is not, properly speaking, what is usually designed as a negation.

Parametric Fuzzy Modelling Framework for Complex Data–Inherent Structures

Arne–Jens Hempel Steffen F. Bocklisch
Department of Electrical Engineering, Chair for Systems Theory, Chemnitz University of Technology
Chemnitz, Germany
Email: arne-jens.hempel@etit.tu-chemnitz.de, steffen.bocklisch@etit.tu-chemnitz.de

Abstract— *The present article dedicates itself to fuzzy modelling of data–inherent structures. In particular two main points are dealt with: the introduction of a fuzzy modelling framework and the elaboration of an automated, data–driven design strategy to model complex data–inherent structures within this framework.*

The innovation concerning the modelling framework lies in the fact that it is consistently built around a single, generic type of parametrical and convex membership function. In the first part of the article this essential building block will be defined and its assets and shortcomings will be discussed.

The novelty regarding the automated, data–driven design strategy consist in the conservation of the modelling framework when modelling complex (nonconvex) data–inherent structures. Instead of applying current clustering methods the design strategy uses the inverse of the data structure in order to created a fuzzy model solely based on convex membership functions.

Throughout the article the whole model design process is illustrated, section by section, with the help of an academic example.

Keywords— pattern recognition, fuzzy classification, fuzzy modelling of data structures, data–driven fuzzy classifier design

1 Introduction

Nowadays the world suffocates in vast amounts of data. To give those data an interpretable and thus economical meaning it has to be analysed. The goal of such an analysis is the creation of a model or the classification of the considered phenomenon, e. g. modelling of the traffic flow in cities, medical or machine diagnosis [1, 2, 3].

Basically there are two main philosophies to deduce such a model, theoretical and experimental modelling. In experimental modelling it is assumed that measurement data (objects) reflect the complexity of the phenomenon under consideration through data–inherent structures. Unfortunately, the same data might also exhibit imprecision (e. g. measuring inaccuracies) or depict interesting phenomena characteristics just vaguely (because of missing information). With the help of fuzzy set theory these occurring inaccuracies can be taken into account as a supplementary model feature [4].

In this work the whole modelling problem is understood as a fuzzy classification task, where specific fuzzy sets form a model equivalent. As it is pointed out in [5], there are a lot of sophisticated solutions for such a task, which in general apply nonparametric fuzzy sets or a composition of different fuzzy sets. Contrary to those approaches, the main philosophy behind this work is the exclusive usage of one specific parametrical fuzzy set to model complex data–inherent structures as well as the data itself. Another aspect of the here pursued type of structure modelling is that it works in the original feature space without any transformation like fuzzy support vector classifiers or any assumption of fuzzy functions [6, 7].

2 Fuzzy Pattern Classes

In order to become acquainted with the modelling philosophy it is necessary to understand its core component, the so called *fuzzy pattern class* (FPC). The subsequent sections provide a basic survey about the definition, composition, capabilities and utilisation of *fuzzy pattern class models*.

From a fuzzy theoretical perspective fuzzy pattern classes correspond to a side–specific parametrical multivariate membership function. FPCs are referred to as classes since they emerge from an agglomeration of class supporting objects (see section 2.2), consequently they represent an superordinate entity.

2.1 Definition of a Fuzzy Pattern Class

Although the usual FPC–membership function is multidimensional it derives from one–dimensional basis functions. Hence, it is reasonable to study this basis functions being equivalent to one–dimensional fuzzy pattern classes first. Generally a one–dimensional fuzzy pattern class A is defined over its class space U based on a side–specific parametrical function concept, see (1).

$$\mu^A(a,\vec{p}) = \begin{cases} \dfrac{a}{1+\left(\dfrac{1}{b_l}-1\right)\left|\dfrac{u}{c_l}\right|^{d_l}}, & u<0 \\ \dfrac{a}{1+\left(\dfrac{1}{b_r}-1\right)\left|\dfrac{u}{c_r}\right|^{d_r}}, & u\geq 0 \end{cases} \tag{1}$$

The function concept comprises a set of seven parameters a and $\vec{p}=(b_l,b_r,c_l,c_r,d_l,d_r)$. The further specification of these parameters results from the fact that the parameter a characterises an entire fuzzy pattern class, whereas the parameters combined in $\vec{p}$ are related to a dimension of the class space [8]. Beyond their mere mathematical functionality all parameters possess the following semantical meaning:

- The parameter a represents the maximum membership value of the FPC μ^A. Regarding a structure of classes the parameter a expresses the weight of a specific class. Considering a dynamic classification process a embodies the topicality or authenticity of the information represented by that class [9, 10].
- In the normalised case $a=1$, the parameters b_l, b_r of $\vec{p}$ assign left– and right–sided membership values at the class borders $u=-c_l$ and $u=c_r$.
- c_l, c_r mark the support of a class in a crisp sense. Both parameters characterise the left– and right–sided expansions of a fuzzy pattern class.
- The continuous descent of the membership function is specified by the parameters d_l, d_r. From a graphical point of view d_l, d_r determine the shape of the membership function, or in

ISBN: 978-989-95079-6-8

other words, the fuzziness of a class. Fig. 1 illustrates the introduced concept of the membership function considering the general unidimensional case.

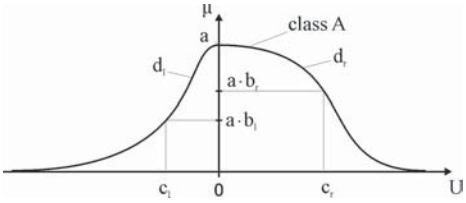

Figure 1: Membership function and parameters.

To obtain the common multidimensional fuzzy pattern class A the basis functions of each class dimension are accumulated using the N-fold compensatory Hamacher intersection operator (2), where n denotes the index of the basis functions and N the total number of dimensions [11].

$$k_{Ham\cap}\mu_N^A = \frac{1}{\frac{1}{N}\sum_{n=1}^{N}\frac{1}{\mu_n^A}} \tag{2}$$

Regarding the main philosophy behind this paper, the most important feature of this intersection operation is the conservation of the parametrical function concept for the multidimensional case [11].

Considering the multidimensional FPC form the class describing set of parameters is supplemented by a class specific position $\vec{u}_0$ in the original feature space and a class specific orientation $\vec{\varphi}$. Fig. 2 depicts the influence of the additional parameters for a two dimensional three class structure. The different location of each class results from $\vec{u}_{c10} = (0.8, 0.2)^T$ $\vec{u}_{c20} = (0.5, 0.5)^T$ and $\vec{u}_{c30} = (0.2, 0.8)^T$, whereas an additional class orientation φ of 60° has been applied to the middle class.

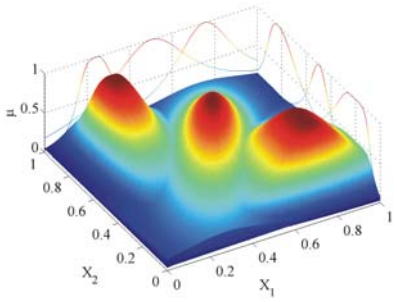

Figure 2: Two dimensional three class structure

2.2 *Data Driven Design of Fuzzy Pattern Classes*

Being familiar with the definition of fuzzy pattern classes a more intriguing question is how fuzzy pattern class models can be deduced. As a matter of principle such models can be obtained via two different approaches [8].

First they can be defined by expertise. That is an expert determines all class parameters based upon task and domain specific knowledge. This approach is not pursued here.

The second approach is a data–driven method, strongly advocating the here featured goal to model data–inherent structures. Based upon a class labelled set of learning data x_l (e.g. measurement objects) all class parameters are assigned automatically by a two step aggregation procedure [9, 10]. The class labels might result from a preliminary conducted cluster analysis.

For the sake of clarity only the basic aggregation principle will be outlined in the following. A full description can be found in [9, 12]. In order to perform the aggregation on sound mathematical foundations, the crisp learning dataset is extended to a set of fuzzy objects, using the introduced function concept (1). This extension is justified by the fact that every observation (measurement) inheres a so called "elementary fuzziness" (e.g impression of a sensor) [9]. In the first aggregation step the class position $\vec{u}_0$, alignment φ and extensions c_l, c_r are calculated in a dimension–wise manner. As exemplified in Fig. 3 the position $\vec{u}_0$ and alignment $\vec{\varphi}$ of the class space is obtained via a principal component analysis (PCA), where $\vec{u}_0$ is defined by the mean over all learning objects and $\vec{\varphi} = (\varphi_1, \varphi_2, \ldots, \varphi_{N-1})^T$ by sequential rotation of the class space U into the principal axes.

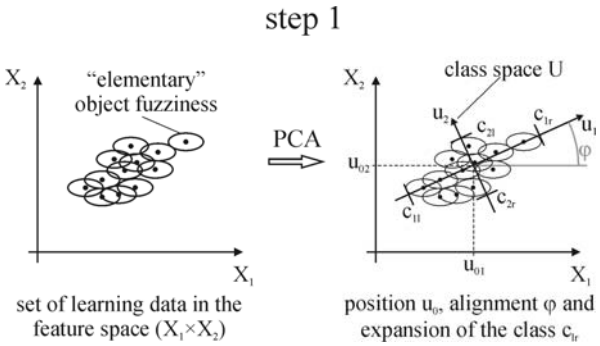

Figure 3: Step 1: aggregation procedure

The extensions c_l, c_r of the class are determined by the outermost objects in each class space dimension. In the subsequent second aggregation step the class shape d_l, d_r and the border memberships b_l, b_r are determined also dimension–wisely.

After the transformation of the objects x_l into their corresponding class space U the shape of a fuzzy patter class (d_l, d_r) is assigned based on their agglomeration properties. The more the data resembles an agglomeration according to a geometric series the smoother the class shape. The rate of resemblance is determined by the mean distance between two adjacent objects. The smoothest class shape is obtained for $d_{lr} = 2$ where the objects are cumulating in the centre of the class conform to a geometric series. The crisp case results for ($d_{lr} \to \infty$) where the objects are equally distributed over the class space, however for calculation purposes $d_{lr} = 20$ has proven to be a sufficient value to represent the crisp case.

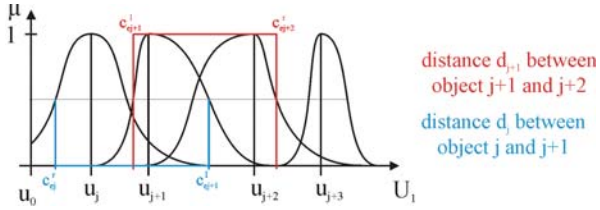

Figure 4: Step 2a: determination of the class form

The values for border memberships b_l, b_r are derived by the

ISBN: 978-989-95079-6-8

conservation of the object cardinality taking into account the results of c_{lr} and d_{lr}. Since the integral over the class membership function (1) cannot be solved analytically the border memberships b_l, b_r are estimated by a binary search over the unity interval $b_{lr} \in [0,1]$ [9].

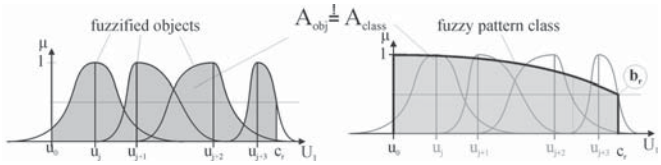

Figure 5: Step 2b: claim for cardinality

The class "weight" a is calculated by a logistic function given the number of the class supporting objects, see [9].

2.3 Application of FPC and Mode of Operation

For applicative purposes all task relevant fuzzy pattern classes are grouped together in a so called fuzzy pattern classifier. In operating mode the fuzzy pattern classifier assigns unknown objects to this class structure. The objects to be classified are each denoted by a vector $\vec{x}$ of their features:

$$\vec{x} = (x_1, x_2, ..., x_N)^T , \tag{3}$$

where N represents the number of feature dimensions. The results of the classification process are stored into a so called vector of sympathy $\vec{s}$. The components of $\vec{s}$ express the membership of a classified object to the corresponding class:

$$\vec{s} = (s_1, s_2, ..., s_K)^T , \tag{4}$$

where K is the total number of classes. The gradual membership of an object to a given class is calculated using (1).

$$s_k = \mu^k(\vec{x}) \quad \text{for } k = 1, 2, ..., K \tag{5}$$

Figure 6 illustrates the process of classification with the help of a one-dimensional three class structure. The object to be classified is situated in the centre of class two, the right outskirts of the first class and in the left centre of the third class. Alongside with the classification task the classification results are listed.

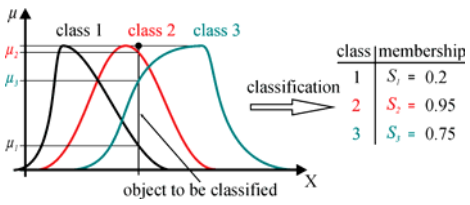

Figure 6: Object classification

According to Fig.6 the vector of sympathy describes a unique assignment of the object to the class structure with respect to its location in the feature space, since there are three classes it contains three values of membership.

2.4 Properties of Fuzzy Pattern Classes

In order to round off the comprehension about the afore introduced concept of fuzzy pattern class models its major properties (advantages and drawbacks) will be outlined subsequently. The main features of the fuzzy pattern class model lie in its versatility, its uniformity and its closed modelling framework. All these features can be attributed to the unimodal, side–specific and parametric class membership function. In the most general case the class membership function offers multivariate FPC models with various and asymmetric shapes, ranging from peak- over bell- to crisp shaped fuzzy sets. In connection with the introduced data–driven design procedure the class membership function allows to map class internal object distributions onto its shape and to model correlative relations without loosing its fuzzy logic basis. Besides this flexibility it has to be stressed that the parameters are semantically motivated or have at least a semantical meaning. It is therefore that the fuzzy pattern classes are considered to be well interpretable and transparent. Another feature resulting from the utilisation of the parametric membership concept is its good trade off between data compression, computational cost and generality. Due to the choice of the membership function (1) each fuzzy pattern class is defined on a set of eight parameters per dimension, providing a sufficient data compression, especially for high dimensional models. Due to the choice of the conjunction operator (2) the intersection operation is exclusively performed on *parameter level* saving computational cost. Both advantages are traded off for generality in so far as class membership functions are convex models, specifying a convex area of the feature space. Consequently FPC are best suited to model convex data–inherent structures. But their convex nature causes fuzzy pattern class models to be afflicted with significant errors when it comes to model nonconvex data–inherent structures.

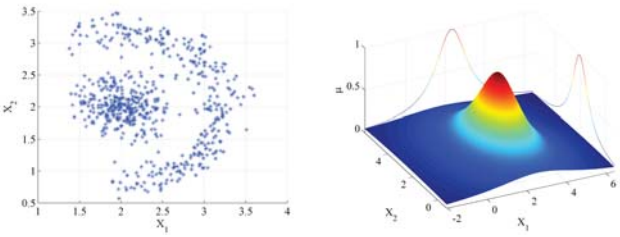

Figure 7: Nonconvex data structure and according FPC model

An example for such an error is depicted in Fig.7 where a central object accumulation enclosed by a half circle shaped data structure was aggregated to a fuzzy pattern class. Obviously the region between the object accumulations does not belong to the given data structure but the associated fuzzy pattern model μ^C will assign high grades of memberships for this region.

In order to circumvent this major drawback two possibilities can be thought of:
The first way, is to segment the data into convex subsets, for example with the help of cluster algorithms. Aside from the fact that this approach works on every data–inherent structure it might create considerably large structures of fuzzy pattern classes at the expenses of model clarity and computational costs.

3 Fuzzy Pattern Anti–classes

The hereafter elaborated access to dissolve the convexity drawback arises from the negation of a class assertion over its unsupported class space. The idea behind this approach

ISBN: 978-989-95079-6-8

can be stated as follows: *The difference of convex sets can be a non–convex set.*
Fig.8 sketches such a negation of the FPC model for a ring shaped problem.

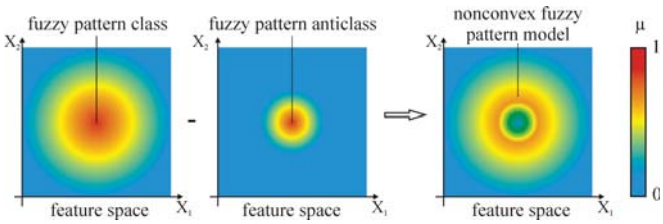

Figure 8: Nonconvex fuzzy pattern model via negation

As it is depicted the negation will be introduced in terms of fuzzy pattern anti–classes (FPAC). It works on semantical level and from this point of view FPACs can be seen as a further specification of a preceding FPC.
Mathematically fuzzy pattern anti–classes are defined upon the same membership function concept as fuzzy pattern classes, see (1). The main concern of of this definition is conservation of the fuzzy pattern modelling framework and with it the *automated model generation* and the *model properties* (such as flexibility, interpretability, computational efficiency, etc.). The enormous shape diversity of fuzzy pattern classes together with the mutual negation of such membership functions allows to model almost any form of data–inherent structures. The only task that needs to be solved can be formulated as follows:
Determine the fuzzy pattern anti–classes given a set of learning data, containing an arbitrary (nonconvex) data–inherent structure and the appendent FPC model.

3.1 Design of Fuzzy Pattern Anti–classes

Assuming that FPACs, like usual fuzzy pattern classes, can be supported by objects or, better so called "anti–objects", then it is in accordance with modelling framework that FPCAs can be designed in a data–driven manner. Aiming to elaborate an automated FPAC design method the already introduced automated databased algorithm can be exploited. However the introduced data–driven FPC design relies on class supporting objects. Correspondingly, in order to setup FPACs these "anti–objects" have to be found first. When considering the general case there are no "anti–objects" given. Consequently they have to be *generated*.
For the sake of clearness the anti–object generation procedure will be illustrated for the two–dimensional case with the help of an academic example. The general multidimensional case follows analogously.

3.1.1 Generation of Anti–objects

According to the task (section 3) the information given are the location of each class supporting object in the learning dataset and the modelling fuzzy pattern class, see Fig.7. Suppose that there is no prior information about the distribution of the learning data it is impossible to make an assumption about the shape of a data–inherent structure. That is why the central idea behind the anti–object generation is led by the assumption that the *anti–objects will agglomerate in the class space being unsupported by learning objects*, such that they will adopt a kind of inverse data–inherent structure and form FPACs.
To ascertain whether a partition of the class space is actually supported by learning objects requires a discretisation of the class space. The size of the class space to be discretised is determined based upon the class borders c_{lr} in each dimension, whereas the discretisation resolution amounts to 2% of the class space leading to a 50×50 matrix F with 2500 cells. A cell of an N–dimensional class space then posses the following the extend:

$$V_c = \frac{1}{50}\left((c_{l1}+c_{r1})\cdot(c_{l2}+c_{r2})\cdot\ldots\cdot(c_{lN}+c_{rN})\right) \qquad (6)$$

Fig.9 depicts the discretised class space for the example along with the class borders in green, the object supported cells highlighted in red and the unsupported class space cells coloured in dark blue.

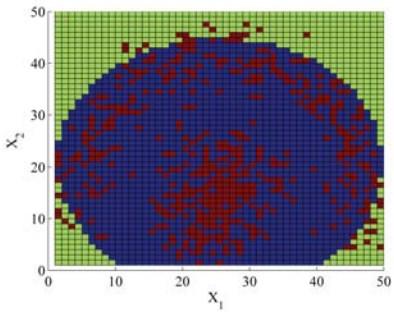

Figure 9: Discretised class space for the example

According to the central idea, the anti–objects have to agglomerate in these unsupported cells. In other words it is necessary to define an model for the agglomeration process. In particular two ways have been pioneered to model the accumulation of anti–objects, namely accumulation based on the elemental fuzziness and accumulation based on power series expansion. The most promising agglomeration model resulted from the assumption of a Fibonacci series.
Its leading thought is the expansion of Fibonacci numbers around the cell of interest until an object supported cell or a class border cell is reached. The result of the expansion around an arbitrary cell (i, j) is a 50×50 matrix $F_{d(i,j)}$ containing only the expanded Fibonacci numbers and zeros.

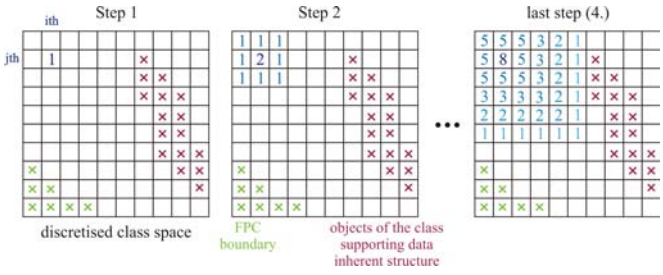

Figure 10: Fibonacci expansion for an arbitrary cell

In this context it has to be mentioned that the fuzzy pattern class borders are treated like objects. Purpose of this procedural manner is to provide an insight of the inner class anti–object distribution by preventing an anti–object accumulation close to the class borders.

ISBN: 978-989-95079-6-8

Fig.10 illustrates the implementation of the Fibonacci expansion for an arbitrary cell at position (i, j). The sum over all Fibonacci matrices $F_{d(i,j)}$ yields the result of the agglomeration process, as in (7).

$$F_d = \sum_{i=1}^{N} \sum_{j=1}^{N} F_{d(i,j)} \tag{7}$$

F_d can be interpreted as a kind of anti–object density matrix. It is broken down into an explicit number of anti–objects per cell based on the maximum object density of all cells d_{max}, see (8).

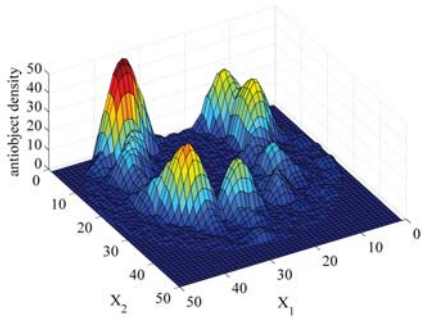

Figure 11: Anti–object density matrix F_d for the example

$$F_a = rd\left(\left(\frac{d_{max}}{max\,(F_d)}\right) F_d\right) \tag{8}$$

With the usual rounding operation rd, in (8), it is assured that each cell contains a natural number of anti–objects ($F_a \in \mathbb{N}^{50\times 50}$).

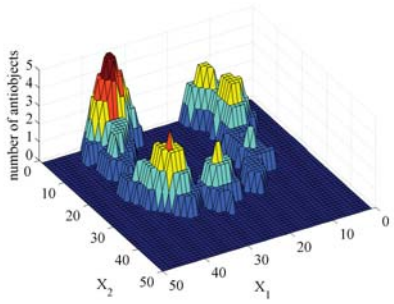

Figure 12: Anti–object matrix F_a for the example

Fig.12 presents the resulting number of anti–objects in their corresponding cells, after applying (8), for the example. The total number of anti–objects, being distributed around the centre region amounts to 887 with a maximum density of five anti–objects per cell.

The final step to complete the anti–object generation comprises the assignment of a position to each anti–object. For this purpose all anti–objects are uniformly distributed over their associated cell. In the here discussed two–dimensional case the anti–object position of an arbitrary cell with the coordinates (i, j) follows from (9), where *rand* draws an random number from the unity interval.

$$\begin{pmatrix} u_{a1} \\ u_{a2} \end{pmatrix} = \begin{pmatrix} i \cdot \frac{1}{50}\,(c_{l1} + c_{r1}) - rand \\ j \cdot \frac{1}{50}\,(c_{l2} + c_{r2}) - rand \end{pmatrix} \tag{9}$$

After their distribution the set of anti–objects forms an inverse of the data–inherent structure, see left–hand side of Fig.13.

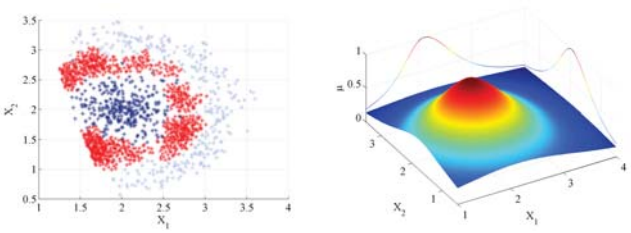

Figure 13: left: Objects, anti–objects, right: according FPAC

However, as it can be seen the anti–objects (in red) form a nonconvex data structure. Modelling this with the help of the automated FPC algorithm again creates a faulty FPAC μ^{AC}, see right–hand side of Fig.13. This might lead to the misconception that the problem was just shifted to the anti–objects. But that is by no means the case, since the whole procedure can be applied again to the created anti–class.

Like a block letter and its print anti–objects and objects complement each other to a complete convex model. Or with another emphasis anti–objects together with objects cover the *entire* class space. Because of that complementary relation, the original objects can be seen as the anti–objects of the anti–objects. Consequently, instead of running through the entire process again for the anti–class, the original objects can be recycled. The reutilisation of the original objects is justified by the facts that a part of the original objects is already complementing the set of anti–objects to a convex description and that their position is already known. Original objects being considered to negate the anti–class are required, firstly to posses a high membership to the anti–class and secondly to be located within the class borders of the anti–class. Generally this applies to original objects with a anti–class membership above $\mu = 0.5$.

For the considered example, the only objects meeting this requirement are the ones located in the centre region, highlighted in dark blue see Fig.13. After setting up the "anti–anti–class" μ^{AAC} by the selected original objects the negation procedure stops owing to the fact the average membership of possible anti–objects drops below a threshold of $\mu = 0.5$.

3.2 Combination of Fuzzy Pattern Anti–class Models

After their generation the anti–class models have to be combined together in order to from an overall model of the data–inherent structure. This combination process is characterised by the following keynote: *If an object does not belong to the anti–class it belongs to the preceding class.* A reasonable implementation of this key concept derives from the concatenation of the natural complement and minimum conjunction [13, 14].

$$\mu = min\left(\mu^{class}, \left(1 - \mu^{anti-class}\right)\right) \tag{10}$$

If the anti–class generation yields several levels of negation their sequence has to be respected for the concatenation. Or differently it has to be respected that *each level of negation creates an new level of hierarchy*. Equation (11) represents this aspect for the example.

ISBN: 978-989-95079-6-8

$$\mu = min\left(\mu^{C}, 1 - min\left(\mu^{AC}, \left(1 - \mu^{AAC}\right)\right)\right) \qquad (11)$$

Fig.14 depicts the nonconvex and fuzzy model, resulting from the class–anti–class combination, together with the supporting objects in black.

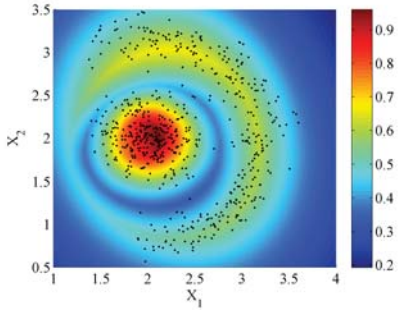

Figure 14: Resulting FPC Model

3.3 Properties of the Fuzzy Pattern Anti–class Design

The introduction of FPAC design is round off by having its assets and drawbacks summarised subsequently.
The main advantage of the introduced design approach lies in the exploitation of a single type of membership function. All the beneficial properties of fuzzy pattern classes, such as transparency, interpretability, computational efficiency etc. are imparted and conserved into the design of nonconvex FPC models. Equally important, by complementing the objects over the considered class space the FPAC design converts the major drawback of fuzzy pattern models (convexity) into an advantage. As a consequence the anti–objects have to be constructed only once. Furthermore the complete object anti–object covering of the class space guarantees convergence of the FPAC design method, since there is no further anti–object generation. Besides that, each anti–class is smaller or equal in size compared to its preceding class such that the area of interest is also converging to zero. Another aspect worth to mention is that the FPAC design works independent from clustering algorithms but features structure capturing.

The major drawback of the design strategy arises from its numerical character, the class space has to be discretised in order to distribute the anti–objects. As a consequence their creation is computationally costly.

4 Conclusions

This paper presents a data driven approach toward modelling of complex data–inherent structures. Its main philosophy is the exclusive usage of a general fuzzy modelling framework. Instead of applying cluster analysis techniques the design strategy aims to complete the convex fuzzy pattern model with the help of so called anti–objects. These anti–objects are not available prior to the design. They have been generated and distributed over the class space. For this purpose a Fibonacci expansion model was elaborated and demonstrated.
With the help of the introduced automated FPC design the anti–objects have been agglomerated to a negating fuzzy pattern classes (FPAC). By preserving the membership function concept the FPAC are on one hand afflicted again with the drawbacks of fuzzy pattern classes. But on the other hand the same design approach can be applied again, eventually leading to a pure convex fuzzy pattern model. A possible combination of the setup FPACs and the original fuzzy pattern model to a hierarchical nonconvex overall FPC model has been demonstrated with the help of an example.

Finally it has to be stressed that the introduced design strategy is a universal approach in so far as it can be applied to any multivariate unimodal convex parametrical membership function.

Further points of research are:
- reducing the numerical character of the method
- combination with cluster algorithms
- creation of fuzzy pattern class and anti–class networks

Abstract— *Description Logics (DLs) are knowledge representation languages useful to represent concepts and roles. Fuzzy Description Logics (FDLs) incorporate both vague concepts and vague roles modeling them as fuzzy sets and fuzzy relations respectively. In the present paper, following ideas from Hájek, we propose the use of t-norm based (fuzzy) logics with truth constants in the language as logics underlying the fuzzy description language. We introduce the languages $\mathcal{ALC}_{L^*(\mathbf{S})}$ and $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$ as an adequate syntactical counterpart of some semantic calculi given in different works dealing with FDLs.*

Keywords— Description Logics, Fuzzy Description Logics, t-Norm Based Fuzzy Logics, Truth-constants, Involutive negation.

1 Introduction

Description Logics (DLs) are knowledge representation languages (particularly suited to specify formal ontologies), which have been studied extensively over the last two decades. A full reference manual of the field is [1]. The vocabulary of DLs consists of *concepts*, which denote sets of individuals, and *roles*, which denote binary relations among individuals. From atomic concepts and roles DL systems allow, by means of *constructors*, to build complex descriptions of both concepts and roles, which are used to describe a domain through a knowledge base (KB) containing the definitions of relevant domain concepts or some hierarchical relationships among them (TBox) and a specification of properties of the domain instances (ABox). One of the main issues of DLs is the fact that the semantics is given in a Tarski-style presentation and the statements in both TBox and ABox can be identified with formulae in first-order logic or a slight extension of it, and hence we can use reasoning to obtain implicit knowledge from the explicit knowledge in the KB.

A natural generalization to cope with vague concepts and relations consists in interpret DL concepts and roles as fuzzy sets and fuzzy relations, respectively. From this point of view, it is at the end of the last decade (from 1998) when several proposals of Fuzzy Description Logics (FDLs) were introduced (e.g., the first ones by Yen [19], Tresp and Molitor [18] and Straccia [14]). However, the logic framework behind these initial works is very limited. With the aim of enriching the expressive possibilities Hájek [9] proposes to take t-norm based fuzzy logics as logics underlying FDLs. This change of view gives a wide number of choices on which a DL can be based: for every particular problem we can consider the t-norm based (fuzzy) logic that seems to be more adequate. As an example, Hájek studies the FDL associated with the description language $\mathcal{ALC}$. After this work, several researchers on FDLs have developed approaches based on the spirit of Hájek's paper, even though their work is more related to expressiveness and algorithms than in its logical base (see for instance [16, 13, 17]).

The main motivation of the present work is based on the following consideration: since the axioms of the bases of knowledge in FDLs include truth degrees (see for instance [14]), a natural choice is to include symbols for these degrees in both, the description language and, as truth constants, in the t-norm based logic where that language is interpreted.

To this goal in the present paper we propose two new families of description languages, denoted by $\mathcal{ALC}_{L^*(\mathbf{S})}$ and $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$ that are extensions of the language $\mathcal{ALC}$ considered by Hájek in [9]. After some introductory notions we define their semantics and describe the corresponding knowledge base (TBox and ABox) from a syntactic and semantic perspective and, taking advantage of having truth constants in the logic, we define graded notions of validity, satisfiability and subsumption. We also give some representative example and some new results for the case of $\mathcal{ALC}$ language over Gödel logic with truth constants and an involutive negation.

2 Fuzzy Logic: basics

In the last decade a family of fuzzy logics as t-norm based fuzzy logics has defined and studied (see, for instance, the monograph [8] for the main notions used in this section). They are multi-valued systems with additive conjunction and disjunction, multiplicative conjunction, implication, negation and the constant $\bar{0}$ which are interpreted in $[0, 1]$ as $\min$, $\max$, a continuous t-norm $*$, its residuum $\rightarrow_*$, the negation function $n(x) = x \rightarrow_* 0$ and 0, respectively. This interpretation is mainly defined by a continuous t-norm and its residuum which justify the name t-norm based logics. Remember that the main continuous t-norms are the minimum, the product and the Lukasiewicz since all other continuous t-norm are ordinal sum of these three basic ones.

2.1 From BL to the logic of a continuous t-norm

The Basic fuzzy Logic (BL) (defined in [8]) has the following basic connectives: *multiplicative conjunction* ($\&$) *implication* ($\rightarrow$) (both binary) and *falsity* ($\bar{0}$) (nullary). It is defined by the inference rule of *Modus Ponens* and the following schemata (taking $\rightarrow$ as the least binding connective):

ISBN: 978-989-95079-6-8

(BL1) $(\varphi \to \psi) \to ((\psi \to \chi) \to (\varphi \to \chi))$
(BL2) $\varphi\&\psi \to \varphi$
(BL3) $\varphi\&\psi \to \psi\&\varphi$
(BL4) $\varphi\&(\varphi \to \psi) \to \psi\&(\psi \to \varphi)$
(BL5a) $(\varphi \to (\psi \to \chi)) \to (\varphi\&\psi \to \chi)$
(BL5b) $(\varphi\&\psi \to \chi) \to (\varphi \to (\psi \to \chi))$
(BL6) $((\varphi \to \psi) \to \chi) \to (((\psi \to \varphi) \to \chi) \to \chi)$
(BL7) $\bar{0} \to \varphi$

The usual defined connectives are introduced as follows:

$\varphi \vee \psi := ((\varphi \to \psi) \to \psi) \wedge ((\psi \to \varphi) \to \varphi)$,
$\varphi \wedge \psi := \varphi\&(\varphi \to \psi)$, $\varphi \leftrightarrow \psi := (\varphi \to \psi)\&(\psi \to \varphi)$,
$\neg\varphi := \varphi \to \bar{0}$, $\bar{1} := \neg\bar{0}$.

Łukasiewicz, Product and Gödel Logics can be obtained as axiomatic extensions of BL with the following axioms: $\neg\neg\varphi \to \varphi$ for Łukasiewicz; $(\varphi \wedge \neg\varphi) \to \bar{0}$ and $\neg\neg\chi \to (((\varphi\&\chi) \to (\psi\&\chi)) \to (\varphi \to \psi))$ for Product; and $\varphi \to \varphi\&\varphi$ for Gödel.

An *evaluation of propositional variables* is a mapping e assigning to each variable p a *truth value* $e(p) \in [0,1]$. Given a continuous t-norm $*$, the evaluation e is extended inductively to a mapping of all formulas into the so-called *standard algebra* $[0,1]_* = \langle [0,1], *, \to_*, \max, \min, 0, 1\rangle$ defined on [0,1] by the t-norm and its residuum in the following way: $e(\varphi\&\psi) = e(\varphi) * e(\psi)$; $e(\varphi \to \psi) = e(\varphi) \to_* e(\psi)$; $e(\bar{0}) = 0$. In [3] it is proved that the formal system BL is sound and complete w.r.t. the standard algebras defined in $[0,1]$ by continuous t-norms and their residua, i.e., a formula φ is provable in BL if and only if it is a common tautology of all standard algebras defined by a continuous t-norm and its residuum. Consequently we say that BL is the logic of continuous t-norms and their residua. It is also well known that Łukasiewicz (Product, Gödel) Logic is the logic of the t-norm of Łukasiewicz (Product, Gödel) and its residuum in the sense that a formula is provable in each logic if and only if it is a tautology over the standard algebra defined by the corresponding t-norm and its residuum.

In [6] the logic L^* of each continuous t-norm $*$ and its residuum is proved to be finitely axiomatizable as extension of BL. Moreover it is also given an algorithm to find a finite set of axioms characterizing each logic L^*. When the negation $\neg\varphi := \varphi \to \bar{0}$ defined in L^* is not involutive, a new logic $L^*_\sim$, expanding L^* by adding an involutive negation, can be considered. This negation, denoted by $\sim$, could be introduced, as is done in the context of intuitionistic logic (see [11]) or in the context of Gödel or Product logics (cf.[5]) by adding the axioms

(~ 1) $\sim\sim\varphi \to \varphi$
(~ 2) $\sim(\varphi \vee \psi) \leftrightarrow (\sim\varphi \wedge \sim\psi)$
(~ 3) $\neg\varphi \to \sim\varphi$

Notice that having an involutive negation in the logic enriches the representational power of the logical language in a non-trivial way because a multiplicative (or strong) disjunction $\varphi \veebar \psi$ is definable now (by duality) as $\sim(\sim\varphi\& \sim\psi)$, being the associated truth function $\oplus$ defined as $x \oplus y := n(n(x) * n(y))$, where n is the truth function of $\sim$ and, on the other hand, a contrapositive implication $\varphi \hookrightarrow \psi$ is definable as $\sim\varphi \veebar \psi$, with truth function $\hookrightarrow_\oplus$ defined as $x \hookrightarrow_\oplus y = n(x) \oplus y$.

2.2 The logics $BL\forall$ and $L^*\forall$

The language of the *basic fuzzy predicate logic* $BL\forall$ consists of a set of *predicate symbols* $\mathcal{P} = \{P, Q, \dots\}$, each together with its *arity* $n \geq 1$ and a set of *constant symbols* $\mathcal{C} = \{c, d, \dots\}$. The logical symbols are *variable symbols* $x, y, \dots$, *connectives* $\&, \to, \bar{0}$ and *quantifiers* $\forall, \exists$. Other connectives $(\vee, \wedge, \neg, \leftrightarrow, \bar{1})$ are defined as in BL. *Terms* are constant symbols and variable symbols. An *atomic formula* is an expression of the form $P(t_1, \dots, t_n)$, where P is a predicate letter of arity n and $t_1, \dots, t_n$ are terms. The set of predicate formulas is built from atomic formulas in the usual way.

A *fuzzy interpretation* for our language is a tuple $\mathbf{M} = \langle M, (r_P)_{P\in\mathcal{P}}, (m_c)_{c\in\mathcal{C}}\rangle$, where M is a set, for each n-ary predicate symbol P, r_P is a fuzzy n-ary relation $M^n \to [0,1]$; and for each constant symbol c, m_c is an element of M.

Given a continuous t-norm $*$, an $\mathbf{M}$-*evaluation* of the variables assigns to each variable x an element $v(x)$ of M. From M and v we define the *truth value of a term* t in the following way: $\|t\|_{\mathbf{M},v} = v(t)$ when t is a variable, and $\|t\|_{\mathbf{M},v} = m_c$ when t is a constant c. The *truth value of a formula* φ *for an evaluation* v, denoted by $\|\varphi\|^*_{\mathbf{M},v}$, is a value in $[0,1]$ defined inductively as follows:

$$\begin{array}{ll} \|\varphi\|_{\mathbf{M},v} & \text{if } \varphi \text{ is an atomic formula,} \\ 0 & \text{if } \varphi = \bar{0}, \\ \|\alpha\|^*_{\mathbf{M},v} * \|\beta\|^*_{\mathbf{M},v} & \text{if } \varphi = \alpha\&\beta, \\ \|\alpha\|^*_{\mathbf{M},v} \to_* \|\beta\|^*_{\mathbf{M},v} & \text{if } \varphi = \alpha \to \beta, \\ \inf\{\|\alpha\|^*_{\mathbf{M},v} : v \equiv_x v'\} & \text{if } \varphi = (\forall x)\alpha, \\ \sup\{\|\alpha\|^*_{\mathbf{M},v} : v \equiv_x v'\} & \text{if } \varphi = (\exists x)\alpha, \end{array}$$

where $v \equiv_x v'$ means that for all variables $y \neq x$, $v(y) = v'(y)$.

The *truth value of a formula* φ is defined by $\|\varphi\|^*_{\mathbf{M}} := \inf\{\|\varphi\|^*_{\mathbf{M},v} : v \text{ is an } \mathbf{M}\text{-evaluation}\}$. A formula φ is a $*$-*tautology* if $\|\varphi\|^*_{\mathbf{M}} = 1$ for every fuzzy interpretation $\mathbf{M}$; φ is a *standard tautology* if it is a $*$-*tautology* for each continuous t-norm $*$. The following standard tautologies are taken as axioms of the basic fuzzy predicate logic $BL\forall$ (see [8]): *a)* the axioms of BL; *b)* the following axioms on quantifiers:

$(\forall 1)$ $(\forall x)\varphi(x) \to \varphi(t)$ (t substitutable for x in $\varphi(x)$),
$(\exists 1)$ $\varphi(t) \to (\exists x)\varphi(x)$ (t substitutable for x in $\varphi(x)$),
$(\forall 2)$ $(\forall x)(\varphi \to \psi) \to (\varphi \to (\forall x)\psi)$ (x not free in φ),
$(\exists 2)$ $(\forall x)(\varphi \to \psi) \to ((\exists x)\varphi \to \psi)$ (x not free in ψ),
$(\forall 3)$ $(\forall x)(\varphi \vee \psi) \to (\forall x)\varphi \vee \psi$ (x not free in ψ).

Deduction rules are (as in classical logic) *Modus Ponens* and *Generalization*. Notions of *proof*, *provability*, *theory*, etc., are defined in the usual way. Let $\mathcal{C}$ be an axiomatic extension of BL. $\mathcal{C}\forall$ is obtained by taking the axioms and rules of $BL\forall$ plus the axioms characterizing $\mathcal{C}$. Thus, given a continuous t-norm $*$, the predicate logic $L^*\forall$ is the logic obtained from L^* by adding to its axiomatization the schemas for quantifiers and the rule of generalization.

2.3 Adding truth constants to the language

T-norm based logics are infinite-valued logics. However, the advantage of being a many-valued logic is not used in current approaches since the semantic deduction of formulas do not take into account the *intermediate or partial truth degrees*. That is to say, current approaches use a truth-preserving con-

ISBN: 978-989-95079-6-8

sequence relation in the same way as in the classical logic, i.e. deduce true formulas (having value 1) from sets of true formulas. An elegant way to take advantage from being many-valued is to introduce truth constants into the language, as it is done by Pavelka in [12] and more recently in [8, 6, 4]. The approach considered in this paper is based in these ideas.

Given a continuous t-norm $*$, its residuum $\rightarrow_*$ and its corresponding logic L^*, let $\mathbf{S} = \langle S, *, \rightarrow_*, \max, \min, 0, 1\rangle$ be a *countable* (i.e., finite or enumerable) *subalgebra* of the corresponding standard algebra $[0,1]_*$. The expansion of L^* adding into the language a truth constant $\bar{r}$ for each $r \in S$, denoted by $L^*(\mathbf{S})$, is defined as follows:

i) the language of $L^*(\mathbf{S})$ is the one of L^* plus a truth constant $\bar{r}$ for each $r \in S$,

ii) the axioms and rules of $L^*(\mathbf{S})$ are those of L^* plus the *book-keeping* axioms: for each $r, s \in S \setminus \{0,1\}$, $\bar{r}\&\bar{s} \leftrightarrow \overline{r * s}$ and $(\bar{r} \rightarrow \bar{s}) \leftrightarrow \overline{r \rightarrow_* s}$.

Completeness results for propositional logic $L^*(\mathbf{S})$ when $*$ is a continuous t-norm has been fully studied in [4].

2.4 *Defining the logics $L^*(\mathbf{S})\forall$ and $L^*_\sim(\mathbf{S})\forall$*

When the negation associated to the continuous t-norm $*$ is not involutive, the logic $L^*_\sim(\mathbf{S})$ can be defined in a similar way although in this case $\mathbf{S}$ has to be a countable subalgebra of the algebra obtained by adding the truth function of the involutive negation $n(x) := 1 - x$ to the operations of $[0,1]_*$. Moreover we need to add the book-keeping axioms for the involutive negation: $\sim \bar{r} \leftrightarrow \overline{n(r)}$. The corresponding predicate logics $L^*(\mathbf{S})\forall$ and $L^*_\sim(\mathbf{S})\forall$ are respectively obtained from $L^*\forall$ and $L^*_\sim\forall$ by expanding the language with a truth constant $\bar{r}$ for every $r \in S$ and by adding the book keeping axioms. The truth value of the formula $\bar{r}$ is given by $\|\bar{r}\|^*_{\mathbf{M}} = r$. The logics $L^*(\mathbf{S})\forall$ and $L^*_\sim(\mathbf{S})\forall$ will be the basis of our proposal for the description languages presented in the next section.

3 The description languages $\mathcal{ALC}_{L^*(\mathbf{S})}$ and $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$

Similarly as first-order logic is the counterpart for interpreting the classic description language $\mathcal{ALC}$, the logics $L^*(\mathbf{S})\forall$ and $L^*_\sim(\mathbf{S})\forall$ will be the counterpart for interpreting the description languages $\mathcal{ALC}_{L^*(\mathbf{S})}$ and $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$ we will define in this section. In these languages, take an special role the so-called evaluated formulas. An *evaluated formula* is a formula of one of the types $\bar{r} \rightarrow \varphi$, $\varphi \rightarrow \bar{r}$ where φ is a formula without new truth constants (i.e., different from $\bar{0}$ and $\bar{1}$). In this setting $\bar{r} \leftrightarrow \varphi$ is definable as $(\bar{r} \rightarrow \varphi)\&(\varphi \rightarrow \bar{r})$. The name of evaluated formulas cames from the fact that $e(\bar{r} \rightarrow \varphi) = 1$ (resp. $e(\varphi \rightarrow \bar{r}) = 1$) if and only if $e(\varphi) \geq r$ (resp. $e(\varphi) \leq r$). Thus, evaluated formulas correspond to the type of formulas (under the notation $\langle \varphi, \succcurlyeq r\rangle$ and $\langle \varphi, \preccurlyeq r\rangle$) used for the knowledge bases in papers on FDLs (cf.[14, 15, 17]). Next we define the description languages $\mathcal{ALC}_{L^*(\mathbf{S})}$ and $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$ from a syntactic and semantic perspective. Then we introduce the notions of *TBox* and *ABox* for that languages.

Syntax. In the languages of description we start from *atomic concepts* and *atomic roles*. Complex descriptions are built inductively with constructors of concepts. We will use the letters A for atomic concepts, R for atomic roles and both C and D for descriptions of concepts. Using the connectives $\bar{0}, \&, \rightarrow$ (falsity, conjunction, implication), the quantifiers $\forall, \exists$ and the point . as an auxiliary symbol, the description of concepts in classic $\mathcal{ALC}$ can be built using the following syntactical rules

$$C, D \rightsquigarrow A \mid \bar{0} \mid C\&D \mid C \rightarrow D \mid \forall R.C \mid \exists R.C$$

Given a continuous t-norm $*$ and a countable subalgebra $\mathbf{S}$ of the corresponding standard algebra $[0,1]_*$, let us consider the logic $L^*(\mathbf{S})$. We define $\mathcal{ALC}_{L^*(\mathbf{S})}$ by adding to $\mathcal{ALC}$, for every $r \in S$, a nullary connective $\bar{r}$ and the rule $C \rightsquigarrow \bar{r}$.

The language $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$ is defined by adding to $\mathcal{ALC}_{L^*(\mathbf{S})}$ the connective $\sim$ and the syntactic rule $C \rightsquigarrow \sim C$.

Following [8], the notions of *instance of a concept* and *instance of a role* allow us to read the formulas of both languages as formulas of the corresponding predicate fuzzy logic. For each term t (variable or constant). The *instance* $D(t)$ of a concept D is defined as follows:

$$\begin{array}{ll} A(t), & \text{if } D \text{ is an atomic concept } A,\\ \bar{0}, & \text{if } D = \bar{0},\\ \sim C(t), & \text{if } D = \sim C,\\ C_1(t) \circ C_2(t), & \text{if } D = C_1 \circ C_2, \text{ where } \circ \in \{\&, \rightarrow\},\end{array}$$

and, if y is a variable not occurring in $C(t)$,

$$\begin{array}{ll} (\forall y)(R(t,y) \rightarrow C(y)), & \text{if } D = \forall R.C,\\ (\exists y)(R(t,y)\&C(y)), & \text{if } D = \exists R.C,\end{array}$$

where, given two terms t_1 and t_2, $R(t_1, t_2)$ is an atomic formula corresponding to the atomic role R. We will refer to the expressions of the form $R(t_1, t_2)$ as *instances of the atomic role R*.

Semantics. According to semantics for $L^*(\mathbf{S})\forall$ and $L^*_\sim(\mathbf{S})\forall$ a fuzzy interpretation $\mathbf{M}$ associates a fuzzy set $A^{\mathbf{M}}$ to each atomic concept A and a fuzzy binary relation $R^{\mathbf{M}}$ to each atomic role R, and the truth value for complex descriptions is given as follows:

$$\begin{array}{rcl} \bar{0}^{\mathbf{M}}(a) & = & 0\\ \bar{r}^{\mathbf{M}}(a) & = & r, \text{ for every } r \in S\\ (C\&D)^{\mathbf{M}}(a) & = & C^{\mathbf{M}}(a) * D^{\mathbf{M}}(a)\\ (C \rightarrow D)^{\mathbf{M}}(a) & = & C^{\mathbf{M}}(a) \rightarrow_* D^{\mathbf{M}}(a)\\ (\forall R.C)^{\mathbf{M}}(a) & = & \inf\{R^{\mathbf{M}}(a,b) \rightarrow_* C^{\mathbf{M}}(b) : b \in M\}\\ (\exists R.C)^{\mathbf{M}}(a) & = & \sup\{R^{\mathbf{M}}(a,b) * C^{\mathbf{M}}(b) : b \in M\}\end{array}$$

In the case of complex descriptions in $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$ we must to add the following:

$$(\sim C)^{\mathbf{M}}(a) \quad = \quad 1 - C^{\mathbf{M}}(a)$$

Fuzzy TBox and Fuzzy ABox. Now we define the notions of $TBox$ and $ABox$ for $\mathcal{ALC}_{L^*(\mathbf{S})}$ and $\mathcal{ALC}_{L^*_\sim(\mathbf{S})}$. In these definitions we use the following graded notion of inclusion between fuzzy sets: $\textit{degree}(C \subseteq D) = \inf_x(C(x) \rightarrow_* D(x))$. Of course this degree is 1 if and only if $C(x) \leq D(x)$ for all x and 0 if the support[1] of the two fuzzy sets are disjoint. Having the truth constants in the language allows us to associate sentences like "*degree* $(C \subseteq D) \leq r$" with formulas such as $(\forall x)(C(x) \rightarrow D(x)) \rightarrow \bar{r}$.

A *fuzzy concept inclusion axiom* is a sentence of one of the following forms:

- $\bar{r} \rightarrow (\forall x)(C(x) \rightarrow D(x))$

[1] The *support* of a fuzzy set is the cardinal of the set of elements which membership degree is greater than 0.

ISBN: 978-989-95079-6-8

Table 1: The graded notation for fuzzy KB.

Evaluated Formula	FDL Graded Notation
$\bar{r} \rightarrow (\forall x)(C(x) \rightarrow D(x))$	$\langle C \sqsubseteq D, \succcurlyeq \bar{r} \rangle$
$(\forall x)(C(x) \rightarrow D(x)) \rightarrow \bar{r}$	$\langle C \sqsubseteq D, \preccurlyeq \bar{r} \rangle$
$\bar{r} \leftrightarrow (\forall x)(C(x) \rightarrow D(x))$	$\langle C \sqsubseteq D, \approx \bar{r} \rangle$
$\bar{r} \rightarrow C(a)$	$\langle a : C, \succcurlyeq \bar{r} \rangle$
$C(a) \rightarrow \bar{r}$	$\langle a : C, \preccurlyeq \bar{r} \rangle$
$\bar{r} \leftrightarrow C(a)$	$\langle a : C, \approx \bar{r} \rangle$
$\bar{r} \rightarrow R(a,b)$	$\langle (a,b) : R, \succcurlyeq \bar{r} \rangle$
$R(a,b) \rightarrow \bar{r}$	$\langle (a,b) : R, \preccurlyeq \bar{r} \rangle$
$\bar{r} \leftrightarrow R(a,b)$	$\langle (a,b) : R, \approx \bar{r} \rangle$

- $(\forall x)(C(x) \rightarrow D(x)) \rightarrow \bar{r}$
- $\bar{r} \leftrightarrow (\forall x)(C(x) \rightarrow D(x))$

A *fuzzy assertion axiom* is a sentence of one of the following forms:

- $\bar{r} \rightarrow C(a)$ or $\bar{r} \rightarrow R(a,b)$
- $C(a) \rightarrow \bar{r}$ or $R(a,b) \rightarrow \bar{r}$
- $C(a) \leftrightarrow \bar{r}$ or $R(a,b) \leftrightarrow \bar{r}$

Now a *fuzzy TBox* is defined as a finite set of *fuzzy concept inclusion axioms* while a *fuzzy ABox* is defined as a finite set of *fuzzy assertion axioms*. A *fuzzy KB* is a pair $\mathcal{K} = \langle \mathcal{T}, \mathcal{A} \rangle$, where the first component is a *fuzzy TBox* and the second one is a *fuzzy ABox*.

Notice that all the axioms of the *fuzzy KB* are evaluated formulas. Thus, the syntactic notion of *fuzzy KB* according to our approach, both the $TBox$ and the $ABox$ can be seen as theories of the logic $L^*(\mathbf{S})\forall$ (or $L^*_{\sim}(\mathbf{S})\forall$).

In Tab. 3 we present an alternative graded notation for fuzzy inclusion and fuzzy assertions that we will use in the example. This notation is similar to the one used in some papers of FDLs (see for instance [17]). Moreover this notation is according to the semantical interpretation in the sense that, for instance,

$$\langle \sigma, \succcurlyeq \bar{r} \rangle^{\mathbf{M}} = r \rightarrow_* \sigma^{\mathbf{M}}$$

and so

$$\mathbf{M} \models \langle \sigma, \succcurlyeq \bar{r} \rangle \quad \text{iff} \quad r \rightarrow_* \sigma^{\mathbf{M}} = 1 \quad \text{iff} \quad \sigma^{\mathbf{M}} \geq r$$

It is interesting to remark that in $\mathcal{ALC}_{L^*_{\sim}(\mathbf{S})\forall}$ the involutive negation allows us to define graded expressions like, for instance, $\langle a : C, \succ \bar{r} \rangle$ as $\sim \langle a : C, \preccurlyeq \bar{r} \rangle$ which corresponds to the formula $\sim (C(a) \rightarrow \bar{r})$.

An example. We will use a data set composed of nine robots (Fig. 1), each one with either the same of different shape of head and body (i.e., they are homogeneous or not homogeneous respectively), they can or cannot wear a tie, they can or cannot smile, and they hold some object. Taking into account all these characteristics, robots can have different *friendliness* degree. The domain of interpretation of the robots is the set: $M_{\mathcal{R}} = \{r_i : 1 \leq i \leq 9\} \cup \{o_i : 1 \leq i \leq 9\}$, where the r_i are the robots and each o_i is the object that the robot r_i holds (e.g., the object o_4 is the flower that r_4 holds). Atomic concepts of the language are the following: Robot, Happy, Object, FriendlyObject, Homogeneous, Balloon, Flag, Flower, Sword, Ax and HasTie. There is only one atomic role: hasObject.

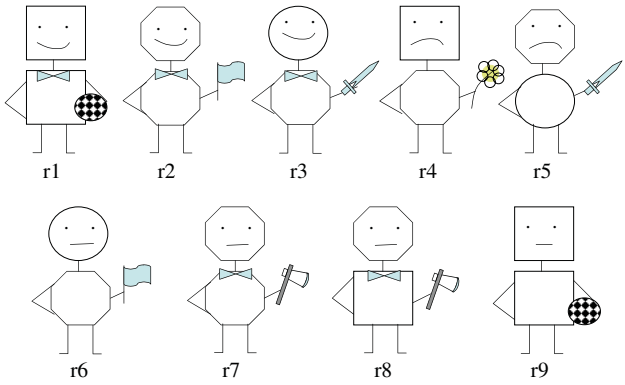

Figure 1: The 9 little robots.

The $TBox$ concerning the robots domain is the following:

Friendly $\equiv$ Robot&(∃hasObject.FriendlyObject)&(Happy $\veebar$ Homogeneous)
$\langle$Robot & Object $\sqsubseteq \bar{0}, \approx \bar{1}\rangle$
$\langle \bar{1} \sqsubseteq$ Robot $\veebar$ Object, $\approx \bar{1}\rangle$
$\langle$Flower $\sqsubseteq$ FriendlyObject, $\approx \bar{1}\rangle$
$\langle$Balloon $\sqsubseteq$ FriendlyObject, $\approx \overline{0.75}\rangle$
$\langle$Flag $\sqsubseteq$ FriendlyObject, $\approx \overline{0.50}\rangle$
$\langle$Sword $\sqsubseteq$ FriendlyObject, $\approx \overline{0.25}\rangle$
$\langle$Ax $\sqsubseteq$ FriendlyObject, $\approx \bar{0}\rangle$

where $C \veebar D$ is an abbreviation of $\sim (\sim C \& \sim D)$ and $C \equiv D$ is an abbreviation for the conjunction of the formulas $\langle C \sqsubseteq D, \approx \bar{1} \rangle$ and $\langle D \sqsubseteq C, \approx \bar{1} \rangle$.

Notice that objects have different friendliness degree. For instance, a sword is a friendly object with degree 0.25 and an ax is a friendly object with degree 0 (i.e., it should be considered unfriendly in the classical case). On the other hand, the $TBox$ also contains a definition of Friendly allowing to assess the friendliness degree of a robot.

The $ABox$ containing the descriptions of the robots is the following:

For each i, $1 \leq i \leq 9$, $\langle r_i$: Robot, $\approx \bar{1}\rangle$, $\langle (r_i, o_i)$: hasObject, $\approx \bar{1}\rangle$
$\langle r_1$: Homogeneous, $\approx \bar{1}\rangle$, $\langle o_1$: Balloon, $\approx \bar{1}\rangle$, $\langle r_1$: Happy, $\approx \bar{1}\rangle$
$\langle r_2$: Homogeneous, $\approx \bar{1}\rangle$, $\langle o_2$: Flag, $\approx \bar{1}\rangle$, $\langle r_2$: Happy, $\approx \bar{1}\rangle$
$\langle r_3$: Homogeneous, $\approx \overline{0.75}\rangle$, $\langle o_3$: Sword, $\approx \bar{1}\rangle$, $\langle r_3$: Happy, $\approx \bar{1}\rangle$
$\langle r_4$: Homogeneous, $\approx \overline{0.50}\rangle$, $\langle o_4$: Flower, $\approx \bar{1}\rangle$, $\langle r_4$: Happy, $\approx \bar{0}\rangle$
$\langle r_5$: Homogeneous, $\approx \overline{0.50}\rangle$, $\langle o_5$: Sword, $\approx \bar{1}\rangle$, $\langle r_5$: Happy, $\approx \bar{0}\rangle$
$\langle r_6$: Homogeneous, $\approx \overline{0.75}\rangle$, $\langle o_6$: Flag, $\approx \bar{1}\rangle$, $\langle r_6$: Happy, $\approx \overline{0.50}\rangle$
$\langle r_7$: Homogeneous, $\approx \bar{1}\rangle$, $\langle o_7$: Ax, $\approx \bar{1}\rangle$, $\langle r_7$: Happy, $\approx \overline{0.50}\rangle$
$\langle r_8$: Homogeneous, $\approx \overline{0.75}\rangle$, $\langle o_8$: Ax, $\approx \bar{1}\rangle$, $\langle r_8$: Happy, $\approx \overline{0.50}\rangle$
$\langle r_9$: Homogeneous, $\approx \bar{1}\rangle$, $\langle o_9$: Balloon, $\approx \bar{1}\rangle$, $\langle r_9$: Happy, $\approx \overline{0.50}\rangle$

Notice that, using truth constants, we can assess different degrees of homogeneity according to the shape of both head and body. In particular, we assess, in a subjective way, that a combination of round shapes of head and body (i.e., a circle and an octagon) give a more homogeneous aspect to the robot than combining round and square shapes. Thus, robots r_6 and r_8 are considered more homogeneous than robot r_4. Similarly, robots have different form of mouth that give them different degree of happiness (i.e., robot r_1 is assessed as more happy than robots r_8 and r_4).

Fuzzy reasoning. Reasoning in fuzzy description logics consists on the same kind of tasks than in the classical case but

ISBN: 978-989-95079-6-8

now they depend on the chosen continuous t-norm $*$. One of the advantages of introducing truth constants in the language is the possibility to define the graded versions of the notions of $*$-satisfiability, $*$-subsumption and $*$-validity defined in [9] without modifying the semantics. Thus, given a concept C, a t-norm $*$ and a truth value $r \in S$ we introduce the following graded notions with respect to a knowledge base $\mathcal{K}$:

• C is *$*$-satisfiable in a degree greater or equal than r* iff there is a model $\mathbf{M}$ of $\mathcal{K}$ such that $\|\bar{r} \to C(a)\|^*_{\mathbf{M}} = 1$ (being a a constant).

• C is *$*$-valid in a degree greater or equal than r* in a model $\mathbf{M}$ of $\mathcal{K}$ iff $\|\bar{r} \to (\forall x)C(x)\|^*_{\mathbf{M}} = 1$.

• C is *$*$-subsumed* by D *in a degree greater or equal than* r in a model $\mathbf{M}$ of $\mathcal{K}$ iff the concept $C \to D$ is *$*$-valid in a degree greater or equal than r* in the model $\mathbf{M}$, that is, iff $\|\bar{r} \to (\forall x)(C(x) \to D(x))\|^*_{\mathbf{M}} = 1$.

On the other hand, we can analogously define the notions of lower thresholds. For instance, a concept C is *$*$-satisfiable in a degree lower or equal than r* iff $\|C(a) \to \bar{r}\|^*_{\mathbf{M}} = 1$ for some model $\mathbf{M}$ of $\mathcal{K}$. Moreover, it is also possible to define an interval where a concept is either valid, satisfiable or subsumed. For instance a concept C is *$*$-satisfiable in an interval of degrees* $[r, s]$ iff $\|\bar{r} \to C(a)\|^*_{\mathbf{M}} = 1$ and $\|C(a) \to \bar{s}\|^*_{\mathbf{M}} = 1$ for some model $\mathbf{M}$. In particular, when $r = s$ the interval became a value called the *degree of satisfiability*.

Example 3.1 *The concept C below is $*$-satisfiable with degree 0.75 in the robots model using any continuous t-norm.*

$$C := \mathsf{Homogeneous} \,\&\exists \mathsf{hasObject}.\mathsf{FriendlyObject}$$

According to the semantics, C is $*$-satisfiable with degree 0.75 if there is at least one robot such that

$C(x) = \mathsf{Homogeneous}(x) * \sup_{y \in M_{\mathcal{R}}}(\mathit{hasObject}(x, y) * \mathit{FriendlyObject}(y)) = 0.75$

The equality is true since the robots r_1 and r_9 have $\mathsf{Homogeneous}(x) = 1$ and both hold a ballon that, as the $TBox$ states, it is a friendly object with degree 0.75. Thus, because 1 is the unity element of any t-norm, both robots have friendliness degree 0.75.

Example 3.2 *Let us to analyze the $*$-subsumption degree of the concept* Object & Sword & FriendlyObject *by* $\bar{0}$ *with respect to the $TBox$.*

According to the definition of $*$-subsumption, we have to analyze the following formula

$$\bar{r} \leftrightarrow (\forall x)((\mathit{Object} \,\&\, \mathit{Sword} \,\&\, \mathit{FriendlyObject})(x) \to \bar{0})$$

and thus, according to the interpretation, the $*$-subsumption has degree

$$r = \inf_{x \in M_{\mathcal{R}}} \{\mathit{Object}(x) * \mathit{Sword}(x) * \mathit{FriendlyObject}(x) \to_* 0\}$$

For all t-norms: a) when x is an element that is neither an object nor a sword, then r is $0 \to_* 0 = 1$, and b) when x is a sword, $r = \mathit{FriendlyObject}(x) \to_* 0$. In such case r depends on the t-norm. For instance, taking the Łukasiewicz's t-norm, $r = \min(1, 1 - \mathit{FriendlyObject}(x) + 0) = 0.75$. Taking either the minimum or the product t-norms $r = 0.25 \to_* 0 = 0$.

Concerning the entailment, we say that a fuzzy assertion α is *$*$-entailed* by the knowledge base $\mathcal{K}$ if every model $\mathbf{M}$ of $\mathcal{K}$ also satisfies α. For instance, the reader can easily prove that the fuzzy $ABox$ of the robots' example $*$-entails the assertion $\langle \mathsf{Friendly}(r_6), \succcurlyeq 0.50\rangle$ with respect to the fuzzy $TBox$ using either Łukasiewicz or minimum t-norms. However, using the product t-norm the above $*$-entailment is not satisfied.

4 A case study: Fuzzy description logics associated to $G_\sim\forall(S)$

The first FDL systems were related to the initial Zadeh proposal for fuzzy sets operations. The logic underlying this proposals is the logic associated to the calculus over $[0, 1]$ defined by the functions $\min$, $\max$, $n(x) = 1 - x$, the Kleene-Dienes implication $x \to y = \max(1 - x, y)$, and quantifiers interpreted as in section 2.2. This is referred as *minimalistic* apparatus of fuzzy logic by Hájek in [9]. But, as already noted by Hájek, the (non residuated) implication of this logic has some no nice behaviour. For example: (a) in this logic $\varphi \to \varphi$ is not a tautology and (b) an implication $\varphi \to \psi$ is evaluated as 1 only if either φ is evaluated as 0 or ψ is evaluated as 1. The languages $\mathcal{ALC}$ based on this logic was studied by Straccia in [14]. The notion of subsumption is defined using the notion of fuzzy subsets ($C \subseteq D$ if and only if $C(x) \leq D(x)$ for all x in the univers) with no relation to implication function due to the lack of a good relation between the implication function of this logic and the order relation in $[0, 1]$. Moreover it is not known any (Hilbert style) axiomatization of this logic.

For these reasons in this short case study we propose the interest of studying the $\mathcal{ALC}$ language associated to Gödel Logic with truth constants $G(\mathbf{S})\forall$ and specially the $\mathcal{ALC}$ language associated to its expansion with an involutive negation $G_\sim(\mathbf{S})\forall$. In [7] the authors prove the canonical completenes of the logic $G(\mathbf{S})\forall$. The canonical completeness can also be proved for $G_\sim(\mathbf{S})\forall$.

Theorem 4.1 *The logic $G_\sim(\mathbf{S})\forall$ has the Canonical Finite Strong completeness, i.e., for every finite set of formulas $\Gamma \cup \{\varphi\}$,*

$$\Gamma \vdash_{G_\sim(\mathbf{S})\forall} \varphi \quad \textit{iff} \quad \Gamma \models_{[0,1]_{G_\sim(\mathbf{S})}} \varphi$$

where
$[0, 1]_{G_\sim(\mathbf{S})} = \langle [0, 1], \min, \max, \to_G, n, \{r \mid r \in S\}, 0, 1\rangle$, *with $n(x) = 1 - x$ being the truth function associated to the involutive negation.*

The proof is a simplified version of [7, Theorem 11]. As a consequence of this theorem, we have an equivalence between $*$-entailment in $\mathcal{ALC}_{G_\sim(\mathbf{S})}$ and the semantics consequence relation on $[0, 1]_{G_\sim(\mathbf{S})}$.

Notice that in $G_\sim(\mathbf{S})\forall$ we have, in addition to the connectives of this logic, the ones being the counterpart of the minimalistic logic, since an implication having as truth function the Kleene-Dienes implication is definable as $\sim \varphi \vee \psi$. Moreover the truth constants allow us to have evaluated formulas and their negation by the involutive negation that makes possible to represent by formulas the semantical expressions saying that the interpretation of a formula is greater, greater or equal, less, and less or equal than a value r.

ISBN: 978-989-95079-6-8

Thus the description language based on $G_\sim\forall(S)$ seems to be a good choice because both it is actually very expressive and it maintains the canonical completeness. In this setting we have two implication connectives, that semantically correspond to the residuum of the minimum plus the Kleene-Dienes implication. Of course, as in the general case of $L^*_\sim(\mathbf{S})\forall$, the degree of subsumption between concepts is defined by means of the residuated implication, i.e, the Gödel implication. The Straccia's work [14] and the Bobillo's work [2] gives algorithms for proving satisfiability and subsumption in the $\mathcal{ALC}$ description language based on the minimalistic logic and in the $\mathcal{SROIQ}(D)$ description language based on Gödel logic respectively. As future work we want to find analogous algorithms for the $\mathcal{ALC}$ description languages based on $G_\sim(\mathbf{S})\forall$.

5 Conclusions

This paper is a first step on the direction proposed by Hájek concerning the relationships between some proposals of FDLs and the recent developments in mathematical fuzzy logics. The main contributions of our approach is the use of truth constants in the language of description and the introduction of an involutive negation in the required cases. This allows us to recover graded notions of satisfiability, validity and subsumption that have been used in the fuzzy logic setting. This choice is oriented to search for the syntactical counterpart of the semantic calculi proposed in some works dealing with FDLs.

Abstract— *To evaluate premises, consequences and hypotheses, on this paper relevance and support ratios are defined for each of them. This allows to distinguish consequences based on the number of premises that support them, and also to reduce the set of premises while maintaining the same consequences. Since the relation between premises and hypotheses is, in some sense, similar to the relation between consequences and premises, analogous ratios are defined for hypotheses and premises.*

Keywords— Conjectures, Consequences, Hypotheses, Relevance, Support.

1 Introduction

The aim of most problems is to make choice between possible solutions, a clear example is a medical diagnosis problem. In this paper we allocate degrees for the elements in the set of consequences, hypotheses or premises in order to choose the consequence, hypothesis or premise with the biggest degree. Papers [2] and [3] had dealt with that idea of graded consequences.

The following section will show Conjectures, Hypotheses, and Consequences (CHC) models introduced in [7], which was suggested, in part by Watanabe in [10], and takes into account the particular case of partial consequence's operator [8] [9]. Partial operators of consequences are that allow to get consequences of each premise, or subset of premises, and obtaining the final set of consequences as the union of all these partial consequences.

To define support for each consequence (section 3) we consider that consequences with bigger support, are those that are supported by more premises or subsets of premises. By the way, different degrees are allocated for consequences. So, for example, following with a medical diagnosis problem in which the premises are diseases and the consequences are symptoms, we can choose between consequences, and select as the stronger, the one with biggest support.

In section 4, we deal with a measure of relevance for premises that is useful for knowing which premises have more importance, in the sense of how many consequences can be deduced from them. Thanks to that measure, the set of premises can be reduced to a smaller set with the same relevance. This reduced set of premises gets rid of superfluous premises and yet allows to work with less premises, while getting the same set of consequences. Till now all premises seemed to have the same importance.

Finally, in section 5, we also consider partial hypotheses, that is, hypotheses of one premise, and not hypotheses of all premises. And analogous measure of support for premises, as well as of relevance for partial hypotheses, are defined. This allows to evaluate subset of partial hypotheses by counting how many premises they give as consequences.

2 Basic concepts

2.1 CHC models

Reasoning can be understood as a process allowing to get conjectures from a set of premises, P. There are three basic types of reasoning: deduction, abduction and induction. A process that allows to get consequences is a deductive reasoning, a process that allows to get hypotheses is an abductive reasoning, and finally, if the process allows to get speculations, it is an speculative reasoning.

In this paper, CHC models are defined on a preordered set $(L, \leq)$, endowed with a negation, $'$. And when it is necessary, the preordered set will be endowed with an infimum, $\cdot$, and a supremum, $+$, operations $(L, \leq, ', \cdot, +)$, a preorder with infimum and supremum operations is a partial ordered set (poset)with these operations. The infimum of L is called first element and it is denoted by 0, the supremum of L is called the last element and it is denoted by 1. The paper only deals with finite algebraic structures, that is, with a finite set L.

CHC models can be based on consequences operators [8, 9],

Definition 2.1 *If L is a set, and $\mathfrak{F} \subset \mathbb{P}(L)$, it is said that $(L, \mathfrak{F}, C)$ is a* structure of consequences*, provided that $C : \mathfrak{F} \to \mathfrak{F}$ verifies,*

1. *$P \subset C(P)$, for all $P \in \mathfrak{F}$ (C is* extensive*)*
2. *If $P \subset Q$, then $C(P) \subset C(Q)$, for all $P, Q \in \mathfrak{F}$ (C is* monotonic*)*
3. *$C(C(P)) = C(P)$, or $C^2 = C$, for all $P \in \mathfrak{F}$ (C is a* clausure*)*

i.e. C is an operator of consequences *(in the sense of Tarski) for $\mathfrak{F}$ in L.*

For each $\{q\} \in \mathfrak{F}$, let us write $C(q) = C(\{q\})$.

*This work has been partially supported by the Foundation for the Advancement of Soft Computing (Asturias, Spain), and CICYT (Spain) under project TIN2008-06890-C02-01

ISBN: 978-989-95079-6-8

Definition 2.2 *A consequences' operator C is consistent in P, if for all $q \in C(P)$, $q' \notin C(P)$.*
A structure of consequences $(L, \mathfrak{F}, C)$ is consistent if C is consistent for all $P \in \mathfrak{F}$.

Let P be the set of premises, $P \neq \emptyset$, and $C(P)$ a set of consequences for P. Conjectures of P can be defined from a consistent consequences operator C, as those elements whose negation is not in $C(P)$, $Conj_C(P) = \{q \in L; q' \notin C(P)\}$. Hypothesis can be defined by $Hyp_C(P) = \{h \in Conj_C(P) - C(P); \{h\} \in \mathfrak{F},\ P \subset C(h)\}$.

Finally, speculations are those conjectures that are neither consequences, nor hypotheses. Hence, $Sp_C(P) = Conj_C(P) - [C(P) \cup Hyp_C(P)] = \{q \in L, q \notin C(P), q' \notin C(P), q \notin Hyp_C(P)\}$.

2.2

Definition 2.3 *A consequences' operation C is a partial consequences operator if $C(P) = \bigcup_{R \subset P, R \in \mathfrak{F}} C(R)$.*

Definition 2.4 *A decomposable consequences operator is a consequences' operator such that $C(P) = \bigcup_{p \in P} C(R)$.*

This paper considers *partial hypothesis*, elements that are hypotheses of a subset of the set of premises P. This idea comes from that of *partial consequences*.

Definition 2.5 *For each set P of premises the partial hypotheses set is,*

$$Hyp^*_C(P) = \{h \in \{L - 0\} - P; \{h\} \in \mathfrak{F}, \exists R \subset P,$$
$$R \subset C(h)\}.$$

Obviously, hypotheses are partial hypotheses, since $P \subset P$ and $P \subset C(h)$, provided h is a hypothesis.

Remark 2.6 *Although hypotheses are anti-monotonic ($P_1 \subset P_2$, implies $Hyp(P_2) \subset Hyp(P_1)$), partial hypotheses are (as it is easy to prove) monotonic ($P_1 \subset P_2$, implies $Hyp^*(P_1) \subset Hyp^*(P_2)$). That is why they can not be considered classical hypotheses.*

2.3

The paper deals with a general concept of measure [6], defined in a preordered set $(L, \leq)$. A measure is a mapping $m : L \to [0, 1]$, such that:

- There exists a minimal $x_0 \in L$, such that $m(x_0) = 0$
- There exists a maximal $x_1 \in L$, such that $m(x_1) = 1$
- If $x \leq y$, then $m(x) \leq m(y)$.

3 Consequences support

This section introduces a ratio in order to distinguish which consequences are the more supported by a given set of premises. And proof in which cases is a measure

Let's recall that in this paper L is assumed to be a finite set.

Definition 3.1 *The support of $q \in L$ is the ratio of subsets of premises that allow getting q as a consequence, to all possible subsets of premises.*

$$Supp_{C,P}(q) = \frac{|\{R \in \mathbb{P}(P); q \in C(R)\}|}{2^{|P|} - 1} = \quad (1)$$
$$\frac{|\{R \in \mathbb{P}(P); q \in C(R)\}|}{|\mathbb{P}(P) - \emptyset|}.$$

Since $P \neq \emptyset$, it is $|P| > 0$ and the quotient in the definition is possible.

The bigger support a consequence has, the more subsets of premises allow deducing it.
Notice that if $q \notin C(P), Supp_{C,P}(q) = 0$, since if there were $R \in \mathbb{P}(P)$ such that $q \in C(R)$, because of the monotonicity of the consequence operator, $C(R) \subset C(P)$ would imply $q \in C(P)$.

This ratio verifies the following properties,

- If $P \subset Q$, it is $Supp_{C,P}(q) \leq Supp_{C,Q}(q)$, for all $q \in L$.
- If $P = \{p\}, \forall q \in C(P)$, it is $Supp_{C,P}(q) = 1$.
- For all $q \in C(P)$, $Supp_{C,P}(q) > 0$.
- $Supp_{C,P}(q) = 1$ means that q is a consequence for all $R \in \mathbb{P}(P)$. Particularly, q is consequence of all $p \in P$.

The support defined by (1), is not a measure in general. For example, if $C(P) = P,\ \forall P \in \mathbb{P}(L)$, let P be a set with more than one element. If $q \in L$, it is either $q \in P$, or $Supp(q) = 0$. If $q \in P$, there exists $p \in P$ such that $p \neq q$, and $q \notin C(p)$ and $Supp(q) \neq 1$. Therefore, there is no $q \in L$ such that $Supp_{C,P}(q) = 1$.

Remark 3.2 *$Supp_{C,P}$ is monotonic with respect to the preorder given by C, $q_1 \leq_C q_2$ iff $q_2 \in C(q_1)$ [1],*

Proof. Since if $q_1 \leq_C q_2$, for each R such that $q_1 \in C(R)$, it is $C(q_1) \in C(C(R)) = C(R)$, and, as $q_2 \in C(q_1)$, it is also $q_2 \in C(R)$. So, $Supp_{C,P}(q_1) \leq Supp_{C,P}(q_2)$.
□

Since, given P, the relation defined between the pairs of elements in L with the same value of $Supp_{C,P}$, is an equivalence, the classes

$$[q] = \{v \in L;\ Supp_{C,P}(v) = Supp_{C,P}(q)\}$$

give a partition on L in a number of parts that is, at most, $2^{|P|}$.

3.1 The case of the operator $C_\bullet$

Let $(L, \leq)$ be now a preordered set in which is defined an infimum operation denoted by '$\cdot$'.

The partial consequences operator $C_\bullet$ gives consequences that are consequences for a subset of the set of premises P, it is $C_\bullet(P) = \{q \in L; \exists \{p_1, p_2, ..., p_n\} \subset P : p_1 \cdot p_2 \cdot ... \cdot p_n \leq q\}$. It is a partial consequences' operator and it obviously verifies $C_\bullet(P) = \bigcup_{R \subset P, R \in \mathfrak{F}} C_\bullet(R)$.

ISBN: 978-989-95079-6-8

Notice, that as L is finite, P is also finite and $C_\bullet(P) = \{q \in L; \inf P \leq q\}$, which equal to the infimum operator of consequences $C_\wedge$.

$$Supp_{C_\bullet,P}(q) = \frac{|\{R \in \mathbb{P}(P) \in P; \inf(R) \leq q\}|}{2^{|P|}-1} \quad (2)$$

Let's see what specific properties are verified by $Supp_{C_\bullet,P}$,

- If L has last element, it implies $1 \in L$, then $1 \in C_\bullet(P)$ and $Supp_{C_\bullet,P}(1) = 1$.
- If $q_1 \leq q_2$, then $Supp_{C_\bullet,P}(q_1) \leq Supp_{C_\bullet,P}(q_2)$. That is the function $Supp_{C_\bullet,P}$ is monotonic.
- $Supp_{C_\bullet,P}(\sup\{q_1,q_2\}) \geq \max\{Supp_{C_\bullet,P}(q_1), Supp_{C_\bullet,P}(q_2)\}$, provided $\sup\{q_1,q_2\}$ exists.
- $Supp_{C_\bullet,P}(\inf\{q_1,q_2\}) \leq \min\{Supp_{C_\bullet,P}(q_1), Supp_{C_\bullet,P}(q_2)\}$

Corollary 3.3 *Let $(L, \leq, ', \cdot, +)$ be a partial ordered set with infimum and supremum operations and first and last elements. If $P \neq \{0\}$, the function $Supp_{C_\bullet,P} : L \to [0,1]$ is a measure.*

Proof. It is monotonic, and it verifies the boundary conditions, since 0 is not a consequence $Supp_{C_\bullet,P}(0) = 0$ and $Supp_{C_\bullet,P}(1) = 1$. □

3.2 The case of the operator $C_\leq$

$C_\leq$ is the partial consequences operator that gives as consequences those elements that follow from at least one premise in P, formally, it is $C_\leq(P) = \{q \in L; \exists p \in P : p \leq q\}$, see [8]. Hence, it can be considered as a decomposable consequences' operator, since allows getting consequences that are not deduced from all premises. It is straightforward that $C_\leq(P) = \bigcup_{R \subset P, R \in \mathfrak{F}} C(R) = \bigcup_{p \in P} C_\leq(p)$.

In this case, a different definition of the support's ratio seems to be more convenient, since it deals only with consequences of each $p \in P$, nor with consequences of each subset of $\mathbb{P}(P)$.

Definition 3.4 *The support of $q \in C_\leq(P)$ is the ratio of premises that allow getting q as consequence to all premises.*

$$\widehat{Supp}_{C_\leq,P}(q) = \frac{|\{p \in P; p \leq q\}|}{|P|} \quad (3)$$

Since $P \neq \emptyset$, it is $|P| > 0$ and the quotient in the definition is possible.

If $q \notin C_\leq$, then $\widehat{Supp}_{C_\leq,P}(q) = 0$.

So, the bigger Support an element has, the more premises allow to reach it.

$\widehat{Supp}_{C_\leq,P}$ verifies,

- If $P = \{p\}, \forall q \in C_\leq(p)$, it is $\widehat{Supp}_{C_\leq,P}(q) = 1$.
- If L has last element, 1, then $1 \in C_\leq(P)$ and $\widehat{Supp}_{C_\leq,P}(1) = 1$.
- For no $q \in C_\leq(P)$ is $\widehat{Supp}_P(q) = 0$. That is, for all $q \in C_\leq(P)$, $\widehat{Supp}_{C_\leq,P}(q) > 0$.
- $\widehat{Supp}_{C_\leq,P}(q) = 1$ means that q is a consequence for all $p \in P$.
- If $q_1 \leq q_2$, then $\widehat{Supp}_{C_\leq,P}(q_1) \leq \widehat{Supp}_{C_\leq,P}(q_2)$. That is the function $\widehat{Supp}_{C_\leq,P}$ is monotonic with respect to $\leq$.

Remark 3.5 *In order to know what happens if we calculate the support for the infimum or supremum, of two consequences, provided it exists and it is a consequence, weak boundaries are found,*

- $\widehat{Supp}_{C_\leq,P}(\sup\{q_1,q_2\}) \geq \max\{\widehat{Supp}_{C_\leq,P}(q_1), \widehat{Supp}_{C_\leq,P}(q_2)\}$
- $\widehat{Supp}_{C_\leq,P}(\inf\{q_1,q_2\}) \leq \min\{\widehat{Supp}_{C_\leq,P}(q_1), \widehat{Supp}_{C_\leq,P}(q_2)\}$

Obviously, if the operator is consistent, that is, if $q \in C_\leq(P)$, then $q' \notin C_\leq(P)$, it follows $\widehat{Supp}_{C_\leq,P}(q') = 0$.

Theorem 3.6 *Let $(L, \leq, ', \cdot, +)$ be a partial ordered set with first and last elements and $P \neq \{0\}$. Function $\widehat{Supp}_{C_\leq,P} : L \to [0,1]$ is a measure.*

Proof. It is monotonic as it is stated above. Since 0 is not a consequence $\widehat{Supp}_{C_\leq,P}(0) = 0$. Finally, it is obvious that $1 \in C_\leq(P)$ and $\widehat{Supp}_{C_\leq,P}(1) = 1$. □

From $\widehat{Supp}_{C_\leq,P}$ we can calculate $Supp_{C_\leq,P}$. If $\widehat{Supp}_{C_\leq,P}(q) = k$ and $|P| = n$, it is $|\{R \in \mathbb{P}(P); q \in C(R)\}| = k \cdot n$. Hence,

$$Supp_{C_\leq,P} = \frac{2^n - \sum_{i \in \{0,\ldots,n-k\cdot n\}} \frac{(n-k\cdot n)!}{i!(n-k\cdot n-i)!}}{2^n - 1}. \quad (4)$$

The numerator in (4) is the number of subsets of premises that contain at least one of the premises supporting q.

Corollary 3.7 *Let $(L, \leq)$ be a preordered set with first and last elements and $P \neq \{0\}$. Function $Supp_{C_\leq,P} : L \to [0,1]$ is a measure.*

Proof. It is monotonic as it is proven at the beginning of this section, and it verifies boundary conditions, since 0 is not a consequence $Supp_{C_\leq,P}(0) = \frac{2^n-2^n}{2^n-1} = 0$ and $Supp_{C_\leq,P}(1) = \frac{2^n-1}{2^n-1} = 1$. □

ISBN: 978-989-95079-6-8

Example 3.8 *Figure 1 represents a preordered set of medical symptoms and deseases for patients. Let's calculate the support for the consequences for a patient with* $P = \{antibody, bacterium\}$. *To such an end, let us notice that,* $C_{\leq}(P) = \{antibody, bacterium, fever, eruption, 1\}$. *Then,*

- $\widehat{Supp}_{C_{\leq},P}(antibody) = \frac{1}{2}$, *and* $Supp_{C_{\leq},P}(antibody) = \frac{2^2-(1+1)}{2^2-1} = \frac{2}{3}$.
- $\widehat{Supp}_{C_{\leq},P}(bacterium) = \frac{1}{2}$, *and* $Supp_{C_{\leq},P}(bacterium) = \frac{2}{3}$.
- $\widehat{Supp}_{C_{\leq},P}(fever) = 1$, *and* $Supp_{C_{\leq},P}(fever) = \frac{3}{3} = 1$.
- $\widehat{Supp}_{C_{\leq},P}(eruption) = \frac{1}{2}$, *and* $Supp_{C_{\leq},P}(eruption) = \frac{2}{3}$.
- $\widehat{Supp}_{C_{\leq},P}(1) = Supp_{C_{\leq},P}(1) = 1$.

Hence, the consequence with greatest support is 'fever'.

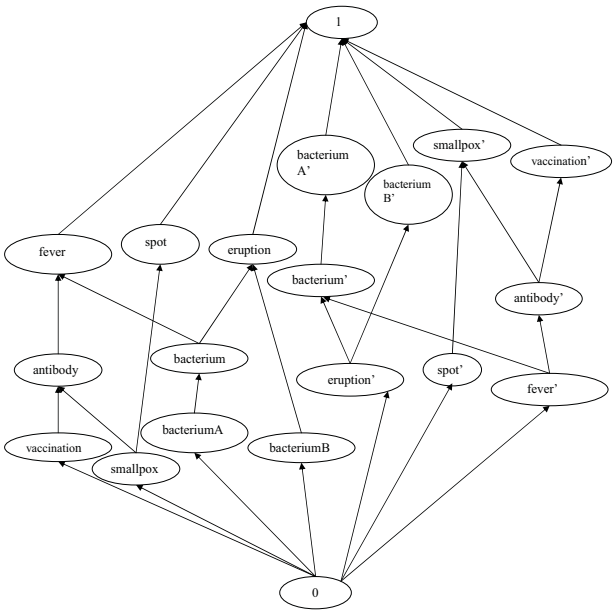

Figure 1: Preorder

4 Relevance for premises

This section introduces a measure to calculate the proportion of consequences that are gotten from a subset of premises, and what is more, it is shown how to reduce the set of premises using this ratio in order to give the same set of consequences.

Definition 4.1 *The relevance of a subset of premises* $R \in \mathbb{P}(P) - \{\emptyset\}$ *is the ratio of consequences deduced from a* R*, to all consequences.*

$$Rel_{C,P}(R) = \frac{|\{q \in L; q \in C(R)\}|}{|C(P)|} = \frac{|C(R)|}{|C(P)|}, \quad \text{if } R \in \mathbb{P}(P) - \{\emptyset\}, \tag{5}$$

and, $Rel_{C,P}(\emptyset) = 0$.

Since $|P| > 0$ *and* $P \subset C(P)$*, it is* $|C(P)| > 0$*, the quotient does exist.*

If a subset of premises allows to deduce all consequences, the set of premises can be reduced to it, since both have the same set of consequences.

There are many properties that $Rel_{C,P}$ verifies,

- If there exists $R \in \mathbb{P}(P)$, such that $Rel_{C,P}(R) = 1$, it means that all consequences for P are consequences of R. So, $C(P) = C(R)$.
- If $R_1 \subset R_2$, then $Rel_{C,P}(R_1) \leq Rel_{C,P}(R_2)$. That is function $Rel_{C,P}$ is monotonic.
- It is $Rel_{C,P}(P) = 1$, and $Rel_{C,P}(\emptyset) = 0$.

Theorem 4.2 *Function* $Rel_{C,P} : \mathbb{P}(P) \to [0,1]$ *is a measure.*

Proof. Straightforward, by the last properties. □

Remark 4.3 *In this case, the concept of fuzzy measure is defined in the preordered set* $(\mathbb{P}(L), \subset)$*, since relevance is defined for all subsets of premises and not only for single premises. Remember that the support is defined for each element.*

The ratio of relevance applying for each premise allows to define a partition into the set of premises, in classes whose elements have the same relevance, $[q] = \{p \in L;\ Supp_{C,P}(p) = Supp_{C,P}(q)\}$. Analogously, it can be built a partition in the set $\mathbb{P}(P)$, defining each class as $[S] = \{R \in \mathbb{P}(P);\ Supp_{C,P}(R) = Supp_{C,P}(S)\}$. The maximum number of classes that can exist is $|C(P)| + 1$.

4.1 Using the operator $C_{\leq}$

For the operator $C_{\leq}$ it is useful to calculate the relevance for each $p \in P$, since it is sufficient to get consequences for each premise and then join them. So, in this case is enough to deals with

$$Rel_{C_{\leq},P} : P \to [0,1]$$

Definition 4.4 *The relevance for a premise* $p \in P$ *is the proportion of consequences deduced from* p.

$$Rel_{C_{\leq},P}(p) = \frac{|\{q \in L; p \leq q\}|}{|C_{\leq}(P)|} = \frac{|C(p)|}{|C(P)|}. \tag{6}$$

If a premise allows to deduce all consequences, the set of premises can be reduced to that premise, since both give the same set of consequences.

There are many properties that $Rel_{C_{\leq},P}(p)$ verifies,

- For all $p \in P$, $Rel_{C_{\leq},P}(p) > 0$, since $p \in \{q \in L; p \leq q\}$ implies $|\{q \in L; p \leq q\}| > 0$.
- If there exists $p \in P$ such that $Rel_{C_{\leq},P}(p) = 1$, it means that all consequence for P is consequence of p. So, $C_{\leq}(P) = C_{\leq}(p)$.

ISBN: 978-989-95079-6-8

- If $p_1 \leq p_2$, then $Rel\,_{C_\leq,P}(p_2) \leq Rel\,_{C_\leq,P}(p_1)$. That is the function $Rel\,_{C_\leq,P}$ is anti-monotonic in this sense. Then, the function $1 - Rel\,_{C_\leq}$ is monotonic.
- Let L be endowed with an infimum operation. If $\inf P \in P$, as $Rel\,_{C_\leq,P}(\inf P) = 1$, because $\forall q \in C_\leq(P)$ there exists $p \in P$ such that $p \leq q$, and $\inf P \leq p \leq q$. Then, $C_\leq(P) = C_\leq(\inf P)$.
  A common consequence's operator is $C_\wedge$, defined by $C_\wedge(P) = \{q \in L; \inf P \leq q\}$, that can be defined as $C_\wedge(P) = C_\leq(\inf P)$, so in that case $C_\leq(P) = C_\wedge(P)$.

Example 4.5 *Using the same preset in figure 1. Let's calculate the relevance for premises. Here, we have an example that allows us to quantify the relevance of deseases of a patient.*

If the patient has $P = \{antibody, smallpox\}$*, then,* $C_\leq(P) = \{antibody, smallpox, spot, fever, 1\}$*. Hence,*

- $Rel\,_{C_\leq,P}(antibody) = \frac{|\{antibody,fever,1\}|}{|C_\leq(P)|} = \frac{3}{5}$.
- $Rel\,_{C_\leq,P}(smallpox) = \frac{|\{antibody,smallpox,spot,fever,1\}|}{|C_\leq(P)|} = \frac{5}{5} = 1$
- *Obviously,* $Rel\,_{C_\leq,P}(P) = 1$.

This example shows the case that a premise allows to deduce all consequences of P, since $C_\leq(P) = C_\leq(smallpox)$.

Theorem 4.6 *If* $(L, \leq, ', \cdot, +)$ *is a partial ordered set and* $P \subset L$ *such that* $\inf P \neq 0$.
There exists $p \in P$ *such that* $Rel\,_{C_\leq,P}(p) = 1$*, if and only if* $p = \inf P$.

Proof. If $Rel\,_{C_\leq}(p) = 1$, it is $p \leq q$ for all $q \in C_\leq(P)$. And since $C_\leq(P) \subset C_\wedge(P)$, it is $\inf P \leq q\ \forall q \in C_\leq(P)$. The infimum is the greatest lower bound of a set, then $p \leq \inf P$. It is also $\inf P \leq p$. Thus, $p = \inf P$, because L is a lattice, so verifies antisymmetric property and has an infimum for each subset.
On the other hand if $p = \inf P$, implies $\inf P \in P$, and as it is said, $Rel\,_{C_\leq,P}(\inf P) = 1$. □

In the theorem and in the above example, it is shown that the set of premises can be reduced to an only premise with relevance one, but if there is no one premise with relevance one, it could be found a subset of premises that allows to obtain the same consequences as the initial set of premises. When models deal with not a very big number of premises, a simple program can be used in order to find a minimal set of premises by calculating all combination of premises.

This algorithm is exponential in the number of premises. So, others algorithms can be designed in order to deal with a big number of premises.

,

The algorithm is as follows.

First of all, we look for premises with greatest relevance, we put one of these premises (p_1) into the set of reduced premises, then we calculate a relative relevance

$$Rel\,_{C_\leq,P-\{p_1\}}(p) = \frac{|\{q \in C_\leq(P) - C_\leq(p_1); p \leq q\}|}{|C_\leq(P) - C_\leq(p_1)|},$$

and we introduce a premise with the greatest relative relevance (p_2), and then we calculate other relative relevance,

$$Rel\,_{C_\leq,P-\{p_1,p_2\}}(p) =$$

$$\frac{|\{q \in (C_\leq(P) - C_\leq(p_1)) - C_\leq(p_2); p \leq q\}|}{|(C_\leq(P) - C_\leq(p_1)) - C_\leq(p_2)|},$$

and this process is repeated till the lowest r that verifies $C_\leq(P) = \bigcup_{i\in\{1,...,r\}} C_\leq(p_i)$. Then the reduced set searched in this way will be $\{p_1, ..., p_r\}$.

4.2 Using the operator $C_\bullet$

In this case we can particularize the definition of relevance for each subset of premises.

The relevance for a subsets of premises $R \subset \mathbb{P}(P) - \{\emptyset\}$ is the ratio of consequences deduced from R, to consequences deduced from P.

$$Rel\,_{C_\bullet,P}(R) = \frac{|\{q \in L; q \in C_\bullet(R)\}|}{|C_\bullet(P)|} =$$

$$\frac{|\{q \in L; \exists \tilde{R} \subset \mathbb{P}(R), \inf \tilde{R} \leq q\}|}{|C_\bullet(P)|}$$

Example 4.7 *Let* P *be* $\{c, d, a'\}$ *defined in the preorder in figure 2. So,* $C_\bullet(P) = \{c, d, f, g, b, e, d', a', 1\}$*. Relevance for all subset of premises are,*

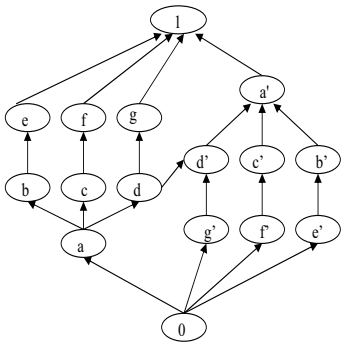

Figure 2: Preorder

- $Rel\,_{C_\bullet,P}(\{c\}) = \frac{3}{7}$, $Rel\,_{C_\bullet,P}(\{d\}) = \frac{5}{7}$, $Rel\,_{C_\bullet,P}(\{a'\}) = \frac{2}{7}$
- $Rel\,_{C_\bullet,P}(\{c, d\}) = 1$, $Rel\,_{C_\bullet,P}(\{c, a'\}) = 1$, $Rel\,_{C_\bullet,P}(\{d, a'\}) = \frac{5}{7}$

This example gives two reduced sets of premises, $\{c, d\}$ *and* $\{c, a'\}$*. Obviously* $C_\bullet(P) = C_\bullet(\{c, d\}) = C_\bullet(\{c, a'\})$.

5 Validating premises and partial hypotheses

Each premise is supported, or explained by hypotheses, so in this section, a support for each premise is defined. Then, we define the relevance of each partial hypothesis. This is analogously to the above section, because premises are consequences of hypotheses.

Let $Hyp^*{}_C(P) \neq \emptyset$.

ISBN: 978-989-95079-6-8

Definition 5.1 *The support of $p \in P$ is the ratio of subsets of hypotheses that allow getting p as consequence, to all subsets of partial hypotheses.*

$$Supp_{C,Hyp^*_C(P)}(p) = \frac{|\{H \subset Hyp^*_C(P); p \in C(H)\}|}{2^{|Hyp^*_C(P)|} - 1} \quad (7)$$

Since $|Hyp^*_C(P)| > 0$ the quotient in the definition is possible.

The bigger Support a premise has, the more hypotheses allow to deduce it.

The $Supp_{C,Hyp^*_C}$ verifies,

- If $P = \{p\}$, it is $Supp_{C,Hyp^*_C(P)}(p) = 1$.
- If $1 \in P$, then $Supp_{C,Hyp^*_C(P)}(1) = 1$.
- $Supp_{C,Hyp^*_C(P)}(p) = 1$ means that p is explained by all $h \in Hyp^*_C(P)$, in particular for all $h \in Hyp(P)$.
- If $p_1 \leq p_2$, then $Supp_{C,Hyp^*_C(P)}(p_1) \leq Supp_{C,Hyp^*_C(P)}(p_2)$. That is, function Sup is monotonic.
- $Supp_{C,Hyp^*_C(P)}(\sup\{p_1, p_2\}) \geq \max\{Supp_{C,Hyp^*_C(P)}(p_1), Supp_{C,Hyp^*_C(P)}(p_2)\}$.
- $Supp_{C,Hyp^*_C(P)}(\inf\{p_1, p_2\}) \leq \min\{Supp_{C,Hyp^*_C(P)}(p_1), Supp_{C,Hyp^*_C(P)}(p_2)\}$.

$Supp_{C,Hyp^*_C(P)}$, allows to compare premises in relation to hypotheses and to allocate different degrees to each premise.

Definition 5.2 *The relevance for a subset of partial hypotheses $H \subset Hyp^*_C(P)$ is the proportion of premises deduced from H.*

$$Rel_{C,Hyp^*_C(P)}(H) = \frac{|\{p \in P; p \in C(H)\}|}{|P|}, \quad (8)$$

if $H \in \mathbb{P}(Hyp^*_C(P)) - \{\emptyset\}$,

and, $Rel_{C,Hyp^*_C(P)}(\emptyset) = 0$.

Since $|P| > 0$, the quotient is possible.

There are many properties that $Rel_{C,Hyp^*_C(P)}$ verifies,

- If $P = \{p\}$, it is $Rel_{C,Hyp^*_C(P)}(H) = 1$, for all $H \subset Hyp^*_C(P)$.
- For all $H \subset Hyp^*_C(P)$, $Rel_{C,Hyp^*_C(P)}(H) > 0$.
- If $H_1 \subset H_2$, then $Rel_{C,Hyp^*_C(P)}(H_1) \leq Rel_{C,Hyp^*_C(P)}(H_2)$. That is, function $Rel_{C,Hyp^*_C(P)}$ is monotonic.
- If there exists $h \in Hyp^*_C(P)$ such that $Rel_{C,Hyp^*_C(P)}(\{h\}) = 1$, it means that h is a partial hypothesis that can explain all premises, so it is hypothesis.

Theorem 5.3 *If $Hyp_C(P) \neq \emptyset$, then $Rel_{C,Hyp^*_C(P)}$ is a measure.*

Proof. It is monotonic as it is stated above, $Rel_{C,Hyp^*_C(P)}(\emptyset) = 0$, and since there exists $h \in Hyp_C(P)$ $Rel_{C,Hyp^*_C(P)}(\{h\}) = 1$.
□

The measure, $Rel_{C,Hyp^*_C(P)}$, allows to compare partial hypotheses, and to distinguish which partial hypotheses are hypotheses in the classical sense, that are those one with relevance one.

6 Conclusions

In this paper, it is built a measure in the set of consequences, premises and partial hypotheses. That can be useful in decision problems in order to choose the consequence, premise or hypotheses with the biggest measure.

It should be also pointed out that by using a relevance measure, we can get rid of premises that do not add information, and still get the same set of consequences.

It is also introduced the concept of set of partial hypotheses, that contains the classical hypotheses one. The measure built allocate value one to that partial hypotheses that are hypotheses in the classical sense.

As future work it can be proposed to apply these measures to practical problems, for examples medical diagnosis problems much more bigger than the one that appears in this paper.

Abstract— *This paper presents a novel approach for medical image storage using a Fuzzy Object-Relational Database Management System (FORDBMS). The system stores medical images along with a set of parameters describing their content. Flexible queries can be performed over these parameters to retrieve images matching visually. To illustrate the capabilities of the FORDBMS, parameter curves are obtained from X-Ray images of patients suffering from scoliosis, and queries are performed when looking for images with a determined curve pattern. Results show that retrieved images visually match the condition established in the query.*

Keywords— Image Retrieval, Fuzzy Databases

1 Introduction

Images are a fundamental tool in health care for diagnosis, clinical studies, research and learning. Currently, there are multiple techniques to capture images from patients to help diagnostic tasks such as X-Ray images, Computer Tomography (CT), Magnetic Resonance Imaging (MRI), Positron Emission Tomography (PET), Ultrasonography, etc. The diagnostic task generates a large amount of images which must be archived for future evaluations. Fortunately, most of these techniques produce digital images, which are more efficiently archived and handled through computer systems than physical ones. In medical imaging, these computer systems are called Picture Archiving and Communication Systems (PACS). PACS are computers or networks devoted to the storage, retrieval, distribution and presentation of images. These systems solve the problem of storaging digital images but do not provide mechanisms to retrieve them based on their content.

Content-Based image retrieval (CBIR) [1] is the application of computer vision techniques to the problem of digital image search in large databases. First image retrieval approaches were based on captions and textual descriptors collected by humans. Nowadays, image retrieval systems improve the textual-based ones using features such as color, texture or shape, which are automatically extracted from images [2]. In this regard, a very important point to take into account is the imprecision in the feature descriptions, as well as the storage and retrieval of that imprecise data. To deal with this vagueness, some interesting approaches introduce the use of fuzzy logic in the feature representation, as well as in the retrieval process [3, 4, 5]. These fuzzy approaches also allow to perform queries on the basis of linguistic terms, avoiding one of the drawbacks of the classical image retrieval systems, where the queries have to be defined on the basis of images or sketches similar to the one we are searching for.

Database Management Systems (DBMS) are crucial in CBIR for retrieval purposes and, as we have explained above, these systems must be able to represent fuzzy data as complex datatype structures to provide flexible content based retrieval. There is a wide variety of proposals for fuzzy data handling in databases [6, 7, 8, 9, 10, 11] but in general these models and/or implementations do not have enough modeling power and performance for image indexing applications. For these kind of applications we propose to use the Fuzzy Object-Relational Database System (FORDBMS) model introduced in [12, 13]. This model evolves classical fuzzy databases models to incorporate object-oriented features for a powerful representation and handling of data, fuzzy or not.

CBIR techniques get more semantical results when applied to a specific domain or application area, as knowledge on the domain and on the image characteristics helps the process to extract the relevant features for this specific area of application. Health care is an application area that may benefit from the CBIR techniques. If we focus the CBIR techniques on the analysis of a certain pathology we can get high level features processing certain types of images. For example, there are some proposals to extract vertebral and spinal shapes from X-rays [14, 15] (these algorithms need some user intervention). The paper [16] describes a technique to automatically measure Cobb angle [17] for scoliosis pathologies given the end vertebras of the curve.

This paper shows how our FORDBMS is suitable for easy image representation and retrieval, using the fuzzy descriptors obtained by means of computer vision algorithms [18] or provided by experts. To illustrate this, we show the process to represent a structure in the FORDBMS describing scoliosis measures (Cobb angles) obtained from anteroposterior X-rays. Aditionally, we will show that the use of fuzzy comparators implemented by the FORDBMS in queries let us retrieve images that match the expected visual characteristics searched.

The rest of the paper is organized as follows. Section 2 describes the scoliosis pathology and the use of X-rays for its diagnosis. Section 3 introduces the fuzzy object-relational database system used to store and retrieve the fuzzy data. Examples of queries are presented in Section 4 and, finally, the main conclusions and future works are summarized in Section 5.

ISBN: 978-989-95079-6-8

2 Idiopathic scoliosis and its X-ray based diagnosis

In order to show how the use of fuzzy databases can help in health care, we have focused on the study of representation and retrieval of images related with idiopathic scoliosis. In this section we will describe the most relevant characteristics of this pathology in relation with our purpose.

Scoliosis is a three-dimensional deformation of the spine that produces vertebral rotation and crushing, and lateral curvature. It is typically classified as congenital (caused by vertebral anomalies present at birth), idiopathic (sub-classified as infantile, juvenile, adolescent, or adult according to when onset occurred) or as having developed as a secondary symptom of another condition, such as cerebral palsy, spinal muscular atrophy or due to physical trauma. Depending on the severity and progression of the deformation may be necessary treatment, consisting of observation, orthotic (brace) treatment, or surgery. About 2-4% of the adolescent population has some degree of scoliosis. Approximately 2.2% of these adolescents will require treatment.

To diagnose and treat scoliosis it is necessary to perform measures of the spine deformity. There are physical examinations to initially detect the presence of the deformity, but a precise diagnosis and treatment needs the help of radiologic techniques. The most accurate technique to measure spinal deformity is Computed Tomography (CT), that provides a three-dimensional view of the spine. However this technique is expensive and exposes the patient to a high radiation. Taking into account that a patient having scoliosis may need observation and treatment for many years and many radiologic tests, the frequent use of this technique may be inappropriate. X-Rays expose the patient to a lower radiation and, because of this, full-length standing spine X-rays are the standard method for evaluating the severity and progression of the scoliosis. Anteroposterior X-rays (AP X-rays) project spinal deformities as curves. The standard method to quantitatively asses curvatures is the measurement of the Cobb angle on AP X-rays. The Cobb angle [17] can be manually measured by calculating the angle between the lines respectively drawn along the upper endplate of the superior end-vertebra and the lower endplate of the inferior end-vertebra, as shown in Fig. 1. Using this measure each curve present in the spine is characterized by means of four parameters: the side of the convexity of the curve (right or left), the superior end-vertebra, the inferior end-vertebra and the angle value. It is important also to identify the apical vertebra associated with the adjacent disc interspaces that have the greatest segmental angulation of all interspaces in the curve. This vertebra occurs at the horizon or apex of a curve (T9 in Fig. 1).

The manual measurement of Cobb angle depends on experience and personal judgment. Errors are due to selecting different end- vertebrae and estimating different slopes of the vertebrae. The standard measurement error is 3° to 5° for the same observer and 5° to 7° for different observers.

The use of AP X-rays is useful for diagnosis, clinical studies and health learning. To help these purposes, it will be interesting to perform storage and retrieval of X-rays from a database based on curves parameters present in the spine. The problem is that, as we have shown, measures are imprecise and the query parameters needs to be flexible. For this reason, classical databases are not suitable for this purpose. It is necessary a Database System that can store imprecise data and can perform flexible queries on them. Moreover, as spine parameter description is complex, the database system must handle complex structures to represent imprecise data and must provide flexible comparators on these structures. Our FORDBMS, as we will show in next sections, have those capabilities.

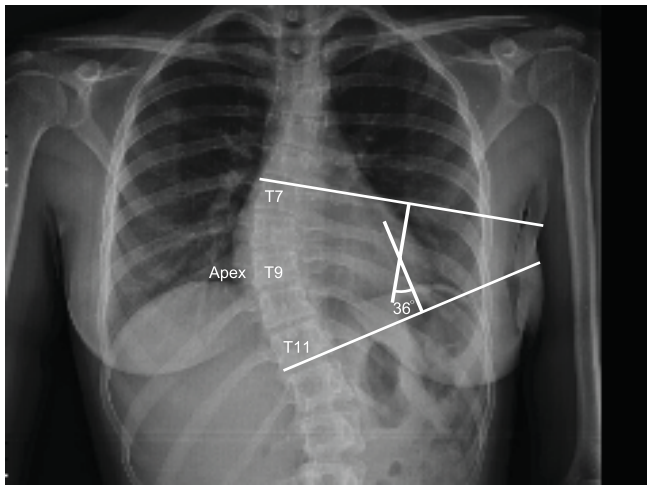

Figure 1: Cobb angle measurement.

3 The fuzzy object-relational database system

The recent proliferation of large image databases leads to the need for DBMS applied to multimedia libraries management to ensure high performance, scalability, availability with fault tolerance and distribution.

Nowadays, market leader DBMSs offer these required features transparently. However, the database models implemented by them, generally the relational model, are not suitable to manage fuzzy data, which is necessary for this kind of image description algorithms. In order to solve this drawback, some database models and DBMSs implementing them have been proposed. Nevertheless, the existing fuzzy DBMSs are in general research prototypes which do not match the high performance and other necessary requirements for this kind of applications.

In [12, 13] we introduce the strategy of implementation of our FORDMS model, that it is based on the extension of a market leader RDBMS (Oracle®) by using its advanced object-relational features. This strategy let us take full advantage of the host RDBMS features (high performance, scalability, etc.) and the ability for representing and handling fuzzy data provided by our extension, making this FORDBMS suitable to support systems for flexible content based retrieval of images.

3.1 Fuzzy datatype support

Our FORDBMS is able to handle and represent a wide variety of fuzzy datatypes, which allows to model any sort of fuzzy data easily. These types of fuzzy data, which are represented as classes with light gray background color in Fig. 2, are the following:

- Atomic fuzzy types (AFT), represented as possibility distributions over ordered (OAFT) or non ordered (NOAFT)

ISBN: 978-989-95079-6-8

domains.

- Fuzzy collections (FC), represented as fuzzy sets of objects with conjunctive (CFC) or disjunctive (DFC) semantics.
- Fuzzy objects (FO), whose attribute types could be crisp or fuzzy, and where each attribute is associated with a degree to weigh its importance in object comparison.

All fuzzy types define a Fuzzy Equal operator (FEQ) that computes the degree of fuzzy equality for each pair of instances. Each fuzzy datatype has its own implementation of this operator in accordance with its nature. Moreover, the FORDBMS provides parameters to adjust the fuzzy equality computation to the semantics of the data handled. For OAFTs the system implements other fuzzy comparators as FGT (fuzzy greater than), FLT (fuzzy less than), etc.

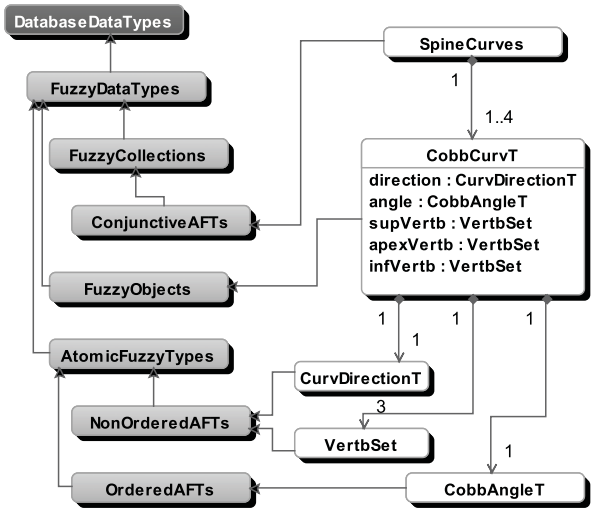

Figure 2: UML Class Diagram for Fuzzy types and SpineCurves Datatype.

3.2 Fuzzy datatype operators

Our FORDBMS can handle flexible comparisons over several types of fuzzy datatypes. Moreover, our system provides the possibility of adapting the behavior of some operators to adjust flexible comparisons to the semantics of the data modeled. The current section describes the most significant operators for the defined fuzzy datatypes, and their adaptation to handle flexible queries on complex objects like the spine curve description structure illustrated in this paper.

3.2.1 Fuzzy inclusion operator

The operator `FInclusion(A,B)` calculates the inclusion degree $A \subseteq B$, where A and B are instances of CFC. The calculus is done using a modification of the *Resemblance Driven Inclusion Degree* introduced in [19], which computes the inclusion degree of two fuzzy sets whose elements are imprecise.

Definition 1 (Resemblance Driven Inclusion Degree). *Let A and B be two fuzzy sets defined over a finite reference universe $\mathscr{U}$, μ_A and μ_B the membership functions of these fuzzy sets, S the resemblance relation defined over the elements of $\mathscr{U}$, $\otimes$ be a t-norm, and I an implication operator. The inclusion degree of A in B driven by the resemblance relation S is calculated as follows:*

$$\Theta_S(B|A) = \min_{x \in \mathscr{U}} \max_{y \in \mathscr{U}} \theta_{A,B,S}(x,y) \tag{1}$$

where

$$\theta_{A,B,S}(x,y) = \otimes(I(\mu_A(x), \mu_B(y)), \mu_S(x,y)) \tag{2}$$

We propose a modification that substitutes the minimum aggregation operator in equation 1 by a weighted mean aggregation operator, whose weight values are the membership degrees in A of the elements of $\mathscr{U}$, divided by the cardinal of A. This modification is made in order to obtain a less extreme resemblance inclusion degree, since it takes into account the importance of each included element. The *Modified Resemblance Inclusion Degree* is defined in equation 3.

$$\Theta_S(B|A) = \sum_{x \in \mathscr{U}} \frac{\mu_A(x)}{|A|} \cdot \max_{y \in \mathscr{U}} \theta_{A,B,S}(x,y) \tag{3}$$

with $|A| = \sum_{x \in \mathscr{U}} \mu_A(x)$. Our implementation of `FInclusion(A,B)` uses the minimum as t-norm, and the Gödel implication as the implication operator.

3.2.2 Fuzzy equality Operator

The operator `FEQ(A,B)` calculates the resemblance degree between two instances of a fuzzy datatype.

When `A` and `B` are two instances of CFC, this resemblance degree is calculated by means of the *Generalized Resemblance between Fuzzy Sets* proposed in [19], which is based on the concept of double inclusion.

Definition 2 *(Generalized resemblance between fuzzy sets). Let A and B be two fuzzy sets defined over a finite reference universe $\mathscr{U}$, over which a resemblance relation S is defined, and $\otimes$ be a t-norm. The generalized resemblance degree between A and B restricted by $\otimes$ is calculated by means of the following formulation:*

$$\beta_{S,\otimes}(A,B) = \otimes(\Theta_S(B|A), \Theta_S(A|B)) \tag{4}$$

Therefore, the implementation of the operator `FEQ(A,B)`, when A and B are instances of CFC, aggregates the results of `FInclusion(A,B)` and `FInclusion(B, A)` using a minimum t-norm.

If the operator `FEQ(A,B)` is applied when `A` and `B` are instances of the class *FO*, then, for the sake of flexibility, the resemblance degree between these objects is calculated as a weighted average of the resemblance degree of their attribute values. In the FORDBMS catalog we store some parameters for the attributes that belong to each fuzzy object. Specifically, the table *SDS_FO_ATTRIBUTES* stores into the column *relevance*, the relevance value of the considered attribute. This value attaches a weight to the attribute for the calculation of the `FEQ` operator. Moreover, if this value is set to -1 for an attribute, this attribute acts as determinant in the object comparison, in the way that, if the resemblance operator on this

ISBN: 978-989-95079-6-8

attribute returns 0, then the complete objects comparison returns 0. This parameter is useful, for example, in the case that we are searching for *"left curves"*, setting *Direction* attribute to -1, the query never retrieves a *"right curve"* even if resemblance for other object attributes is greater than 0. Another parameter that modifies the computation of the operator `FEQ` on fuzzy objects is the minimum percentage of attributes comparison greater than 0 (*min_pct*). This parameter, stored in the catalog table *SDS_FO_TYPES*, set the necessary number of attributes comparisons greater than 0 to get a value greater than 0 for the whole object comparison.

The following definition formalizes the ideas exposed above.

Definition 3 *(Parameterized Object Resemblance Degree). Let o_1 and o_2 be two objects of the class C, $obj.a_i$ the value of the i-th attribute of the object obj, $rel(a_i)$, relevance degree of the i-th attribute of the object obj, n the number of attributes defined in the class C, min_pct the necessary minimum percentage of attributes comparison greater than 0, and FEQ the resemblance operator.*

$$OR(o_1,o_2) = \begin{cases} 0 \text{ if} \\ (\exists i \in \mathcal{A} : FEQ(o1.a_i, o2.a_i) = 0 \wedge rel(a_i) = -1) \vee \\ (|\{a_i : i \in \mathcal{A} \wedge FEQ(o1.a_i, o2.a_i) > 0\}| < n.min\_pct) \\ \\ \sum_{i\in\mathcal{A}}^{n} FEQ(o1.a_i, o2.a_i).|rel(a_i)| / \sum_{i\in\mathcal{A}}^{n} |rel(a_i)| \\ otherwise \end{cases} \tag{5}$$

Our FORDBMS also let us relax the resemblance operator `FEQ` applied on *OAFT* values. To do this, the user must use the static method `relax(kernel_pct,support_pct)`, where `kernel_pct` sets the percentage that the kernel increases for each pair of values being compared, and `support_pct` sets the percentage increase for the support of these values.

4 Retrieving X-Ray images from database using its fuzzy description

Our FORDBMS can handle complex fuzzy data structures to represent rich semantic problems. It can store instances of these structures and provides a powerful set of operators to retrieve data based on flexible parameters. We have chosen an example based on the representation of the characteristics of the spine curves taken from AP X-rays to illustrate how flexible queries can retrieve interesting results for the specialists. Let us show how to model the data structure of this example on our FORDBMS, then we will perform some queries and we will analyze the retrieved results.

4.1 Database modeling for spine curve description

Our FORDBMS is capable of representing curves structures present in the spine measured from AP X-Rays, taking into account that the measures can be imprecise due to errors. It also provides parameters to adjust the fuzzy comparators used to get good query results.

The classes whose background color is white in Fig. 2 integrate the datatype structure of the database that represents spine parameters. As this figure illustrates, we model the curve description of the spine as a fuzzy conjunctive collection datatype (*SpineCurves*) which includes up to four fuzzy object datatypes (*CobbCurveT*). *CobbCurveT* datatype represents a spine curve measure. This datatype has five attributes: *Direction*, *Angle*, *SupVertb*, *ApexVertb* and *InfVertb* that store: the side of the convexity of the curve (right or left), the angle measure and, the superior, apical and inferior vertebra of the curve, respectively. Attribute *Direction* is of NOAFT type, this allows to perform queries with a not determined value for the side of convexity of the curve. The attributes *SupVertb*, *ApexVertb* and *InfVertb* store values of type NOAFT. The domain of this attributes (*vertbSetT*) includes 24 vertebrae that are enumerated as follows: $v_1 = L5, v_2 = L4, v_3 = L3, v_4 = L2, v_5 = L1, v_6 = T12, v_7 = T11, v_8 = T10, v_9 = T9, v_{10} = T8, v_{11} = T7, v_{12} = T6, v_{13} = T5, v_{14} = T4, v_{15} = T3, v_{16} = T2, v_{17} = T1, v_{18} = C7, v_{19} = C6, v_{20} = C5, v_{21} = C4, v_{22} = C3, v_{23} = C2, v_{24} = C1$. We will define a nearness relation on this underlined domain to take into account the adjacency between each pair of vertebrae as follows:

$$\forall i,j \in Cardinal(VertbSett): \quad nearness(v_i,v_j) = \begin{cases} 1 & if\ i = j \vee i = j+1 \vee \\ & i = j-1 \\ 0.66 & if\ i = j+2 \vee i = j-2 \\ 0.33 & if\ i = j+3 \vee i = j-3 \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

The attribute *Angle* is of type OAFT, so we can store on this attribute numerical values, crisp or fuzzy (using a trapezoidal membership function). Measures obtained with errors for the angle can be represented as a fuzzy value for the attribute. This attribute allows flexible comparisons also. We can use the method `relax` described in the previous section on this attribute.

Once we have defined the type structure for the spine description, we can create a table that stores X-rays images together with their fuzzy descriptions as follows:

```
create table APXRay (
 image# number, xray bfile, SpineDescription SpineCurves);
```

We have inserted twenty images with their curve description to illustrate query examples; the statement for one image insertion is like this:

```
Insert into apxray values (
 313701 ,BFILENAME('APXRays','313701.gif'),
 SpineCurves(
     1,cobbCurvT(
        CurvDirectionT('RIGHT'),
        CobbAngleT(trapezoid(10.1)),
        VertbSetT('T2'),
        VertbSetT('T5'),
        VertbSetT('T10')
             ),
     1,cobbCurvT(
        CurvDirectionT('LEFT'),
        CobbAngleT(trapezoid(16.5)),
        VertbSetT('T9'),
        VertbSetT('T12'),
        VertbSetT('L2')
             ),
     1,cobbCurvT(
        CurvDirectionT('RIGHT'),
        CobbAngleT(trapezoid(12.5)),
        VertbSetT('L2'),
        VertbSetT('L4'),
        VertbSetT('L5')
             )
  )
);
```

ISBN: 978-989-95079-6-8

4.2 *Examples of Queries*

In this section we will illustrate some capabilities by performing a query that uses the `FInclusion` operator and a second one that uses the `FEQ` operator on `CFC` datatypes. To get flexible results on queries that involve whole fuzzy object comparison, it is advisable to relax comparison on angle attribute. To perform it we invoke the static method `relax` described in Section 3.2.2. In this case we relax 40% the kernel and 70% the support. This is the SQL sentence: `Execute CobbAngleT.relax(0.4,0.7);`

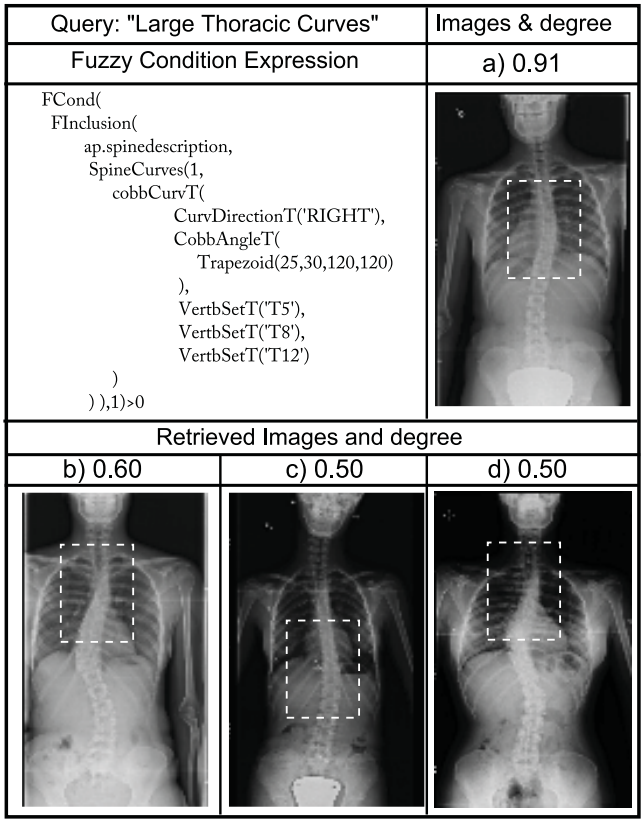

Figure 3: Searching images that include a thoracic pattern curve.

As shown in Fig. 3, we can perform queries that search images including a determined pattern of curves. In the example we illustrate the following query: *"Show X-Ray images and its compliance degree that include a large thoracic curve"*. The "thoracic curve" pattern proposed in [20] is described by the following approximate parameters: the convexity of the curve is on the right side, the superior end-vertebra is between T4 and T6, the apex vertebra is between T8 and T9 and, the inferior end-vertebra is between T11 and L2. The Fuzzy Condition Expression cell of the Fig. 3 shows the parameters used for the `WHERE` clause of the query statement, where the concept "large" is modeled as a trapezoidal distribution that matches Cobb angles that are approximately greater or equal than 25-30 degrees.

To perform the query we use the `FInclusion` operator, described in Section 3.2.1, which evaluates the similarity of the queried curve with respect to each curve included in the spine description. The query retrieves four images from the database. The image a), includes a curve, highlighted with a rectangular area, witch takes the values 'Right', 21.8, T5, T8, T10 for the parameters: orientation, angle size, superior, apex and inferior vertebrae, respectively. The compliance degree for this image with respect the query is 0.91. As we can see, this image includes a curve that appreciably matches the concept "large thoracic curve", this is the reason for the high degree computed. Visually, the marked curve in image b) weakly matches the concept "thoracic curve", this is the reason for a minor compliance degree. Image c) includes a curve that tends to a "thoracolumbar curve" concept; because of this, the retrieved compliance degree is low, 0.5. Finally, image d) includes a curve that tends to a "cervicothoracic curve" concept, the compliance degree (0.50) confirms this fact.

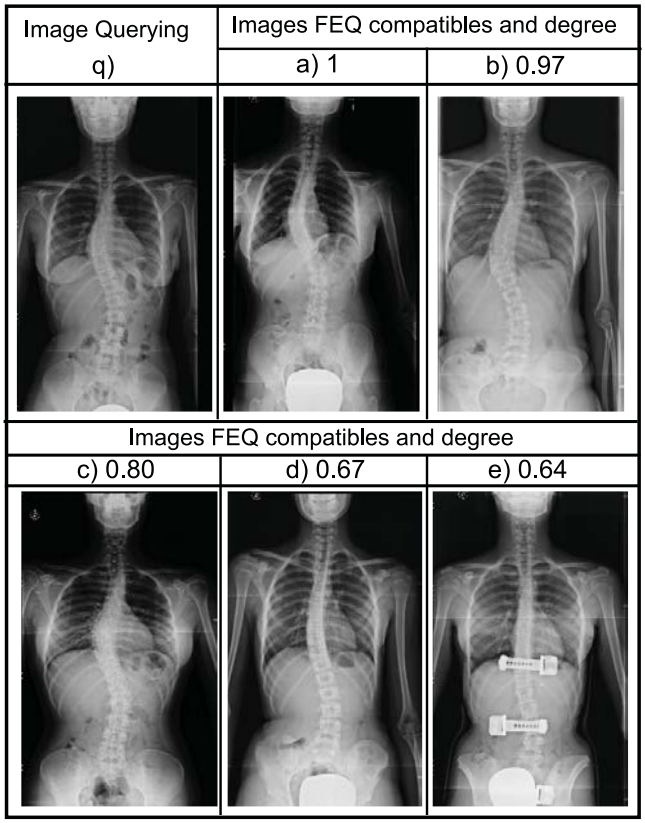

Figure 4: Searching images that present similar spine curvature that image q).

In some studies it may be interesting to find X-rays of patients that present a similar curve pattern to a given one. In our database, we model these curve patterns present in the spine as a *CFC*. To find similar curve patterns, our FORDBMS provides the operator `FEQ` which operates on *CFC* as has been described in Section 3.2.2. The query shown in Fig. 4 searches for X-rays of patients presenting similar curve patterns that the image query q). The SQL syntax is:

```
SELECT ap1.image#,ap1.xray,ap1.cdeg(1)
FROM apxray ap1, apxray ap2
WHERE ap1.image='q'
     AND FCOND(
          FEQ(ap1.spinedescription, ap2.spinedescription),1
         )>0 order by cdeg(1) desc;
```

As can be seen, higher compliance degree for an image denotes better visual matching with the queried image. Another interesting aspect of our results is the following: the images retrieved by the two kinds of queries evaluated hold that, the

ISBN: 978-989-95079-6-8

lower is the curve pattern matching, the lower the compliance degree computed for these one is.

5 Concluding remarks and future work

This paper shows that a FORDBMS is a powerful tool to represent flexible descriptors obtained from images by means of computer vision algorithms or provided by experts. The system also provides parameterized fuzzy comparators to retrieve images based on those descriptors in a flexible way. To the best of our knowledge, there is no system for flexible image retrieval that provides same capabilities on the subject considered in this paper. The prototype of FORDBMS used to show these results are implemented on the RDBMS Oracle® 10.2. Thereon, it is interesting to make the following remarks:

- The prototype has not implemented yet any index technique to accelerate the data retrieval based on fuzzy conditions. For this reason, the queries shown have been computed by means of a sequential search; moreover, the complex fuzzy datatype structure used for the spine curve representation more decreases the efficiency if none index technique is used. We are working on the implementation of the indexes techniques for fuzzy data proposed in [21, 22]; this will provide us mechanisms to optimize retrieval process.
- The scalability of our FORDBMS and CBIR system shown is guaranteed by the scalability of the host ORDBMS system, Oracle® 10.2.

Future work will involve too the enrichment of fuzzy features of the FORDBMS to enhance support for image content based retrieval. Finally we will study another application domains to perform content based retrieval using our FORDBMS.

Abstract-*The ability to identify text fragments can benefit many information extraction tasks. The main challenge in this matter is to recognise the multiple patterns that exist across possibly heterogeneous sources. Traditional machine learning methods can generate grammars for a set of training examples but the disadvantage is their potential heavy computational overhead. The proposed incremental grammar learning method offers immediate learning of new examples by slight alteration of the existing grammar collections by measuring the changes needed to equalize two grammars. This minimal combination approach avoids overgeneralization and maintains the coverage of newly learnt and past examples without a need to repeat the training process. Our experimental results suggest that the proposed algorithm outperforms a fuzzy grammar learning algorithm implemented in normal supervised learning setting.*

Keywords- evolving fuzzy grammar, grammar fragments, incremental learning, grammar similarity, tagging, text mining.

1 Introduction

The "digital obesity" phenomenon is a pressing problem at both the individual and corporate level [1]. This is partly because information is recorded using different formats for similar purposes and according to different hierarchies and categories. However, it is likely for the objects placed within similar categories to have similar properties and with some degree of correspondence.

These information sources often contain text segments with additional structure that can be utilized to assist in the identification of matching items. For example, within a text segment such as: 'Burger King, 12, Meredith Lane, Ipswich IP2 3AX Ipswich' lies an embedded structure: business name, number, street name, placename, post code and county name while a brief comment such as: 'the Voyager has stopped receiving signal' contains information on the product name and problem description.

Works on lexical semantics and word disambiguation have studied text structures by focusing on linguistic patterns using formal language models i.e in the subject-verb-object structure. However, these methods are normally well-suited for texts that are in complete grammatical form. On the other hand, text segments such as addresses, dates and times, names of products, people, as well as simple sentence forms such as questions, complaints, and news are frequently contained within "casual" text such as email, posts on a web forum, text messages, etc which often does not follow formal grammar rules.

Humans are able to use clues that identify structured segments without necessarily following a strict pattern. There can be many variations of the patterns and humans are normally better at seeing the answer in a specific case than being able to define a pattern that is universally applicable. As such, this is an ideal problem for machine learning; the key subproblem is converting small sections of texts into a more structured form by using grammar fragments to add tags. Note that we are not attempting to parse the entire piece of free text, merely to locate sections within it that can be tagged with an additional structure. For this reason, we refer to grammar fragments, as they are not intended to be a complete language model.

We define grammar fragment learning as the extraction of text fragments that comply with the predefined grammar. In contrast to in-depth whole sentence understanding, the grammar fragments learning focus only on portions of text that are relevant to specific domains. For example, UK address grammars might extract the following patterns:

a. Chicago Rock Cafe Northgate St Ipswich IP1 3BX Suffolk
b. Lattice Lodge Guest House 499 Woodbridge Rd Ipswich
c. 25 St Nicholas Street Ipswich Suffolk IP1 1TW

while grammar collections for posts on a telecom provider forum will recognize the following question entries:

a. Can I use an apple with BT Broadband Talk and Softphone?
b. When does BT plan to develop and support a Softphone client for NON windows platforms such as Mac OSX or Linux?
c. What is Softphone and how much does it cost?

Several authors have proposed the use of genetic algorithm [2,3,4,5], fuzzy [6,7,8], semantic net [9] and hybrid probabilistic [10] to learn grammars mostly from structured examples but these follow the traditional route of training a fixed system on a set of examples, followed by application of that system. Adaptation to new examples (when the training set is found to be inadequate) will be computationally expensive and hence inefficient. The training set needs to be sufficiently diverse to cover all unseen examples or the training phase will need to be repeated in order to improve the training set. Thus, it is highly desirable for a method that can support the incremental learning of a new example by slight modification of the learned rules without reconsidering past examples.

The purpose of this study is to investigate an evolutionary grammar fragment learning with *incremental* feature i.e. it can be updated each time a new pattern is encountered (or each time a string is read) without extensive re-computation as compared to other supervised learning methods. The evolved grammar ensures the ability to encompass the newly learnt, as well as the previously seen, examples. Main issues in evolutionary grammar learning are also highlighted which are defining the fuzzy grammar learning operators and its representation aspect. This algorithm will benefit

ISBN: 978-989-95079-6-8

works in intelligent text pattern recognition and its relevant applications such as intelligent agent and recommendation system.
The paper is organised as follows: the first part gives the introduction to incremental grammar learning while section two describes some of existing works relating to text pattern learning. The third section details the proposed evolutionary algorithm setting followed by observed results in section four. The final section summarises the investigated issues and some future works related to the study.

2 Related Works

Text annotation and text tagging are among the active text extraction research areas. Information tagging has been applied for sentence structure learning in question answering system [11] as well as specific domains including finding medical terms in legal text [12,13], detecting contact information and address [14] and gene and protein interaction information identification [15,16]. Among the popular techniques that have been employed are CFG, statistical, and evolutionary method.
Viola and Narasimhan [14] reported the advantage of marrying statistical natural language processing to the analysis of non-natural language text through the Discriminative Context Free Grammar (Discriminative CFG) approach which has extracted contact information more accurately than a similar conditional Markov model. The hierarchically structured CFG method [3,7,14] is more powerful than the formal English language model such as the subject-verb-object and noun-adverb-adjective model because these models have limitations when more complex sentence forms are involved.
The CFG method provides a rich collection of features that can measure and tag the properties of a sequence of tokens. Another advantage is that the CFG can propagate long range token dependencies efficiently. CFG method can also result in the detection of semantic information (encoded in the form of a parse tree) within a sentence - for example the word *fish and chips* in the restaurant address entry can be classified as broad as a type of business, or a food business genre, or even as specific as a food name.
Backus-Naur-Form (BNF) is a simple method for specifying CFG. It consists of a set of production rules with various operators such as "[ ]" which means "*this part is optional*", "|" for *or*, etc. A BNF grammar is usually more easily deciphered than a regular expression. A method for generating BNF grammars from data was described in [17]. As with regular expressions, a BNF grammar does not generally allow partial matching and there are no methods for finding the similarity between two BNF grammars.
An alternative approach to this is the fuzzy grammar similarity algorithm [2,3,9] which can measure the degree of similarity between grammars. The incorporated fuzzy approach supports the uncertainty and redundancy notion in deriving the grammar. The fuzzy grammar method was applied in evolutionary grammar learning using genetic algorithm.
However, in common with other supervised learning algorithms, the grammars generated using GA method [2,3,4,5,6,10], can only recognize data belonging to the trained pattern and needs to be rebuilt to include newly added patterns. Our preliminary study on GA [6] shows that GA is unfeasible because of the slow convergence towards creation of a good parsing grammar. The genetic operators and random concept in GA had also ignored the semantic properties (sequence of the tokens that bears meaning) in the dataset.
The minimal combination approach discussed in this paper is a revised version from the maximal combination approach [6] which avoids overgeneralization. On the contrary, [6] has generated a lot of unseen examples which has also led to low accuracy. The preliminary experiment on genetic algorithm in [6] has shown that genetic algorithm method is unsuitable for the grammar learning task because it cannot support grammar similarity and is also burden by the slow convergence. Work described in this paper concentrates on an alternative minimal combination approach and demonstrates that different permutations of the training set have no significant effect on incremental evolutionary grammar learning.

3 Brief Introduction to Grammar Fragment Learning

The fuzzy parsing concept allows for the learning of the pattern in the strings and can be seen as an extension of sequence matching, in which: i) we allow one sequence to be defined by a grammar, so that the matching process is potentially more complex and ii) we allow the standard edit operations (insert, delete, substitute) on the string in order to make it conform to the grammar.
It is adapted from the Cocke-Younger-Kasami (CYK) algorithm to allow for:

a. fuzzy grammar fragments that can contain fuzzy sets of terminal symbols;
b. calculation of the overlap between fuzzy grammar fragments;
c. partial parsing, measured by the proportion of a string that has to be altered by Levenshtein-style operations in order to make it conform to a fuzzy grammar fragment.

We identify a grammar fragment with the set of strings that are parsed by the grammar fragment. Because we allow partial parsing, this is a fuzzy set. The fuzzy membership, $\mu_G(Si)$ calculates the similarity between string and grammar, estimated by the minimum number of edit operations needed to convert a string into one which is parsed by the grammar. A string's membership decreases as it needs more changes to make it conform to the grammar.

$$\mu_G(Si) = 1 - \min\left(1, \frac{\min_{P \in Ext(G)} (totalCost(Si, P))}{length(Si)}\right)$$

We define a cost to be a five-tuple *(I D S Rs Rt)* where *I*, *D* and *S* are nonnegative real numbers representing, respectively, the approximate number of insertions, deletions, and substitutions needed to convert a string parsed by the source grammar into one that satisfies the target grammar. *Rs* and *Rt* represent sequences of grammar elements remaining (respectively) in the source and target after the match; at least one of *Rs* and *Rt* is null in every valid cost. Table 1 shows a simple example of grammar similarity comparison between a source and a target grammar in a UK postal address. In this case, *Cost(sg,tg)=(0 1 1 countyName Null)* to substitute *word* with *placename*, and leave *word* and countyName unmatched.

ISBN: 978-989-95079-6-8

Table 1: Example of Grammar Edit Distance Operation
(*I:Insert, D:Delete, S:Substitute, Rs: remainder of source grammar, Rt: remainder of target grammar)

Source grammar, sg	Number	Word	Word	Streetending	Placename	
Target grammar, tg	Number	Placename		Streetending	Placename	Countyname
Edit distance*	0	S=1	D=1	0	0	Rt=1

The *totalCost* function defines a total order on costs by $C1 \le C2$ iff $totalCost(C1) \le totalCost(C2)$.

$$\text{totalCost}((I, D, S, Rs, Rt)) = I + D + S + \text{minLength}(Rs) + \text{minLength}(Rt)$$

Addition of costs is order dependent and is defined by

$$(I1, D1, S1, Rs1, Rt1) + (I2, D2, S2, Rs2, Rt2) = (I3, D3, S1 + S2, Rs2, Rt2)$$

where

$$I3 = I1 + I2 + \text{minLength}(Rt1)$$

$$D3 = D1 + D2 + \text{minLength}(Rs1)$$

For two grammars, *GS* and *GT*, *Overlap(GS, GT)* is the approximate degree to which an arbitrary string parsed by the source grammar *GS* is also parsed by the target grammar *GT*. We define the degree of overlap of a source grammar GS with a target grammar GT as

$$\text{Overlap}(GS, GT) = 1 - \min(1, \text{totalCost}(C)/\text{minLength}(GS))$$

where $C = CostGG(GS,GT)$ is an estimate of the cost of changing a string parsed by the grammar *GS* into one parsed by the grammar *GT*.

The *CostGG* function is defined as follows, where S and T are arbitrary sequences of grammar elements, *s*, *t* are terminal symbols, and *TSi* and *TSj* are (fuzzy) sets of terminal symbols.

$$\text{CostGG}(\text{nu}\mathbf{l}, T) = (0, 0, 0, \text{null}, T)$$

$$\text{CostGG}(S, \text{null}) = (0, 0, 0, S, \text{null})$$

$$\text{CostGG}(s, t) = (0, 0, \delta(s, t), null, null)$$

where $\delta(s, t)$ measures the cost of the symbol *s* replacing symbol *t*. By default $\delta(s, t) = 1$, if $t \neq s$ and $\delta(s, t) = 0$, if $t = s$.

A given grammar has full overlap with itself or any equivalent grammar, where we define equivalence as the ability to parse exactly the same set of strings. Conversely, two grammars have zero overlap if there is no string that both grammars can parse. For example, if *G1* defines postal address and *G2* defines email address then they have zero overlap as there are no strings that both can parse.

The degree of overlap is not symmetric, as can be seen if we consider two grammar fragments *G3* and *G4*, where the set of strings parsed by *G3* is a strict subset of those parsed by *G4* . In this case,

$$overlap(G3, G4) = 1$$

but

$$overlap(G4, G3) < 1.$$

Clearly, the degree of overlap could be determined by repeatedly generating and checking candidate strings—such an approach would be very computationally demanding.

Instead, we propose a method [2,3,9] based on estimating the number of edit operations needed to change an arbitrary string parsed by the first (source) grammar sequence into a string that would be parsed by the second (target) grammar. This will result the coverage of strings belonging to both grammars and is implemented through the grammar combination technique.

The former *maximal combination* technique [9] allows combination of grammars without filtering their cost. E.g, for the set of strings $S = \begin{Bmatrix} (a-b-c-d-e-f), \\ (a-b-a-c-d-e-f), \\ (b-c-d), \\ (a-d-e-f) \end{Bmatrix}$ the learned grammar is $G' = \{[a]-[b]-[a]-[c]-d-[e]-[f]\}$. Although this method can parse all the strings belonging to S, but it also allows for the parsing of strings which does not exist in S. Therefore our current method focuses on minimal combination; combination of grammars that have a difference of 1 and this have managed to avoid overgeneralization.

3.1 Incremental Evolutionary Grammar Learning Algorithm

As the fundamental of the study is to look at the pattern similarities within the strings, a parser that can tokenize and extract relevant symbols from each input is essential. This grammar derivation process will re-label the symbols with significant grammar markup (Fig. 2 and Fig. 3).

The incremental learning has allowed for the update of the available grammars when new pattern is triggered without needed to repeat the whole learning process (Fig.1). The employed minimal combination is governed by the cost between the source and the grammar; combination will only be executed when the change is one. This process contributes to the evolution of the whole grammar collection and the persistence of the parsing coverage.

A chosen grammar from the existing collection will be altered according to the grammar combination rules. Table 2 shows guidelines of grammar combination operations; insert, merge and create. These operations are based on the cost of changing the source to the target and the other way

Table 2: Grammar Combination Operation

Source Grammar	Target Grammar	Cost (Source,Target)	Cost (Target,Source)	Combination Operation	Combined grammar
a-b-c	a-b	0 1 0 - -	1 0 0 - -	Insert	a-b-[c]
a-b	a-b-c	1 0 0 - -	0 1 0 - -	Insert	a-b-[c]
a-b-c	a-B-c	0 0 0 - -	0 0 1 - -	Merge	a-B-c
a-B-c	a-b-c	0 0 0 - -	0 0 1 - -	Merge	a-B-c, B>b
a-F-c	a-G-c	0 0 1 - -	0 0 1 - -	Create	a-X-c , X:=F||G, $F \neq G$

ISBN: 978-989-95079-6-8

around. The *insert* operation is executed when the change based in the cost is a deletion or an insertion (Fig. 5). The combined grammar is always the altered version (with optional tags) of the longer grammar. When cost needs a substitute action and when generalization can be performed, *merge* operation is executed while *create* is executed when generalization is not suitable (Fig. 4). Note that the grammar combination is sensitive to the matched position of the grammar pairs. The notation '||' is only used as a convenience of the paper and not practised in the system development.

Figure 5: Combine (Insertion or Deletion) Algorithm

The impact of the grammar learning when the training set is prepared in various orders is being observed. Fig. 6 shows an example of a collection of grammars while Table 3 shows the grammar generated when the grammars are learned in the different orders as follows:

Order1: G_2-G_8-G_3-G_5-G_4-G_7-G_6-G_1.
Order 2: G_6-G_3-G_2-G_8-G_4-G_7-G_5-G_1
Order 3: G_2-G_5-G_3-G_8-G_4-G_7-G_6-G_1

Our observation has shown that the final set of evolved grammars can parse the same set of strings, with the same accuracy. Section 5 gives some remarks on this issue. However, further work is ongoing to investigate this in more detail from a theoretical and practical perspective.

$$G = \{G_1, G_2, ..., G_8\}$$
$$g_n = \{a, b, c, d, e, f, j, k\}, a > k > j$$
$$G_1 = w - n - w - se - pn - pc - cN$$
$$G_2 = w - w - n - w - se - pn - pc - cN$$
$$G_3 = w - w - acc - w - se - w - pn - pc - cN$$
$$G_4 = w - bt - w - se - pn - pc - cN$$
$$G_5 = w - w - n - w - se - w - pn - pc - cN$$
$$G_6 = w - w - acc - w - se - pn - pc - cN$$
$$G_7 = w - acc - w - se - pn - pc - cN$$
$$G_8 = w - w - bt - w - se - pn - pc - cN$$

4 Results and Discussion

The underlying ideas of the experiment are to examine approximate parsing, fuzzy overlap of grammar fragments, and their use in the incremental evolution of fuzzy grammars. To demonstrate the benefit of incremental evolution an experiment was carried out to compare the parsing scores of the grammars generated through fuzzy grammar learner (FG) versus the proposed incremental evolutionary learning grammar (IEG).

The term incremental is coined so that the grammar will always be able to parse all supplied string patterns (identified by grammars) including the triggered new string pattern. This simulates interaction with a human expert who would be able to correct errors—although clearly this disadvantages the FG method, which is not designed to undergo multiple training phases. On the other hand, the FG method is performed according to the normal supervised learning setting; the performance of the training dataset is measured by its parsing on the test dataset. No additional learning is allowed even the parsing score is lower than 1. Table 4 shows the terminal sets used in this experiment.

Table 4: Terminal Sets

Word (w)	Any token composed entirely of alphabetical characters
Number (n)	Any token composed of digits
Streetending (se)	One of {road, rd, avenue, ave, street, st, lane, ln} or similar
Placename (pn)	A handcrafted set of UK placenames
CountyName (cN)	A handcrafted set of UK district names
BusinessType (bt)	One of {café, restaurant, bar} or similar
Accommodation (acc)	One of {hotel, lodge} or similar
Alphanumeric (aN)	A token composed of alphabetical characters and digits

Two sets of address dataset in UK format are prepared; restaurant.xml and yellowpages.xml. The restaurant dataset contains a small set of restaurant addresses in the UK while the yellowpages dataset contains domestic addresses. Each dataset is split into 25% for training and 75% for testing. The restaurant dataset contains 85 entries while the yellowpages dataset contains 396 entries. Both have no repeated entries but naturally consist of similar or repeated string patterns. This experiment was repeated using three different orders of the training and test dataset, to test the validity of the results and the sensitivity and reliability of the algorithm. The same result was produced in the different data permutations. Future work on this study will focus on the formal theoretical proving of order independent learning to support this hypothesis.

Table 5 shows the comparison between the mean of maximum parsing score of the grammars learned. The average of exact parsing is a measure of the average of the maximum parsing score of the grammars on each string in the test dataset. Score of 100% means that all strings have been recognized by the grammar.

The IEG method generates new rules immediately and shows good incremental learning behavior as the grammar fragments evolve; meaning that the grammar fragments may be altered according to the change required to transform the source and target grammars so that they will be equally parsed with increased coverage. Thus, the IEG method will always give an optimal parsing score of 1 for each string it has encountered, as shown in Table 5. For each string in the dataset, there is either a grammar that can parse it partially or accurately; and a grammar can thoroughly parse a minimum of 1 string. This indicates that for every string in the dataset, there is at least a grammar that can parse it accurately (100% parsing). As opposed to the IEG method, the average of exact parsing in FG is much lower. Observation in the restaurant dataset shows that the minimum parsing score of the entries in FG is 0.667 and 0.75 in the yellowpages dataset. Both share a maximum of score=1.

As discussed in section 2, supervised learning method is constrained by its training stage; the training dataset should contain all the patterns expected to be seen in the test dataset. As shown in Table 5 the performance of the grammars generated in FG is lower than of IEG due to its insufficient training. The FG score in yellowpages dataset is higher than the restaurant dataset because the yellowpages dataset is larger than the restaurant dataset so during training a better coverage has been provided.

Table 5: Average of Exact Parsing

Setting	Dataset	Average of Exact Parsing (%)
FG	Restaurant	89.5
IEG	Restaurant	100
FG	Yellowpages	97
IEG	Yellowpages	100

This shows that the evolutionary learning method has successfully provided immediate and gradual learning to the grammars even when the training is found to be insufficient. The set of evolved grammars have successfully maintained the parsing coverage of the existing and newly combined

ISBN: 978-989-95079-6-8

patterns. The goal has been achieved where the adaptations are performed in light of new examples while preserving its current knowledge.

5 Summary and Conclusion

Incremental evolutionary grammar learning (IEG) is a method that can cope with newly found text pattern. It is an advantage over the expensive retrain-retest setting in traditional machine learning approaches when examples in the training phase are found to be insufficient. Empirical result shows that the IEG method has 100% parsing of the dataset compared to 89.5% and 97% achieved by the fuzzy grammar method. The incremental feature in IEG has also surpassed the genetic algorithm method both in the processing time and accuracy.

The underlying structure (grammar) of the text is first detected and corresponding grammar that represents the text is derived. The novel fuzzy grammar similarity is utilized to find similarity of the grammars. The evolution concept featured in this algorithm is reflected by the enrichment of the learnt patterns; where its incremental learning characteristic gradually updates its knowledge on the various patterns. Each time a new pattern is encountered, the adaptation is executed by a minimal adaptation which provides a *fit* coverage corresponding to the newly found and the altered grammar as well as all the strings that they belong. Over time, the set of evolved grammars become more concise, wider coverage yet sustaining its persistence.

Further work is ongoing to study the theoretical proving of the order-dependency effect on the evolved grammars, investigating a method to create more compact grammars and to expand the application of fuzzy grammar fragments to softer structures (e.g., identification of questions, negative comments, positive reviews, etc.).

Abstract—*In this paper we analyze the limitations of current recommendations of the INSPIRE (Infrastructure for Spatial Information in Europe) Directive as far as the temporal metadata definition for discovery purposes, and propose its extension so as to allow the representation and management of imperfect spatio-temporal metadata. We propose to extend the metadata in order to cope with the requirements of both metadata producers, who often are unable to specify precise values, and users who submit queries to catalog services for discovering interesting data, who may express soft selection conditions on metadata values. The proposal is illustrated and explained through an example taken from an active Spatial Data Infrastructure (SDI).*

Keywords— Geo-data, INSPIRE, metadata, Spatial Data Infrastructure, spatio-temporal imperfection.

1 Introduction

Infrastructures are complex systems in which a network of interconnected but autonomous components is used for the exchange and mobility of goods, persons, information. Their successful exploitation requires technologies, policies, investments in money and personnel, common standards and harmonised rules. Typical examples of infrastructures which are critical for society are transportation and water supply. In Information Technology, the term infrastructure could be related to communication channels through which information can be located, exchanged, accessed, and possibly elaborated. Since the last decade of the past Century, creation of infrastructures for spatial information emerged as an issue in some countries in order to prevent wasting of money in geo-data multiple creation, to favour their shares at multiple levels in the society, and to support decision making in various fields, such as the environment [1]. In 2007, the INSPIRE Directive of the European Parliament and of the Council entered into force [2] to trigger the creation of a European Spatial Data Infrastructure (ESDI) that delivers to the users integrated spatial information services*. These services should allow users to discover and possibly access spatial or geographical information from a wide range of sources, from the local to the global level, in an inter-operable way for a variety of uses. Discovery is performed through services that should follow INSPIRE standards and can be implemented through some products (either proprietary or not) that declare their compliance. Users' conditions, expressed through discovery service clients, are matched against archived metadata, describing associated geo-data, in order to give an answer to the above conditions. The matching result is a list (sometimes empty) of records of metadata satisfying the match. Discovery services currently provide an exact matching: users cannot express flexible selection conditions, enabling partial matching mechanisms between the ideal metadata and the archived metadata.

On the metadata side, their creation is usually in charge of data/services providers: metadata fields, their meaning, and their types/ranges of values are defined in INSPIRE through recommendation documents aimed at easing discovery [3], [4]. With respect to the temporal characterisation, current recommendations for metadata specification are inadequate for metadata providers: some needed fields are missing; the semantics of the recommended fields is ambiguous; they do not consider nor manage representation of uncertain or vague information due to incomplete knowledge.

In this paper we take into account this last drawback and propose to let imperfect temporal values be used by both metadata providers in describing the temporal validity of the geodata, and SDI users in expressing discovery conditions. Moreover we suggest mechanisms to introduce partial matching in discovery services.

2 Metadata extension proposal within SDI architecture of INSPIRE

2.1 SDI Architecture

An overview of the current understanding of the technical architecture of INSPIRE is depicted in figure 1; it has been adopted by the ESDI [5].

Discovery services are the element aimed at discovering information of interest to the users. They are connected to metadata catalogues, necessary due to the intrinsically distributed nature of an SDI, where information repositories

* Following the Directive, components of European SDIs include: metadata, spatial data themes (as described in Annexes I, II, III of the Directive), spatial data services; network services and technologies; agreements on data and service sharing, access and use; coordination and monitoring mechanisms, processes and procedures.

ISBN: 978-989-95079-6-8

are owned and maintained on the Web servers of different organisations. Services managing catalogues could have the twofold function of archives of metadata, which describe either geo-data or geo-services available in the SDI, and of discovery tools, able to match users' search conditions with archived metadata. Catalogues services should be fitted to let users express selection conditions that specify "what" is of interest through content keywords (e.g., landslides), "why" they are searched (e.g., to detect recurrence of landslides), "where" the interesting features should be located (e.g., in a bounding box surrounding the Alps), and "when" these features should have been observed (e.g., the date/s of the observations).

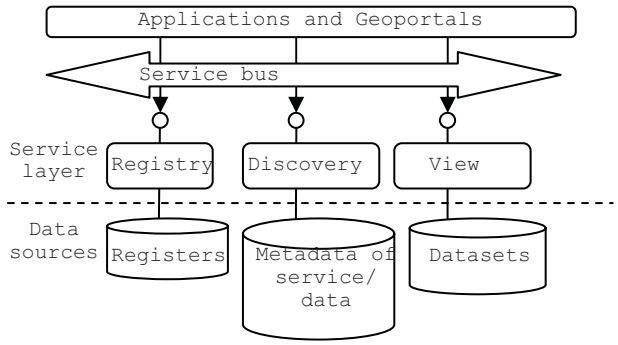

Figure 1: INSPIRE technical architecture overview; discovery service and metadata

2.2 Temporal metadata in INSPIRE SDIs

In order to ensure that the SDIs participating in the ESDI are compatible and usable in a trans-boundary, multicultural context such as Europe, the INSPIRE Directive requires that common Implementing Rules (IR) are adopted in a number of specific areas, in particular in metadata definition. The INSPIRE Metadata IR Version 3 of 26th October 2007 [4] defines four elements of temporal information, i.e.:

1. *Temporal extent*, the time period covered by the content of the resource
2. *Date of publication* of the resource
3. *Date of last revision* of the resource if the resource has been revised
4. *Date of creation* of the resource if it has not been revised

Only the first element (Temporal reference-5.1 Temporal extension) can be used to describe a temporal aspect of the content of geo-data itself, since the following three elements are referred to geo-data life cycle as a document. Nevertheless it plays an unavoidable role in numerous use cases, such as searching for events occurring in a particular period of time, looking for multiple observations of the same geographic area, evaluating if data can be used for a particular process, etc.

A specific study has been commissioned in order to improve temporal metadata specification [6]. It introduces some recommendations that rise attention to the role of 'Temporal extent' element; specifies the type and format of time values to be adopted either in expressing dates or time periods; suggests how to preserve precision in exchange or conversion processes.

2.3 Proposal of extension of temporal metadata

In our opinion and based on the experience as partners in the European Project IDE-Univers (http://www.ideunivers.eu), some further extensions should be adopted to improve temporal characterisation of geo-data in an SDI. In fact, the current specification of INSPIRE does not allow to specify the time relative to the occurrence of the event that is observed in one, several or a series of spatial data. Furthermore, current formats do not allow to specify imperfect values for metadata, both temporal, spatial, and thematic, which are the only kind of values that metadata producers can sometime provide, given that they often do not have enough information to specify precise values.

For example, if one has to create the metadata of a series of remote sensing images of a landslide that occurred in 1986 taken in distinct periods during its monitoring after its occurrence, the current specification just allows to indicate the time of the observations and not the time of the event, i.e. of the landslide occurrence. Nevertheless, this can be a very important information in an SDI context, because one can be interested in comparing the status of a landslide in different periods of time in the same place, as they appear in distinct images. One then, must be sure that the compared images refer to the same event, and not to distinct ones.

Moreover, in real situations, it often happens that the date or time of occurrence of an event is ill-known. This is due to several reasons: either because the event was not observed during its occurrence, and thus it can only be guessed by experts, or because it occurred long time ago so that its date can be deduced only imprecisely by the dating methods available (e.g., this is the case or archeological sites, geologic and paleontological findings).

In summary we propose:

- To introduce the possibility to include in metadata one or more events/processes/phenomena of reference for the geo-data: a satellite image can be an observation of fires in a region; a set of meteo records are measures of a rainfall; some thematic maps can be subsequent representations of urban growth, etc. A temporal extent element should be defined also for the reference event(s), of course.
- To allow the definition in metadata of soft temporal values in the temporal extent element of both geodata and related event(s); soft values should be allowed in the expression of single time points (by ex. the landslide occurred in the night of 15th December, 2005), of time intervals (by ex. snow precipitation of three days starting from 14th December 2008), and of subsequent either periodic or aperiodic dates/intervals (ex. fires occurring each Summer).

ISBN: 978-989-95079-6-8

3 Basic framework of the proposal

3.1 Extension of temporal metadata in INSPIRE

Notwithstanding we are aware that further extensions are possible, in this contribution we propose to include the following temporal metadata:

Instant in which the observation/event occurred:

- Date, time (e.g. the landslide occurred the 11-07-2008 at 8:00:00)

Period of validity, or duration of an observation/event:

- period (interval of dates, times) (e.g. the duration of a fire was from 11-07-2008 to 13-07-2008)

Sequence of instances of occurrences/events:

- multiple instants of time or dates (e.g. the dates of the distinct fires were 11-07-2008 , and 12-07-2008)

Sequence of periods of validity or duration of occurrences/events:

- multiple periods or durations (e.g. the times of the distinct fires were from 11-07-2008 to 13-07-2008 and from 20-08-2008 to 23-08-2008)

We also extend the time metadata format so as to allow the specification of ill-known instants, intervals and time series by means of fuzzy instant, fuzzy intervals and fuzzy time series associated with any kind of observation/event.

First of all we describe a formal framework in which all these fuzzy temporal indications are modeled, adopting the proposal of [7]. In order to express such fuzzy temporal indications into an eXtended Markup Language (XML)-type language, that is required for INSPIRE metadata, we adopt TimeML specification language [8].

The use of TimeML is motivated by the fact that it is a textual meta language, thus easy to read and to index by common Information Retrieval techniques, that can be employed in a catalog service context in order to represent the metadata contents for a successive search and discovery. It is enough flexible to allow the annotation (description) of the kind of event/observation and its temporal information, possibly imprecise and vague.

In the following subsections, let us first describe the representation within fuzzy set theory and possibility theory of time expressions, then introduce TimeML and specifically the tags we adopt, and finally, the partial matching mechanism we propose.

3.2 Modeling flexible time indications within the fuzzy set and possibility framework

The representation of temporal information requires the choice of a numeric scale to describe the order of events and phenomena; this scale is defined by an origin (time t=0) and a time unit, so that events occurred before t=0 have a negative time values and those occurred after have positive values. The choice of the time unit depends on the cycles of an observed periodic phenomenon, such as the movement of the sun. Nevertheless almost every time scale shares the basic unit *second*, and other units with lower granularity such as *minute*, *hour* and *day*. Besides these units of time, there are other natural language time indications such as *week*, *month*, *season*, *year*, *century* that are artificial notions, defined within a calendar such as the Julian and Gregorian ones. Other notions of time, related to human experience such as *now*, *soon*, *recent*, *often*, *end of the year*, are approximate time indications.

Several time models have been proposed [9], their common limitation is that they deal with crisp time indications.

A flexible framework has been defined within fuzzy set and possibility theory to express approximate hierarchical time indications close to natural language at distinct level of granularity [7]. It takes inspiration from the time hierarchy proposed in [10] and the time granularity defined as a mapping from the set of positive integers to the absolute time proposed in [11], and builds up a multi-granular hierarchical time structure in which also vague and imprecise time granules can be defined.

We assume this approach at the basis of our proposal. In this way it is possible to express temporal indications in several time units with distinct granularities, the less refined ones obtained by grouping units of the higher level granularity.

A *basic domain* G_0, consists of granules of time points below which the elements are not discernable. For example if G_0 is *hour* we cannot discern the *minutes* within an hour. Notice that, a granule of a domain G' (e.g. G'=*week*) that is not the basic domain G_0 (e.g. G_0=*hour*) can be defined by recursively grouping granules of its parent domains G=*day* and G_0 in the hierarchy. For example G'=*week*=7**day* =7*24*G_0=168*hours*.

The set of temporal specifications that we adopt are listed here following.

A *time point* indication is defined as a pair [t, G] in which t is an ordinal indicating the position with respect to the time origin on a domain G of granules. An example is: [t=2, *day*] that indicates the second day from the time origin; a fuzzy example is [t={0.8/3, 1./4, 0.7/5}, *day*] that means around the fourth day after the time origin.

A duration in time, i.e. a *time span*, is a pair [Δt, G] and can be denoted by either a set or a range of time points. A fuzzy time span example is [Δt ={0.8/3, 1./4, 0.7/5}, *year*] that means a duration of about 4 years.

A temporal distance from the origin, i.e. a *time distance*, is defined as a pair [d, G] in which d is a positive or negative value, indicating the distance in time granules on G from the origin. In this case [d=2, *day*] means two days after the origin. As t, also d can be a fuzzy set indicating a fuzzy time distance.

A *time interval* is a triple [t, Δd, G]; in a crisp case [t=1991, Δd=3, *year*] means 3 years from 1991.

A *composite span* is a union of spans $\cup[\Delta t_i, G_i]$, not necessarily adjacent and on the same basic domain G.

An *aperiodic time element* is a union of time intervals $\cup[t_i, \Delta d_i, G_i]$. The crisp example [t=1-11-2008, Δd=28, *day*] ∪ [t=30-11-2008, Δd=31, *day*] means 28 days from 1-11-2008 and 31 days from 30-11-2008.

A *periodic time element* is a union of a time interval and a time distance: $\cup[t_i, \Delta d_i, G_i], [d_k, G_k]$. By example ∪[t=1-8-2000, Δd=31, *day*], [d=1, *year*] means every August from

ISBN: 978-989-95079-6-8

year 2000. An example of vague periodic time element is ∪ [t=1-2000, Δd={0.2/1, 0.8/2, 1./3, 0,8/4}, *week*], [d=1, *year*] that means around the third week of every January from year 2000.

Since in the context of metadata compilation we may have time series that are related to finite repetitions of observations or events a *finite periodic time element* is defined as a composition of a periodic time element and a time point: $\cup[t_i, \Delta d_i, G_i], [d_k, G_k], [t, G]$ in which the time point t specifies the end of the repetition. An example of finite periodic time element is "*every autumn from 2000 to 2005*" that is formally expressed as: ∪[22-09-2000, 90, *day*], [1, *year*], [21-12-2005, *day*].

3.3 TimeML specification language for flexible time indications

TimeML is a markup language of the XML family for describing events, signals and temporal expressions into a text written in natural language. It is designed to address four situations:

1. Time stamping of events (identifying an event in time, instant or interval of validity).
2. Ordering events with respect to one another (relative ordering).
3. Reasoning with contextually underspecified temporal expressions (temporal functions such as 'last week' and 'two weeks before').
4. Reasoning about the persistence of events (how long does an event or the outcome of an event lasts).

The tags in TimeML[†] that we adopt to extend the INSPIRE metadata and that we model within the fuzzy framework previously described, are listed and illustrated in Table 1.

Table 1: TimeML tags adopted in this proposal

EVENT
Tag used to annotate the semantics of the event described. Syntactically, EVENT can be a verb (such as "raining"), but also a nominal, such as "fire"
MAKEINSTANCE
It indicates different instances (observations) of a given event. Different instances can have different attribute values, and every EVENT introduces at least one corresponding MAKEINSTANCE
TIMEX3
This tag is central to our objectives since it is primarily used to mark up explicit temporal expressions, such as times, dates, durations, etc. TIMEX3 allows marking up the following types of temporal indications specified by the attribute `type`: *Durations* such as "four weeks", "half a year"; *Calendar dates* (points in time equal or bigger than a day) both precise such as "13 August 2007" and imprecise or vague such as "few days ago", "end of July", "at the beginning of summer"; *Times of day* (smaller than a day) both precise such as "at 9.50.00 a.m." and imprecise or vague such as "before noon"; *Sets* (Recurring time expressions) such as "every month", "twice a week" The `value` attribute can assume XML datatypes based on the 2002 TIDES guideline, which extends the ISO 8601 standard for representing dates, times, and durations. E.g. "twelve weeks" becomes "P12W" and "21 February 2008 at 8.30.00 a.m." becomes "2008-2-21T8:30:00" The `mod` attribute allows specifying temporal modifiers that cannot be expressed either within `value` proper, or via links or temporal functions, such as "before", "after", "equal or less", "end".
TLINK
one of the TimeML link tags which encodes the relations that exist between two temporal elements (e.g., `BEGINS, HOLDS, INCLUDES, AFTER`)

For example the expression "*every autumn from 2000 to 2005*" is formulated in TimeML as follows:

```
<TIMEX3 tid="t10" type="SET" value="R6/2000-09-
22/P1Y0M0D">
every autumn from 2000 to 2005
</TIMEX3>
```

Finally, in TimeML it is possible to mark confidence values to be assigned to any tag and to any attribute of any tag. The confidence value associated with the `value` attribute of TIMEX3 expresses the uncertainty that the metadata provider has in assigning the temporal indication to an event or observation. For example, we can add the confidence annotation to TIMEX3 so as to specify the uncertain date of an observation that might have occurred the first or second of January 2000 as follows:

```
<TIMEX3 tid="t1" type="DATE" value="2000-01-01">
On January 1st, 2000
</TIMEX3>
<CONFIDENCE tagType="TIMEX3" tagID="t1"
confidenceValue="1."/>

<TIMEX3 tid="t2" type="DATE" value="2000-01-02">
On January 2nd, 2000
</TIMEX3>
<CONFIDENCE tagType="TIMEX3" tagID="t2"
confidenceValue="0.80"/>
```

4 Management of the proposed temporal metadata extension

The frameworks and assumptions of section 3 can be used to define the temporal fields associated with events and observations in the metadata of a SDI catalogue.

The metadata provider defines the time indications of events and observations by means of a metadata editor. We propose an example of the metadata of two thematic maps representing subsequent observations from satellite of the same event, i.e. the melting of the Lys Glacier (a glacier of the Italian Alps), during Summer 2007. In this example, the temporal indications of the occurrence of the observations

[†] TimeML vers. 1.2.1 <http://www.timeml.org>

ISBN: 978-989-95079-6-8

are known precisely. Following the extension we propose, in the metadata of the first map we could have fields such as:

Metadata 1
…
Event="Lys Glacier melting"
Occurrence="observation of Lys Glacier melting"
Time Position of Occurrence="1.7.2007"
…

In the metadata of the second map we could have:

Metadata 2
…
Event="Lys Glacier melting"
Occurrence="observation of Lys Glacier melting"
Time Position of Occurrence="3.9.2007"
…

Metadata are translated into TimeML sentences like in Table 2.

To allow partial matching with respect to flexible selection conditions specified by a user a parser translates the external TimeML definitions of temporal metadata into their internal fuzzy set representation μ_t. We can have fuzzy sets defined on distinct domains (G). The hierarchy of basic temporal concepts defining the temporal domains with distinct granularity, is represented by a graph that contains in each edge connecting node i to node j a mapping function $F_{i,j}$ that allows converting the current granule of the i-th node in terms of aggregation of granules of the j-th node (see Fig 2 which is a simplification to illustrate how the concept works).

This function $F_{i,j}$:G'→G, with G⊂G', and i,j identifiers of the i-th and j-th nodes, with i-th node defined on domain G' and j-th defined on G, associates a granule g'∈G'→$F_{i,j}$(g')∈G, where $F_{i,j}$(g') is a fuzzy set of granules on G. A temporal indication *t*, defined on G' (e.g., 2002 year) can be converted on another domain G (e.g., day) by repeatedly applying the mapping functions $F_{i,j}$ associated to the edges on the path from node G*'* to node G as proposed in [12].

Table 2: TimeML example

Lys Glacier
<EVENT eid="e10" class="OCCURRENCE">
is melting
</EVENT>
<MAKEINSTANCE eiid="ei1" eventID="e10"
pos="VERB" tense="PRESENT" aspect="PROGRESSIVE"
/>
<TIMEX3 tid="t2" type="DATE" value="2007-07-01">
On July 1st, 2007
</TIMEX3>
<TLINK eventInstanceID="ei1" relatedToTime="t2"
relType="DURING"/>
<MAKEINSTANCE eiid="ei2" eventID="e10"
pos="VERB" tense="PRESENT" aspect="PROGRESSIVE"
/>
<TIMEX3 tid="t3" type="DATE" value="2007-09-03">
On September 3rd, 2007
</TIMEX3>
<TLINK eventInstanceID="ei2" relatedToTime="t3"
relType="DURING"/>
…

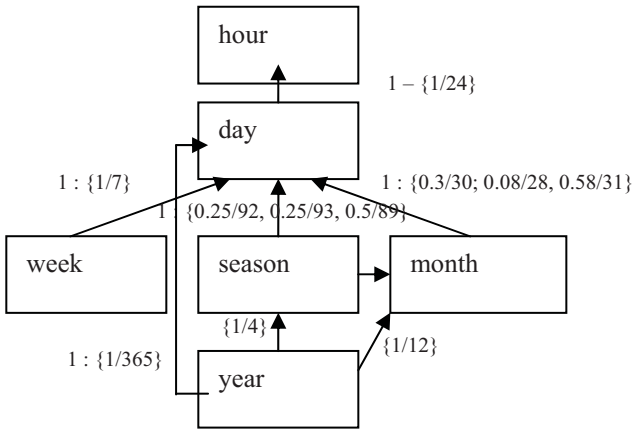

Figure 2: Simplified example of temporal graph: on each edge the fuzzy set defining the conversion function F of granules.

However, since there can be more than a single path P_1, ..P_k, connecting two nodes (e.g., P_1=*year*, *season*, *day* and P_2= *year, month, day*), multiple definitions of *t* on the domain G can be obtained t_{P1}, .. t_{Pk} In order to reconcile these definitions we choose the one obtained by considering the shortest path connecting the two nodes. If there exists more than one of such short paths with same length we generate the maximum bound of their definitions:

$$t_{P1 \oplus P2 \oplus Pk}(g) = \max(t_{P1}(g) .. t_{Pk}(g))$$

The reason for this choice is that the maximum bound comprehends all possible definitions of the temporal indication on the domain G.

For example, the sentences in Table 2 correspond to the two *time points* [t_1=1-7-2007, *day*], and [t_2=3-9-2007, *day*], with crisp pointwise membership functions.

On the other side, the user specifies her/his temporal soft selection conditions Q within a catalog service interface. They can be expressed by specifying soft constraints, i.e. with a desired membership function μ_Q, defined on a time line with a given granularity, chosen among one of the available in the temporal hierarchy (e.g. see fig. 3). An example of user selection condition for the Lys Glacier melting case reported in table 2 could be: *"Search for occurrences of glacier melting observations, occurring close to late Summer 2007"*.

Users' temporal query specifications are converted into the internal fuzzy set representation and, if necessary, transformed into the granularity of the data they have to be matched. The soft constraint of the example corresponds to a vague *time interval* with trapezoidal membership function μ_Q such as [t=15-6-2007, Δd={ 1-8-2007, 15-8-07, 23-9-2007, 10-10-2007}, *day*].

The internal fuzzy representation of the temporal metadata μ_t are then matched with the fuzzy representations of the soft query constraint μ_Q by applying a representation-based matching function as proposed in [13][14].

In this representation-based framework, both the metadata values μ_t, possibly uncertain, and the soft query condition μ_Q are interpreted as soft constraints and one can match

ISBN: 978-989-95079-6-8

them to obtain a degree of satisfaction $RSV(t,Q) \in [0,1]$, by computing either a measure of similarity [14] or a fuzzy inclusion measure [13] between the two fuzzy sets μ_Q and μ_t.

In the specific case of matching temporal constraints, it makes sense to allow the choice of both matching functions. One could be interested in selecting observations of an event taken in a date *close* to another date. This corresponds to select the similarity matching function [14]:

$$RSV(t,Q)=Similarity(\mu_t,\mu_q)=\frac{\sum_{i\in G} min(\mu_t(i),\mu_Q(i))}{\sum_{i\in G} max(\mu_t(i),\mu_Q(i))}$$

in which $\mu_t(i)$ and $\mu_Q(i)$ are the membership degrees of a time point i in a fuzzy metadata value t and in the query constraint Q.

Another case is when one wants to select observations that occurred *within* a period. This corresponds to select a matching function defined as a fuzzy inclusion [13]:

$$RSV(t,Q)=Inclusion(\mu_t,\mu_q)=\frac{\sum_{i\in G} min(\mu_t(i),\mu_Q(i))}{\sum_{i\in G}(\mu_t(i))}$$

Other matching functions could be defined corresponding with other temporal relations such as "*close before*" "*close after*" "*recent*" and so on.

The retrieved metadata can be ranked in decreasing order on the basis of *RSV* values, thus avoiding empty answers and suggesting an access order to the referred geo-data. In the example, both metadata are retrieved: Metadata 2 has a *RSV* score "1" being situated in late Summer, while Metadata 1 is also retrieved since it partially satisfies the query condition "*close*", thus meaning that it is associated to an observation of glacier melting that is in proximity of the limits of the temporal range 'late Summer'.

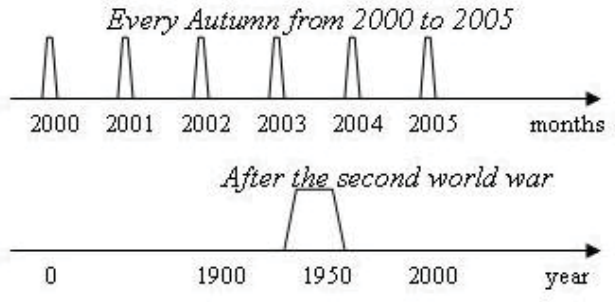

Figure 3: Examples of two soft temporal constraints defined on two timelines with distinct granularity (months and years, respectively). The constraint "*every Autumn from 2000 to 2005*" is defined as a fuzzy finite periodic time element, while "*after the second world war"* as a fuzzy time interval.

5 Conclusions

Spatial Data Infrastructures are becoming a common practice for discovering and accessing distributed heterogeneous geo-data. Nevertheless, the catalogue services on which SDIs are based are still founded on old database paradigms, that do not allow partial matching mechanisms, nor the representation and management of ill-defined metadata.

The present paper represents a first step in the proposal of a fuzzy framework to model catalogue services functionalities to manage ill-defined metadata and flexible queries. Specifically, we proposed a solution to express, represent, and manage temporal metadata, possibly imperfect, in a flexible way even if the revising policy within INSPIRE is long and needs to overcome several reviewing steps.

On Some Fuzzy Categories of Many-valued Topological Spaces

Abstract— *The aim of this paper is to construct some new fuzzy categories related to many-valued sets and many valued topologies and to consider their properties.*

Keywords— Fuzzy categories, GL-monoids, L-valued equalities, L-topologies and L-fuzzy topologies.

1 Introduction

Since the inception of the notion of a fuzzy set by Zadeh [19] and its generalization as an (L)-fuzzy set where L is a complete lattice by Goguen [3], the efforts of many researchers were forced to introduce the appropriate fuzzy counterparts of the classical mathematical concepts and to develop substantial corresponding theories. However from the categorical point of view in most cases the work was done in the context of ordinary, that is crisp categories. To explain our idea we give some examples

1. Following the works of Chang [2] and Goguen [4], an L-fuzzy topological space is a pair (X, τ) where X is a set and τ is a subfamily of L^X satisfying axioms which are natural analogues of classical topological axioms. The continuity of mappings between L-fuzzy topological spaces is defined just by "translating" the definition of continuity in fuzzy enviroment.

2. In [18] Mingsheng Ying introduced the concept of a fuzzifying topological space by semantical analysis of usual topological axioms, cf also [6]. Namely a fuzzifying topological space is a pair $(X, \mathcal{T})$ where X is a set and $\mathcal{T} : L^X \to L$ is a mapping satisfying the axioms which are obtained by logical interpretation of the standard topological axioms. Continuity of mappings between two fuzzifying topological spaces is defined by logical interpretation of the axiom "the preimage of an open set is open".

3. In [11] A. Rosenfeld defined a fuzzy subgroup of a group $(G, \cdot, e)$ as a mapping $H : G \to [0, 1]$ such that $H(x \cdot y) \geq H(x) \wedge H(y)$ and $H(x) = H(x^{-1})$ for all $x, y \in G$. A homomorphism between fuzzy subgroups H_1 and H_2 is defined as a homomorhism between the underlying groups $f : G_1 \to G_2$ such that $H_1(x) \leq H_2(f(x))$ for every $x \in G_1$.

Thus in all these cases as well as in many other situations, the authors work in the following context: they consider a (usual) category whose objects are certain mathematical structures involving fuzzy sets as objects and mappings satisfying certain properties between these objects as morphisms.

On the other hand in [13] the concept of a fuzzy category was introduced. A fuzzy category is some category-type conglomerate whose objects and morphisms may be such only to a certain degree, see the next section for the precise definition. The foundations of the theory of fuzzy categories were developed in a series of subsequent papers, see e.g. [14], [10], [15], etc. These works contain also description of some concrete fuzzy categories related to algebra and topology, which are obtained by a certain fuzzification of classical categories.

The aim of this paper is to construct some new fuzzy categories related to many-valued sets and many valued topologies and to consider their properties. They can be regarded as fuzzy counterparts of the category $\mathbf{SET}(L)$ [7] and categories $\mathbf{TOP}(L)$ and $\mathbf{FTOP}(L)$ introduced in our work [16]. The fuzzy categories considered in this paper were first defined in our talk at the Czech-Latvian Seminar *"Advanced methods in Soft Computing",* in Trojanovice, Czech Republic, November 19-22, 2008.

2 Fuzzy categories

First we recall the concept of an (L)-fuzzy category (where L is a GL-monoid) in a special form appropriate for our merits.

Recall (see [7]) that a $GL-$monoid is an infinitely distributive lattice $(L, \leq, \wedge, \vee)$ [1] enriched with a monotone, commutative and associative binary operation $*$ such that

1. $a * 1 = a$ and $a * 0 = 0$ for all $a \in L$ where 0 and 1 are the bottom and the top elements of L respectively;

2. $a * \left(\bigvee\limits_{i \in \mathcal{I}} b_i \right) = \bigvee\limits_{i \in \mathcal{I}} (a * b_i)$ $\forall a \in L$, $\forall \{b_i : i \in \mathcal{I}\} \subseteq L$;

3. If $a \leq b$, then there exists $c \in L$ such that $a = b * c$. (The last property of a GL-monoid is called divisability.)

Such operation $*$ will be refered to as the conjunction in the GL-monoid. Important examples of GL-monoids are Heyting algebras (in this case $* = \wedge$) and Łukasiewicz MV-algebra (in this case L = [0,1] and $a * b = \max\{a + b - 1, 0\}$) [5].

It is known that every $GL-$monoid is residuated, i.e. there exists a further binary operation " $\mapsto$ " (residuation) on L linked to $*$ with the Galois condition:

$$a * b \leq c \Longleftrightarrow a \leq (b \mapsto c) \qquad \forall a, b, c \in L.$$

Explicitely implication is given by

$$a \mapsto b = \bigvee \{\lambda \in L \mid a * \lambda \leq b\}.$$

ISBN: 978-989-95079-6-8

Let $L = (L, \leq, \wedge, \vee, *)$ be a GL-monoid. *An (L)-fuzzy category* [13] is a pair $(\mathcal{C}, \mu)$ where $\mathcal{C}$ is an ordinary category with the class of objects $\mathcal{O}b(\mathcal{C})$, the class of morphisms $\mathcal{M}or(\mathcal{C})$, and where $\mu : \mathcal{M}or(\mathcal{C}) \to L$ is an L-subclass of the class of morphism such that:

(i) $\mu(g \circ f) \geq \mu(g) * \mu(f)$ whenever composition $g \circ f$ is defined in the category $\mathcal{C}$;

(ii) for each $X \in \mathcal{O}b(\mathcal{C})$ $\mu(id_X) = 1$ where id_X is the identity morphism.

3 Category SET(L) and fuzzy category $\mathcal{F}$-SET(L)

Category **SET**(L) was first defined in [7], see also [8]. The objects of the category **SET**(L) are L-valued sets, that is pairs (X, E) where X is a set and E is an L-valued equality, that is a mapping $E : X \times X \to L$ such that

1) $E(x, x) = 1$;

2) $E(x, y) = E(y, x)$;

3) $E(x, y) * E(y, z) \leq E(x, z)\ \forall x, y, z \in X$.

An L-subset A of an L-valued set (X, E) (that is a mapping $A : X \to L$) is called extensional if $A(x) * E(x, x') \leq A(x')$ for all $x, x' \in X$. The family of all extensional L-subsets of (X, E) will be denoted L^X_E.
The morphisms $f : (X, E_X) \to (Y, E_Y)$ in the category **SET**(L) are extensional mappings, that is mappings $f : X \to Y$ such that

$$E_X(x, x') \leq E_Y(f(x), f(x')) \quad \forall x, x' \in X.$$

Consider the category

$$\mathcal{C}(L) = (\mathcal{O}b(\mathbf{SET}(L)), \mathcal{M}or(\mathbf{SET})),$$

that is $\mathcal{C}(L)$ has objects from **SET**(L) and morphisms from **SET**, that is all mappings between the corresponding sets.
We define the measure μ of extensionality for a mapping $f : X \to Y$ by

$$\mu(f) = \bigwedge_{x,x' \in X} (E_X(x, x') \mapsto E_Y(f(x), f(x'))).$$

Theorem 3.1 *The triple $(\mathcal{O}b(\mathbf{SET}(L)), \mathcal{M}or(\mathbf{SET}), \mu)$ is an L-fuzzy category. It will be denoted by $\mathcal{F}$-**SET**(L) and called the L-fuzzification of the category* **SET**(L).

Proof: Let $id_X : (X, E) \to (X, E)$ be the identity mapping. Then, obviously, $\mu(id_X) = 1$. Hence, to prove the theorem, we have to show that if $f : (X, E_X) \to (Y, E_Y)$ and $g : (Y, E_Y) \to (Z, E_Z)$ are potential morphisms (that is mappings between the corresponding sets), then $\mu(g \circ f) \geq \mu(g) * \mu(f)$. Indeed,

$$\mu(g \circ f) =$$
$$= \bigwedge_{x,x' \in X} (E_X(x, x') \mapsto E_Z((g \circ f)(x), (g \circ f)(x'))) \geq$$
$$\bigwedge_{x,x' \in X} (E_X(x, x') \mapsto E_Y(f(x), f(x'))) *$$
$$\bigwedge_{x,x' \in X} (E_Y(f(x), f(x')) \mapsto E_Z(g(f(x)), g(f(x')))) \geq$$
$$\mu(f) * \bigwedge_{y,y' \in Y} (E_Y(y, y') \mapsto E_Z(g(y), g(y'))) =$$
$$\mu(f) * \mu(g).$$

□

4 Category TOP(L) and fuzzy category $\mathcal{F}$-TOP(L).

Definition 4.1 *Let $L = (L, \wedge, \vee, *)$ be a GL-monoid and (X, E) be an L-valued set. A family $\tau \subseteq L^X$ is called an L-topology on an L-valued set (X, E) if*

1. *$0_X \in \tau; 1_X \in \tau$ (where $0_X, 1_X$ are constant L-sets with values 0 and 1 respectively;*
2. *if $U, V \in \tau$, then $U \wedge V \in \tau$;*
3. *if $U_i \in \tau \quad \forall i \in \mathcal{I}$, then $\bigvee_{i \in \mathcal{I}} U_i \in \tau$;*
4. *if $U \in \tau$, then $U(x) * E(x, x') \leq U(x')\ \forall x, x' \in X$.*

The last condition means that all L-sets in τ are extensional and hence $\tau \subseteq L^X_E$.
The triple (X, E, τ) where τ is an L-topology on an L-valued set is called an L-valued L-topological space. Respectively, the elements $U \in \tau$ are called open L-sets in this L-valued L-topological space.

Definition 4.2 *A mapping $f : (X, E_X, \tau_X) \to (Y, E_Y, \tau_Y)$ is called continuous if*

1. *$E_X(x, x') \leq E_Y(f(x), f(x'))$ for all $x, x' \in X$,* that is f is an extensional mapping between the corresponding L-valued sets (X, E_X) and (Y, E_Y), and
2. *$f^{-1}(V) \in \tau_X$ whenever $V \in \tau_Y$.*

Obviously, if $f : (X, E_X, \tau_X) \to (Y, E_Y, \tau_Y)$ and

$$g : (Y, E_Y, \tau_Y) \to (Z, E_Z, \tau_Z)$$

are continuous, then the composition

$$g \circ f : (X, E_X, \tau_X) \to (Z, E_Z, \tau_Z)$$

is continuous and the identity mapping

$$id_X : (X, E_X, \tau_X) \to (X, E_X, \tau_X)$$

is continuous. Hence L-valued L-topological spaces and continuous mappings between them form a category **TOP**(L).
One can easily see that in case E is crisp, that is $E(x, x') = 0$ if $x \neq x'$ and $E(x, x) = 1$, the L-valued toplogical space is just an L-topologcal space in the sense of [2], [4] and the category of L-topological spaces is actually a complete subcategory of **TOP**(L).

Notice that, by lower-semicontinuity of conjunction, for extensional L-sets U_i, we have

$$\left(\bigvee_{i \in \mathcal{I}} U_i(x)\right) * E(x, x') \leq$$
$$\bigvee_{i \in \mathcal{I}} (U_i(x) * E(x, x')) \leq \bigvee_{i \in \mathcal{I}} U_i(x') \quad \forall x, x' \in X.$$

Thus the supremum of extensional L-subsets of an L-valued set is extensional itself. Therefore, in an analogy with classical topology we can define the interior $int(A)$ of an L-subset A of an L-valued L-topological space (X, E, τ) as the largest $(\geq)$ one of all open L-subsets of (X, E, τ) contained $(\leq)$ in A. Equivalently, it can be defined by the formula

$$int(A) = \bigvee \{U \in \tau \mid U \leq A\}.$$

ISBN: 978-989-95079-6-8

One can easily verify that the resulting operator

$$int : L^X \to L^X$$

satisfies all properties, analogous to the properties of the interior operator in classical topology.

The interior operator allows us to measure "the degree of openess" of an L-set A in an L-valued L-topological space by evaluating, to what extent an L-set A is contained in its interior. To realize this we need to extend an L-valued equality E from a set X to its extensional L-powerset L_E^X. This can be done as follows (see [17]):
Given $A, B \in L_E^X$ let

$$\mathcal{R}(A,B) = \bigwedge_{x,z\in X} ((E(x,z) * A(x)) \mapsto B(z)).$$

It is shown in [17] that $\mathcal{R} : L_E^X \times L_E^X \to L$ is an L-fuzzy order relation on L_E^X, that is it is refelexive ($\mathcal{R}(A,A) = 1$ for all $A \in L_E^X$) and transitive ($\mathcal{R}(A,B) * \mathcal{R}(B,C) \le \mathcal{R}(A,C)$ for all $A, B, C \in L_E^X$). By setting $\mathcal{E}(A,B) = \mathcal{R}(A,B) \wedge \mathcal{R}(B,A)$ an L-valued equality on L_E^X is obtained [17].
Now to fuzzify the category **TOP**(L) we consider the category

$$(\mathcal{O}b(\mathbf{TOP}(L)), \mathcal{M}or(\mathbf{SET}), \circ),$$

where objects are L-valued L-topological space (X, E, τ), but morphisms are from the category **SET**, that is mapings between corresponding sets. For a given mapping

$$f : (X, E_X, \tau_X) \to (Y, E_Y, \tau_Y)$$

we define the degree of extensionality by

$$\mu_1(f) = \bigwedge_{x,x'\in X} (E_X(x,x') \mapsto E_Y(f(x), f(x')),$$

the degree of continuity by

$$\mu_2(f) = \bigwedge_{V\in\tau_Y} \mathcal{R}(f^{-1}(V), int(f^{-1}(V)))$$

and finally the degree of being a morphism by

$$\mu(f) = \mu_1(f) \wedge \mu_2(f).$$

Theorem 4.3 *$(\mathcal{O}b(\mathbf{TOP}(L)), \mathcal{M}or(\mathbf{SET}), \circ, \mu)$ is a fuzzy category.*

Proof Let $f : (X, E_X, \tau_X) \to (Y, E_Y, \tau_Y)$ and

$$g : (Y, E_Y, \tau_Y) \to (Z, E_Z, \tau_Z).$$

The inequality

$$\mu_1(g \circ f) \ge \mu_1(g) * \mu_1(f)$$

was established in the previous section. To establish the inequality

$$\mu_2(g \circ f) \ge \mu_2(g) * \mu_2(f)$$

we are reasoning as follows:

Let $f : (X, E_X, \tau_X) \to (Y, E_Y, \tau_Y)$,
$g : (Y, E_Y, \tau_Y) \to (Z, E_Z, \tau_Z)$.
We fix $W \in \tau_Z$. Then by transitivity of $\mathcal{R}$

$$\mathcal{R}(f^{-1}(g^{-1}(W)), int_X(f^{-1}(g^{-1}(W)))) \ge \mathcal{R}(f^{-1}(g^{-1}(W)), f^{-1}(int_Y(g^{-1}(W))))* \mathcal{R}(f^{-1}(int_Y(g^{-1}(W))), int_X(f^{-1}(g^{-1}(W)))).$$

We estimate each member separately:

$$\mathcal{R}(f^{-1}(int_Y(g^{-1}(W))), int_X(f^{-1}(g^{-1}(W)))) \ge \mathcal{R}(f^{-1}(int_Y(g^{-1}(W))), int_X(f^{-1}(int_Y g^{-1}(W)))) \ge \mu_2(f).$$

$$\mathcal{R}(f^{-1}(g^{-1}(W)), f^{-1}(int_Y(g^{-1}(W)))) = \bigwedge_{x,x'} ((E(x,x') * g^{-1}(W)(f(x))) \mapsto int_Y(g^{-1}(W)(f(x')))) \ge$$

(by extentionality of f)

$$\ge \bigwedge_{x,x'} ((E(f(x),f(x')) * g^{-1}(W)(f(x))) \mapsto int_Y(g^{-1}(W)(f(x')))) \ge \bigwedge_{y,y'} \left((E(y,y') * g^{-1}(W)(y)) \mapsto int_Y(g^{-1}(W)(y'))\right) \ge \mu_2(g).$$

Thus

$$\mathcal{R}(f^{-1}(g^{-1}(W)), int_X(f^{-1}(g^{-1}(W)))) \ge \mu_2(g) * \mu_2(f).$$

Since this is valid for any $W \in \tau_Z$ we obtain the requested

$$\mu_2(g \circ f) \ge \mu_2(g) * \mu_2(f).$$

Finally referring to the properties of a GL-monoid, we get

$$\mu(g \circ f) = \mu_1(g \circ f) \wedge \mu_2(g \circ f) \ge (\mu_1(f) * \mu_1(g)) \wedge (\mu_2(f) * \mu_2(g)) \ge (\mu_1(f) \wedge \mu_2(f)) * (\mu_1(g) \wedge \mu_2(g)) = \mu(f) * \mu(g).$$

We conclude the proof by noticing that obviously $\mu(id_X) = 1$ for the identity morphism

$$id_X : (X, E_X, \tau_X) \to (X, E_X, \tau_X).$$

□

5 Category FTOP(L) and fuzzy category $\mathcal{F}$-FTOP(L)

The concept of an L-valued L-fuzzy topological space as a generalization of the concept of an L-fuzzy topological space [12], [9] and the corresponding category **FTOP**(L) were introduced in [17]. The objects of this category are triples $(X, E, \mathcal{T})$ where (X, E) is an L-valued set and $\mathcal{T} : L^X \to L$ is an L-fuzzy topology, that is an extensional subset of L_E^X such that

1) $\mathcal{T}(1) = \mathcal{T}(0) = 1$;

2) $\mathcal{T}(U \wedge V) \ge \mathcal{T}(U) \wedge \mathcal{T}(V) \quad \forall U, V \in L_E^X$;

3) $\mathcal{T}\left(\bigvee_{i\in I} U_i\right) \ge \bigwedge_{i\in\mathcal{I}} \mathcal{T}(U_i) \quad \forall \{U_i \mid i \in \mathcal{I}\} \subseteq L_E^X$.

and morphisms are extensional mappings

$$f : (X, E_X) \to (Y, E_Y)$$

such that $\mathcal{T}(f^{-1}(V)) \ge \mathcal{T}(V)$.
One can easily see that in case E is crisp, that is $E(x,x') = 0$

ISBN: 978-989-95079-6-8

if $x \neq x'$ and $E(x,x) = 1$, the L-valued L-fuzzy toplogical space is just an L-fuzzy topological space as it was defined in [12], [4] and the category of L-fuzzy topological spaces is actually a complete subcategory of $\mathbf{FTOP}(L)$.

Let $(X, E_X, \mathcal{T}_X)$, $(Y, E_Y, \mathcal{T}_Y)$ be L-valued L-fuzzy topological spaces and $f : X \to Y$ be a mapping of the corresponding underlying sets. The measure of the extensionality μ_1 of the mapping $f : (X, E_X) \to (Y, E_Y)$ is defined as above. The measure of continuity μ_2 of a mapping $f : (X, \mathcal{T}_X) \to (Y, \mathcal{T}_Y)$ is defined by

$$\mu_2(f) = \bigwedge_{V \in L_E^Y} \left(\mathcal{T}_Y(V) \mapsto \mathcal{T}_X(f^{-1}(V))\right).$$

Further, for a mapping $f : (X, E_X, \mathcal{T}_X) \to (Y, E_Y, \mathcal{T}_Y)$ we set $\mu(f) = \mu_1(f) \wedge \mu_2(f)$.

Theorem 5.1

$$\mathcal{F}-\mathbf{FTOP}(L) = (\mathcal{O}b(\mathbf{FTOP}(L)), \mathcal{M}or(\mathbf{SET}), \mu)$$

is an L-fuzzy category.

Proof: Since for the identity morphism

$$id_X : (X, E_X, \mathcal{T}_X) \to (X, E_X, \mathcal{T}_X)$$

obviously $\mu_1(id_X) = 1$ and $\mu_2(id_X) = 1$, we have $\mu(id_X) = 1$. Therefore to prove the theorem we have to establish that given two functions $f : (X, E_X, \mathcal{T}_X) \to (Y, E_Y, \mathcal{T}_Y)$ and $g : (Y, E_Y, \mathcal{T}_Y) \to (Z, E_Z, \mathcal{T}_Z)$, viewed as the mappings of the corresponding underlying sets it holds

$$\mu(g \circ f) \geq \mu(g) * \mu(f).$$

The inequality $\mu_1(g \circ f) \geq \mu_1(g) * \mu_1(f)$ was established in subsection 3. The inequality

$$\mu_2(g \circ f) \geq \mu_2(g) * \mu_2(f)$$

was established in [14], see also [15]. Now, referring to the properties of a GL-monoid, we get

$$\begin{gathered}\mu(g \circ f) = \mu_1(g \circ f) \wedge \mu_2(g \circ f) \geq \\ (\mu_1(g) * \mu_1(f)) \wedge (\mu_2(g) * \mu_2(f)) \geq \\ (\mu_1(g) \wedge \mu_2(g)) * (\mu_1(f) \wedge \mu_2(f)) = \mu(g) * \mu(f).\end{gathered}$$

Valued Constraint Satisfaction Problems Applied to Functional Harmony

Nele Verbiest, Chris Cornelis and Yvan Saeys
Ghent University, Ghent, Belgium
Email: {Nele.Verbiest, Chris.Cornelis, Yvan.Saeys}@UGent.be

***Abstract*— *Harmonization with four voices is a musical problem which is subject to hard constraints, which absolutely need to be fulfilled, as well as to soft constraints, which preferably hold, but are not mandatory. In this paper, we model this problem as a valued constraint satisfaction problem (VCSP): costs are assigned to possible solutions based on the constraints they violate. We design an algorithm that finds a minimal-cost solution, thus solving the harmonization problem, and we present initial results obtained by this algorithm.*

Keywords— functional harmony, valued constraint satisfaction problems, soft constraints

1 Introduction

Ever since people have had computers at their use, they have attempted to make them acquire human skills like rational thought and creativity. While the prospect of computers actually creating art might still seem out of reach, in musical composition some successful efforts have already been made; in [1], Truchet and Codognet give an overview of musical problems that were solved using computers.

In this paper, we discuss the use of Valued Constraint Satisfaction Problems (VCSPs) in functional harmony with four voices (soprano, alto, tenor, bass). Solving harmonization problems is a basic skill that every composer has to acquire before attempting more serious work. These problems range from very simple to advanced, with many gradations in between. Their solution is governed by a set of strict rules that have to be verified, but also by a variety of "softer" guidelines with varying, subjective importance, imposed to make the result more interesting, more varied, ... Valued constraints can be constructed and enforced sensibly to model them.

The structure of this paper is as follows: in Section 2, we discuss related work, and in particular solvers that have already been proposed for this problem, and position our own contribution. In Section 3, we briefly explain what functional harmony is about, and which constraints govern harmonization problems. In Section 4, we give the necessary background on VCSPs, while in Section 5 we translate the musical composition problem and its constraints to this framework. In Section 6 we describe the algorithm designed for solving our VCSP. In Section 7 we present some results obtained by this algorithm, and in the last section we discuss its practical use and suggest future research directions.

2 Related work

Programs to compose music have been designed since the 50s. We are specifically interested in harmonization problems with four voices, a problem that can be stated as a constraint satisfaction problem [2]. To solve this problem, two main classes of techniques have been described in the literature: backtracking and genetic algorithms.

Backtracking algorithms tackle the problem in the following way. The harmonization of a piece of music proceeds in a left to right fashion, analyzing every subsequent note. For each note, one seeks a possible chord for that note, and if there is no solution for this note, the algorithm goes back to a preceding note to try other possibilities. The standard work in this class is due to Ebcioğlu [3]: he introduced an expert system for harmonizing chorales with four voices, based on a set with about 350 rules. Apart from this, there are also backtracking algorithms where possible chords for a note are ranked by musical suitability. At every step, one tries the best chord. If this chord does not lead to a solution, the chord is removed from the ranking and a solution with the second best chord is sought [4]. Existing backtracking solvers look for one solution and then stop.

Genetic Algorithms (GAs) use an evaluation function to judge the musical quality of a set of solutions, and proceed in an iterative way to optimize these solutions [5, 6], using evolutionary reproduction operators like mutation and crossover.

Both approaches have their advantages and disadvantages. Backtracking algorithms are very efficient in finding a single solution, but little can be said about its quality: any solution found by the algorithm is guaranteed to meet the imposed hard constraints, but soft constraints are generally not considered. Ranking possible chords for a note deals only partially with this problem; this tactic will find a good solution, but it is not guaranteed to be the best one. By virtue of the evaluation function, genetic algorithms are better at catering for soft constraints, but they also suffer from the fact that their solutions are often suboptimal.

The solver we describe in this paper combines the use of soft constraints (which can be seen as the analogon of the evaluation function in GAs) with the potential to find an optimal solution in the search space.

3 Functional harmony with four voices

We briefly describe the essentials of functional harmony, and refer the interested reader to [7, 8] for more details. The problem we consider is a simplification of the general harmonization problem: given a melody for a soprano, we aim to find corresponding melodies for alto, tenor and bass. We suppose that only quarter notes are used in all the melodies and we work in C major. In tonal music, one speaks about grades, which —for a particular tuning— coincide with a set of chords. The most important grades that are always considered are I, IV and V. Other grades that often appear are VI and sometimes II. In C major tuning, the first note is c which results in grade I being the chord built on c; the fourth note is f,

ISBN: 978-989-95079-6-8

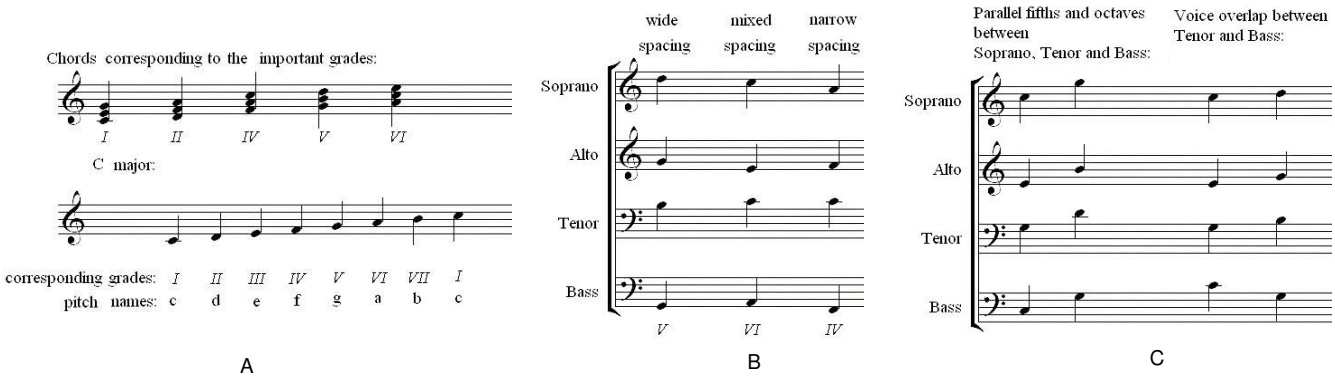

Figure 1: Essentials of functional harmony, illustrating the grades and chords of C Major (A), the concepts of narrow, mixed and wide spacing (B), and some examples of constructs that are not allowed (C).

so the chord corresponding to grade IV is the chord built on f. Fig. 1A illustrates the grades and chords of C major.

Now consider a note in the soprano. This note is in one or more of these chords. In harmonizing the soprano, one must choose a chord, and attribute the corresponding notes in the other voices to a note of this particular chord. The bass must always be the ground note (the lowest note) of the chord. For example, if IV is chosen, then the bass must be f. The soprano, alto and tenor have to be different from each other, so each note of the chord appears once, except for the ground note which appears twice.

We now introduce the concepts *wide* and *narrow* spacing. For every note in the soprano, we still have some freedom for the notes in alto, tenor and bass. We now restrict the possibilities a bit more. For each chord we choose, we have to decide whether we write it in wide or in narrow spacing. Narrow spacing means that between soprano and alto, and between alto and tenor there is no other note of the chord. Wide spacing means that there is always one note of the chord between soprano and alto, and between alto and tenor. This is illustrated in Fig. 1B. If the previous chord is written in narrow spacing, then the next chord must be narrow spaced as well. If the previous chord is wide spaced, then so must be the next chord.

The VIth grade chord is written like the other chords, except for the case when it is preceded by a Vth grade. In this case, the second note of the chord is written twice. This means that it has neither wide nor narrow spacing; we refer to this situation as *mixed* spacing. When we encounter a sequence V-VI it is possible to go from wide to narrow spacing or vice versa using mixed spacing on the VIth grade. Fig. 1B shows a good V-VI-IV sequence where we switch spacing.

Now we know how to write the chords we must consider the problem of choosing the right grade. To this end, a number of rules have been defined in the domain of functional harmony:

- The first and the last grade of a music piece must be I. The other grades depend on the previous grades.
- Some transitions between grades are not allowed, others are considered very good, while still others are not considered wrong but should be avoided as much as possible.
- Each of the different voices has its own range of notes that it can sing. The soprano can sing the highest notes, the bass sings the lower notes, and care has to be taken that these ranges are respected.
- It is forbidden to write parallel fifths or parallel octaves, to write the same grade before and after a bar or to overlap voices.

Some of these forbidden constructs are shown in Fig. 1C.

4 Valued constraint satisfaction problems

A constraint satisfaction problem (CSP) involves assigning values to variables that are subject to some constraints [9]. If there are constraints that are preferred but not essential, we can consider the problem of assigning values to the variables in such a way that the more important constraints are fulfilled and the less important ones are fulfilled to the extent possible. The latter yields a valued CSP (VCSP), which is characterized by a set of hard constraints (that must be fulfilled), and a set of so-called *valued constraints*. If the valued constraints are treated as mandatory, the problem is often unsolvable. If the valued constraints are ignored, we get solutions of bad quality. Our interest is therefore in the solution that best respects the set of constraints. To express what the best solution is, we assign costs to valued constraints. Every time a valued constraint is violated, we count the cost of this violation. In the end, we are interested in the solution with the lowest cost. We recall a formal definition of VCSP's.

Definition 1. *A Valued Constraint Satisfaction Problem (VCSP) is a quadruple* (X, D, C, V)*, where*
$X = \{X_1, ..., X_n\}$ *is a set of variables,*
$D = \{D_1, ..., D_n\}$ *is a set of finite domains:* D_i *is the set of possible values for* X_i*,*
$C = \{C_1, ..., C_r\}$ *is a set of hard constraints and*
$V = \{V_1, ..., V_s\}$ *is a set of valued constraints.*

A hard constraint C_i on the ordered set of variables $var(C_i)$ is the relation of the allowed combinations of values for the variables in $var(C_i)$; C_i is a mapping from the cartesian product of domains of variables in $var(C_i)$ to $\{0, 1\}$.

A valued constraint V_i on the ordered set of variables $var(V_i)$ specifies the cost of the combination of the values for the variables in $var(V_i)$; V_i is a mapping from the cartesian product of domains of variables in $var(V_i)$ to $[0, 1]$.

For example, if V_i pertains to the variables X_1, X_2 (i.e.

ISBN: 978-989-95079-6-8

$Var(V_i) = (X_1, X_2)$) and we assign values x_1 and x_2 to X_1 and X_2 respectively, the cost of this combination is given by $V_i(x_1, x_2)$. If C_i pertains to the variables X_1, X_2, X_3 (i.e. $Var(C_i) = (X_1, X_2, X_3)$) and we assign values x_1, x_2 and x_3 to these variables, the combination (x_1, x_2, x_3) is allowed if $C_i(x_1, x_2, x_3) = 1$ and forbidden if $C_i(x_1, x_2, x_3) = 0$.

5 Modeling the problem

We can now translate the musical problem of harmonizing a soprano to a purely mathematical problem. Suppose we have a soprano that lasts n times, with every time divided in 4 counts. All the times contain four quarter notes, except for the last time which contains one whole note. This makes a total of $l := (n-1) * 4 + 1$ notes. We call l the length of the problem. For every note, we want to store the notes for the bass, tenor, alto and soprano and we want to store the grade we use. This can be done using a $5 \times l$ matrix X.
The grades and notes are represented by a positive integer, and the central c is represented by the number 24. We assign integers to the other notes as follows: if the note is higher/lower than the central c, we count the number of half tones between the central c and this note and add/subtract it to 24. In this way, we fix the domain and variables of our VCSP. The variables are the entries $x_{i,j}, i = 1, ..., 5, j = 1, ..., l$ of the matrix X and the domain is the set of natural numbers $\mathbb{N}$.

5.1 Hard constraints

We will first translate the hard constraints to mathematical formulas. We only use grades I, II, IV, V and VI, which entails:

$$x_{5,j} \in \{1, 2, 4, 5, 6\}\ \forall j = 1, ..., l.$$

The first and last grade must be I, so

$$x_{5,1} = x_{5,l} = 1.$$

Every voice has a specific range of notes that it can sing, which can be expressed as:

$$\text{alto} : 19 \leq x_{2,j} \leq 38\ \forall j = 1, ..., l$$

$$\text{tenor} : 12 \leq x_{2,j} \leq 28\ \forall j = 1, ..., l$$

$$\text{bass} : 5 \leq x_{2,j} \leq 26\ \forall j = 1, ..., l$$

The grades before and after a bar must be different:

$$\forall j = 1, ..., l :$$

$$\text{if } j \bmod 4 \equiv 1 \text{ and } j \neq 1$$

$$\text{then } x_{5,j} \neq x_{5,j-1}$$

No parallel fifths or octaves are allowed:

$$\forall i, k, j : i, k = 1, 2, 3, 4, j = 1, ...l - 1 :$$

$$\text{if } (x_{i,j} - x_{k,j} \bmod 12 \equiv 0) \text{ and } k \neq i$$

$$\text{then } (x_{i,j+1} - x_{k,j+1} \bmod 12 \not\equiv 0)$$

and

$$\text{if } (x_{i,j} - x_{k,j} \bmod 12 \equiv 7) \text{ and } k \neq i$$

$$\text{then} (x_{i,j+1} - x_{k,j+1} \bmod 12 \not\equiv 7).$$

It is forbidden to write voice overlap (strictly between soprano, alto and tenor, not strictly between tenor and bass):

$$\forall j = 1, ..., l :$$

$$x_{1,j} > x_{2,j} > x_{3,j} \geq x_{4,j},$$

$$\forall j = 1, ..., l - 1 :$$

$$x_{2,j+1} < x_{1,j}$$

$$x_{3,j+1} < x_{2,j}$$

$$x_{4,j+1} \leq x_{3,j}.$$

The possibilities for the notes in the bass, tenor and alto and the forming of the chords (with wide and narrow spacing) are also hard constraints. We will not explicitly state these constraints here as mathematical formulas due to space constraints.

5.2 Valued constraints

We are now ready to introduce some valued constraints. There are five aspects of functional harmony we model using valued constraints. In the following subsections we propose techniques for calculating the cost of certain combinations. The results are five costs in $[0, 1]$ that correspond to the transition of one grade to another (c_1), the frequency of grades (c_2), the range of notes a voice can sing (c_3), the distance between two succeeding notes (c_4) and the use of contrary motion between bass and soprano (c_5). To allow a composer to determine the relative importance of each type of valued constraints, we attach weights $\{w_1, w_2, ..., w_5\}$ and define the total cost as $\sum_{i=1}^{5} w_i c_i$ where all weights sum to one. Assigning these weights depends on personal taste. Some composers might think it is important to have a lot of variation in the use of grades, while others might prefer to write music that is in the right range for the different voices. The weights we propose are as follows: $w_1 = 0.3, w_2 = 0.2, w_3 = 0.1, w_4 = 0.2, w_5 = 0.2$.

5.2.1 Grade transition constraints

As stated before, we only work with grades I, II, IV, V and VI. The most important grades are I, IV and V. V can be seen as a chord that builds up tension, I creates rest and IV is an advancing chord (to V). In music, it is important to have enough tension but there are points of rest needed as well.
II is a grade that can be used as a replacement grade for IV. It is also an advancing grade to V. VI is a grade that can replace I or IV, depending on the context. Generally speaking, when followed by V or preceded by I, VI is a replacement grade for IV, while when preceded by V or followed by IV, VI is a replacement grade for I. (This is also valid if we replace IV by II.) So depending on the context, VI can bring rest in music or can advance to tension. II and VI are used to bring more variation in music. For example, instead of writing I-IV-V-I (a very good sequence) all the time, we can also write I-II-V-VI. To express the aptitude of grade sequences, we introduce a valued constraint G. It is a mapping from the cartesian product of the possible grades to the interval $[0, 1]$ that represents the cost of the sequence:
$G : \{1, 2, 4, 5, 6\} \times \{1, 2, 4, 5, 6\} \rightarrow [0, 1]$.
To determine the cost of a sequence, we only look at two consecutive grades. This is sufficient since every bad sequence is

ISBN: 978-989-95079-6-8

the result of one or more separate bad successions in the sequence.
The assignment of the costs is an intuitive and subjective task. However, we try to bring some structure in it. The model sequence is I-IV-V-I. Therefore, we assign cost zero to every subsequence of length two that appears in it. All sequences that can be obtained from those subsequences by substituting a grade by its replacement grade (we call it *derivative sequences*) also have no cost.
Going from advancing to tension to rest is not very interesting. Therefore, we assign cost 1 to the sequence IV-I and all derivative sequences. Going from rest to tension without advancing should be avoided but is not particularly bad, so we assign cost 0.5 to the sequence I-V. Using the same sequence two times is not always interesting. We assign cost 0.3 to sequences I-I, V-V and derivatives, and cost 0.4 to sequences IV-IV and derivatives. An overview of the assignments is given in Table 1.

5.2.2 Grade frequency constraints

As stated before, in music it is important to maintain sufficient variation. This is not covered by the previous constraints: writing I-IV-V-I the whole time would give zero cost, but it would be boring to listen to. To express this we introduce additional valued constraints.
The algorithm designed in Section 6.1 has three options: it can generate a solution with only grades I, IV and V, only grades I, IV, V and VI, or using all grades I,II, IV, V and VI. The number of times a grade should ideally be used depends on this option, so we introduce three different valued constraints. First consider the option where only grades I, IV and V can be used. The best sequence here is I-IV-V-I. We want some variation so we sometimes write I-I, I-IV-I or I-V-I. Say that ideally, every three times we write I-IV-V, we should write I-I, I-IV-I or I-V-I once. The corresponding grade occurence percentages are given in Table 2.
We now define the valued constraint $H_1 : \{1, 4, 5\}^l \rightarrow [0, 1]$ as follows: for the whole piece of music, count how many times grades I, IV or V are used and calculate the percentages. Now for every grade, add the absolute difference between the ideal and real percentage, and divide the result by three to obtain a value in $[0, 1]$.
Since grade VI is a replacement grade for I, in the option where I, IV, V and VI can be used, we consider the same percentages as in the first option for IV and V, but we split the ideal percentage for grade I. Analogously, as grade II has the same function as grade IV, we split the ideal percentage for grade IV in the third option. The percentages are presented in Table 2. The valued constraints H_2 and H_3 are defined as before.
Again, these ideal percentages are constructed subjectively and intuitively. Different composers would propose different percentages, but they should be similar. Moreover, as for the previous valued constraints, the exact percentages are not very important, more significant are the gradations.

5.2.3 Voice range constraints

The problem we consider is to write a music piece for four voices. Of course, these voices cannot sing all existing notes. Theoretically, a bass can sing notes presented by integers from 5 to 26, yet there exist very good basses that can not reach the very low note presented by 5 or the very high note presented by 26. It is not wrong to write these extreme notes but it should be avoided, because even if the bass can sing these notes, they will not sound as good as the notes in the middle of their register. To express this mathematically, we introduce new valued constraints R_a, R_b and R_t as follows: for every note in the reach of a voice, R_b, R_t and R_a express how bad this note is for bass, tenor or alto respectively. Fig. 2 presents the values of R_a, R_b and R_t. The total cost is given by $(R_a + R_b + R_t)/3 \in [0, 1]$.

5.2.4 Distance constraints

In tonal music, it is important to have fluent melodies. Modeling this requires counterpoint techniques, which we do not consider here. Instead, we model the soundness of the melodies by considering the distances between the notes. Furthermore, it is hard to sing large intervals correctly. Therefore, we introduce a valued constraint D that limits the distance between two notes. We assign cost 1 to all intervals larger than an octave (12 half tones). Intervals smaller than an octave get cost $c_4 = d/12$, proportional to the distance d between the notes. An exception is made for the octave, which gets the same cost as a fifth because it sounds equally well and is equally easy to sing. The costs are presented in Table 3.

5.2.5 Contrary motion constraints

Contrary motion is the general movement of two melodic lines in opposite directions. That is, when one of the lines moves up, the other line moves down. In tonal music, contrary motion is important to maintain independence of melodic movement. To express this as a valued constraint we assign a cost

Table 1: The mapping G that assigns a cost to every allowed succession of two grades

GRADE1-GRADE2	COST=G(GRADE1,GRADE2)
II-V, V-I, I-II, IV-V	0
VI-V, VI-II, I-IV, V-VI	0
VI-IV, V-I, I-VI	0
I-I, V-V, VI-I, VI-VI	0.3
IV-II, IV-IV, II-II	0.4
I-V	0.5
IV-I, II-I, II-VI	1.0

Table 2: valued constraint H compares the count of grades to the ideal percentages.

GRADE	IDEAL PERCENTAGES		
	OPTION 1: I, IV AND V	OPTION 2: I, IV, V AND VI	OPTION 3: I, II, IV, V, VI
I	0.394	0.263	0.263
II	-	-	0.075
IV	0.303	0.303	0.228
V	0.303	0.303	0.303
VI	-	0.131	0.131

Figure 2: Costs that are incrurred when notes at the extreme ends of a voice's scale are used.

$c_5 = 1$ if there is no contrary motion between bass and soprano.

6 Solving the four voices harmonization VCSP

Now we translated the musical problem to a purely mathematical problem, we can design an algorithm that solves it. There exist good solvers for VCSPs [9] but we choose to design and implement a separate algorithm for the harmonization problem. The algorithm follows the thinking of a composer that solves the exercise: from left to right, try out all the possibilities and return when a solution gets stuck.

6.1 A backtracking algorithm

Algorithm 1 shows the outline of the main part of the algorithm. First note that it returns a single minimal-cost solution; if there are several such solutions, our algorithm returns the first one encountered. At each stage, max_cost and total_cost represent the cost of the optimal solution so far, and of the currently investigated solution, respectively. They are initialized in lines 1 and 2.

From Section 2, we know that the grade on the first note must be I. Either narrow or wide spacing can be used for the first chord; the former option is considered in lines 3–5, the second one in line 6–8.

The central part of the algorithm is in the recursive procedure Calculate_Solution. For every note i except the last one, all possible solutions are generated (line 2), that is, all permissible combinations of grades for note i, and corresponding notes for bass, tenor and alto. Assuming no hard constraints are violated (line 3), the cost of a solution w.r.t. the valued constraints is evaluated (line 4); all costs can be calculated directly, except from c_2 which is calculated considering the problem from the beginning until position i. c_2 is only calculated when $i > 4$. If the total cost for the current solution is smaller than the new costs added up to the total cost, one has to try the next possibility, because from here we will never find a solution that is cheaper than the solution we already found (line 5-6). Otherwise, one adds the costs except from c_2 up to the total cost and goes further looking for a solution (lines 8-9). c_2 is not added up to the total cost since this cost is calculated every step and it counts for the whole piece.

When we have reached the final note, we change the current solution and the maximum cost and we return in the recursion to find a cheaper solution (lines 16-17).

This can lead to a solution or to failure. In both cases we return to try the next posibilities. If there are no posibilities left, the algorithm does not go further in this branch of the recursion.

Table 3: valued constraint D is a measure for the soundness of an interval.

INTERVAL (IN HALF TONES)	COST c_4	INTERVAL (IN HALF TONES)	COST c_4
> 12	1.000	6	0.500
12	0.583	5	0.417
11	0.917	4	0.333
10	0.833	3	0.250
9	0.750	2	0.167
8	0.667	1	0.083
7	0.583	0	0.000

Algorithm 1: Algorithm that solves the problem of harmonizing a melody for a soprano, l is the length of the problem.

7 Results

In this section we present some test results. We tested the program for several problems but we will show only one representative example here.

We illustrate the suitability of our approach by showing four

ISBN: 978-989-95079-6-8

Figure 3: A representative harmonization exercise, showing four solutions: (A), (B), (C) show solutions with weights as proposed in Section 5. (A) has cost 3.14, (B) has cost 1.12 and (C) is the optimal solution with cost 0.65. (D) shows the optimal solution with weights $w_1 = 0.3, w_2 = 0.2, w_3 = 0.1, w_4 = 0.3$ and $w_5 = 0.1$. It has cost 0.47.

solutions with different costs. In Fig. 3A we show the solution with the highest cost (3.14). In this solution there are unacceptable distances in the bass. Furthermore, the melodies in the alto and tenor are not fluent, there is almost no contrary motion between soprano and bass and the grade sequence is bad.

Fig. 3B shows a solution with cost 1.12. This solution has a better bass line. The grade sequence is slightly better since we now have tension (grade V) in the second bar. This solution sometimes lacks contrary movement and there is no second grade used.

The optimal solution is shown in Fig. 3C. The grade sequence and grade frequencies are very well but there are many large distances between the bass notes. This can be explained by the weights we assigned to the costs: contrary motion is considered equally important as the distances between the notes. If we raise the weights corresponding to the distances between notes and we lower the weight corresponding to the use of contrary movement we obtain the result in Fig. 3D. Except from the fact that there is no tension in the second bar this is a good solution.

8 Practical Use And Further Work

The algorithm we presented is designed to solve harmonizing problems. It can be used as a didactic tool: teachers can use it to test quickly if problems have solutions, if these solutions are interesting enough and if they are not too difficult to solve. For instance, if a problem has only one solution where only grades I and IV are used, this problem cannot be solved well. Furthermore, students can use this program to compare their solutions to an optimal solution.

The model we presented can be extended in various ways. First of all, we can overcome the simplification of the harmonization problem by allowing modulations, chord inversions, non-chord tones, rhythm and ornaments, seventh chords and so on. This requires an extension of the domains and the introduction of new hard constraints. Furthermore, we can also introduce more soft constraints. For instance, some counterpoint rules can be expressed as soft constraints.

As illustrated in the previous section, the assignment of the weights is important. Fine-tuning of these parameters is needed and should be done more profoundly.

Abstract— *In this paper, we present new approaches to handle* drift *and* shift *in on-line data streams using evolving fuzzy systems (EFS), which are characterized by the fact that their structure is not fixed and not pre-determined. When dealing with* drifts *and* shifts *in data streams one needs to take into account two major issues: a) automatic detection of, and b) automatic reaction to this. To address the first problem we propose an approach based on the concepts of* age *and* utility *of fuzzy rules/clusters. The second problem itself is composed of two sub-problems concerning the influence of the* drifts *and* shifts *on: 1) the antecedent parts (fuzzy set and rule structure) and 2) the consequent parts (parameters) of the fuzzy models. To address the latter sub-problem we propose an approach that introduces a gradual forgetting strategy in the local learning process. To address the former sub-problem we introduce two alternative methods: one that is based on the evolving density-based clustering, eClustering (used in* eTS*); and one that is based on the automatic adaptation of the learning rate of the evolving vector quantization approach (eVQ) (used in* FLEXFIS*). The paper is concluded with an empirical evaluation of the impact of the proposed approaches in (on-line) real-world data sets where* drifts *and* shifts *occur.*

Keywords— drifts and shifts in data streams, evolving fuzzy systems, detection and reaction to drifts and shifts, age of a cluster/fuzzy rule, gradual forgetting

1 Introduction

1.1 Motivation and State of the Art

Nowadays data-driven fuzzy systems enjoy a great attraction in many industrial applications, as opposed to expert-based fuzzy systems. They can be automatically generated from process data such as measurements, images (features) or signal streams. Furthermore, they are proven universal approximators [27], i.e. being able to model a given problem to (theoretically) any degree of accuracy. Moreover, they also allow an insight in the form of linguistically and visually interpretable rules to be gained [8].

During the last decade, the research field of 'evolving fuzzy systems' (EFS) emerged as an important part of the fuzzy systems research [4] [11], as they are capable to include new information on demand into the models and on-the-fly without necessarily using prior knowledge. EFS can also permanently learn from their environment and are applicable in fast on-line identification [4] and modelling processes as well as huge data bases which cannot be loaded into the virtual memory at once [18]. Often, there are no enough data in advance (off-line) to build reliable models with high predictive quality which can also require application of EFS as in [23].

Various approaches for EFS have been set up during the last years, one of the most popular and pioneering approach is the *eTS* family which comes with a regression [4], [3] and a classification variant [5]. Another approach for adaptation and evolution of clusters inspired by the evolving vector quantization (eVQ) [19] is the so-called *FLEXFIS* family [21], in particular *FLEXFIS* for regression [20] and for classification [22] (denoted as *FLEXFIS-Class*). A range of other alternative approaches includes ePL [16], SAFIS [12], and evolving fuzzy neural networks such as SOFNN [15] or GDFNN [28].

All these methods have a common denominator: they all are life-long learning approaches, which means that they incorporate all the data samples into the fuzzy models with equal weights in the same order as they are coming in during the on-line process. Hence, fuzzy models reflect a compact information of all the samples seen so far with equal importance. This is a beneficial to adapt the models, especially when a convergence to an optimality criterion or stable state of the model structure is achievable [20]. However, this benefit is only true in case of data streams which are generated from the same underlying data distribution respectively which do not show any *drift* or *shift* to other parts of the input/output space [26]. *Drift* (respectively *shift*) indicate the necessity of out-dating of previously learned relationships (in terms of structure and parameters) as these are not valid any longer and hence should be eliminated from the model. In order to cope with this problem, *drift* handling was already applied in other machine learning techniques, e.g. in connection with SVMs [14], ensemble classifiers [24] or instance-based (lazy) learning approaches [7] but to the best of our knowledge this concept was not yet applied to fuzzy systems.

1.2 Our Approach

Hence, in this paper we are dealing with approaches for an appropriate handling of *drifts* and *shifts* by EFS. However, parts of the concepts, especially the detection of, and reaction to *drifts* in the consequent parts of the rules, can be applied to a wider range of EFS approaches including *eTS* and *FLEXFIS*. A more detailed description will be given in Section 2. For achieving an automatic approach, we propose 1.) the detection of a *drift* respectively *shift* based on the concepts of fuzzy rule *age* and *utility* function, and 2.) the reaction to a detected *drift* respectively *shift*, both in rule antecedent (for *eClustering* as applied in *eTS* and *eVQ* as applied in *FLEXFIS*) as well as consequent parts of Takagi-Sugeno fuzzy models [25].

The paper is concluded with an empirical evaluation of the impact of the proposed approaches on predictive accuracy of the evolving fuzzy models when applying to real-world data streams where *drifts* and *shifts* occur (Section 5). Note, that no benchmark data from the Internet or well-known data bases can be applied for empirical evaluation as these are usually all smooth in the sense that no *drift* occurs therein.

2 Problem Statement

In machine learning literature, they distinguish between different types of 'concept change' of the underlying distribution of (on-line) data streams: a) *drifts*, and b) *shifts*, see [26]. *Drift* refers to a *gradual* evolution of the concept over time. The concept *drift* concerns the way the data distribution slides smoothly through the data/feature space from one region to another. For instance, one may consider a data cluster moving from one position to another. This concept is closely related to the time-space representation of the data streams. While the concept of (data) density is represented in the data space domain, *drift* and *shift* are concepts in the joint data-time space domain.

An (artificial) example of a *drift* is demonstrated in Figure 1. There, the original data distribution (in a 2-D data space) is marked by circular samples, which changes over time into a data distribution marked by rectangular samples. If a conventional clustering process is applied by weighting all new incoming samples equally, the cluster center would end up exactly in the middle of the whole data bunch, averaging old and new data. Such a clustering approach is applied in EFS approaches to identify the local regions that can be used to form (the antecedent parts of the) fuzzy rules.

On the other hand, the concept *shift* refers to a sudden, abrupt change of the underlying concept to be learned. A *shift* in the input space opens up a data cloud in an unexplored region and hence usually automatically causes a new rule to be evolved by the incremental/evolving clustering algorithm. In Figure 2 a case of a *shift* in the output variable is shown: the original trajectory (consisting of dense data samples) on the right-hand side is marked with a light line, whereas the *shift* is represented by the dark data samples forming a trajectory above the other one. In case if only apply the usual adaptation

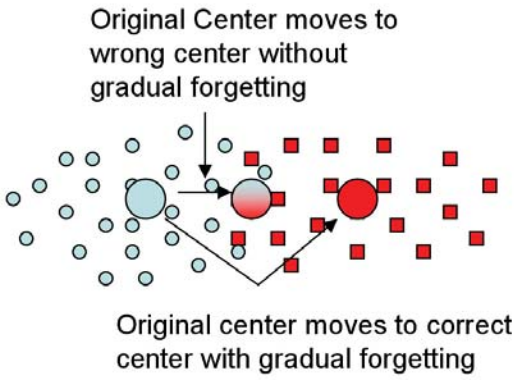

Figure 1: A *drift* in an evolving cluster (used for learning the antecedent parts of EFS), the distribution before the drift shown in circular, after the drift shown in rectangular samples.

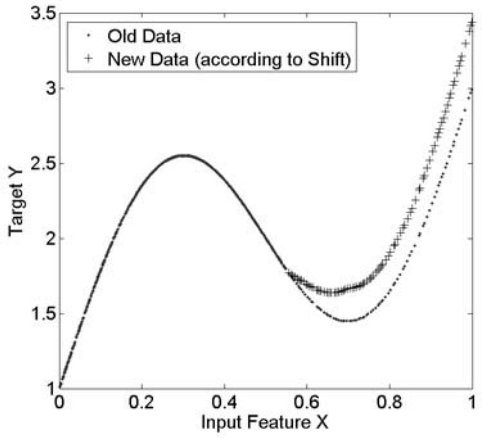

Figure 2: Example of a *shift* in the output variable; compare light dots (original data distribution) with dark dots (data distribution after the *shift*) on the right-hand side of the image (also marked by arrows)

of the consequent parameters with weighted recursive least squares without forgetting the old data due to the *shift* the approximation curve of the fuzzy model will end up exactly in-between these two.

In this paper, we demonstrate novel approaches for autonomous *drift* and *shift* detection and handling when learning fuzzy rule-based systems of Takagi-Sugeno type from on-line data streams in an evolving manner [4]. We focus on EFS approaches exploiting the Takagi-Sugeno model architecture [25].

3 Autonomous Detection of Drifts and Shifts in Data Streams by EFS

In this section the method for autonomous detection of *shifts* and *drifts* in data streams based on the *age* and *utility* of the cluster/fuzzy rule [1], [10] is described. This is an important step in the process of handling non-stationarity in data streams and for building au-

ISBN: 978-989-95079-6-8

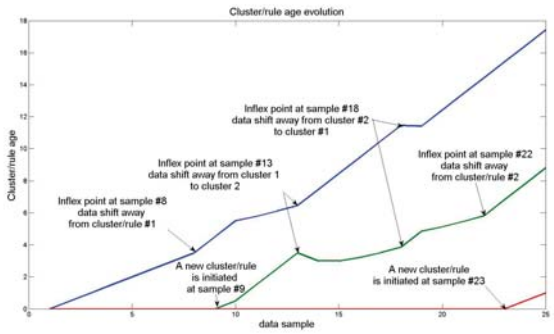

Figure 3: Evolution of the *age* of the clusters/fuzzy rules; *drifts* are related to the inflexion points; *shifts* are related to forming new clusters/fuzzy rules.

tonomous self-developing, self-learning, and evolving models and systems.

3.1 Detecting Drifts by Age of Clusters (Rules) [1]

In [1], the concept of cluster (respectively fuzzy rule) *age* was introduced. We extend this by including the membership degrees of the rules ($\Phi_{i,l}$ in case of the ith rule for the lth sample)

$$age^i = k - \frac{\sum_{l=1}^{n_i} I_l \Phi_{i,l}}{n_i} \quad (1)$$

where i is the rule index; n_i denotes the support of rule i; I_j denotes the time instance when the data sample was read; k is the current time instance. Since $\frac{\sum_{l=1}^{n_i} I_l}{n_i}$ can also be accumulated recursively, the *age* can be easily calculated when necessary. *Age* of the cluster/rule changes with each new data sample being read. If the newly read data sample does not fall into that cluster (supports that fuzzy rule with a low or even 0 value of $\Phi_{i,l}$ in case of fuzzy sets with finite support) the *age* grows by the rate of one sample at a time. That means, if a certain cluster (fuzzy rule) is not supported by any future samples after being initiated (say in the time instant, t_i) then its *age* at any time instant, k will be $k - t_i$. However, if any new data sample (between t_i and k) falls into that cluster (supports that fuzzy rule with a high value of $\Phi_{i,l}$), the *age* does not grow with the same rate, but with a smaller one and one can say that the cluster (fuzzy rule) is being *refreshed*.

The fuzzy rule *age* is important and closely linked to the data streams (which are sequences of data in time) and to the concept *drift*. We propose to analyze the *age* of clusters (respectively, fuzzy rules) on-line by using the gradient of the *ageing* curve as well as its second derivative which indicate a change in the slope of the *ageing* curve. When there is a **significant** change of the *ageing* which results in a significant change of the slope, then obviously the second derivative of the *age* curve will be indicative of this inflection points. An example is demonstrated in Figure 3, where the *drift* and *shift* are clearly marked on the *age* evolution curves.

3.2 Detecting Shifts by Utility Function

Shift in the data streams is a more significant, abrupt and sudden change of the data concept. Therefore, the distinction between *drift* and *shift* is the pace, the degree and speed of the changes, while both indicate a change in the data distributions with time. Essentially, the reaction to a detected *shift* has to be reflected in the structure evolution of the fuzzy rule base. While *drift* is related more to a smooth forgetting of parameters, learning and forgetting, *shift* is closely related to changes in the structural components.

Shift can be detected by the *utility* of the fuzzy rule. *Utility* is a parameter of the quality of the fuzzy rule that is defined [2] as the accumulated firing level of each rule given by Ψ_i summed over the life of each rule:

$$U_k^i = \frac{1}{k - I_k^i} \sum_{l=1}^{I_k^i} \Psi^l \quad (2)$$

$Utility$, U accumulates the weight of the rule contributions to the overall output during the life of the rule (from the current time instant back to the moment when this rule was generated). It is a measure of importance of the respective fuzzy rule comparing to the other rules (comparison is hidden in the relative nature of Ψ).

If the *utility* of a fuzzy rule is *low* then this rule becomes obsolete or not used very much. A *shift* away from or to a cluster/fuzzy rule can be detected by the derivative of the *utility* — if the value of the first derivative of the *utility* is *large* then there is a *shift* towards the cluster. The *shift* is away from a cluster if the derivative of the *utility* is *large* negative. Then this fuzzy rule is deemed obsolete (does not contribute significantly to the overall prediction/estimation/classification) and can be removed from the rule base [10].

4 Reactions to Drifts and Shifts in Data Streams by EFS

4.1 Reaction to Drift and Shift in the Antecedents

In this section, we introduce methods for addressing both *drifts* and *shifts* in data streams by adapting learning mechanisms for consequent parts and by evolving antecedent part. We demonstrate this on the example of the popular *eTS* method [4] and on *FLEXFIS* [20].

4.1.1 *By* eClustering

Reaction to a detected *shift* is by either a) forming a new rule around a new data sample which becomes an attraction point for the global data distribution, or b) replacement of a fuzzy rule which itself consists of; i) forming a new rule around the new point, and ii) removal of the rule which has lower density and is close to this newly added one [2] — see Figure 4. If locally optimal learning is being applied then removing a cluster and respectively a locally valid Kalman filter/RLS does not affect the overall learning significantly (only through the fuzzy weight Ψ [4]). If globally optimal learning is being applied, removal of a cluster (respectively fuzzy rules) does affect n columns and n rows of the covariance matrix directly and the remaining values of the covariance

ISBN: 978-989-95079-6-8

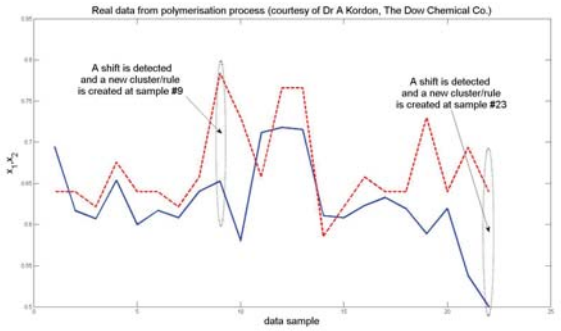

Figure 4: Shift in the time domain representation and two new rules evolved as a reaction to it.

matrix indirectly [4]. Deleting *old* fuzzy rules was applied in classification in [5] and in prediction [2].

4.1.2 *By* eVQ

When *shifts* in the data stream occur, usually new clusters are evolved automatically in *eVQ*, as they cause new data clouds in previously unexplored regions of the data space (in regions further away than a fraction of the space diagonal in the input space to which the vigilance parameter ρ is usually set, i.e. 0.1 to 0.3 of the space diagonal, see [19]. Synchronously, older clusters can be deleted by the concept of *utility* [9] [10] as discussed in Section 3.2. This does not affect the learning of consequent parameters for the other rules if local learning is applied.

For reacting to *drifts* in the antecedent parts of the rules we propose to re-adjust the parameter in the eVQ clustering algorithm η [19] which steers the learning gain. We define the tracking concepts for the ith rule throughout this section, which can be generalized to any rule in a straightforward manner. Currently, in *eVQ* the learning gain is defined by the following formula [18]:

$$\eta_i = \frac{0.5}{n_i} \tag{3}$$

If a *drift* occurs in a data stream, the centers and widths of the cluster(s) should change to the new data distribution (as shown in Figure 1). For re-activating the converged clusters, i.e. re-animating them for stronger movements in a drifting case, we suggest a sudden increase for the first sample in the *drift* phase, followed by a gradual decrease for the next samples in order to balance in the new sample distribution in the same manner as is done for original ones.

Here, we propose the following mechanisms for the learning gain η: first we transform the forgetting factor λ, used in the gradual out-weighting when doing consequent learning (see next section) and denoting the intensity of a *drift*, to a value in $[0, 1]$. Hereby, 0.9 (minimal value for λ) is mapped to 0.99, whereas 1 is mapped to 0, hence:

$$\lambda\_trans = -9.9\lambda + 9.9 \tag{4}$$

Then, when a *drift* occurs, we re-set the number of samples forming the ith cluster (n_i) (used in the denominator of the calculation of η_i) by

$$n_i = n_i - n_i * \lambda\_trans \tag{5}$$

This means that the stronger the drift is, the more n_i is decreased and hence the stronger the forgetting effect will be. In Figure 5 it is demonstrated how η_i develops (lines) in usual (non-drift) case (for the first 100 samples), then a drifting scenario is artificially caused with three intensities leading to the three λ values (in different line styles). After the *drift* indicator (at sample 100), it is decreased in usual way such that the jumped center can converge to the new data distribution.

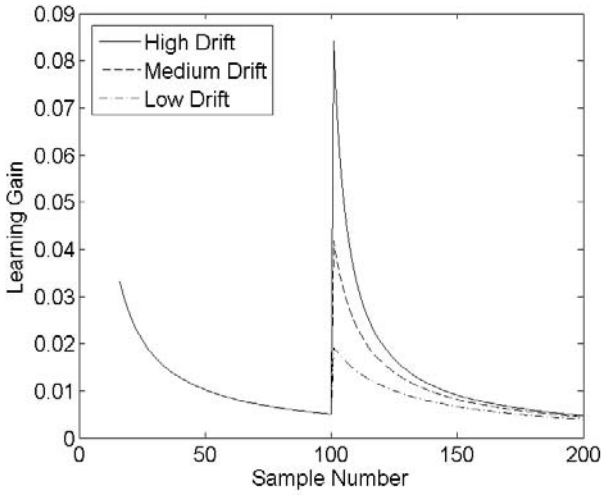

Figure 5: Abrupt increasing learning gain η during in case of a *drift* (after 100 samples) when applying different values for the forgetting factor λ.

4.2 *Reaction to Drifts and Shifts in the Consequents*

For the rule consequents *drifts* and *shifts* can be handled in one sweep as it is just a matter of the setting of the forgetting factor as we will see below. Whenever a *drift* in the output variable occurs (as shown in Figure 2) and is detected, it is necessary to apply a specific mechanism in the sample-wise incremental learning steps of the consequent parameters in Takagi-Sugeno fuzzy systems. When locally optimal fuzzily weighted Recursive Least Squares (wRLS) learning approach [4] is used this can easily be accommodated as detailed later on.

If we do not take *drift* into account all newer samples lying in the same local positions relative to the rules as the older samples are included with the same rule weights in the update process. Then the fuzzy model will end up with approximation curve as shown in the left image of Figure 6 with dotted lines. Obviously, the approximation ends up in the middle of the two trajectories (the newer after the *drift* shown in light font, the older shown in darker font), as trying to minimize the quadratic errors (least squares) of all samples to the curve. Hence, it is necessary to include a parameter in the update process, which forces older samples to be out-dated over time. Gradualism is important here in

ISBN: 978-989-95079-6-8

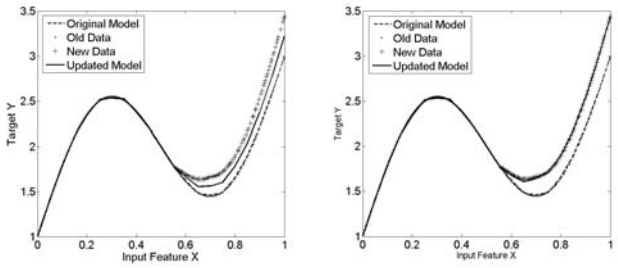

Figure 6: Left: The adapted model (dotted line) with the new incoming samples (dark dots) when applying conventional recursive weighted least squares approach; right: the adapted model (dotted line) by including a forgetting factor of 0.95 and using (7)-(9), the approximation surface lying exactly on the trajectory of the data samples denoting the novel data distribution

order to guarantee a smooth forgetting and to prevent abrupt changes in the approximation surface. For doing so, we re-define the least squares optimization function for the ith rule by

$$J_i = \sum_{k=1}^{N} \lambda^{N-k} \Psi_i(\vec{x}(k)) e_i^2(k) \longrightarrow \min_w \quad (6)$$

with $e_i(k) = y(k) - \hat{y}(k)$ the error of the ith rule in sample k. Assuming N the number of samples loaded so far, this function out-dates the sample processed i steps ago by λ^{N-k}. Usual values of λ lie between 0.9 and 1, where a value near 1 means a slow forgetting and a value near 0.9 a fast forgetting of former loaded data samples and the exact choice depends strongly on the strength of the *drift* (see below). Following a similar recursive deduction scheme as in conventional recursive least squares (RLS) [17], we obtain the following incremental update formulas for consequent parameters $\vec{w}_i$ for the ith rule:

$$\hat{\vec{w}}_i(k+1) = \hat{\vec{w}}_i(k) + \gamma(k)(y(k+1) - \vec{r}^T(k+1)\hat{\vec{w}}_i(k)) \quad (7)$$

$$\gamma(k) = \frac{P_i(k)\vec{r}(k+1)}{\frac{\lambda}{\Psi_i(\vec{x}(k+1))} + \vec{r}^T(k+1)P_i(k)\vec{r}(k+1)} \quad (8)$$

$$P_i(k+1) = (I - \gamma(k)\vec{r}^T(k+1))P_i(k)\frac{1}{\lambda} \quad (9)$$

with $P_i(k) = (R_i(k)^T Q_i(k) R_i(k))^{-1}$ the covariance matrix and $\vec{r}(k+1) = [1 \;\; x_1(k+1) \;\; x_2(k+1) \;\; \ldots \;\; x_p(k+1)]^T$ the regressor values of the $k+1$th data sample, Ψ_i the fulfillment degree of the ith rule, serving as weight in the recursive least squares algorithm.

The final question is how to set the parameter λ in order to guarantee an appropriate *drift* tracking. We propose a strategy to deduce it directly from the *age* curves analysis [10] since they are indicative of the speed of a *drift* (see Section 3). In Section 3, it was mentioned that the age of a rule always lies in $[0, k]$. Hence, we normalize the *age* of the ith rule to $[0, 1]$ by $age_i\_norm = \frac{age_i}{k}$ in order to achieve gradients of the normalized rule ages Δage_i_norm also lying in $[0, 1]$. Whenever the change of the gradient in the rule *age* curve is significant, recursive weighted RLS with forgetting (wRLSf) should be triggered. We use the following estimation for λ:

$$\lambda = 1 - 0.1\Delta^2 age_i\_norm \quad (10)$$

This guarantees a λ between 0.9 (strong forgetting) and 1 (no forgetting), according to the degree of the gradient change (1 = maximal change, 0 = no change). The forgetting factor is then kept for a while at this level (otherwise only one single sample would cause a gradual forgetting) and set back to 1, after a stable gradient phase is achieved (usually after around 20 to 30 samples showing a moderate value of $\Delta^2 age_i\_norm$). Setting back to 1 is necessary, as otherwise the forgetting will go on inside the new data distribution. This cause the drift phase in the antecedents to stop.

5 Evaluation

This section deals with the evaluation of the impact of reacting on *drifts* and *shifts* in case of data streams where actually *drifts* and *shifts* occur. This is done by implementing the approaches discussed throughout this paper. One application example is coming from a rolling mill, where the task was to identify a prediction model on-line for the resistance value of a steel plate at a rolling mill. The other application concerns a polymerization process in chemical industry.

5.1 On-Line Prediction Models at Rolling Mills

The task was to identify a prediction model for the resistance value of a steel plate at a rolling mill. This should be done in a first step with some off-line (precollected) measurement data in order to obtain a feeling about the achieved quality of the fuzzy model and then to refine the prediction model with newly recorded online data. The later step was possible as first a prediction for the resistance is given, influencing the whole process at the rolling mill, whereas a few seconds later (after the steel plate is passed), the real value for the resistance is measured, which can then be incorporated into the model adaptation process. In this sense, the correct measured value not the predicted (which might have been wrong)one is taken for learning. In fact, an improvement in terms of predictive power could be achieved when updating the fuzzy models trained in batch mode with 6000 samples during on-line operation mode with further 6600 samples. For details of the experimental setup and results see [20] (and also Table 1 below summarizing all the results).

Now, in this paper we want to examine whether a reaction onto drifts by a gradual forgetting of older samples during the on-line process may further improve the quality of the models. A justification of an application of reaction onto *drifts* is that the operation process at rolling mills is divided into different "stitches". One stitch represents one closed cycle in the rolling process. In the on-line mode the measurements come in continuously from stitch to stitch. However, for the current processed stitch, the previous stitch should play only little or even no role. However, the measurements from the

ISBN: 978-989-95079-6-8

Table 1: Comparison of prediction with and without applying gradual forgetting

Method	**MAE**	**Max MAE Too High / Max MAE Too Low / # MAEs > 20**
Analytical	7.84	63.47 / 87.37 / 259
Static fuzzy models	6.76	45.05 / 81.65 / 176
FLEXFIS	5.41	38.05 / 78.88 / 159
FLEXFIS with forg.	4.65	31.99 / 74 / 68

previous stitch are already included in the fuzzy models as updated by their samples. Thus, this means that older samples from the previous stitch should be forgotten when including samples from the current stitch. Another aspect is that here we do not need any drift/shift detection, as the drift/shift is indicated by the beginning of a new stitch. As no *drift* detection was carried out, λ was set to 0.97, which is a good compromise between fast forgetting (=strong locality of models) and low forgetting (=weak locality of models). The results are demonstrated in Table 1. Here, we also demonstrate the improvement of the predictive accuracy over analytical models by both, static and evolving fuzzy models. Three different types of errors are reported: the mean absolute error over all on-line samples (note that first a prediction is done and then the model updated with the same samples and based on feedback), the number of mean absolute error greater than 20, the maximal mean absolute error over all samples where the prediction was too low and the maximal mean absolute error over all samples where the prediction was too high. The latter value is the most important one as harming the steel plate is more dangerous as in case of predicting too low values. The results (Table 1) demonstrate the impact of the gradual forgetting.

Another interesting aspect is that the error on the single measurements starts to *drift* over time when gradual forgetting is not applied. This is underlined in the left image of Figure 7 which shows the single errors over the 6600 on-line samples: note the *drift* of the main error area away from the zero line at the end of the data stream.

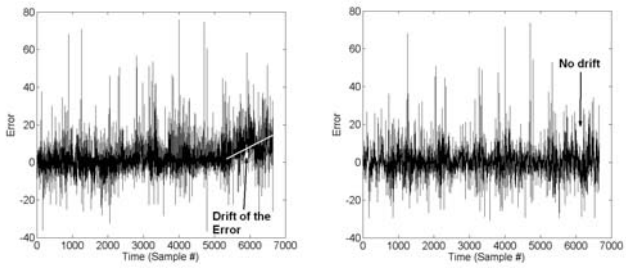

Figure 7: Left: The error curve for the 6600 on-line samples when no forgetting is applied: at the end the error starts drifting; right: no *drift*.

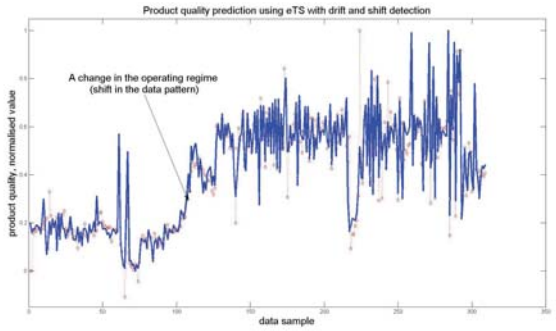

Figure 8: A comparison of the predicted and real data of product quality. Solid line - predictions by *eTS* with *shift* and *drift* detection; diamonds - real data.

5.2 *Another application example*

A case study based on real data (courtesy of Dr. Arthur Kordon, The Dow Chemical Co.) from the chemical industry is used as an illustration of the detection and reaction to *drift* and *shift* in *eTS* [6]. The *eTS* has been applied for prediction of the properties of a chemical composition by modelling the product composition in a distillation tower. The data set includes a change of the operating regime of the process which brings a challenge to the structure of the model (fuzzy rule based system). The data set includes also a number of other challenges, such as noise in the data, a large number of initial variables, etc. These problems cover a wide range of real issues in the industry. The process data is retrieved from physical ('hard') sensors used as inputs to the *eTS* applying hourly averages for every eight hours. The product composition (real output) is estimated by a laboratory analysis for comparison (it is given with diamonds in the Figure 8).

The estimation of the product composition contains noise due to the nature of the analysis. A significant operating condition change takes place after sample 127 (please see the Figure 8). The *eTS* was able to efficiently detect and react to this *shift* as well as to the *drifts* as depicted in Figures 3 and 4. The overall prediction is very good and compares favorably with the conventional models as detailed in the Table 2. Note, that the non-dimensional error index (NDEI) is defined as the ratio of the root mean square error over the standard deviation of the target data and should be ideally 0 while the variance accounted for (VAF) is defined as the ratio between the variance of the real data and the model output and is given out of a maximum of 100 (when the predictions coincide with the real data).

6 Conclusion

In this paper, we propose novel strategies and techniques for addressing concept *drift* and *shift* in on-line data streams. Therefore, two EFS approaches (*eTS* and *FLEXFIS*) are exploited as on-line modelling methodologies. These are extended by mechanisms which are 1.) able to detect *drifts* and *shifts* with fuzzy rule *age* and *util-*

ity, and 2.) to react on such occurrences appropriately. The latter is applied 1.) to the rule antecedent parts directly in the cluster space for reacting on *drifts* and *shifts* in the input space and 2.) to rule consequent parameters for reacting on *drifts* and *shifts* in the output variable, applicable to any EFS technique exploiting Takagi-Sugeno type fuzzy systems. Evaluation on real-world data sets shows that the novel techniques are able to improve the accuracy and stability of the fuzzy models, whenever the occurrence of *drifts* and *shifts* is present.

***Abstract*— *This paper studies a possibility to learn a complex user preference model, based on CP-nets, from user ratings. This work is motivated by the need of user modelling in decision making support, for example in e-commerce. We extend our user model based on fuzzy logic to capture variation of preference objectives. The proposed method 2CP-regression is described and tested. 2CP-regression uses CP-nets idea behind and can be considered as learning of a simple CP-net from user ratings.*

***Keywords*—** user preferences, data mining, ceteris paribus

1 Introduction

The problem studied in this paper is based on the idea of helping user in making decisions. The main motivation lies in e-commerce, where user might benefit a recommendation of objects that might interest her without needing to process all objects manually. This recommendation should be rather automatic and transparent, because user typically does not want to fill in any complicated forms or invest much time in search.

When a user is buying a notebook, for example, she is considering the attributes such as price, manufacturer, size of RAM, harddisk, display. In traditional e-shop environment, it is possible to make some restrictions on these attributes and lower the number of notebooks the user has to process manually this way. But these restrictions are inflexible - when the user selects price from 1000$ to 2000$, a notebook with price 999$ would not appear in the result set. This is the reason for a flexible search, based on fuzzy user preferences.

In this paper we propose a method for handling more complicated user preferences. In [1] a phenomenon called ceteris paribus was described. Preference ceteris paribus means preference "all else being equal". When a user is comparing two notebooks, we can say that the size of RAM of 2GB is preferred to 1GB ceteris paribus, meaning that we assume that the remaining attributes of these notebooks are the same and their values are not important. A user model based on this idea was later proposed in [2] - a CP-network is a graph that captures preferences ceteris paribus or, in different view, it represents attributes, on which the preferences over the attribute RAM depend. And yet, as far as we know, there are no study of learning of CP-nets from user ratings. Our paper is a first subtle contribution to this field. We work with our user model based on fuzzy sets rather than CP-nets, still the proposal of learning the relations between attributes is strongly related to CP-nets.

In Section 2 our user model is described. Related work is studied in Section 3. In Section 4 is described in depth the proposed method for learning the relation between attributes. Then this approach is tested in Section 5 and we end with conclusion and future work in Section 6.

2 Two step user model

2.1 Notation

We will work with a set of objects X. Overall rating of an object is a fuzzy subset of X, i.e. a function $r(o) : X \to [0,1]$, where 0 means least preferred and 1 means most preferred. Every object has attributes $A_1, ..., A_N$ with domains $D_{A_1}, ..., D_{A_N}$, with one special attribute that serves as identification of object (ID). Let $X \subseteq \prod_{i=1}^{N} D_{A_i}$. We will use $X(a)$ when denoting a set of objects that have the attribute value a.

User model, in our view, is a method for representing user decision when considering user's preference of an object $o \in X$. Our user model consists of two steps. At the first step, attributes of o are normalised using fuzzy sets $f_i : D_{A_i} \to [0,1]$ (and here again, 0 is least preferred and 1 is most preferred value), so that the transformed object is in $[0,1]^N$. These fuzzy sets are also called objectives or preferences over attributes. At the second step, preference over attributes are aggregated into the rating of the whole object via a fuzzy aggregation function $@ : [0,1]^N \to [0,1]$. Aggregation function is also often called utility function.

We concentrate on learning of user models. User is expected to rate a small sample $S \subseteq X$ of objects ($r : S \to \{1,2,3,4,5\}$), where $|S| \ll |X|$. The size of training set is expected to be very small. We assume that these ratings were created by the user using some fuzzy sets $f_1, ..., f_N$ and an aggregation function $@$. Of course the user does not compute the result of a function, but her decision corresponds to this two step process.

Our model consist of $f_1, ..., f_N$ and of $@$ so we expect to construct these functions from user ratings of S. The learnt functions will be denoted as $\widehat{f_1}, ..., \widehat{f_N}$ and $\widehat{@}$. Learning of aggregation function is described in Section 2.2. This paper concentrates on learning of local preferences, which is described in Section 4.

2.2 Aggregation function learning

Aggregation function serves to combine preferences over attributes into a single rating that represents the preference of the object as a whole. There are many ways to aggregate local preferences, we are currently using a weighted average with

ISBN: 978-989-95079-6-8

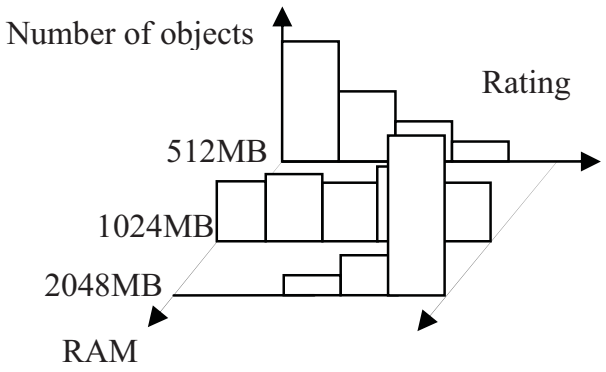

Figure 1: Uniform and expressive distributions of ratings.

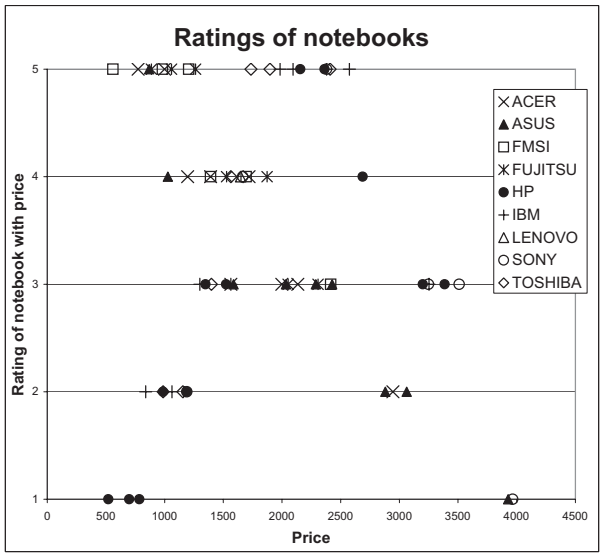

Figure 2: Distribution of ratings of notebooks with regard to price.

weights learnt from user ratings. Method called "Statistical" was described in [3], [4]. The distribution of ratings for attribute values $a_i \in A_i$ are considered when determining the weight of attribute A_i. In Figure 1 is an example of distribution of ratings across a domain of attribute RAM for a user that prefers larger sizes of RAM. If ratings are distributed near one point as in Figure 1 for 2048GB RAM, the attribute value is considered as decisive when doing the overall rating. However, if the distribution is rather uniform such as in Figure 1 for 1024MB RAM, then attribute value a_i does not play an important role in the overall rating. The measure of importance of an attribute value is computed with formula

$$imp(a_i) = 1/\sum_{o \in X(a_i)} |r(o) - avg_{o \in X(a_i)} r(o)|/|X(a_i)|$$

when taking only those objects o that have attribute value a_i. Then the importance of attribute A_i is computed as $W(A_i) = 1/(\sum_{a_i \in A_i} imp(a_i/|A_i|)$.

Our approach is not the only one - any data mining technique can be used here. Reader can simply imagine training a multilayer perceptron with normalised attribute values.

In Figure 2 is attribute price with ratings of notebooks. When a standard linear regression (described in Section 4.1) is used, attribute price would get a small weight. However, when notebooks of only a single manufacturer are used, then the error would be much lower and importance of price would be considerably higher. This may be visible for human, after a short inspection of the graph. Another visualisation of this situation is in Figure 3 with discretised attribute price. Ratings of all attribute values are distributed uniformly, so the importance of this attribute will be considered small.

3 Related work

User preferences are a wide field so there are plenty of research areas. For our case, user preference learning is the most important one. There are two totally different approaches to recommendation : content based and collaborative. For collaborative filtering, we may cite for example [5] but there are many other interesting works. Collaborative filtering is based on the idea that similar users tend to have similar preferences of an object. However, we do not consider this approach in this paper.

We concentrate here on content based, that means that the preferences are based on attributes of objects. For example, user considers the size of harddisk and other features when buying a notebook. This approach in our view corresponds more to how users decide in the real world. The difficulty here is that users are often inconsistent or take into account attributes that are not known or impossible to quantify, such as the design of notebook.

In this area, the main focus was on search of documents in the past [6, 7]. This is a specific area, because features of documents are of little structure. We are interested more in recommendation of more complicated objects like notebooks, with different types of attributes. Following works :[8, 9, 10, 11] deal with general, more structured, objects.

One of our main inspirations was CP-nets [2]. This user preference model captures complex user preferences in a graph representation, where a preference over one attribute may depend on the values of other attributes. There are many papers dealing with CP-nets, but there is none which describes a way to construct a CP-net automatically, by learning from ratings. Because preferences over attribute A_1 may depend on other attribute/s, e.g. A_2, user has to specify her preferences not only for all values of A_1 but she has to do it for every possible value of A_2. This means very much work and insight for the user, work that probably few people will undergo.

There is also another concept for representing user preferences other than ratings as in our case. These are preference relations, or specially fuzzy preference relations [12]. We do not consider this model, we rather follow approach identified by R.Fagin in [13] and consider user ratings as fuzzy sets.

4 Local preferences learning

As mentioned in Section 2, our user model is divided into two steps.

The first step is used for normalisation of every attribute to interval $[0, 1]$, so that the best object would have coordinates $[1, ..., 1]$. This can be viewed also as monotonisation of data - if for object o_1, the normalised value of its attribute value is lower in all attributes than object o_2, then o_2 is surely preferred to o_1 (if the normalisation is determined correctly).

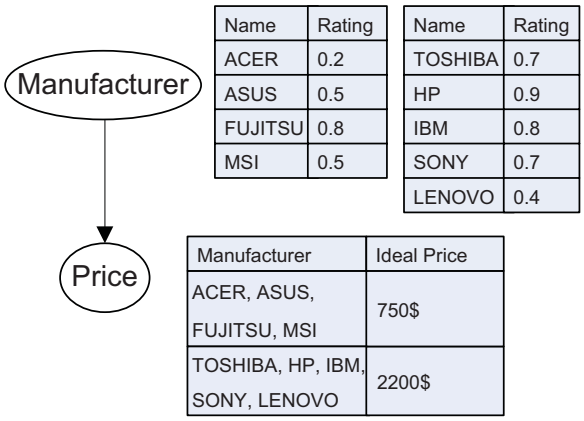

Figure 4: Example of a CP-net representing data about notebooks.

4.1 Linear regression

Linear regression is very useful method that serves to find a relation in a set of data in form of a linear function. It can be used for finding the preference of attribute values for numerical attributes, e.g. price. When given a set of notebooks' prices and ratings, linear regression will create a linear function $r(price) = \alpha * price + \beta$. Then we can normalise values of price using this function.

Traditional linear regression works on method of minimizing least squares of errors. This is not always useful, because it is dependent on the distribution of data points. For this reason, we proposed a method in [14] to accommodate better to the whole interval we study.

As a future work, we would like to implement a method for finding also more complicated functions, e.g. triangular fuzzy functions. The motivation is clear - linear functions are good for preferences of extreme values, e.g. lowest price, largest LCD etc. But if user prefers some value in the middle, like LCD of size 15", linear function would not capture this preference correctly.

4.2 2CP-regression

The main contribution of this paper is the proposal of a new method for acquisition of local preferences for numerical attributes, 2CP-regression. This method is motivated by preferences ceteris paribus [2] and CP-nets. Basic idea that represents ceteris paribus is that there are relations between attributes. For example, the manufacturer of a notebook influences the preferences of the price of that notebook. In our example, we present a user that prefers the price of 2200$ for manufacturers HP, IBM, Lenovo, Toshiba and Sony, and the price of 750$ for manufacturers Fujitsu-Siemens, Acer, Asus and MSI. A simple CP-net representing this scenario is in Figure 4, with ratings of manufacturers and ideal prices. Ideal price depends on the value of manufacturer, not on its preference. There are other examples and often the decisive attribute is a nominal one with rather small domain.

When constructing a fuzzy set for a numerical attribute A_1 (price in our case), we look at the values of other nominal attributes. For simplicity, let us consider only one, A_2. A_2 will be referred to as a "dividing attribute". The construction of the set is restricted to objects with value $a_2 \in A_2$; let us note this set $X(a_2) \subset X$. If dividing attribute A_2 really influences attribute A_1, then the values of A_1 should be "better" distributed in $X(a_2)$ than in whole X and the fuzzy set should better match the real preferences. The fuzzy set trained on $X(a_2)$ will be denoted as $\widehat{f_{a_2}^{A_1}}$. However, the size of training set may be radically decreased in this way. For that reason a general fuzzy set $\widehat{f^{A_1}}$ is constructed as in 4.1, which is used for values that did not occur during the construction of local preferences in the training set.

A method for construction of several fuzzy sets and a general one, all represented by linear functions, is described in the following pseudo code. Method `getObjectsWithA2(`a_2`)` returns the set $X(a_2)$, i.e. only those objects with attribute value a_2. Method `leaveOnlyA1AndRating` leaves only couples (A1, Rating) in the given set, which makes it suitable for linear regression that follows. Finally, the attribute value a_2 and the corresponding linear function $\widehat{f_{a_2}^{A_1}}$ are stored.

```
leaveOnlyA1AndRating(X);
f^{A_1} = buildClassifier(X);
for (∀a_2 ∈ A_2) {
    X(a_2) = getObjectsWithA2(a_2);
    if (|X(a_2)|< 2)
        continue;
    leaveOnlyA1AndRating(X(a_2));
    f_{a_2}^{A_1} = doLinearRegressionOn(X(a_2));
    storeCouple(a_2, f_{a_2}^{A_1});
}
```

Let us have an object o with unknown rating, with attribute values $a_1, ..., a_n$. When we want to normalise value a_1, we use the following method:

```
if(existsFuzzySetFor(a_2)){
    f_{a_2}^{A_1} = getFuzzySetFor(a_2);
    return f_{a_2}^{A_1}(a_1) ;
}
else
    return  f^{A_1}(a_1);
```

ISBN: 978-989-95079-6-8

It is possible that we did not encounter value a_2 in the training phase at all or only once. In such case, we use general function $\widehat{f^{A_1}}$ for normalisation of a_1.

4.3 A method for clustering results CP-regressions

In the previous section, we mentioned a problem that when using 2CP-regression, the number of training examples for linear regression decreases rapidly when the number of attribute values in the dividing attribute is high. In the following, we present a method for overcoming this problem.

Let us have a set of fuzzy sets $\widehat{f_{a_i}^{A_1}}$ for normalisation of attribute A_1 that depends on values of attribute A_2. Each fuzzy set is of the form $\widehat{f_{a_i}^{A_1}}(x) = \alpha * x + \beta$.

Now we start with fuzzy set $\widehat{f_{a_1}^{A_1}} = \alpha * x + \beta$ and match together those fuzzy sets, that have similar shape, ie. the values of α and β. After finding similar fuzzy sets, without the loss of generality let it be $\widehat{f_{a_2}^{A_1}}, ..., \widehat{f_{a_k}^{A_1}}$. Values $a_1, ..., a_k$ are grouped together and we construct a new linear function; we will use all objects $o \in X(a_1) \cup ... \cup X(a_k)$ for its construction. This new linear function should accommodate better to testing data, because it is constructed using a larger training set. When using this set, we treat it as $\widehat{f_{a_1,...,a_k}^{A_1}}$ so it is used for every object with attribute value in $a_1, ..., a_k$.

This method of using clusters for CP-regression was not fully implemented yet, but plan to implement it and test it in near future. We expect better performance especially for smaller training sets. In this case, we can do a bottom-up clustering that stops at a specified threshold of minimal training set size.

5 Experiments

5.1 Experiment settings

Our experiment was done on a set of 200 notebooks crawled from a web shop. There are five attributes: harddisk, display, price, producer and ram. We have created an artificial user U with preferences on the scale {1,2,3,4,5} for every notebook. Preferences were generated using a set of fuzzy sets f_i and an aggregation function @.

The user preferences on price were dependent on the actual value of the producer of the notebook. As it was mentioned in Section 4.2, for producers HP, IBM, Lenovo, Toshiba and Sony the best price was set to 2200$ and for Fujitsu-Siemens, Acer, Asus and MSI the best price was set to 750$. Hence the same price would produce different degree of preference for different manufacturers. Distribution of ratings of notebooks with regard to their price is in Figure 2. We can clearly see that the ratings are distributed more or less evenly across all the domain. However, a peak at about 2500$ appears when only the triangles are taken into account and another peak at about 1000$ is for crosses. Peaks do not correspond exactly to the artificial preferences; this is because the overall rating is influenced by other attributes, too. The overall trend is clearly visible for human - with increasing price crosses tend to go down and on the opposite triangles go up.

Testing was performed with a traditional cross-validation method. Because we are dealing with user ratings, it can not be expected that the user will rate many objects. That is why we limited the size of the training set (TSS in following text) to 75 ratings at maximum. Methods were tested on the rest of the set. When the user model is constructed from the first 10 notebooks, then it is tested on the remaining 190 notebooks. Then the next 10 notebooks are taken as training set and again the model is tested on the remaining 190. For TSS = 75 the model is tested on remaining 125 notebooks. Resulting errors are averaged for every TSS so the results should be reliable.

There are five methods tested: Mean, Statistical with Linear regression, Statistical with 2CP-regression, Support Vector Machine and Multilayer perceptron. Mean is a baseline. This method always returns the average rating from the training set. Multilayer perceptron and Support Vector Machine are traditional data mining methods. Implementation from Weka [15] was used.

Statistical method as aggregation function was used with two different normalisations. The first one is traditional linear regression; the second is our proposed method 2CP-regression.

No tuning of any method was performed - these methods are supposed to work on arbitrary data automatically without the need of adjusting any parameters.

5.2 Experiment results

We studied three types of error measures. First, most commonly used, is RMSE - root mean squared error. This captures the average error across the whole testing set. Second, Weighted RMSE, adds weight to each contribution to error. The weight associated is the same as the real rating, because good objects are of more concern than objects that are not preferred. In other words, it is worse if a good notebook does not appear on the first page of results than if a bad notebook does. Finally, we used tau coefficient to study the methods. Tau coefficient is a measure of correspondence between two ordered lists. Objects from testing set ordered by real user preferences are in the first list. The second list consists of the same objects, ordered by preferences proposed by the method. In this way, we can estimate the similarity of the ordering of objects by the method and by the real user. Tau coefficient ranges from -1 to 1; 1 means absolute correlation, e.g. the same lists, and -1 means the opposite correlation, e.g. reversed lists. Tau coefficient of 0 means that there is no relation between the two lists.

In Figure 5 are represented counts of unpredicted rating for each method. At TSS = 2 there were 40 notebooks that every method failed to predict and SVM failed even for 90 notebooks. At TSS = 5, there were 5 notebooks for all methods and 25 notebooks for SVM without prediction. So SVM performed worse than the rest of methods for small TSS.

In Figure 6 are results for RMSE. 2CP regression is an overall winner, only at TSS = 40 it was outperformed by Multilayer perceptron and at TSS = 2 by SVM, but SVM failed to predict far more notebooks.

The results are about the same for Weighted RMSE, as we can see in Figure 7.

Finally, results for Tau coefficient are in Figure 8. 2CP-regression was outperformed by Mean for the three smallest TSS, otherwise it was again the best method.

In all cases, 2CP-regression was better than simple Linear regression and Statistical with 2CP-regression outperformed even SVM and Multilayer perceptron.

6 Conclusions

We have proposed a method for finding preference dependence between two attributes, which was demonstrated on the example of a user for whom the ideal price depends on the manufacturer of the notebook. As far as we know this is the first contribution for learning ceteris paribus-network like structure from user ratings. We are aware that our model does not correspond to CP-nets completely, but the proposed part of our fuzzy model can be considered as a simple CP-net.

In our experiments, 2CP-regression performed very well, outperforming traditional data-mining techniques and also the normalisation with linear regression. Three different error measures were taken into account and in every one our proposed method was the best.

For future work, we would like to extend this approach for finding relations between more than two attributes, making a more general nCP-regression. We would also like to test it on real user preferences data, for example on NetFlix data [16].

Multi-Dimensional Scaling applied to Hierarchical Rule Systems

Thomas R. Gabriel Kilian Thiel Michael R. Berthold

Abstract *— This paper presents an approach for visualizing high-dimensional fuzzy rules arranged in a hierarchy together with the training patterns they cover. A standard multi-dimensional scaling method is used to map the rule centers of the top hierarchy level to one coherent picture. Rules of the underlying levels are projected relatively to their parent level(s). In addition to the rules, all patterns are mapped onto the two-dimensional projection in relation to the positions of the corresponding rule centers. Visualization is further extended by showing hierarchical relationships between overlapping rules of different levels, which are generated by a hierarchical rule learner. This delivers interesting insights into the rule hierarchy and offers better explorative properties. Additionally, rules can be highlighted interactively emphasizing the subsequent rules at all underlying levels together with the patterns they cover. We demonstrate that this technique allows investigation of interesting rules at different levels of granularity, which makes this approach applicable even for a large number of rules. The proposed technique is illustrated and discussed based on a number of hierarchical rule model visualizations generated from well-known benchmark data sets.*

Keywords— Multi-Dimensional Scaling, Fuzzy Rule Induction, Rule Hierarchy, Rule Visualization.

1 Introduction

Rule learning algorithms are widely used in data mining to automatically extract rules from data. In [7, 15] and [20], algorithms are described that construct hyperrectangles in feature space. The resulting set of rules encapsulates regions in feature space that contain patterns of the same class. Other approaches, which construct fuzzy rules instead of crisp rules, are presented, for example, in [1, 12, 18] and [19]. All of these approaches have in common that they tend to build very complex rule systems for large data sets originating from a complicated underlying system. In addition, high-dimensional feature spaces result in complex rules relying on many attributes further increasing the number of required rules to cover the solution space. An approach that aims to reduce the number of constraints on each rule individually is presented in [3]. The generated fuzzy rules only constrain a few of the available attributes and hence remain readable even in the case of high-dimensional spaces. The fuzzy rules generated by this method have been visualized by parallel coordinates [4, 10].

In [8], we described a method that attempts to tackle this inherent problem of interpretability of large rule models. We achieve this by constructing rule models with varying degrees of complexity. The method builds a rule hierarchy for a given data set. The rules are arranged in a hierarchy of different levels of precision. Lower levels of the model describe regions in input space with low evidence in the given data, whereas rules at higher levels describe more strongly supported concepts of the underlying data. The method is based on the fuzzy rule learning algorithm described in [3, 9], which builds a single layer of rules autonomously. We use the resulting rule system recursively to determine rules of low relevance, which are then used as a filter for the next training phase. The result is a hierarchy of rule systems with the desired properties of simplicity and interpretability on each level. Experimental results demonstrated that fuzzy models at higher hierarchical levels show a dramatic decrease in number of rules while still achieving a better or similar generalization performance than the fuzzy rule system generated by the original, non-hierarchical algorithm.

In this paper we present an approach that enables the visualization of hierarchically structured rules and data in one coherent plot. A standard multi-dimensional scaling (MDS) method is applied to project rules of a certain level from the original, high-dimensional space, into a lower, usually two-dimensional space. Rules of the underlying levels are projected relatively to their parent level(s), likewise all data points are projected in relation to the positions of the corresponding rule centers. Furthermore, the visualization shows hierarchical relationships between overlapping rules of different levels as generated by a hierarchical rule learner. Due to the hierarchical nature of the induced rule system, interactive exploration becomes possible across the entire rule model and provides interesting insights into the underlying concept.

The paper is organized as follows: In the next section we briefly describe the used hierarchical rule learning method, followed by a short introduction to multi-dimensional scaling methods, and how data and hierarchical rules can be visualized by applying an extended multi-dimensional scaling method. In the following section, we describe how rule hierarchies, together with their original data, can be explored within this visualization. To illustrate the proposed method, hierarchical rule systems are generated based on the well-known iris data and on the vehicle silhouettes data.

2 Learning Hierarchical Rule Systems

The rule induction algorithm used here is based on a method described in [3], which is based on an iterative algorithm. During each learning epoch, i. e. presentation of all training patterns, new fuzzy rules are induced when necessary and existing ones are adjusted whenever a conflict occurs. For each pattern three main steps are executed. First, if a new training pattern lies inside the support-region of an existing fuzzy rule of the correct class, its core-region is extended in order to cover the new pattern. Second, if the new pattern is not yet

ISBN: 978-989-95079-6-8

covered, a new fuzzy rule of the correct class is introduced. The new example is assigned to its core, whereas the support-region is initialized by infinity, that is, the new fuzzy rule covers the entire domain. Finally, if a new pattern is incorrectly covered by an existing fuzzy rule, the fuzzy rules' support-region is reduced to avoid the conflict. This heuristic for conflict avoidance aims to minimize the loss in volume. In [9], three different heuristics are compared to determine the loss in volume. As discussed in [3], the algorithm terminates after only a few iterations over the set of example patterns.

The final set of fuzzy rules can be described as an n-dimensional IF clause as antecedence and one assigned $class$ in the rule's conclusion:

$$\begin{array}{lllll}
\mathcal{R}_1^1 & \texttt{IF} & x_1 \texttt{ IS } \mu_{1,1}^1 & \wedge\cdots\wedge & x_n \texttt{ IS } \mu_{n,1}^1 \quad \texttt{THEN class } 1 \\
 & & \vdots & \vdots & \vdots \\
\mathcal{R}_{r_1}^1 & \texttt{IF} & x_1 \texttt{ IS } \mu_{1,r_1}^1 & \wedge\cdots\wedge & x_n \texttt{ IS } \mu_{n,r_1}^1 \quad \texttt{THEN class } 1 \\
 & & \vdots & \vdots & \vdots \\
\mathcal{R}_j^k & \texttt{IF} & x_1 \texttt{ IS } \mu_{1,j}^k & \wedge\cdots\wedge & x_n \texttt{ IS } \mu_{n,j}^k \quad \texttt{THEN class } k \\
 & & \vdots & \vdots & \vdots \\
\mathcal{R}_{r_c}^c & \texttt{IF} & x_1 \texttt{ IS } \mu_{1,r_c}^c & \wedge\cdots\wedge & x_n \texttt{ IS } \mu_{n,r_c}^c \quad \texttt{THEN class } c
\end{array}$$

where $\mathcal{R}_j^k$ represents rule j for class k. The rule base contains rules for c classes and r_k indicates the number of rules for class k ($1 \leq j \leq r_k$ and $1 \leq k \leq c$). The fuzzy sets $\mu_{i,j}^k : \mathbb{R} \mapsto [0,1]$ are defined for every feature i ($1 \leq i \leq n$), but in cases of unconstrained features the membership degree constantly remains 1. The overall degree of fulfillment of a specific rule for an input pattern $\vec{x} = (x_1, \ldots, x_n)$ can be computed using the fuzzy set operator for conjunction, called T-norm ($\top$):

$$\mu_j^k(\vec{x}) = \top_{i=1,\cdots,n} \left\{ \mu_{i,j}^k(x_i) \right\}.$$

The combined degree of membership for all rules of class k can be calculated using the fuzzy set operator for disjunction, called S-norm ($\perp$):

$$\mu^k(\vec{x}) = \perp_{j=1,\cdots,r_k} \left\{ \mu_j^k(\vec{x}) \right\}.$$

From these membership values the predicted class k_{best} for an input pattern $\vec{x}$ is derived as:

$$k_{\text{best}}(\vec{x}) = \arg\max_{k=1,\ldots,c} \left\{ \mu^k(\vec{x}) \right\}.$$

The algorithm uses trapezoidal membership functions, which can be described by four parameters $\langle a_i, b_i, c_i, d_i \rangle$, where a_i and d_i define the fuzzy rule's support-, and b_i and c_i its core-region for each attribute i of the input dimension. The core-region is defined as a rectangular area with an activation of 1, whereby the support-region decreases linearly to its boundaries with a degree of fulfillment of 0.

The resulting set of fuzzy rules can then be used to classify new patterns by computing the overall degree of membership for each class. The accumulated membership degrees over all input dimensions and across multiple rules are calculated by a fuzzy norm. For the purpose of this paper, we concentrate on the rules' core-regions only, that is, the part of each rule where the degree of membership is equal to 1 – resulting in crisp rules – is considered.

An extension of this rule learning algorithm is proposed in [8], which allows the generation of a hierarchy of rules. Therefore, the classical fuzzy rule algorithm is used to determine rules of low relevance recursively, which are then used as a filter for the next training phase. Training examples that cause the creation of small, less important rules are therefore excluded from the training phase of the next layer, resulting in a more general rule system, ignoring the withheld, small details in the training data. An example of a two-stage rule induction process is illustrated in Fig 1.

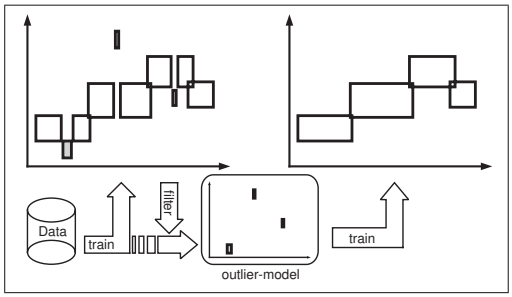

Figure 1: Two-stage outlier filtering as described in [2].

This process can be repeated to generate the desired hierarchy of rule systems with an increasing generality towards higher levels. The rule layers are arranged in a hierarchy of different levels of precision. Lower levels of the model describe regions in input space with low evidence in the training data, whereas rules at higher levels describe more strongly supported aspects of the underlying data.

3 Multi-Dimensional Scaling

To visualize objects of high-dimensional feature spaces, multi-dimensional scaling methods [6] can be applied to map them onto lower-dimensional spaces with usually two or three dimensions. In order to avoid a loss of proximity information, MDS methods try to preserve the pairwise distances between objects during the mapping process by minimizing an appropriate error function. The reduction of dimensions allows the visualization of high-dimensional objects in a lower-dimensional space, using traditional methods such as scatter plots or scatter matrices.

One technique to apply this kind of mapping by minimizing a particular error function is the well known Sammon algorithm [17]. For each object $\vec{X}_i$ in high-dimensional space $\mathbb{R}^H$, a spatial representation $\vec{x_i} \in \mathbb{R}^L$ in low-dimensional space (usually $L = 2$) has to be computed ($1 \leq i \leq N$ with N as the number of objects).

To approximate the distance information, the position of each object in the low-dimensional space has to be adjusted such that the pairwise distances between each two objects $(\vec{x_i}, \vec{x_j})$ in the low-dimensional space, $d_{ij} = d(\vec{x_i}, \vec{x_j})$, approximate the distances of the two corresponding objects $(\vec{X}_i, \vec{X}_j)$ in the high-dimensional space, $D_{ij} = D\left(\vec{X}_i, \vec{X}_j\right)$:

$$\forall_{i \neq j} : D_{ij} \approx d_{ij}, 1 \leq i, j \leq N.$$

Usually the Euclidean metric is used to measure these distances in the low-dimensional space, and often in the high-

ISBN: 978-989-95079-6-8

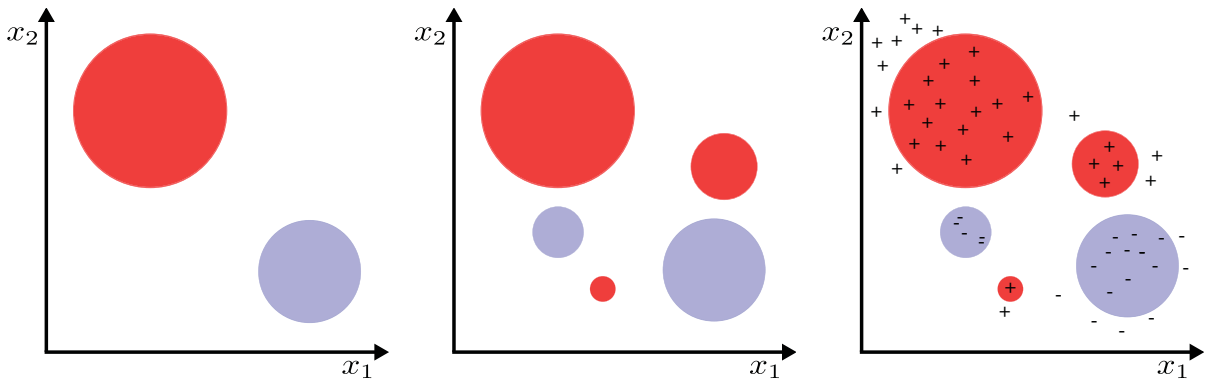

Figure 2: Shows a two-level rule hierarchy. (a) Two top-level rules assigned to two different classes, + (red) and − (blue), (b) three additional rules on the next level, (c) all rules together with their underlying data points.

dimensional space as well:

$$d_{ij}^2 = \sum_{l=1}^{L} (x_{i,l} - x_{j,l})^2.$$

Approximation of the pairwise distances in high- and low-dimensional space is formulated by Sammon as a minimization problem of a cost function, which aggregates the weighted squared differences of the distances in high- and low-dimensional space:

$$E = \sum_{i=1}^{N} \sum_{j>i}^{N} \omega_{ij} (d_{ij} - D_{ij})^2.$$

where the factors ω_{ij} are introduced to weight the distances individually and normalize the stress function E in order to be independent from the absolute values D_{ij}. The steepest gradient method is applied to minimize iteratively a cost function E for each object $\vec{x_i}$ at each step. Usually several iterations are needed by the algorithm to converge to a local cost minimum.

3.1 *Projective Multi-Dimensional Scaling*

As mentioned above, the original Sammon algorithm tries to preserve the pairwise distances of all objects. This means that the position of each object in the low-dimensional space is adjusted iteratively according to the position of the other objects in the high- and low-dimensional space. Subsequently this leads to a change of the positions of all objects in the low-dimensional space. With our projective multi-dimensional scaling approach, the positions of the objects in the low-dimensional space are adjusted according to a set of fixed projection objects.

First a set of objects in the high-dimensional space is selected. For each of these objects $\vec{X_p} \in \mathbb{R}^H$ a spatial representation $\vec{x_p} \in \mathbb{R}^L$ ($1 \leq p \leq M$ with $M \ll N$ as the number of fixed projection objects $\vec{x_p}$) has to be found by means of the standard MDS algorithm described above. Once these objects have been mapped onto the low-dimensional space, they are used as fixed objects and are not changed anymore. Furthermore, each of the other objects $\vec{X_i} \in \mathbb{R}^H$ are mapped onto the low-dimensional space according to the fixed projection objects. Therefore, the distance between a regular object $\vec{x_i} \in \mathbb{R}^L$ and a fixed projection object $\vec{x_p}$ in the low-dimensional space $d_{ip} = d(\vec{x_i}, \vec{x_p})$ has to be approximated to the distance between the two corresponding objects $(\vec{X_i}, \vec{X_p})$ in the high-dimensional space $D_{ip} = D\left(\vec{X_i}, \vec{X_p}\right)$, which translates to:

$$\forall_{i \neq p} : D_{ip} \approx d_{ip}, 1 \leq i \leq N, 1 \leq p \leq M.$$

Again, a cost function E_P is defined that aggregates the weighted squared differences of the distances in the high- and low-dimensional space:

$$E_P = \sum_{i=1}^{N} \sum_{p=1}^{M} \omega_{ip} (d_{ip} - D_{ip})^2.$$

The projective MDS method is useful if a set of objects has to be mapped according to an already existing set of mapped objects without modifying the mapping of the latter.

In the case of high-dimensional hierarchical data, projective MDS can be used to determine a spatial representation in several iterations. First the standard MDS method is applied to the top-level data. Once this data is mapped, projective MDS can be applied stepwise to the data of the lower levels using the data of higher levels as fixed projection objects. The low-dimensional representation of the already mapped data does not change anymore when applying projective MDS to the remaining levels.

3.2 *Hierarchical Rules in Multi-Dimensional Scaling*

It is more complex to visualize rule models on lower dimensions than simple data points. The main challenge is the mapping of the rules' antecedences, which are usually hyperrectangles in the original high-dimensional feature space. In order to visualize high-dimensional fuzzy rules by means of MDS, the center points of a rules' core-regions are mapped onto a low-dimensional space, as described in [11, 16]. For hierarchical fuzzy rule systems, the center points of the top-level rules are mapped onto the low-dimensional space using standard MDS. Subsequently, the rules of the underlying levels are mapped level by level via the projective MDS with the parent rule centers as fixed projection points. Finally, the data points are mapped according to all projected rules, whereas the neighborhood of rules and data points is approximated by the proposed MDS. The overlapping relation between rules of different levels may get lost in the visualization, but is again

ISBN: 978-989-95079-6-8

taken into account when rule systems are visually explored by interactive highlighting, see Sec. 4.2 for an example.

In addition to the rules' center points, the spread of a fuzzy rule has to be mapped onto the low-dimensional space in order to visualize the rules' sizes, possible overlaps, and the coverage according to the data points the rules are based on. In [11], we visualize the overlap of rules of flat rule systems. Dealing with hierarchical fuzzy rules, we only focus on the visualization of the spread and the number of covered data points of a rule as well as the rules' level and not on overlap with other rules.

The spread is visualized by a sphere around the mapped rule center with a radius $r_i = \rho(\lambda\omega_i + (1-\lambda)\sigma_i^2)$ according to the variance σ_i^2 and the number of the points ω_i covered by a rule $\mathcal{R}_i$, with λ as weighting coefficient $\lambda \in [0,1]$ and $\rho(\cdot)$ as scaling function. The number of vertices $v = 2^H$ of a hyperplane grows exponentially with the number of dimensions H whereas all vertices have the same distance to the center point. All vertices of a high-dimensional hyperplane are mapped by MDS, representing vertices of a low-dimensional polygon; all with the same distance to the polygons center point. With increasing dimensionality, the polygon spanned by the projected vertices converges to a sphere.

In Fig. 2 (a), two top-level rules are shown, covering data points of two different classes. The red rule covers data points of class $+$, while the blue covers data points of class $-$. Fig. 2 (b) illustrates rules of the primary and the secondary level, which consists of three smaller rules, two rules covering data points of class $+$ and two of class $-$. Fig. 2 (c) shows rules of all levels as well as the data points. It can be seen that the spheres representing the rules do not necessarily cover all the data points in the low-dimensional space as they do in the high-dimensional space. This is because the radius is based on the number of covered data instances of a rule as well as the variance of the covered data points in the high-dimensional space, but is not based on the position of the data points in the low-dimensional space.

4 Visualization Hierarchical Rules and Data

The following section illustrates the proposed approach on the well-known iris dataset before looking at a larger dataset, the vehicle silhouettes data. We compare the classical, non-hierarchical rule model to the hierarchical structured rules by visualizing all the rules together with their originating data instances in one coherent picture.

4.1 Iris Dataset

The first example shows a small two-level hierarchy trained on the iris data, which consists of 150 four-dimensional patterns assigned to three classes. Fig. 3 (a) shows the top-rule level containing three rules – one for each class, (b) the top and bottom-rule levels with additional 11 rules (some cover only a single or a few instances and therefore appear as small points), and (c) all data points and all rules together. The top-level rules are projected into the low-dimensional space based on each center point. The second level is then projected based on the first rule level. In the last step, data points are projected according to both hierarchical levels as shown in Fig. 3. The bottom picture shows rules and data instances of all three classes, which are almost perfectly separated from each other by three large rules. Smaller rules in-between are needed to cover artifacts and details in the data.

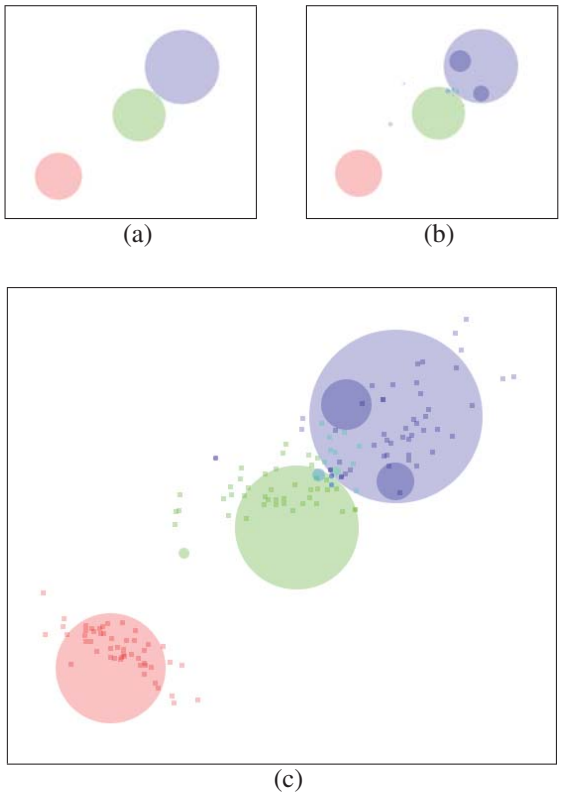

Figure 3: Two-level rule hierarchy trained on iris data: (a) three top-most rules, (b) additional 11 rules from the bottom-level, and all data points in (c).

4.2 Vehicle Silhouettes Dataset

The vehicle silhouettes dataset consists of 846 samples belonging to four car classes – Opel, Saab, bus, and van – represented in an 18-dimensional feature space. To demonstrate the usefulness of our proposed method, we trained a three-level fuzzy rule hierarchy on this data from the European StatLog–Project [14]. In a first experiment, a classical rule model with 222 rules without hierarchy information is trained on the vehicle data. As can be seen in Fig. 4, exploration is hardly pos-

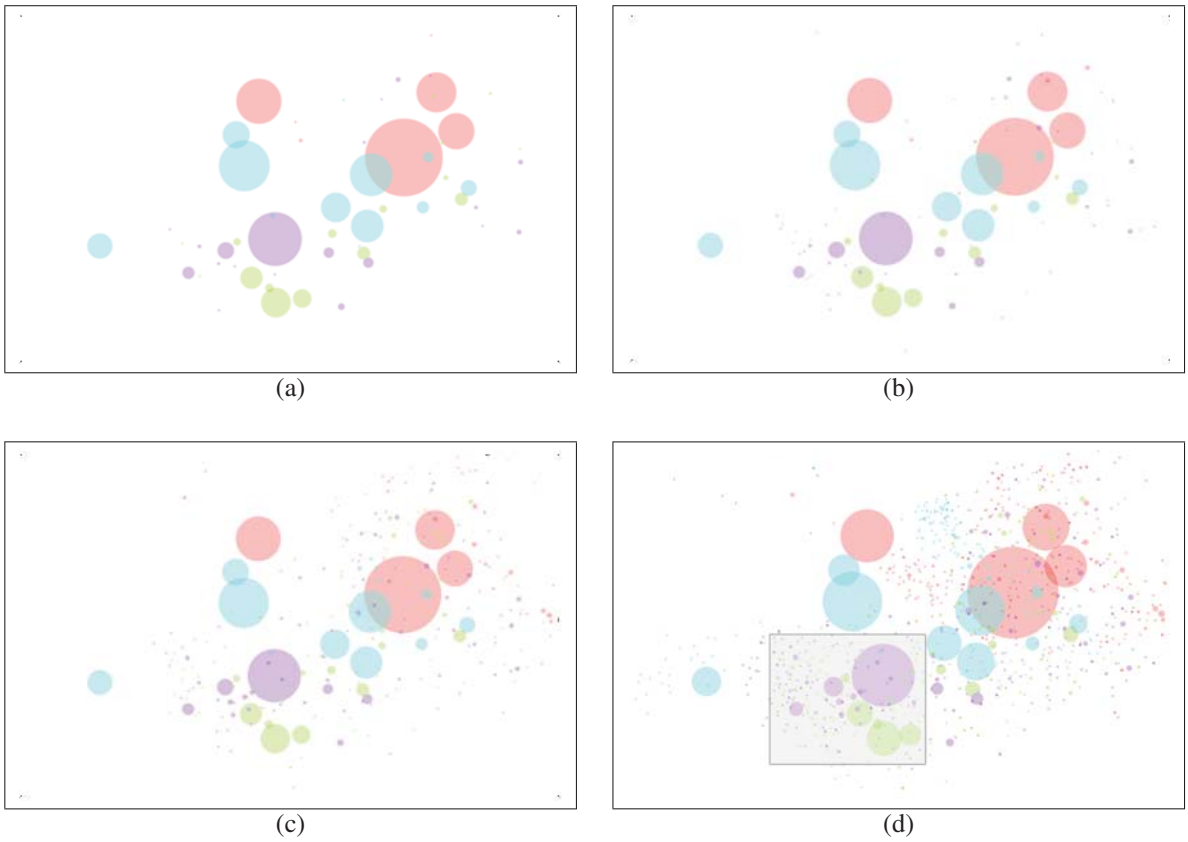

Figure 5: Stepwise rule hierarchy projection on vehicle data starting from top- to bottom-level (a)-(c), and (d) rules of all levels and data points.

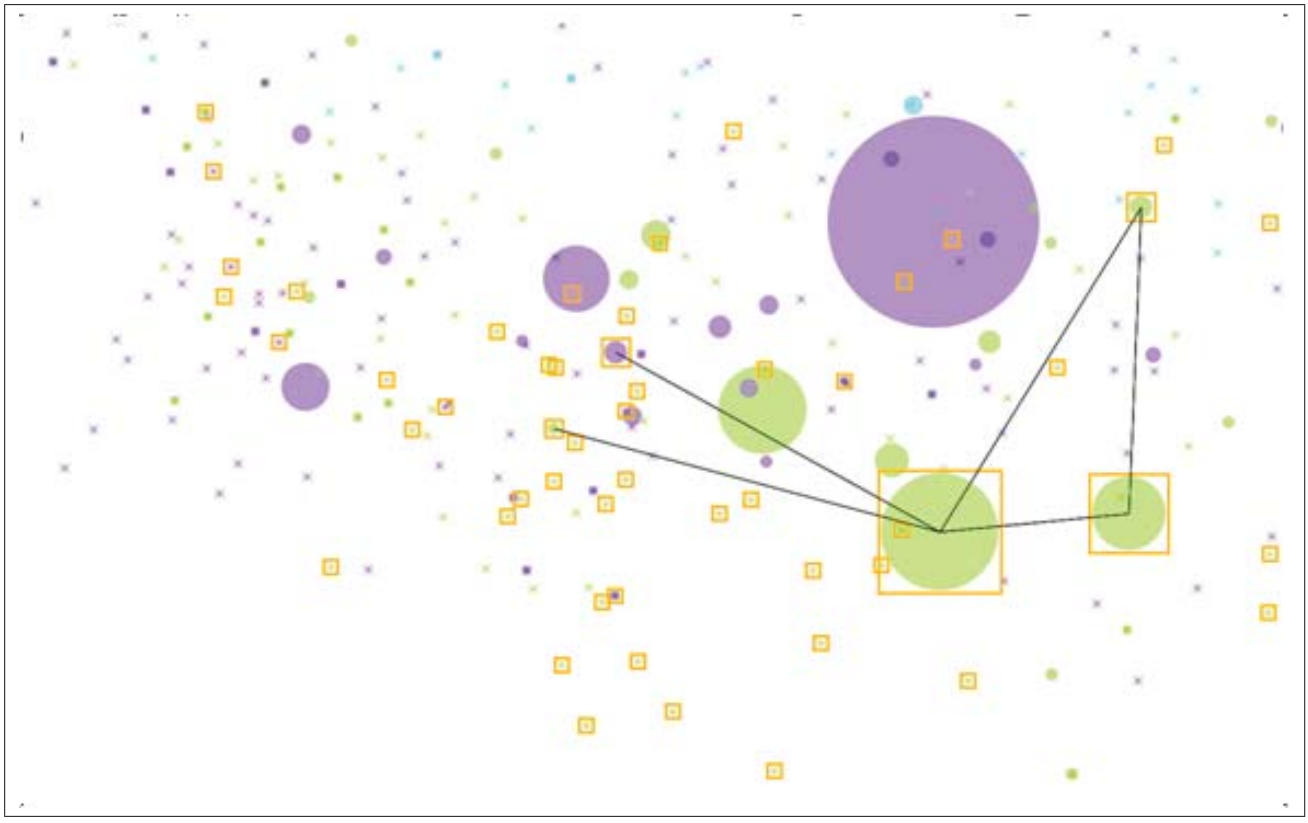

Figure 6: Exploration by zooming and highlighting (orange square) interesting rules and data points in the vehicle hierarchy.

ISBN: 978-989-95079-6-8

sible since overlapping information is only available between rules of the same single level [1].

The hierarchical rule induction algorithm is applied to generate a hierarchy of rule models in a second test. The three levels of the fuzzy rule hierarchy contain 55 rules in the top, 40 in the middle, and 174 at the bottom-most level. Fig. 5 shows each level together with its parent levels starting from (a) to (c), and (d) rules of all levels and data points. All levels are subsequently projected into the two-dimensional space always with respect to their parent level(s), as well as all data points that are projected relatively to all rule levels. Fig. 6 shows the surrounded area from Fig. 5 (d) enlarged. Selecting one rule highlights all overlapping rules in the levels above along with the data points they cover. All highlighted rules (orange square) that cover the same set of patterns are connected by a line to visually identify overlapping rules between different levels of the hierarchy. The figure shows five connected rules where a violet rule from a lower level completely overlaps with a large, green rule of a higher level. This is typically an indication for outliers and artifacts in the data expressed by smaller, more specific rules at lower levels generated by the rule learning algorithm at first place; whereas rules generated at higher levels of the hierarchy explain more general aspects of the data and are usually covered by larger rules. This visual line-up of rules of different levels allows further exploration by highlighting interesting data instances.

5 Conclusions

Hierarchically structured rules induced by a classical rule learning algorithm lead to a well-defined hierarchy of rules where levels further up explain more general aspects and rule models at lower levels concentrate on artifacts or outliers of the underlying concept. Combining this information with a mapping mechanism to visualize both this type of hierarchy and the data points enables interactive exploration across rule levels by focusing on overlapping regions. On the other hand, it highlights data points covered throughout the rule hierarchy. We demonstrated the explorative power of the proposed projective multi-dimensional scaling method based on the vehicle silhouettes dataset, delivering interesting insights into the underlying concept. Our approach is well suited for projecting other hierarchical structured data and rules driving interactive explorative data analysis.

Abstract *— In this paper, we are dealing with a novel data-driven learning method (*SparseFIS*) for Takagi-Sugeno fuzzy systems, extended by including rule weights. Our learning method consists of three phases: the first phase conducts a clustering process in the input/output feature space with iterative vector quantization. Hereby, the number of clusters = rules is pre-defined and denotes a kind of upper bound on a reasonable granularity. The second phase optimize the rule weights in the fuzzy systems with respect to least squares error measure by applying a sparsity-constrained steepest descent optimization procedure. This is done in a coherent optimization procedure together with elicitation of consequent parameters. Depending on the sparsity threshold, more or less rules weights can be forced towards 0, switching off some rules. In this sense, a rule selection is achieved. The third phase estimates the linear consequent parameters by a regularized sparsity constrained optimization procedure for each rule separately (local learning approach). Sparsity constraints are applied here in order to force linear parameters to be 0, triggering a feature selection mechanism per rule. In some cases, this may also yield a global feature selection, whenever the linear parameters of some features in each rule are near 0. The method is evaluated based on high-dimensional data from industrial processes and based on benchmark data sets from the internet and compared to well-known batch training methods in terms of accuracy and complexity of the fuzzy systems.*

Keywords— Takagi-Sugeno fuzzy systems, iterative vector quantization, rule weight optimization, sparsity constraints, rule selection, embedded feature selection

1 Introduction

1.1 Motivation and State of the Art

Nowadays data-driven learning of fuzzy systems enjoy a great attraction in many industrial applications, as, opposed to expert-based fuzzy systems, they can be fully automatically generated from process data such as measurements, images (features) or signal streams and hence save a lot of time and money for the development of system models. Their big advantage over other methods such as neural networks or genetic programming are that they are universal approximators [22] (i.e. being able to model a given problem to any degree of accuracy) and at the same time they still allow some insights in form of linguistically [5] and visually interpretable rules [19]. Due to these benefits, data-driven fuzzy systems are applied in many application areas such as fault detection, image classification or identification models in control systems and hence serve as important components in these systems.

During the recent 15 to 20 years a lot of data-driven fuzzy systems approaches were developed: some methods such as popular *genfis2* [23] (as implemented in MATLAB's fuzzy logic toolbox) and its successor *genfis3*, *FMCLUST* [2], exploit various clustering techniques (e.g. Gustafsson-Kessel [14] or variations of mountain and subtractive clustering [6]) for extraction clusters out of the data which are directly associated with the rules. A big family of design methods use genetic algorithms [9] for 1.) eliciting the optimal number of rules by achieving a reasonable tradeoff between accuracy and model complexity and 2.) for (fine-)tuning the parameters: these are also called genetic fuzzy systems [10] and enjoy a great attraction in the fuzzy community since more than 10 years [8].

Other methods use numerical optimization procedures for linear (consequent) and non-linear (antecedent) parameters in the fuzzy systems for minimizing the least squares errors (and variants) between estimated and predicted target values: a well-known method is the *ANFIS* approach [15] exploiting a neuro-fuzzy system architecture similar to a Takagi-Sugeno type system; another method demonstrated in [3] uses Levenberg-Marquardt algorithm for optimizing non-linear antecedent parameters in triangular and Gaussian fuzzy sets. *RENO* [4] exploits a generalized Gauss-Newton like method as a second-order approximation method with (regularized) smoothing constraints.

None of these methods perform an implicit feature selection approach, neither globally nor locally, which may be important in case of high-dimensional spaces for decreasing curse of dimensionality effect. Moreover, most of these methods do not have an integrated approach for a deterministic optimization of rule structure (number of rules) and consequent parts in a coherent procedure at the same time. Indeed, genetic fuzzy systems provide this aspect, however are non-deterministic and often lack efficiency in terms of computational performance.

1.2 Our Approach

In this paper, we present a novel technique for data-driven learning of Takagi-Sugeno fuzzy systems called *SparseFIS*, which is short for *Sparse Fuzzy Inference Systems*. This approach is characterized by mainly three issues (more details in Section 2):

1. it applies a top-down approach where the upper bound on the number of rules are allowed to be predefined (e.g. by an expert) and the non-linear parameters in the fuzzy sets of the antecedent parts are pre-estimated by an iterative vector quantization approach (Section 3).

2. it performs a rule selection strategy by optimizing rule weights together with the linear consequent parameters within one non-linear optimization procedure (Section 4). The application of a threshold operator therein (for forcing as much as possible rule weights towards zero) allows optimality in the least squares sense and readability at the same time.

3. it includes an embedded local (=for each rule separately) feature selection technique by applying a semi-smooth Newton method for a sparsity regularized estimation of the linear consequent parameters (Section 5). This may decrease the curse of dimensionality effect and improves interpretability of the achieved fuzzy systems.

Combining these three concepts together will guide us to the *SparseFIS* algorithm in Section 6, which is able to generate accurate and sparse fuzzy systems at the same time. Section 7 compares the novel method in terms of predictive accuracy and complexity with other well-known (and in MATLAB achievable) data-driven fuzzy system methods based on four data sets from the UCI respository and on noisy engine test bench data.

2 Problem Statement

Let us first define the Takagi-Sugeno fuzzy model with rule weights and by applying product t-norm with Gaussian fuzzy sets (in case of C rules):

$$y_{fuz} = \sum_{i=1}^{C} l_i(x)\Psi_i(x,\rho), \quad l_i(x) = \sum_{k=1}^{p} w_{i,k}x_k \qquad (1)$$

with

$$\mu_i(x) = \Pi_{j=1}^{p}\mu_{i,j}(x_j), \quad \mu_{i,j}(x_j) = e^{-\frac{(x_j - c_{i,j})^2}{2\sigma_{i,j}^2}}$$

and

$$\Psi_i(x,\rho) = \frac{\rho_i\mu_i(x)}{\sum_{j=1}^{C}\rho_j\mu_j(x)} \qquad (2)$$

Here $\rho = (\rho_1, \ldots \rho_C)$ are positive weights, which more or less steer the number of rules (as weights smaller than a low number $\epsilon > 0$ can be seen as not useful and hence omitted). For optimization purposes we use the least squares error measure, which, when applying TS fuzzy systems as above and in dependency of the unknown parameters, can be written as

$$J(w,c,\sigma,\rho) = \sum_{k=1}^{N}(y_k - \sum_{i=1}^{C} l_i(\vec{x}_k)\Psi_i(\vec{x}_k))^2 \qquad (3)$$

The training goals (=steps in the algorithm) in this paper can be summarized as follows:

1. Estimating the non-linear antecedent parameters in a preliminary phase due to a pre-defined upper bound on the number of rules.

2. Minimizing the least squares error by keeping the model complexity (in terms of the number of rules) as low as possible (rule selection from the initial number). This is done in a coherent procedure with optimization of the consequent parameter synchronously.

3. Minimizing the least squares error by keeping the number of significant linear consequent parameters in each rule as low as possible. This has the effect of a kind of local feature selection (which can turn into a global one if certain parameters belonging to the same input variable are not significant in any rule) and hence serves as an additional interpretability aspect as well as regularization property.

The last two steps guarantee a reasonable tradeoff between accuracy and complexity resp. readability of the achieved models, as we optimize the rules resp. consequent parameters according to an optimization criterion by applying synchronously constraints on the number of significant rules resp. significant features in the consequents. This also means that this technique does not need any computational intensive post-processing techniques (such as e.g. [20]) for reducing complexity. In the next three sections we describe how to achieve these three goals.

3 Estimating Antecedent Parts of the Rules

The first step is to yield a proper estimation of the non-linear premise parameters c and σ in the Gaussian fuzzy sets of the rules antecedent parts. For doing so, we apply a clustering approach, which is called iterative vector quantization as iterating over the whole data set a multiple times, and associate each cluster to one rule. The fuzzy sets of the rules antecedent parts are obtained by projection onto the one-dimensional axis: the centers of the fuzzy sets are the center components of a cluster in each dimension, the widths are achieved by calculating the variance in each dimension. In principle, any clustering method requiring a fixed number of cluster as input and delivering cluster prototypes = centers of fuzzy sets and rules as well as the range of influence of the clusters in each dimension can be applied here. In fact, the projection concept is also carried out in many other approaches such as genfis2 [6] or FMCLUST [2] and hence not new. The difference in this paper is that we are applying vector quantization [12] where the

ISBN: 978-989-95079-6-8

a-forementioned methods apply other clustering algorithms (such as subtractive clustering and Gustafson-Kessel).

First, we estimate an initial number of rules (=clusters) and send these to the iterative vector quantization algorithm for fine tuning the non-linear parameters. The number of initial rules are

- Either pre-defined according to user knowledge, interpretability or computational aspects (usually $<$ 100 rules).
- Or automatically extracted from the data by using an evolving clustering approach (*eVQ* [16]) which starts with 0 clusters and evolve new ones according to the distribution and characteristics of new data.

Then, we apply the iterative vector quantization (VQ) algorithm (please refer to [12]) plus estimate the ranges of influence of each cluster in each dimension after the end of VQ.

4 Rule Selection by Optimizing the Rule Weights

Once having the centers and widths of the predefined number (upper bound) of rules estimated, it is a big challenge to reduce the rules in order to enhance interpretability by synchronously not loosing significant accuracy. In this sense, we propose to optimize the rule weights as defined in (2) within a iterative optimization process using sparsity constraints. In a sense, we try to find a minimal least squares error solution subject to the constraint that a significant number of rule weights should be zero. In an optimization formulation a goal would be to minimize the least squares error (3) subject to the constraint that the number of weights ρ_i should be bounded:

$$\min J(w,c,\sigma,\rho) \quad \text{such that} \#\{\rho_i \ / \tag{4}$$

where $\#$ denotes the cardinality of a set and K is an appropriate constant. A minimizer of such a problem is expected to achieve a small error together with a small number of nonzero rule weights. However, there is an intrinsic difficulty with this formulation, as this is a combinatorial optimization procedure (note that we only bound the number of nonzero elements, there is no restriction, where the nonzero elements are). A method that solves such a problem would have to test all subsets of $\{1,\dots N\}$ as candidates for the nonzero entry index of ρ and hence requires exponential complexity in N. However, recently the surprising fact came up, that an almost optimal solution to (4) can be computed by l^1-minimization [7]: That is, instead of (4) the problem

$$\min J(w,c,\sigma,\rho) \quad \text{such that} \sum_{m=1}^{N} |\rho_i| \leq K, \tag{5}$$

is solved. This is a much more accessible approach, because the constraints are convex and there are efficient methods to solve it.

Our algorithm is a nonlinear version of the well-known iteration proposed by [11]. The iteration is basically a projected gradient descent algorithms. The gradient of least squares functional with respect to the jth rule weight ρ can be calculated to:

$$\frac{\partial y_{fuz}}{\partial \rho_j} = \sum_{n=1}^{C}\sum_{k=1}^{N} e_k l_n(x_k) \frac{\partial \Psi_n(x_k)}{\partial \rho_j} \tag{6}$$

with $l_n(x_k)$ the linear rule consequent functions in sample x_k, e_k the residual in sample x_k defined by:

$$e_k(c,\sigma,\rho) := y_k - \sum_{i=1}^{C} l_i(\vec{x}_k)\Psi_i(c,\sigma,\rho)(\vec{x}_k)) \tag{7}$$

and $\frac{\partial \Psi_n(x_k)}{\partial \rho_j}$ the partial derivative of the nth basis function with respect to ρ_j:

$$\frac{\partial \Psi_i}{\partial \rho_k} = \frac{\mu_i}{\sum_{j=1}^{C} \rho_j \mu_j(x)} \left(\delta_{i,k} - \frac{\rho_i \mu_k}{\sum_{j=1}^{C} \rho_j \mu_j(x)} \right) \tag{8}$$

where

$$\delta_{i,j} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

The idea of the projected gradient method is to apply a threshold operator on the rule weight update in each gradient descent iteration step T_α. Additionally, we also have to optimize the consequent parameters in each update step as needed in $l_n(x_k)$ and e_k. This is done by the local learning approach, estimating the parameters for each rule separately and independently. This has some robustness [18], computational, flexibility [1] and interpretability [24] advantages over global learning approach. In this sense, the whole rule weight optimization procedure becomes as in algorithm 1.

Algorithm 1 Rule Weight Optimization with Sparsity Constraints

1. Initialization of w^0 is done by using local learning with (11) on the initial number of rules (see Step 5 below); ρ^0 is set to a vector of ones (all rules contribute equally at the beginning).
2. w^k, ρ^k are given in iteration k.
3. Calculate $\frac{\partial \Psi_n}{\partial \rho_j}$ as given in (8).
4. Update the rule weights $j = 1,...,C$ componentwise separately by:

$$\rho_j^{k+1} = T_\alpha \left(\rho_j^k - \tau \sum_{n=1}^{C}\sum_{k=1}^{N} e_k l_n(x_k) \frac{\partial \Psi_n(x_k)}{\partial \rho_j} \right) \tag{9}$$

with τ a small constant defining the step size per iteration (usual setting $\tau = 0.1$) and T_α the soft-thresholding operator defined by:

$$T_\alpha = \max(\rho_j^{k+1}, \alpha) - \alpha \tag{10}$$

with α set to a small constant (usual guess is 0.1).

ISBN: 978-989-95079-6-8

5. Calculate $\Psi(c, \sigma, \rho^{k+1})$ for the new $\rho_j^{k+1}, j = 1, ..., C$ and generate the regression matrix $\sqrt{Q_i}R_i, i = 1, ..., C$ for each rule separately with R_i containing the original variables and a column of ones for the intercept and the weighting matrix Q_i defined by $diag(\Psi_i(\vec{x}(k))), k = 1, ..., N$.

6. Perform the weighted least squares approach for the linear consequent parameters whose analytical solution in closed form is:

$$\hat{\vec{w}_i} = (R_i^T Q_i R_i)^{-1} R_i^T Q_i \vec{y} \tag{11}$$

   Here, we also apply Tikhonov regularization [21] if required, i.e. when the condition of the matrix $R_i^T Q_i R_i$ is very high, indicating a matrix close to singular and hence an unstable solution in (11).

7. If the difference between two iterations $\|\rho^{k+1} - \rho^k\|$ is low enough or a pre-defined maximal number of iterations is reached, then stop, otherwise perform next iteration (goto Step 2).

After this optimization procedure, the rules with weights close to 0 are eliminated and the remaining rules C_{rem} are kept for further processing through the last step (described in the subsequent section). Note the in view of our derivation of this iteration, the output of this method should be on the one hand close to the data (this is done by minimizing the least squares functional), and have many rule weights as zero, (which can be discarded afterwards).

In order to visualize the update progress of the rule weights through Algorithm 1, Figure 1 shows the rule weights from three iterations (1, 7 and 13). The weights are sorted in order to get an idea how they are reduced through the optimization procedure by applying T_α. Clearly, after the first iteration almost all rule weights are bigger than zero, whereas after the 13th iterations more than 60 rules can be deleted.

5 Feature Selection by Learning of Consequent Parameters with Sparsity Constraints

Now the final step in our algorithm is to perform a final estimation of the linear consequent parameters $\vec{w}_i, i = 1, ...C_{rem}$ for all rules separately. Indeed, the outcome of Algorithm 1 contains not only the rule weights but also estimates the consequent parameters: these are optimized with standard weighted least squares method (and eventually plus a regularization term) in order to minimize least squares error. Here, we want to go a step further and make the consequent parameters also sparse, i.e. forcing as many of these as possible towards zero, again without loosing (significant) accuracy as optimized in an iterative optimization procedure called Semi-smooth Newton method. This evoke a local feature selection, as variables with low weights may be ignored. Furthermore, if through this selection scenario it turns out that certain variables have very low weights in all rules, it can be concluded that these ones are not necessary for the whole global fuzzy model at all.

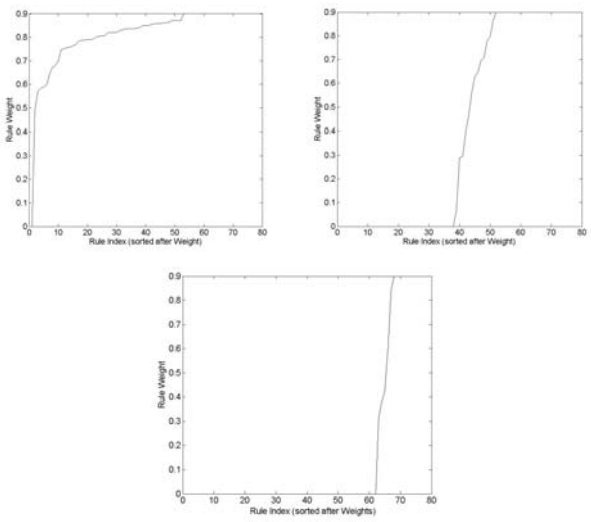

Figure 1: From left to right: sorted rule weights after iteration step 1, 7 and 13; note how the rule base is sparsed out from iteration to iteration (more and more rule weights become 0)

The consequent parameter $\vec{w}_i$ appear linearly in the Function F, in contrast to the rule weights. Although adding sparsity constraints make the optimization a nonlinear problem, because of the linear structure it seems favorable to use a Newton-type method for this problem. Despite the fact that a sparsity constraint problem is usually not differentiable, a generalized version of derivative (the slant derivative) can be defined and subsequently a Newton-type iteration (the Semi-smooth Newton method, [13]) can be applied. The main steps are a soft shrinkage operation on the residual and a Newton step, which makes use of active and inactive sets, see Algorithm 2. For the sake of simplicity, we define this algorithm for the ith rule. Local convergence for this iteration has been shown e.g. in [13].

Algorithm 2 Semi-Smooth Newton with Sparsity Constraints
Let $\sigma > 0$ and parameter k be an iteration index, and M_i the following covariance matrix for local learning

$$M_i = R_i^T Q_i R_i$$

then we apply the following steps:

1. Initialization is done by simply taking the latest estimated $\vec{w}$ (in the last iteration of Algorithm 1).
2. For the kth step we have already $\vec{w}_i^k$ evaluated
3. Step $k \to k + 1$:
   Calculate

$$\vec{u}_{ik} := \vec{w}_i^k - \sigma(R_i^T Q_i (R_i \vec{w}_i^k - \vec{y}))$$

4. Elicit in $\vec{u}_{ik}$ those indices which are greater or smaller than σ (with σ a small value, usually set to 0.1 and not sensitive):

$$\mathcal{A} := \{j : |(\vec{u}_i^k)_j| > \sigma\} \quad \mathcal{I} := \{j : |(\vec{u}_i^k)_j| \leq \sigma\}$$

ISBN: 978-989-95079-6-8

5. Calculate the residual by applying the sparsity constraint operator T_α as defined in (10):

$$\vec{r}_i^{\,k} = T_\alpha(\vec{w}_i^{\,k} - \sigma(R_i^T Q_i(R_i \vec{w}_i^{\,k} - \vec{y})))$$

6. Calculate the update: for all indices on the inactive set:

$$(update_I)_j = -(\vec{r}_i^{\,k})_j \quad \text{für all } j \in \mathcal{I}$$

7. Divide matrix M_i in active and inactive sets:

$$M_{\mathcal{A},\mathcal{A}} := (M_i)_{k,l}, \quad k,l \in calA$$

$$M_{\mathcal{A},\mathcal{I}} := (M_i)_{k,l}, \quad k \in calA, l \in calI$$

8. Calculate update on the inactive set:

$$(update_A)_j = (M_{\mathcal{A},\mathcal{A}})^{-1}\left(\frac{1}{\sigma}(-\vec{r}_i^{\,k})) - M_{\mathcal{A},\mathcal{I}} update_I\right)$$

9. Assign the consequent vector the current update vector one times for the active, one times for the inactive set:

$$\vec{w}_i^{\,k+1} = update$$

10. **If** the residual $\|\vec{r}_i^{\,k}\|$ is large and the iteration smaller than the maximal # of iterations, goto Step 2

An example of the impact of this algorithm on the development of the sparseness of the consequent parameters and hence local/global feature selection will be demonstrated in Section 7.

6 SparseFIS - The Algorithm

The whole *SpareFIS* method is simply obtained by combining the three algorithms described in the previous three sections to one, so applying iterative vector quantization first, then rule weight optimization and finally semi-smooth Newton method for sparse learning of consequent parameters. The explicit formulation is not made here due to space restrictions.

7 Evaluation

7.1 Experimental Setup

The evaluation of the novel method *SparseFIS* includes a comparison with other famous fuzzy batch learning algorithms such as *genfis2* [6] [23], *ANFIS* [15], *FMCLUST* [2] and the batch off-line version of the evolving fuzzy system approach *FLEXFIS* [17], which are all available as implementations in MATLAB. The evaluation will be based on five different high-dimensional data sets for regression: 1.) four data sets from the UCI repository [1] (clean, noise-free): auto-mpg, housing, forrest fires and concrete and 2.) one data set from an engine test bench, where measurement data were collected on-line and is affected by some white noise and disturbances.

The engine test bench data set includes various measurement channels together with their time delay (up to 10), the task was to build a high-performance k-step ahead prediction model for the emission channel NOX for two purposes: 1.) in order to save expenses for the sensor channel and 2.) to perform early recognition of faults (pipe leakage, sensor overheating, interface defects etc.) when using this model in a multi-channel fault detection approach.

A summary of the characteristics of all the data sets used in this evaluation is shown in Table 1. In all data set cases, the evaluation will be based on the accuracy of the models obtained by applying 10-fold cross-validation with a coupled best parameter grid search scenario. The later means that a parameter grid for the most essential parameter(s) in each method is defined consisting of a lower bound, an upper bound and a step-size and for each grid point cross-validation is performed. The best solution with respect to the CV-error (averaged mean absolute error over all folds or averaged maximal error over all folds) will be reported. For *SparseFIS* we will observe the impact of the sparsity constraints on local variable selection (per rule separately). The parameter grids were defined in the following way:

- *genfis2*: radius cluster is varied from 0.1 to 0.9 in steps of 0.05
- *ANFIS*: an initial model is constructed with genfis1 by specifying the number of fuzzy sets per input dimension varied from 2 to 5 in steps of 1
- *FMCLUST*: the number of rules is varied from 1 to 50 in steps of 1
- *FLEXFIS*: the vigilance parameter responsible for the number of clusters = rules is varied from 0.1 to 0.9 in steps of 0.05

For *SparseFIS*, we set the number of maximal allowed (initial) rules to 50 and τ to 0.05 for all experiments, requiring no parameter grid at all. All other parameters are set as mentioned in above algorithms.

7.2 Results

The obtained results are reported in Table 2. The rows represent the different methods and the columns the different data sets: the first number is the CV-error, i.e. the minimal averaged mean absolute error (averaged over the CV-folds, minimal over all parameter settings) plus-minus the standard deviation over these folds. The second number denotes the maximal error over all samples for the minimal averaged mean absolute error (so worst-case prediction error). The third number reports the complexity of the fuzzy models in terms of the number of rules (belonging to the model with minimal CV-error). The results on *SparseFIS* are reported two times, one time by using the full algorithm, one time without applying the sparsity constraint threshold T_α, so without forcing rule weights and consequent parameters towards zero (denoted as *SparseFIS uncon.*). From this table it can be realized that the full *SparseFIS* approach (with constraints) can outperform all other methods in three data sets (forrest fires, housing and NOX) in terms of mean absolute error (MAE), in the case of forest fires

even significantly. In the case of the auto-mpg data set, the new method performs similar than the other approaches, whereas for the concrete data set the *SparseFIS* is worse than the others. A similar interpretation of the results can be reported when inspecting the maximal error rate. The standard deviations shows us how sensitive the method is with respect to variations in the training data samples. Lower values represent less variations and hence more robust methods. The best performing methods for each data set with respect to the mean absolute error are shown in bold face. It is also worth mentioning that *SparseFIS* in its unconstrained version performs (mostly) weaker as the full approach; an explanation of this occurrence is that the short version tends to over-fit, as it does not reduce any rules or consequent parameters (and hence complexity).

Another important aspect when training fuzzy systems from data is a reasonable complexity of the obtained models in order to guide the models to more interpretable power [5]. Otherwise, the benefit of fuzzy models over other modelling techniques (such as neural networks, genetic programming etc.) is diminished. We measure the complexity of the final fuzzy models by the number of generated rules by the learning procedure applied onto the whole data set with the optimal parameter setting as obtained in the best parameter grid search and CV procedure. This number is reported in the third columns of each single part in Table 2. Here, we can realize that *SparseFIS* can compete with the other methods, although *genfis2* is mostly the best performer with respect to the number of generated rules. It is also remarkable that the numerical rule weight optimization concept as described in Algorithm 1 is able to reduce the number of rules from 50 to below 10 for all data sets (and this with a reasonable accuracy), confirming Figure 1.

Finally, in Figure 2 we inspect the impact of the sparsity constraints onto the linear consequent parameters as applied in Algorithm 2 (Step 4). Therefore, we show a plot of consequent parameters for all extracted rules (=rows) for the second (upper row) and the third features (lower row) in case of auto-mpg and using all input variables in *SparseFIS* method. While for the second feature four rules are sparsed out (compare left and right image in upper row), for the third feature all consequent parameters are forced to a small value around 0 which is not significant (note the range of this feature is 184). This means that feature #3 is not significant for modelling the target in the auto-mpg data set.

ISBN: 978-989-95079-6-8

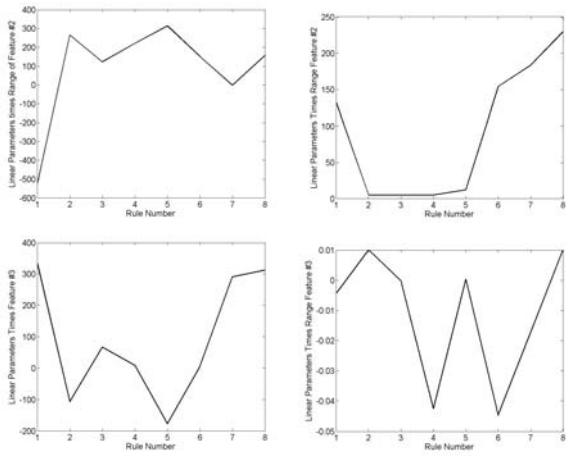

Figure 2: Left: Linear parameters times the ranges for features #2 (upper) and #3 (lower) when not applying sparsity constraints in consequent learning; right: the same as in left, but applying sparsity constraints

8 Conclusion

In this paper, we presented a novel data-driven learning technique for Takagi-Sugeno type fuzzy systems, called *SparseFIS*, which is able 1.) to perform rule selection together with consequent parameter estimation in a coherent optimization procedure and 2.) to gain more insight into the fuzzy models by yielding a local feature selection through sparsing out unimportant features in each rule. As a top-down method, it is possible to elicit an initial upper bound of number of (allowed) rules by expert-knowledge or by initial guess from the data. Tests on various multi-dimensional data sets from UCI repository and real-world applications show that the novel method can compete with other well-known learning methods in terms of both, accuracy and complexity and synchronously is able to put in more interpretation in from of local importance of the features.

Abstract— *We propose an approach for indexing fuzzy data based on inverted files that speeds up retrieval considerably by stopping the traversal of postings lists early. This is possible because the entries in the postings lists are organized in a way that guarantees that there are no matching items beyond a certain point in a list. Consequently, we can reduce the number of false positives significantly, leading to an increase in retrieval performance. We have implemented our approach and evaluated it experimentally, comparing it to an approach that has previously been shown to be superior to other methods.*

Keywords— fuzzy databases, access methods, inverted files, physical design

1 Introduction

Being able to handle imprecise or uncertain data becomes ever more important in today's world. There are numerous applications that have to manage imperfect data in areas such as knowledge discovery, mediator systems, information retrieval, multimedia, and profiling (vague) users' preferences. One way to model imprecision and uncertainty is to employ concepts from fuzzy set theory. Fuzzy sets are making their way into the database world, evidenced by the fact that several proposals for fuzzy database models and systems exist [1, 2, 3, 4, 5] (for an overview see [6]).

We are focusing on a well-known model for fuzzy databases, namely the possibilistic database model [5]. This approach uses the concepts of possibility and necessity measures for flexible querying. While this is an elegant way to formulate queries, indexing possibility distributions is not straightforward. Bosc and Galibourg introduced an indexing principle based on α-cuts (i.e. the elements of a fuzzy set with a membership degree of at least α) [7]. The parameter α is tied directly to a threshold value determined by a user defining a query, which makes it unrealistic to materialize dozens or even hundreds of α-cuts in different indexes to be able to answer various queries efficiently. For that reason Bosc and Galibourg developed a filtering mechanism based on the supports and cores of the indexed possibility distributions[1]. However, this can introduce a large number of false positives, as the filter only acts as a "quick-and-dirty" test. All the candidates that pass the filter have to be checked for eligibility in a second step.

We propose an access method for indexing possibility distributions that cuts down the number of false positives significantly. Many different α-cuts are stored compactly in a single index structure by arranging the references to possibility distributions in a clever way. The idea is based on impact ordering of inverted files used in information retrieval (IR). In IR systems, document references are sorted in descending order according to the term frequency value to make sure that important documents for a query are processed first [8]. In our case references to possibility distributions are sorted according to the certainty degrees of their elements, making it possible to stop scanning lists of references at an early stage (because we know that no eligible data items can follow). By applying customized gap compression schemes to the inverted files, we can store the lists very compactly.

The remainder of this paper is organized as follows. In the section immediately following this introduction, we cover basic definitions of possibilistic database systems and how to query them. In Section 3 we describe our access method in more detail and explain how to answer queries based on the possibility measure and those based on the necessity measure. Section 4 includes a brief description of the approach that we compared ours to. This is followed by a section on the experimental evaluation, specifying the environment in which this evaluation was run and presenting the results of the evaluation. We wrap up the paper with a conclusion and outlook in Section 6.

2 Preliminaries

Before going into details about indexing, let us briefly define possibility distributions and their application in flexible querying as defined in [5].

2.1 Possibilistic Databases

We assume (without loss of generality) n data items $(o_1, o_2, \ldots, o_n)$ in our database, all of which have an attribute A with a discrete domain Ω. The value of attribute A of data item o_i is described by a possibility distribution function $\pi_{A(o_i)}$ on Ω.

The possibility distribution $\pi_{A(o_i)}$ is a set of possible values for the attribute A of the data item o_i (together with the certainty of each value) and is defined as:

$$\pi_{A(o_i)} : \Omega \mapsto [0, 1] \tag{1}$$

$\pi_{A(o_i)}(\omega_j) = 0$ (for $\omega_j \in \Omega$) means that it is *impossible* that the attribute A can take on the value ω_j. $\pi_{A(o_i)}(\omega_j) = 1$, on the other hand, means that it is *completely* possible that A can take on the value ω_j. If we want to express that it might

[1]Supports and cores are special α-cuts.

ISBN: 978-989-95079-6-8

ω_1	$\rightarrow$	$\alpha_{1,1}$	$r(o_1^{1,1}), r(o_2^{1,1}), r(o_3^{1,1}), \ldots$	$\alpha_{1,2}$	$r(o_1^{1,2}), r(o_2^{1,2}), r(o_3^{1,2}), \ldots$	$\ldots$	$\ldots$
ω_2	$\rightarrow$	$\alpha_{2,1}$	$r(o_1^{2,1}), r(o_2^{2,1}), r(o_3^{2,1}), \ldots$	$\alpha_{2,2}$	$r(o_1^{2,2}), r(o_2^{2,2}), r(o_3^{2,2}), \ldots$	$\ldots$	$\ldots$
$\vdots$							
ω_m	$\rightarrow$	$\alpha_{m,1}$	$r(o_1^{m,1}), r(o_2^{m,1}), r(o_3^{m,1}), \ldots$	$\alpha_{m,2}$	$r(o_1^{m,2}), r(o_2^{m,2}), r(o_3^{m,2}), \ldots$	$\ldots$	$\ldots$

Figure 1: Inverted file index for fuzzy retrieval

be possible for A to take on the value ω_j, then we can assign a value from the interval $(0, 1)$ to $\pi_{A(o_i)}(\omega_j)$, depending on how plausible we think it is that A takes on this value. Not that the possible values for A are mutually exclusive, i.e. A takes on a single value, we are just uncertain about which one is the correct value. For reasons of consistency, $\pi_{A(o_i)}$ should be normalized, i.e. $\exists\omega \in \Omega : \pi_{A(o_i)}(\omega) = 1$.

As already mentioned, we assume that Ω is discrete, since we are interested in indexing scalar data. In the case of applications using continuous numerical data, we either have to discretize the possibility distribution or use a different kind of index structure [9]).

2.2 Flexible Querying

We not only allow imprecision in the data, but also flexible querying, i.e. the query condition c determining the acceptable values of an attribute is described by a normalized fuzzy set $\mu_c : \Omega \mapsto [0, 1]$.

In order to be able to check whether a data item satisfies a query condition, we need to introduce the concept of a fuzzy measure. Let X be an element of the power set of Ω ($X \in \mathcal{P}(\Omega)A$). The *possibility* of X, $\Pi(X)$, is measured by looking at the elements of X:

$$\Pi(X) = \max_{\omega \in X} \pi(\omega) \tag{2}$$

Possibility theory uses two concepts to measure the likeliness of X: the possibility measure, as already described above, $\Pi(X)$ and the necessity measure $N(X)$. The *necessity* of X, $N(X)$, is defined by the unlikeliness of the complement of X:

$$N(X) = 1 - \Pi(\overline{X}) \tag{3}$$

What does this mean for an attribute value satisfying a query condition c? The possibility of doing so is measured with the help of the possibility measure:

$$\Pi(c|A(o_i)) = \max_{\omega \in \Omega} \min(\mu_c(\omega), \pi_{A(o_i)}(\omega)) \tag{4}$$

Informally speaking, $\Pi(c|A(o_i))$ returns the highest degree to which $A(o_i)$ can possibly satisfy c.

The necessity of an attribute value satisfying query condition c is defined as:

$$N(c|A(o_i)) = \min_{\omega \in \Omega} \max(\mu_c(\omega), 1 - \pi_{A(o_i)}(\omega)) \tag{5}$$

$N(c|A(o_i))$, on the other hand, returns the degree to which $A(o_i)$ certainly satisfies c.

Usually users are interested in a small subset of data items in the database. Selective queries can be formulated by providing an acceptance threshold α (e.g. return all data items whose attribute values possibly satisfy c to at least a degree of 0.8: $\{o_i|\Pi(c|A(o_i)) \geq 0.8\}$). Furthermore, using the necessity measure also leads to more selective queries than using the possibility measure.

3 Indexing Possibility Distributions

As mentioned in Section 1 we use an inverted file index to index possibility distributions. An inverted file consists of a *directory* containing all distinct values $\omega_1, \omega_2, \ldots, \omega_m$ of the domain Ω and a *list* (also called a *postings list*) for each value.[2] Within each postings list of the inverted file, we sort the references to data items o_j, denoted by $r(o_j)$, in descending order of the degree of membership of w_i in $\pi_{A(o_j)}$. Since we want to apply gap compression (more on this later in Section 3.3), we arrange the references in blocks, each block preceded by a value $\alpha_{i,k}$, meaning that this is the k-th block of the posting list associated with ω_i. All attributes of the data items referenced in a block satisfy $\pi_{A(o_j)}(\omega_i) \geq \alpha_{i,k}$. Figure 1 illustrates the layout described above; note that the data items have superscripts indicating which block they belong to. The threshold values $\alpha_{i,k}$ divide up the interval [0,1] into equally-sized partitions (i.e. each block covers an equally-sized interval). Within each block all references to data items (in the form of IDs) are sorted in ascending order.

Depending on the query type, we access the inverted file index slightly differently. We will first look at queries based on the possibility measure and then turn to those based on the necessity measure.

3.1 Possibility Measure Queries

If we are searching for all data items o_j whose attribute A satisfies condition c possibly to a degree of at least α, we only have to look up the values ω_i in the inverted file for which $\mu_c(\omega_i) \geq \alpha$ (see Equation (4)). In addition to that, only data items for which $\pi_{A(o_j)}(\omega_i) \geq \alpha$ will qualify. During a search, we scan a postings list until we reach the first block whose value $\alpha_{i,l}$ is smaller than the query threshold value α.[3] If α is between $\alpha_{i,l-1}$ and $\alpha_{i,l}$, then we still have to check the data items referenced in this block whether they are false positives or not (as some of them could satisfy the query predicate). However, only the data items in this last block can be false

[2] For an overview of traditional inverted files see [10].

[3] Obviously, we also stop when we reach the end of a postings list.

ISBN: 978-989-95079-6-8

positives and have to be checked, all other data items referenced in earlier blocks will satisfy the query predicate and can be retrieved without checking for false positives. If α is equal to $\alpha_{i,l-1}$ we do not have to check the items of block $\alpha_{i,l}$. Actually, in this case we do not have to check for false positives at all.

3.2 Necessity Measure Queries

Processing queries based on the necessity measure can be done in two different ways, depending on the cardinality of the domain Ω. For large domains we can simply use possibility measure queries as a filter (we will call this method 'simplified' in the following); for small domains we can use the index described above to determine the answer set (without accessing the data items themselves).

The inequality $N(X) \leq \Pi(X)$ always holds for necessity and possibility measures, i.e. $N(c|A(o_i)) \geq \alpha \Rightarrow \Pi(c|A(o_i)) \geq \alpha$. So instead of directly searching for the data items that satisfy the query condition c necessarily to the degree α, we search for data items satisfying c possibly. We retrieve these data items and check if they also satisfy c necessarily. A drawback of this technique is that we introduce false positives, due to the data items that satisfy c possibly but not necessarily.

Accessing all the candidates returned by the possibility measure query in the simplified processing will cause a lot of random I/O. However, we can use the inverted file index to help us in sorting out false positives returned by a possibility measure search. If we can find an ω_i for a data item o_j such that $\max(\mu_c(\omega_i), 1 - \pi_{A(o_j)}(\omega_i)) < \alpha$, then we know that $A(o_j)$ cannot satisfy c necessarily (more on this in just a moment, see also Equation 5). Having a value for $\mu_c(\omega_i)$ that is greater or equal to α will never result in $\max(\mu_c(\omega_i), 1-\pi_{A(o_j)}(\omega_i)) < \alpha$. So in order to sort out false positives, we have to access the postings lists of the values ω_i for which $\mu_c(\omega_i) < \alpha$. Unfortunately, this means we have to look up the complement of the values ω_i used for the possibility measure query and scan the corresponding postings lists.[4] (Consequently, this will only be efficient for relatively small domains.) During query processing, we keep scanning such a postings list in a blockwise fashion as long as $\alpha_{i,l} > 1 - \alpha$ holds and we stop as soon as this condition is not satisfied anymore.[5] Any references to data items found during this scan can be safely discarded from the candidates determined by the possibility measure query. The reasoning is the following: while $\alpha_{i,l} > 1 - \alpha$, we know that for all data items referenced in this block $\pi_{A(o_j)}(\omega_i) > 1 - \alpha$ ($\Leftrightarrow 1 - \pi_{A(o_j)}(\omega_i) < \alpha$) holds. Together with $\mu_c(\omega_i) < \alpha$, this means that $A(o_j)$ cannot satisfy c necessarily. Once $\alpha_{i,l}$ drops below $1 - \alpha$, we do not have enough information to determine whether the data items referenced in this block (and the following blocks) satisfy c necessarily or not and we stop scanning the list further. All the data items remaining in the candidate set after scanning the lists of the ω_i for which $\mu_c(\omega_i) < \alpha$ have to be fetched and checked for false positives.

[4] This is why we will also call this approach complement-based.

[5] Again, we also stop when reaching the end of a list.

3.3 Index Compression

The reason for arranging the references to data items in blocks is that we can use gap encoding on the ascending sequences of data item IDs. For example, instead of storing the sequence 103,110,114,116,121 we store 103,7,4,2,5. Compared to absolute ID numbers, relative gaps can be stored using less storage space. However, from time to time even gaps can become quite large, i.e. a large gap could need almost as much storage space as a regular ID. So that we do not have to allocate the same space for each gap, we use variable length encoding [11]. The main idea is to use few bits for small gaps and many bits for large gaps.

In order to keep the codewords byte-aligned for faster processing, we use Variable-Byte (VB) code [12]. Each byte contains a so-called continuation bit, which signals if the end of the current codeword has been reached or if we have to continue decoding. Usually the high bit is dedicated to this purpose, while the lower 7 bits of each byte encode gap information. If a gap fits into 7 bits, then we encode this gap in the lower 7 bits and set the continuation bit to 1. Otherwise, we encode the highest bits of the gap and set the continuation bit to 0. The remaining bits are encoded in the same manner. VB-encoding is a good compromise between compression ratio and processing speed. For example, encoding 5 in VB-code would result in **1**0000101, while encoding 824 would result in **0**0000110 **1**0111000 (where the bits in boldface are the continuation bits).

Instead of using floating-point numbers for the threshold levels $\alpha_{i,k}$ directly in the index, we store IDs of threshold levels using a one-byte integer, looking up the floating-point values in a table mapping the IDs to these values. Due to the fixed threshold levels we use throughout the whole index, we can do this. As we will see later in the evaluation section, 256 different threshold levels are more than enough. If more than 256 threshold levels should be needed, we can apply VB-encoding to the threshold levels as well.

4 Comparison to Existing Approach

We use the approach by Bosc and Galibourg [7] as a reference for comparison. There are two special α-cuts, the *core* $L_1(\mu_F)$ and the *support* $L_{>0}(\mu_F)$ of a fuzzy set F. Bosc and Galibourg have shown that the following implications hold (for all $\alpha > 0$):

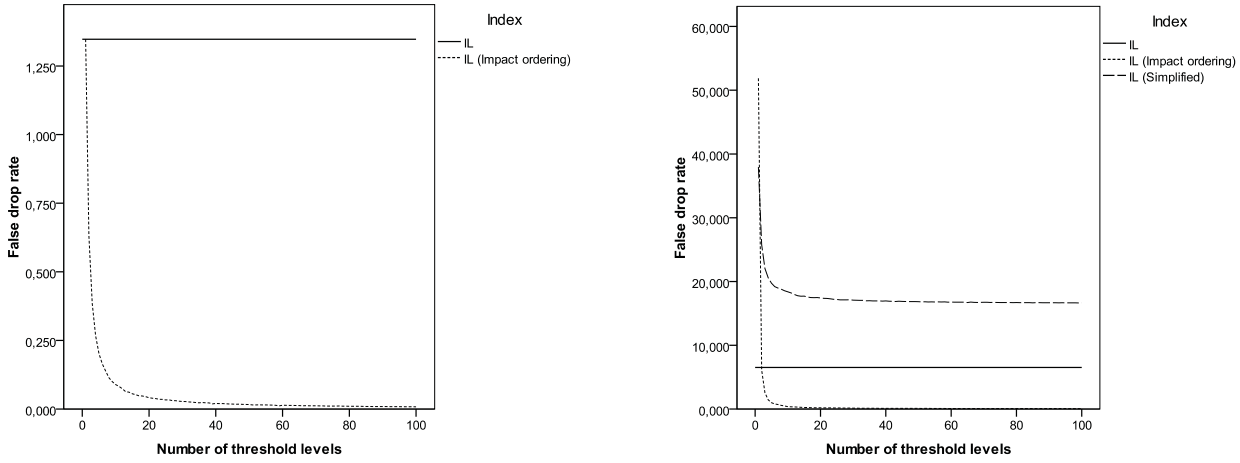
$$\Pi(c|A(o_i)) \geq \alpha \quad \Rightarrow \quad L_{>0}(\pi_{A(o_i)}) \cap L_\alpha(\mu_c) \neq \emptyset \qquad (6)$$

$$N(c|A(o_i)) \geq \alpha \quad \Rightarrow \quad L_1(\pi_{A(o_i)}) \subseteq L_\alpha(\mu_c) \qquad (7)$$

Given a query condition c we have to determine whether the α-cut of μ_c ($L_\alpha(\mu_c)$ intersects with the support of a data item's attribute value (for possibility queries) or if the core of the attribute value is a subset of $L_\alpha(\mu_c)$ (for necessity queries). If this is not the case, then we can safely discard a data item, as it will not satisfy the original query condition.

We implemented this technique using the same framework as for our approach, i.e. using compressed inverted files for indexing the cores and supports of possibility distributions. The index containing the cores stores the cardinality of each core together with the reference to the possibility distribution. In

ISBN: 978-989-95079-6-8



(a) Possibility measure

(b) Necessity measure

Figure 2: False drop rates

this way, superset queries (as described in Equation (7)) can be answered using an inverted file by filtering out all references whose cores have a higher cardinality than the query set. For a more detailed description on how to optimize this kind of data structure, see [13] (comparisons to other data structures can also be found in this paper; the inverted file approach, however, was the data structure with the best performance among all those that were tested).

5 Experimental Evaluation

5.1 Benchmark Environment

The benchmarks were run on a Pentium 4 (3.2 GHz) PC with 1GByte main memory running Windows XP. The index structures and a simulator for the storage system were implemented in Java 1.6. We decided to implement the simulator in Java, as this makes us platform-independent. The simulator allows us to avoid unwanted effects due to caching. We set the block size of the simulator to a page size of 4K, which is the page size of the underlying operating system.

We generated possibility distributions for the data items using the following parameters: the domain size ($|\Omega|$) is equal to 25 and the database size is equal to 100K data items (each data item is associated with a possibility distribution). The elements of a particular possibility distribution are taken randomly from the domain, using a uniform distribution. This means that we first determine the cardinality of the support of a possibility distribution, which is uniformly distributed in [1,22] (22 elements cover 90% of the domain). All the elements in the domain have the same probability of making it into the support. The membership degrees of the chosen elements are uniformly distributed in (0,1.0]. If a possibility distribution is not normalized, the highest degree is converted to 1.0.

In this paper we wanted to focus on typical fuzzy scalar domains, therefore we decided to keep the domain cardinality rather small. This is motivated by the fact that the elements of fuzzy domains usually represent categories. Normally these categories are determined by experts based on the criteria (1) that they should be easy to use by ordinary users and (2) that fuzzy relations (allowing flexible comparisons) can be defined on them. It is much easier to satisfy both criteria with a small domain cardinality; that is why typical fuzzy scalar domains are rather small.

Another important parameter is the clustering of the data items on disk pages. For the results shown in this paper we assume a "worst-case scenario" in terms of indexing, meaning that all the candidate items returned by the index are stored in consecutive blocks with 64.5 data items sharing a block on average. This will lessen the effect that false drops have on the retrieval performance, as we do not need a separate page access to fetch each of the false drops.

5.2 Results

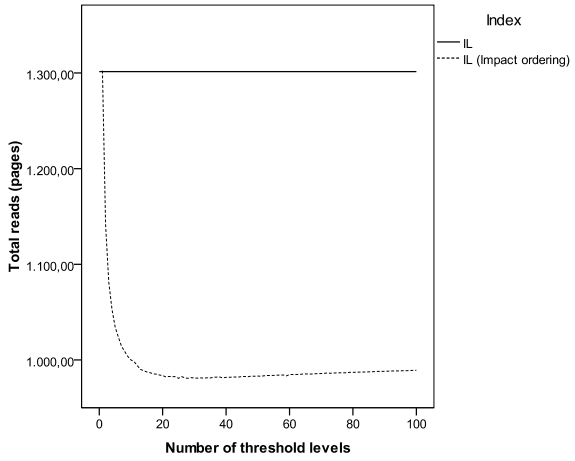
We were interested in several criteria, most importantly in the false drop ratio of the two different approaches and its impact on the query performance. To a lesser extent we also wanted to make sure that the overhead in terms of the index size is not prohibitive. Furthermore, we investigate the impact of the query threshold α on the performance of the indexes. In Sections 5.2.1 to 5.2.3 our competitor is included as a reference; the parameter we vary (number of threshold levels) only applies to our approach in these cases.

5.2.1 False Drop Rate

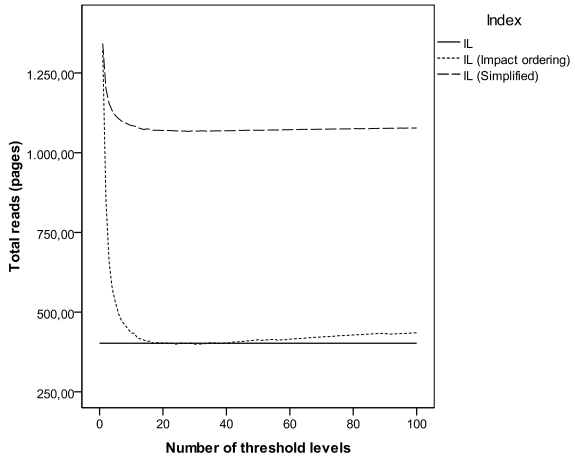
Figure 2 shows the results we obtained for measuring the false drop rate for varying the number of threshold levels in our index (Figure 2(a) depicts the results for possibility measure queries, while Figure 2(b) depicts those for necessity measure queries[6]). Each threshold level covers an equally-sized interval in [0,1]. The false drop rate is measured in the following way: (total number of IDs returned by index - number of true positives)/number of true positives. As can be clearly seen, adding more threshold levels to the data structure reduces the false drop ratio. However, the law of diminishing returns applies to this, i.e. with each added threshold level the improvement gain decreases. We can also notice that using a

[6]The method labeled 'simplified' applies possibility measures as a filter, while the other curve shows the results for the complement-based approach.

ISBN: 978-989-95079-6-8



(a) Possibility measure



(b) Necessity measure

Figure 3: Total number of page accesses

possibility measure as a filter for a necessity measure is not competitive in this scenario.

5.2.2 Retrieval Performance

While the false drop rate suggests to use a very high number of threshold levels, it is not as simple as that to determine the optimal number of threshold levels. By increasing the number of threshold levels we introduce an overhead in terms of index size and retrieval performance (larger indexes result in a longer query processing time). Let us first look at the retrieval performance of the access methods. Figure 3 shows the retrieval performance in total number of page accesses (part (a) for possibility measure queries and part (b) for necessity measure queries). The total number of page accesses includes the page accesses needed to navigate the index and the pages accessed for retrieving all candidate data items (false and true positives).

There is a sharp decrease in the number of page accesses when going from one threshold level to about twenty threshold levels. This is caused by the rapidly dropping false drop ratio. Then the curve peters out and slowly goes up again. In this part of the curve, the drop in performance, due to the aforementioned overhead, gains the upper hand over the slowly decreasing false drop rate. In our benchmark scenario we have identified 25 to be the optimal number of threshold levels for possibility measure queries and 28 to be the optimum for necessity measure queries. Again, the approach using the possibility measure as a filter for necessity measure queries is not competitive, so we will drop it from the graphs in the following sections.

5.2.3 Index Size

In Figure 4 we present the size of the index structures in terms of disk pages. The overhead added for introducing a larger number of threshold levels can be clearly seen. This is caused by a deterioration of the compression ratio. A few larger threshold blocks with smaller gaps between the IDs can be compressed better than a lot of smaller blocks with larger gaps. The stair-like appearance is caused by postings lists expanding by one page at roughly the same time (due to the uniform distribution of domain elements in the possibility distributions). At first glance it seems that our index structure needs more storage space than our competitor. However, as we only need about 20 to 30 threshold levels, this increase is only moderate and, more importantly, we can answer both, possibility measure and necessity measure, queries with the same index. For the other scheme separate indexes are needed (one storing the supports and one storing the cores of the possibility distributions).

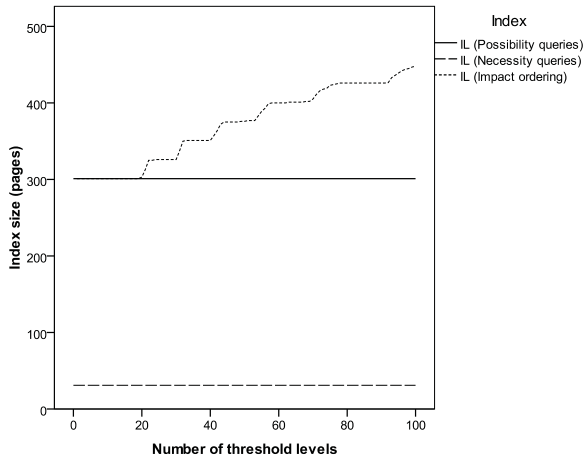


Figure 4: Index size

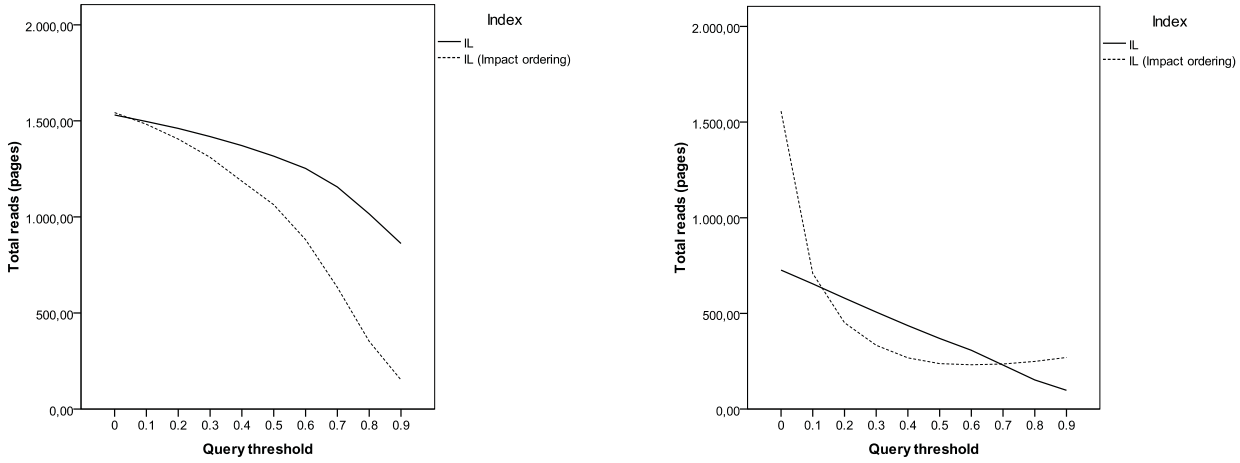
5.2.4 Impact of Query Threshold

Figure 5 shows the impact of the query threshold (α) on the performance. Generally, as the query threshold grows for possibility measure queries (Figure 5(a)), we have to check smaller and smaller parts of the query set (only elements that have a membership degree larger than or equal to α have to be considered). This in turn decreases the number of postings lists we have to traverse, leading to less page accesses. In addition to this, our approach can stop scanning postings lists earlier for higher query thresholds, leading to further improve-

ISBN: 978-989-95079-6-8



(a) Possibility measure

(b) Necessity measure

Figure 5: Impact of query threshold

ment in terms of the number of page accesses.

For necessity measure queries ((Figure 5(b)), things are more complicated. For the core-filtering approach by Bosc and Galibourg the number of postings lists we have to scan decreases with increasing threshold α. For our approach there are two effects at work. With increasing α the false drop rate drops, which leads to fewer page accesses due to false positives. However, with increasing threshold values the number of page accesses in the index increases. Although the number and lengths of postings list traversals for the possibility measure filter step goes down, the number and lengths of postings list scans for the subsequent complementary check on the necessity measure goes up at quite a fast rate. At some point this effect catches up with us and the number of accessed blocks increases again.

6 Conclusion and Outlook

We have shown how to build an index that stores threshold levels of possibility distributions in a compact way. Being able to represent possibility distributions using a much finer granularity than existing approaches helps us in reducing the number of false positives significantly. Even in an unfavorable environment, our index far outperforms existing approaches for possibility measure queries and was on a par for necessity measure queries. This kind of performance can already be achieved by introducing only a moderate number of threshold levels, meaning that there is practically no overhead, since we only need to maintain one index (while our main competitor needs one for possibility measure queries and one for necessity measure queries).

For future work we would like to analyze how to optimize the number and distribution of threshold levels given a fixed database. Even more interesting would be to optimize and update the index in a dynamic way, given a database with statistics on query workloads.

***Abstract*— *The problem of segmentation is an important research field and often a critical and decisive preprocessing step for many image processing applications. During the past years, the use of colour images instead of gray images is growing fast in many research areas. Moreover, the use of segmentation over colour images is advised when additional colour information conveyed is necessary to further discriminate the image regions. Recently, fuzzy logic theory, and Atanassov's intuitionistic fuzzy sets (A-IFSs), have been successfully applied to image segmentation and, in this paper we propose a general methodology for RGB colour image segmentation based on A-IFSs. The proposed methodology is based on a multilevel colour thresholding framework that uses Atanassov's intuitionistic index values for representing the uncertainty present in the assigning of the pixels to the different regions. This framework is to be applied to each RGB component separately to finally aggregate the results of the three components. The number of thresholds is auto established by the methodology based on the image entropy. Experimental results are presented.*

Keywords— Atanassov's Intuitionistic Fuzzy Sets, Color Image Segmentation, Fuzzy Logic, Multi-Thresholding.

1 Introduction

Color image segmentation deals with the subdivision of an image into disjoined regions according to the pixels colour with the goal of finding the image objects. As a result of the segmentation, the original set of pixels in the image is partitioned into a finite set of separated regions (objects).

Within the framework of fuzzy theory [1, 2, 3, 4], segmentation algorithms that use the concept of fuzzy entropy [1, 3, 5] are widely used in image processing applications. In previous works [6] we have proposed methodologies for image segmentation that use A-IFSs [7, 8, 9]. In those methodologies, Atanassov's intuitionistic fuzzy index values are used for representing the uncertainty/impresision on determining whether a pixel of the image belongs to an object of that image.

The general framework presented in [6] is the basis for colour segmentation framework proposed in this paper where it is extended to a multi-level thresholding framework since, often, images include several regions and, thus, it is necessary to compute more than one threshold in order to correctly segment the image.

In this methodology we use RGB images in such way that each RGB component is primarily segmented separately. After the three components are segmented we then aggregate the three segmented components into the final segmented image. For each component, the number of computed thresholds is automatically determined by the methodology on the basis of the images intuitionistic fuzzy entropy. This entropy is obtained trough the Atanassov's intuitionistic fuzzy index values.

The remainder of this paper is organized as follows: In Section 2 we describe the proposed methodology. Section 3 presents the experimental results obtained and, finally, in Section 4 some conclusions and some lines of future work are presented.

2 Proposed methodology

In this section we present the proposed methodology for colour image segmentation that besides its low computational cost is also able to auto determine the number of required thresholds based on the image intuitionistic fuzzy entropy.

Since this methodology deals with each RGB component separately, we will only describe the algorithm for one of the components. The exact same algorithm is to be applied to the other two components.

This methodology successively applies the bi-level thresholding algorithm proposed in [6], for the computation of one threshold, an unspecified number of times to an image, resulting in a set of thresholds for each RGB component. After the number of required thresholds needed for each RGB component are computed, the total number of thresholds is calculated and, on the basis of that number, the three component segmentations are combined in order to create a resulting gray segmented image. The combination of the components is made by adding all three intensities and afterwards normalizing them back to the original scale. Different ways of combining the three RGB thresholds can be explored.

Thus, in the following sub-sections, we will first describe the bi-level thresholding algorithm used and, in the last subsection the multi-level thresholding algorithm.

2.1 Bi-level Thresholding Algorithm

In this section we describe the general framework for image thresholding using A-IFSs and restricted dissimilarity functions proposed in [6]. The goal is to obtain the better threshold in order to separate the object from the background.

We will denote by (x, y) the coordinates of each pixel on the image Q, being $q(x, y)$ the gray level of the pixel (x, y) so that $0 \leq q(x, y) \leq L - 1$ for each $(x, y) \in Q$ where L is the image grayscale.

In this methodology Atanassov Intuitionistic Fuzzy Sets are used in the following way: In order to choose/construct the

ISBN: 978-989-95079-6-8

membership function of each pixel of the image to the associated fuzzy set, three numerical values are assigned to each one of them.

- A value for representing the expert knowledge of the membership of the pixel to the background. A membership function, constructed using dissimilarity functions, is used to obtain this value (see [10]).
- Dissimilarity functions are also used by the expert to construct a membership function to retrieve a value for representing the expert knowledge of the membership of the pixel to the object.
- The expert knowledge/ignorance, in determining the above mentioned membership functions, is represented by a third value obtained trough Atanassov's intuitionistic index.

In this sense, L fuzzy sets Q_{Bt} associated with the background and L fuzzy sets Q_{Ot} associated with the object are constructed. Each one of these fuzzy sets is associated with a gray level t of the grayscale L used. The membership functions of these sets are defined by means of restricted dissimilarity functions and, two of the possible expressions one might use are:

$$\mu_{Q_{Bt}}(q) = F\left(d\left(\frac{q}{L-1}, \frac{m_{\mathrm{B}}(t)}{L-1}\right)\right)$$

$$\mu_{Q_{Ot}}(q) = F\left(d\left(\frac{q}{L-1}, \frac{m_{\mathrm{O}}(t)}{L-1}\right)\right)$$

where

$$m_{\mathrm{B}}(t) = \frac{\sum_{q=0}^{t} qh(q)}{\sum_{q=0}^{t} h(q)} \quad (1)$$

$$m_{\mathrm{O}}(t) = \frac{\sum_{q=t+1}^{L-1} qh(q)}{\sum_{q=t+1}^{L-1} h(q)} \quad (2)$$

being $h(q)$ the number of pixels of the image with the gray level q, $F(x) = 1-0.5x$ and, the restricted dissimilarity function $d(x, y) = |x - y|$ (see [6, 11, 12]).

Due to these constructions, the membership functions constructed are always greater than or equal to 0.5 and, a pixel unequivocally belongs to one of the regions (object or background) if and only if its intensity q is equal to the mean of intensities of the that region ($m_O(t)$ or $m_B(t)$). When the difference between the pixel's intensity q and the mean of intensities of the region is maximal, then the value of its membership function to that region is minimal. Thus, the lesser the distance between a pixel's intensity q and the mean of intensities of the region, the greater the value of its membership to that region.

In this methodology, it is considered that the membership functions ($\mu_{Q_{Bt}}$ and $\mu_{Q_{Ot}}$) indicate the expert's degree of knowledge of the pixel belonging to the regions, meaning that, the Atanassov's intuitionistic fuzzy index (π) represents the ignorance/intuition present in the construction of these fuzzy sets.

Thus, the value represented by Atanassov's intuitionistic index indicates the knowledge/ignorance of the expert when assigning a pixel either to the background or the object. The Atanassov's intuitionistic index value associated with a pixel has the value of zero, when the expert is absolutely sure of that pixel belonging (either to the background or the object). The Atanassov's intuitionistic index value increases with respect to the ignorance/intuition of the expert as to whether the pixel belongs to the background or the object. If the expert doesn't know if a pixel belongs to the background or the object, its membership to both must be represented with the value 0.5 and, it is said that the expert used the greatest ignorance/intuition allowed in the construction of the membership functions, of the set associated with that pixel, to the background and the object resulting in a Atanassov's Intuitionistic Fuzzy Index maximum value. For this reason, A-IFSs (Atanassov's Intuitionistic Fuzzy Set [8, 13]) are used.

However, the ignorance/intuition should have the least possible influence on the choice of the membership degree. In this methodology the ignorance/intuition will have a maximum influence of 25 percent.

Under these conditions, within the set of all the possible expressions(see [6]), the following expression is used to calculate π:

$$\pi(q) = \wedge(1 - \mu_{Q_{Bt}}(q), 1 - \mu_{Q_{Ot}}(q)).$$

This π is now used to construct an A-IFS with each one of the fuzzy sets Q_{Bt} and Q_{Ot}.

$$\tilde{Q}_{Bt} = \{(q, \mu_{\tilde{Q}_{Bt}}(q), \nu_{\tilde{Q}_{Bt}}(q)) | q = 0, 1, \cdots, L-1\},$$

given by

$$\mu_{\tilde{Q}_{Bt}}(q) = \mu_{Q_{Bt}}(q)$$
$$\nu_{\tilde{Q}_{Bt}}(q) = 1 - \mu_{\tilde{Q}_{Bt}}(q) - \pi(q)$$

and

$$\tilde{Q}_{Ot} = \{(q, \mu_{\tilde{Q}_{Ot}}(q), \nu_{\tilde{Q}_{Ot}}(q)) | q = 0, 1, \cdots, L-1\},$$

given by

$$\mu_{\tilde{Q}_{Ot}}(q) = \mu_{Q_{Ot}}(q)$$
$$\nu_{\tilde{Q}_{Ot}}(q) = 1 - \mu_{\tilde{Q}_{Ot}}(q) - \pi(q)$$

At this stage, the Atanassov's intuitionistic fuzzy index is used to calculate the entropy IE of each one of the L Atanassov's intuitionistic fuzzy sets associated with the image.

The following expression is used to calculate the entropy IE, so that $0 \leq IE(\tilde{Q}_{Bt}) \leq 0.25$.

$$IE(\tilde{Q}_{Bt}) = \frac{1}{N \times M} \sum_{q=0}^{L-1} h(q) \cdot \pi(q) \quad (3)$$

where $N \times M$ are the image dimensions in pixels.

This way, the entropy on A-IFSs is interpreted as a measure of the degree of a A-IFS that a set has with respect to the fuzzyness of the said set (see [14]). Under these conditions, the entropy will be null when the set is a FSs and will be maximum when the set is totally intuitionistic.

ISBN: 978-989-95079-6-8

Finally, the gray level associated with the Atanassov's intuitionistic fuzzy set $\tilde{Q}_{Bt}$ of lowest entropy IE is selected as the best threshold.

2.2 *Multi-level Thresholding Algorithm*

In this approach, the goal is to obtain a set of thresholds in order to separate all the image objects. This method is based on a divide and conquer strategy and its main idea is to successively apply the algorithm proposed in [6] and presented in the last section, for the computation of one threshold, an unspecified number of times to an image. In Fig. 1 we illustrate the methodology computational process progress.

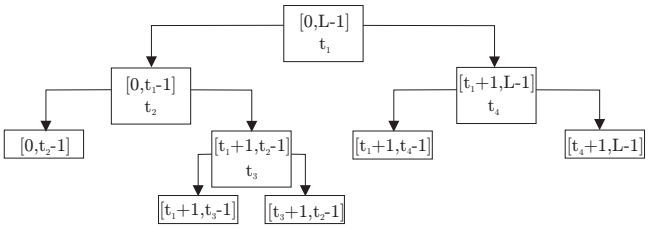

Figure 1: Computational process progress

First, the algorithm is applied to the original image resulting in the determination of the threshold value t_i. This threshold value is then used to create two sub-images: the sub-image with intensity values lower than t_i and the sub-image with intensity values greater than t_i. Then, the algorithm is to be applied to the sub-image which has the greater amplitude between gray-levels entropy values (difference between the intensity value of maximum entropy and the one of minimum entropy).

Hence, The proposed algorithm consecutively divides the resulting sub-images by means of the threshold value t_i obtained through the application of the algorithm for the computation of one threshold to each one of them.

The algorithms stopping criteria is based on the sub-images gray-levels entropy values in such way that the process stops when the difference between the entropy of the computed threshold value t_i and the maximum entropy of the sub-image that generated it, is inferior to the difference between the maximum and minimum entropies of the entire image divided by a constant K.

After experimental evaluation, the value of the constant K was set to 2.

The number of computed thresholds is closely related to the value of this constant K. This value is directly proportional to the number of computed thresholds since, the maximum difference of global entropy allowed for each sub-image to produce a new threshold is inversely proportional to the value of K. Thus, the value of the constant K can be chosen according to the purpose of the application where the algorithm is to be applied.

3 Experimental results

In order to illustrate the methodology we used the "Lena" image in Fig. 2 and Fig. 3.

In Fig. 2 the original "Lena" image and the segmentation result are presented. In Fig. 3, in the first column, we present

Figure 2: Original and segmented "Lena" image.

the image decomposed in its RGB components and, in the second column, each RGB component segmentation result is presented. For all the "Lena" segmented images the number of computed thresholds is also presented.

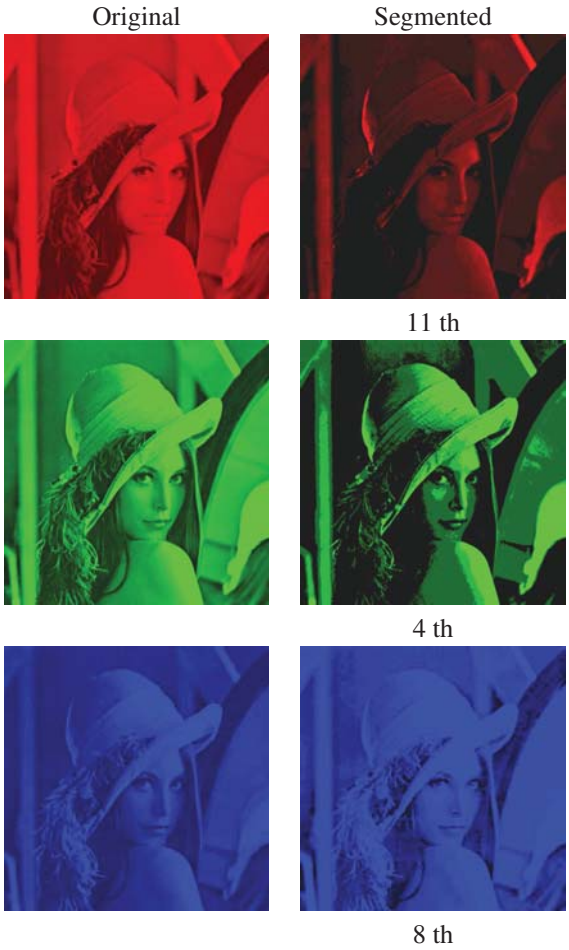

Figure 3: Original and segmented RGB components of "Lena" image.

Regarding the number of computed thresholds in each RGB component we can conclude that, as one can see looking at he original image, the red component is the one that has more information regarding the segmentation of the image and, therefore the red component was the one with more computed thresholds. We think that this is an indicator of the goodness of the methodology since it was able to accurately auto determine the required number of thresholds in each component

ISBN: 978-989-95079-6-8

separately.

Looking at Fig. 3, we can also see that the RGB components are highly related. We consider this to be the major drawback of segmenting images in the RGB colour space.

To test the performance of the proposed approach, more than a hundred images where segmented. However, in order to illustrate the obtained results, 5 images from the original set of images (taken form the Berkeley Segmentation Dataset: `http://www.eecs.berkeley.edu/Research/Projects/CS/vision/grouping/segbench/`) were selected and used as test images (see Fig. 4).

Figure 4: Original and segmented test images.

In Fig 4 we present the results from the application of the proposed methodology to complex images where, the value of the constant K was also set at 2 and, where we can see that the main features of the images are preserved.

4 Conclusions and Future Work

Since, an image usually contains more than one region, in this paper we presented a new extension of an existing method, that uses A-IFSs for multi-level colour image segmentation. The algorithm first segments each RGB component separately and finally combines them in order to obtain the final segmented image. The use of A-IFSs allowed us to use entropy in the same sense as fuzzy entropy is used in the fuzzy algorithms and, consequently, allowed us to endow the methodology with the capability of dealing with uncertainty.

The proposed methodology successively applies a bi-level thresholding algorithm an undetermined number of times to an image RGB component subdividing it into several disjoined regions. Moreover, the algorithm is able to auto determine the number of thresholds required to segment each RGB image component.

Considering the experimental results, we can say that, in general terms, the proposed algorithm provides suitable results and therefore can be considered when colour image segmentation applications are needed.

The proposed methodology is parameterizable through the setting of a constant K. The value of this constant is directly proportional to the optimal number of thresholds computed. Thus, the value of the constant K should always depend of the application needs. Future work is intended to study the incorporation of heuristics in the algorithm through the setting of the constant K value. Different combinations of the resulting thresholds of each one of the RGB components can be an object of future work in order to incorporate the perceptual differences among the three components.

Due to the high correlation between the three RGB components, further work is also intended to apply an extension of this algorithm to images in the HSV colour space. Being the HSV colour space a more intuitive color space, it's our belief that a more coherent segmentation will be achieved.

***Abstract*—*This paper presents SaM, a split and merge algorithm for frequent item set mining. Its distinguishing qualities are an exceptionally simple algorithm and data structure, which not only render it easy to implement, but also convenient to execute on external storage. Furthermore, it can easily be extended to allow for "fuzzy" frequent item set mining in the sense that missing items can be inserted into transactions with a user-specified penalty. In order to demonstrate its performance, we report experiments comparing it with the "fuzzy" frequent item set mining version of RElim (an algorithm we suggested in an earlier paper [15] and improved in the meantime).*

Keywords— data mining, frequent item set mining, fuzzy frequent item set, fault tolerant data mining

1 Introduction

Although frequent item set mining and association rule induction has been a focus of research in data mining for a long time now, leading to well-known algorithms like Apriori [1], Eclat [11] and FP-growth [7], there is still room for improvement. Recent research lines include filtering the found frequent item sets and association rules [16, 17], identifying temporal changes in discovered patterns [3, 4], and mining fault-tolerant or "fuzzy" frequent item sets [6, 10, 15].

In this paper we follow the last of these lines by presenting SaM, a split and merge algorithm for frequent item set mining, which can easily be extended to allow for "fuzzy" mining in the sense that missing items can be inserted into transactions with a user-specified penalty. Other distinguishing qualities of our method are its exceptionally simple processing scheme and data structure, which not only render it very easy to implement, but also convenient to execute on external storage.

2 Frequent Item Set Mining

Frequent item set mining is the following task: we are given a set B of *items*, called the *item base*, and a database T of *transactions*. An item may, for example, represent a product, and the item base may then represent the set of all products offered by a supermarket. The term *item set* refers to any subset of the item base B. Each transaction is an item set and may represent, in the supermarket setting, a set of products that has been bought by a customer. Since several customers may have bought the exact same set of products, the total of all transactions must be represented as a vector or a multiset (or, alternatively, each transaction must be enhanced by a *transaction identifier (tid)*). Note that the item base B is usually not given explicitly, but only implicitly as the union of all transactions. The *support* $s_T(I)$ of an item set $I \subseteq B$ is the number of transactions in the database T it is contained in. Given a user-specified *minimum support* $s_{\min} \in \mathbb{N}$, an item set I is called *frequent* (in T) iff $s_T(I) \geq s_{\min}$. The goal of frequent item set mining is to find all item sets $I \subseteq B$ that are frequent in the database T and thus, in the supermarket setting, to identify all sets of products that are frequently bought together.

A standard approach to find all frequent item sets w.r.t. a given database T and a support threshold $s_{\min}$, is a *depth-first search* in the subset lattice of the item base B. This approach can be seen as a simple *divide-and-conquer* scheme. For a chosen item i, the problem to find all frequent item sets is split into two subproblems: (1) find all frequent item sets containing i and (2) find all frequent item sets *not* containing i. Each subproblem is then further divided based on another item j: find all frequent item sets containing (1.1) both i and j, (1.2) i, but not j, (2.1) j, but not i, (2.2) neither i nor j etc.

All subproblems occurring in this recursion can be defined by a *conditional transaction database* and a *prefix*. The prefix is a set of items that has to be added to all frequent item sets that are discovered in the conditional database. Formally, all subproblems are tuples $S = (C, P)$, where C is a conditional database and $P \subseteq B$ is a prefix. The initial problem, with which the recursion is started, is $S = (T, \emptyset)$, where T is the given transaction database and the prefix is empty.

A subproblem $S_0 = (C_0, P_0)$ is processed as follows: choose an item $i \in B_0$, where B_0 is the set of items occurring in C_0. This choice is arbitrary, but usually follows some predefined order of the items. If $s_{C_0}(i) \geq s_{\min}$, then report the item set $P_0 \cup \{i\}$ as frequent with the support $s_{C_0}(i)$, and form the subproblem $S_1 = (C_1, P_1)$ with $P_1 = P_0 \cup \{i\}$. The conditional database C_1 comprises all transactions in C_0 that contain i, but with this item removed. This implies that all transactions are removed that do not contain any no other item than i. If C_1 is not empty, process S_1 recursively. In any case (that is, regardless of whether $s_{C_0}(i) \geq s_{\min}$ or not), form the subproblem $S_2 = (C_2, P_2)$ with $P_2 = P_0$. The conditional database C_2 comprises all transactions in C_0 (including those that do not contain i), but again with the item i removed. If C_2 is not empty, process S_2 recursively.

This recursive scheme is adopted by Eclat, FP-growth, RElim and several other frequent item set mining algorithms. They differ in how conditional transaction databases are represented: in a *horizontal representation*, a database is stored as a list (or array) of transactions, each of which lists the items contained in it. In a *vertical representation*, the items are first referred to with a list (or array) and for each item the transactions containing it are listed. However, this distinction is not pure, since there are combinations of the two forms of representing a database. Our SaM algorithm is, as far as we know, the first algorithm that is based on the general scheme outlined above and uses a purely horizontal representation.

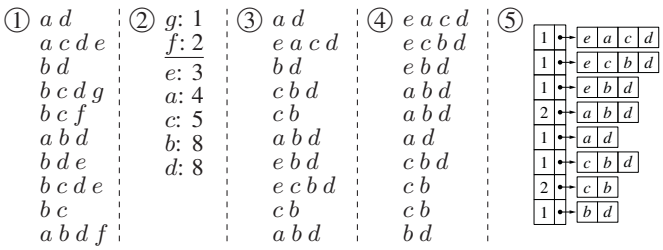

Figure 1: An example database: original form (1), item frequencies (2), transactions with sorted items (3), lexicographically sorted transactions (4), and the used data structure (5).

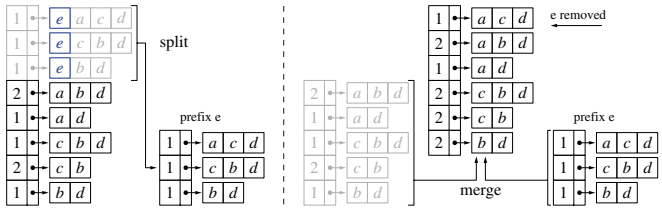

Figure 2: The basic operations: split (left) and merge (right).

The basic processing scheme can be improved with so-called *perfect extension pruning*: an item $i \notin I$ is called a *perfect extension* of an item set I, iff I and $I \cup \{i\}$ have the same support. Perfect extensions have the following properties: (1) if an item i is a perfect extension of an item set I, then it is also a perfect extension of any item set $J \supseteq I$ as long as $i \notin J$ and (2) if K is the set of all perfect extensions of an item set I, then all sets $I \cup J$ with $J \in 2^K$ (where 2^K denotes the power set of K) have the same support as I. These properties can be exploited by collecting in the recursion not only prefix items, but also, in a third element of a subproblem description, perfect extension items. They are also removed from the conditional databases and are only used to generate all supersets of the prefix that have the same support.

3 A Simple Split and Merge Algorithm

In this section we describe the basic form of our SaM (split and merge) algorithm. Preprocessing is very similar to many other frequent item set mining algorithms. The steps are illustrated in Figure 1 for a simple example transaction database: step 1 shows the transaction database in its original form. In step 2 the item frequencies are determined in order to discard infrequent items. With a minimum support of 3, items f and g are infrequent and thus eliminated. In step 3 the (frequent) items in each transaction are sorted according to their frequency, because processing the items in the order of increasing frequency usually leads to the shortest execution times. In step 4 the transactions are sorted lexicographically into descending order, with an item with higher frequency preceding an item with lower frequency. In step 5 the basic data structure is built by combining equal transactions and setting up an array, in which each element consists of two fields: an occurrence counter and a pointer to the sorted transaction.

The basic operations of the recursive processing, which follows the general divide-and-conquer scheme reviewed in Section 2, are illustrated in Figure 2: in the *split step* (left) the given array is split w.r.t. the leading item of the first transaction (item e in our example): all elements referring to transactions starting with this item are transferred to a new array. In this process the pointer (in)to the transaction is advanced by one item, so that the common leading item is "removed" from all transactions. Obviously, this new array represents the conditional database of the first subproblem (see Section 2), which is then processed recursively to find all frequent item sets containing the split item (provided this item is frequent).

The conditional database for frequent item sets *not* containing this item (second subproblem, see Section 2) is obtained with a simple *merge step* (right part of Figure 2). The new array and the rest of the original array are combined with a procedure that is almost identical to one phase of the well-known *mergesort* algorithm. Since both arrays are lexicographically sorted, one merging traversal suffices to create a lexicographically sorted merged array. The only difference to a *mergesort* phase is that equal transactions (or transaction suffixes) are combined: There is always only one instance of each transaction (suffix), while its number of occurrences is kept in a counter. In our example this results in the merged array having two elements less than the input arrays together: the transaction (suffixes) cbd and bd, which occur in both arrays, are combined and their occurrence counters are increased to 2.

Pseudo-code of SaM is shown in Figure 3: a single page of code suffices to describe the whole recursion in detail. The actual C code is even shorter, despite the fact that it contains additional functionality (like perfect extension pruning, Section 2), because certain operations can be written very concisely in C (especially when using pointer arithmetic).

4 Fuzzy Frequent Item Set Mining

There are many applications of frequent item set mining, in which the transactions do not contain all items that are actually present. However, standard algorithms are based on exact matching and therefore are not equipped to meet the needs arising in such applications. An example is the analysis of alarm sequences in telecommunication networks, where a core task is to find collections of alarms occurring frequently together, so-called *episodes*. One approach to accomplish this task is to slide a time window over the alarm sequence. Each window position then captures a specific slice of the alarm sequence [12]. The underlying idea is that in this way the problem of finding frequent episodes is reduced to that of finding frequent item sets in a database of transactions: each alarm can be seen as an item and the alarms in a time window as a transaction. The support of an episode is the number of window positions, so that the episode occurred in the window.

Unfortunately, alarms often get delayed, lost, or repeated due to noise, transmission errors, failing links etc. If alarms do not get through or are delayed, they are missing from the transaction (time window) its associated items (alarms) occur in. If we required exact containment of an item set in this case, the support of some item sets, which would be frequent if the items did not get lost, may be lower than the user-specified minimum. This leads to a possible loss of potentially interesting frequent item sets and to distorted support values.

To cope with such missing information, we rely on the notion of a "fuzzy" or approximate frequent item set. In contrast to research on fuzzy association rules (see, for example, [13]),

  return n;                                (* return num. of freq. item sets *)
end;    (* function SaM() *)
```

Figure 3: Pseudo-code of the SaM algorithm.

where a fuzzy approach is used to handle quantitative items, we use the term "fuzzy" to refer to an item set that may not be present exactly in all supporting transactions, but only approximately. Related work in this direction suggested Apriori-like algorithms and mining with approximate matching was performed by counting the number of different items in the two item sets to be compared [6, 10]. However, here we adopt a more general scheme, based on an approximate matching approach exhibiting much greater flexibility. Our approach has two core ingredients: *edit costs* and *transaction weights* [15].

Edit costs: A convenient way of defining the distance between item sets is to consider the costs of a cheapest sequence of edit operations needed to transform one item set into the other [14]. Here we consider only insertions, since they are most easily implemented with our algorithm[1]. With the help of an *insertion cost* or *penalty* a flexible and general framework for approximately matching two item sets can be established. How one interprets such costs or penalties depends, of course, on the application. Note also that different items may be associated with different costs. For example, in telecommunication networks different alarms can have a different probability of getting lost: usually alarms raised in lower levels of the module hierarchy get lost more easily than alarms originating in higher levels. In such cases it is convenient to be able to associate the former with lower insertion costs than the latter. Insertions of a certain item may also be completely inhibited by assigning a very high insertion cost.

Transaction weights: Each transaction t is associated with a weight $w(t)$, the initial value of which is 1. If an item i is inserted into a transaction t, the transaction weight is "penalized" with a cost $c(i)$ associated with the item. Formally, this can be described as applying a combination function: the new weight of the transaction t after inserting an item $i \notin t$ is $w_{\{i\}}(t) = f(w(t), c(i))$, where f is a function that combines the weight $w(t)$ before editing and the insertion cost $c(i)$. The combination function f depends, of course, on the application and may be chosen from a wide range of possible functions. For example, any t-norm may be used. We choose multiplication here, that is, $w_{\{i\}}(t) = w(t) \cdot c(i)$, mainly for reasons of simplicity. Note, however, that with this choice lower values of $c(i)$ mean higher costs as they penalize the weight more, but that it has the advantage that it is easy to extend to inserting several items: $w_{\{i_1,\ldots,i_m\}}(t) = w(t) \cdot \prod_{k=1}^{m} c(i_k)$. It should be clear that it is $w_\emptyset(t) = 1$ due to the initial weighting $w(t) = 1$.

How many insertions into a transaction are allowed may be limited by a user-specified lower bound $w_{\min}$ for the transaction weight. If the weight of a transaction falls below this threshold, it is not considered in further mining steps. Of course, this weight may also be set to zero (unlimited insertions). As a consequence, the *fuzzy support* of an item set I w.r.t. a transaction database T can be defined as $s_T^{(\text{fuzzy})}(I) = \sum_{t \in T} \tau(w_{I-t}(t) \geq w_{\min}) \cdot w_{I-t}(t)$, where $\tau(\phi)$ is a kind of "truth function", which is 1 if ϕ is true and 0 otherwise.

Note that SaM is particularly well suited to handle item insertions, because its purely horizontal transaction representation makes it easy to incorporate transaction weights. With other algorithms, more effort is usually needed in order to extend them to approximate frequent item set mining.

For an implementation, it is beneficial to distinguish between unlimited item insertions ($w_{\min} = 0$) and limited item insertions ($w_{\min} > 0$). If $w_{\min} = 0$, it is possible to combine equal transactions (or transaction suffixes) without restriction: two equal transactions (or suffixes) t_1 and t_2 with weights w_1 and w_2, respectively, can be combined into one transaction (suffix) t with weight $w_1 + w_2$ even if $w_1 \neq w_2$. If another item i needs to be inserted into t_1 and t_2 in order to make them contain a given item set I, the distributive law (that is, $w_1 \cdot c(i) + w_2 \cdot c(i) = (w_1 + w_2) \cdot c(i)$) ensures that we still compute the correct support for the item set I. If, however, we have $w_{\min} > 0$ and, say, $w_1 > w_2$, then using $(w_1 + w_2) \cdot c(i)$ as the contribution of the combined transaction t to the support of the item set I may be wrong, because it may be that $w_1 \cdot c(i) \geq w_{\min}$, but $w_2 \cdot c(i) < w_{\min}$. Then the support contributed by the two transactions t_1 and t_2 would rather be $w_1 \cdot c(i)$. Effectively, transaction t_2 does not contribute, since its weight has fallen below the transaction weight threshold. Hence, with limited insertions, we may combine equal transactions (or suffixes) only if they have the same weight.

[1] Note that deletions are implicit in the mining process (as we search for *subsets* of the transactions). Only replacements are an additional case we do not consider here.

ISBN: 978-989-95079-6-8

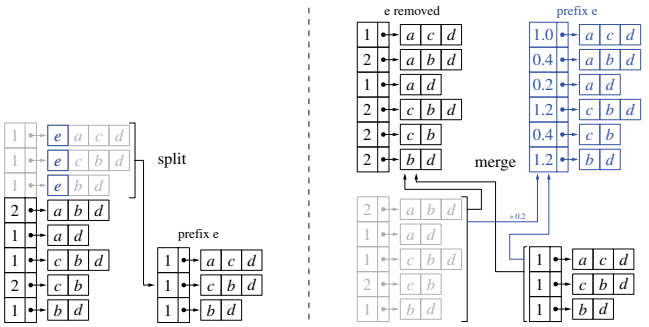

Figure 4: Unlimited item insertions, first recursion level.

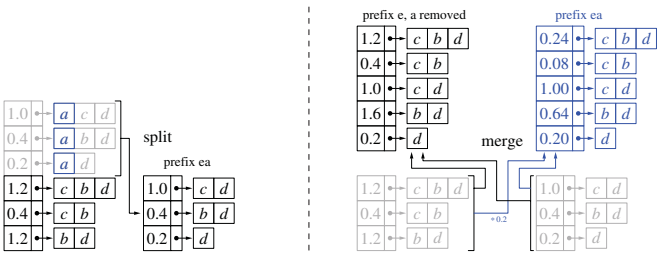

Figure 5: Unlimited item insertions, second recursion level.

5 Unlimited Item Insertions

If unlimited item insertions are possible ($w_{\min} = 0$), only a minor change of the data structure is needed: the integer occurrence counter for the transactions (or suffixes) has to be replaced by a real-valued transaction weight. In the processing, the split step stays the same (see Figure 4 on the left), but now it only yields an intermediate database with all transactions (or suffixes) that actually contain the split item under consideration (item e in the example). In order to form the full conditional database, we have to add those transactions that do not contain the split item, but can be made to contain it by inserting it. This is achieved in the merge step, in which two parallel merge operations are carried out now (see Figure 4 on the right). The first part (shown in black) is the merge that yields the conditional database for frequent item sets *not* containing the split item. The second part (shown in blue/grey) adds those transactions that do not contain the split item, weighted down with the insertion penalty, to the intermediate database created in the split step. Of course, this second part of the merge operation is only carried out, if $c(i) > 0$, where i is the split item, because otherwise no support would be contributed by the transactions not containing the item i and hence it would not be necessary to add them. In such a case the result of the split step would already yield the conditional database for frequent item sets containing the split item.

Note that in both merge operations equal transactions (or suffixes) can be combined regardless of their weights. As a consequence we have in Figure 4 entries like for the transaction (suffix) cbd, with a weight of 1.2, which stands for one occurrence with weight 1 and one occurrence with weight 0.2 (due to the penalty factor 0.2, needed due to the insertion of item e). As an additional illustration, Figure 5 shows the split and merge operations for the second recursion level.

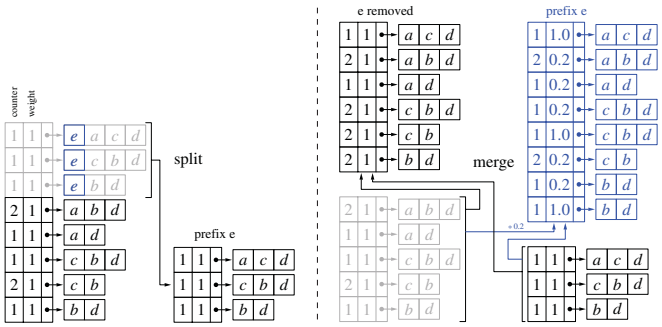

Figure 6: Limited item insertions, first recursion level.

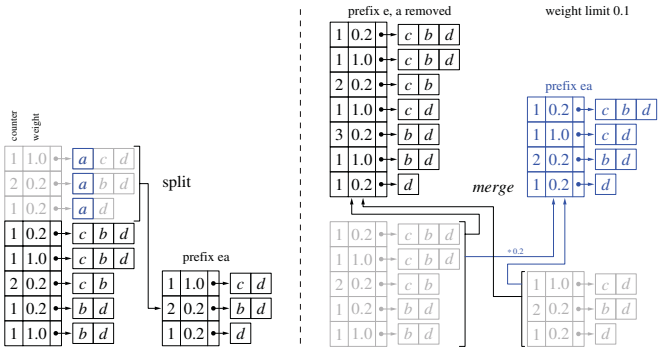

Figure 7: Limited item insertions, second recursion level.

6 Limited Item Insertions

If item insertions are limited by a transaction weight threshold ($w_{\min} > 0$), the transaction weight has to be represented explicitly and kept separate from the number of occurrences. Therefore the data structure must comprise, per transaction (suffix), (1) a pointer to the item array, (2) an integer occurrence counter, and (3) a real-valued transaction weight. The last field will be subject to a thresholding operation by $w_{\min}$, which eliminates all transactions with a weight less than $w_{\min}$. Hence there may now be array elements that refer to the same transaction (suffix), but differ in the transaction weight.

The processing scheme is illustrated in Figure 6. The split step is still essentially the same. However, the merge step differs due to the fact that equal transactions (or suffixes) can no longer be combined if their weight differs. As a consequence, there are now, in the result of the second merge operation (shown in blue) two array elements for cbd and two for bd, which carry different weights. This is necessary, because they may reach, due to item insertions, the transaction weight threshold at different times and thus cannot be combined.

That transactions are discarded due to the weight threshold rarely happens on the first level of the recursion. (This can occur only if the insertion penalty factor of the split item is smaller than the transaction weight threshold, which is equivalent to inhibiting insertions of this item altogether). Therefore, in order to illustrate how transactions are discarded, Figure 7 shows the second recursion level, where the conditional database with prefix e is processed. Here the second merge operation actually discards transactions if we set a transaction weight limit of 0.1: all transactions, which need two items (namely both e and a) to be inserted, are not copied.

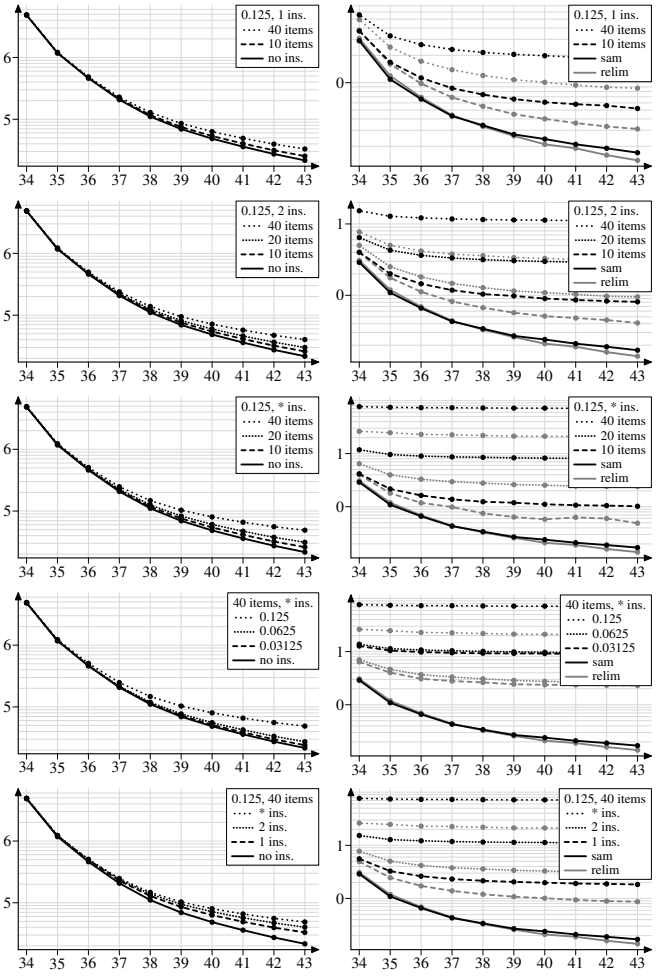

Figure 9: Experimental results on the BMS-Webview-1 data; left: frequent item sets, right: execution times.

7 Experiments

We ran experiments on several data sets, of which we chose two for this paper: Census (aka Adult, a data set derived from an extract of the US census bureau data of 1994, which was preprocessed by discretizing numeric attributes [2]) and BMS-Webview-1 (a web click stream from a leg-care company that no longer exists, which has been used in the KDD cup 2000 [8]). We chose these data sets, because Census is rather dense (a rather large fraction of all items occur in each transaction), while BMS-Webview-1 is rather sparse, and SaM and RElim [15] (the two algorithms of which we have implementations that can find approximate frequent item sets) exhibit a significantly different behavior on dense and sparse data sets.

The results are shown in Figure 8 for the census data set and in Figure 9 for the BMS-Webview-1 data set. In both figures the diagrams on the left show the decimal logarithm of the number of found frequent item sets, while the diagrams on the right show the decimal logarithm of the execution times (in seconds) for our implementations of SaM and RElim.[2] We tested insertion penalty factors of $\frac{1}{8} = 0.125$, $\frac{1}{16} = 0.0625$, and $\frac{1}{32} = 0.03125$, non-vanishing insertion penalty factors for 10, 20, and 40 items, and transaction weight thresholds that allowed for 1, 2 or an unlimited number of insertions.

As can be seen from the diagrams on the left of each figure, the two data sets react very differently to the possibility of inserting items into transactions. While the number of found frequent item sets rises steeply with all parameters for Census, it rises only very moderately for BMS-Webview-1, with the factor even leveling off for lower support values. As it seems, this effect is due, to a large degree, to the sparseness of BMS-Webview-1 (this still needs closer examination, though).

SaM fares considerably better on the dense data set (Census), beating RElim by basically the same margin (factor) in all parameter settings, while SaM is clearly outperformed by RElim on the sparse data set (BMS-Webview-1), even though the two algorithms are actually on par without item insertion (solid lines). On both data sets, the number of insertions that are allowed has the strongest influence: with two insertions execution times are about an order of magnitude larger than with only one insertion. However, the possibility to combine equal transactions with different weights still seems to keep the execution times for unlimited insertions within limits.

The number of items with a non-vanishing penalty factor and the value of the penalty factor itself seem to have a similar influence: doubling the number of items leads to roughly the same effect as keeping the number the same and doubling the

[2]Execution times were measured on an Intel Core 2 Quad Q9300 machine with 3 GB of main memory running openSuSE Linux 11.0 (32 bit) and gcc version 4.3.1.

ISBN: 978-989-95079-6-8

penalty factor. This is plausible, since there should not be much difference in having the possibility to insert twice the number of items or preserving twice the transaction weight per item insertion. Note, however, that doubling the penalty factor from from $\frac{1}{32}$ to $\frac{1}{16}$ has only a comparatively small effect on the BMS-Webview-1 data compared to doubling from $\frac{1}{16}$ to $\frac{1}{8}$. On the census data set the effects are a bit more in line.

Overall it should be noted that the execution times, although considerably increased over those obtained without item insertions, still remain within acceptable limits. Even with 40 items having an insertion penalty factor of $\frac{1}{8}$ and unlimited insertions, few execution times exceed 180 seconds ($\log_{10}(180) \approx 2.25$). In addition, we can observe the interesting effect on the BMS-Webview-1 data that at the highest parameter settings the execution times become almost independent of the minimum support threshold.

8 Conclusions

In this paper we presented a very simple split and merge algorithm for frequent item set mining, which, due to the fact that it uses a purely horizontal transaction representation, lends itself well to an extension to "fuzzy" or approximate frequent item set mining. In addition, it is a highly recommendable method if the data to mine cannot be loaded into main memory and thus the data has to be processed on external storage or in a (relational) database system. As our experimental results show, the SaM algorithm performs the task of "fuzzy" frequent item set mining excellently on the dense Census data, but shows certain weaknesses on the sparse BMS-Webview-1 data. However, our experiments provided some evidence (to be substantiated on more data sets) that "fuzzy" frequent item set mining is much more useful for dense data sets as more additional frequent item sets can be found. Hence SaM performs better in the (likely) more relevant case. Most importantly, however, one should note that with both SaM and RElim the execution times remain bearable.

Email: {gernot.herbst, steffen.bocklisch}@etit.tu-chemnitz.de

Abstract— *This article deals with the recognition of recurring multivariate time series patterns modelled sample-point-wise by parametric fuzzy sets. An efficient classification-based approach for the online recognition of incompleted developing patterns in streaming time series is being presented. Furthermore, means are introduced to enable users of the recognition system to restrict results to certain stages of a pattern's development, e. g. for forecasting purposes, all in a consistently fuzzy manner.*

Keywords— Fuzzy classification, fuzzy automata, multivariate time series, pattern recognition.

1 Introduction

Fuzzy sets have been successfully used for a long time for a model-free or model-based representation of time series or time series sequences, e. g. for the classification and prediction of nonlinear systems behaviour [1–4]. This article aims at extending the fuzzy time series classification approach of [2, 3] to an *always aware* online recognition system for nonstationary recurring patterns in multivariate streaming time series. *Always aware* refers to the ability of the recognition system presented in this paper to constantly expect to find an (incompleted) pattern in a time series in any of its possible stages of development, which will be achieved by classification of pattern subsequences. It will be shown how the computationally expensive classification results for all possible subsequences can be obtained at almost no additional cost compared to the classification of completed patterns by relating the recognition procedure to ideas from fuzzy automata.

2 Fuzzy Modelling of Time Series Patterns

2.1 A Multivariate Parametric Fuzzy Set

In this section a parametric membership function type will be presented, which will serve as the common basis for the classifiers developed in this article. For the univariate case, the membership function is defined in (1). Based upon a potential function, it has already been successfully used in numerous applications such as process or medical surveillance [1], time series modelling and prediction [2, 3] and classifier networks [5]. One important property of this function is its capability of modelling asymmetric fuzzy sets by individual parameters for the left- and right-hand function branches.

$$\mu(x) = \begin{cases} \dfrac{a}{1+\left(\dfrac{1}{b_l}-1\right)\left(\dfrac{r-x}{c_l}\right)^{d_l}} & : \quad x < r \\ \dfrac{a}{1+\left(\dfrac{1}{b_r}-1\right)\left(\dfrac{x-r}{c_r}\right)^{d_r}} & : \quad x \geq r \end{cases} \tag{1}$$

The maximum truth value a of the fuzzy set occurs at its modal point: $\mu(x = r) = a$. For normalised fuzzy sets, $a = 1$ holds, as will be the case throughout this paper. The six parameters $b_{l/r}$, $c_{l/r}$ and $d_{l/r}$ determine the extent and shape of the class. From Fig. 1, the effect of b ($0 < b < 1$) and c ($c > 0$) can be understood. Semantically, they correspond to the class borders. The d parameter ($d \geq 2$) influences the shape of μ's descent to zero, with increasing d leading to a sharper descent and $d \to \infty$ resulting in a rectangular shape. This is particularly interesting since crisp sets may be represented by (1) as well.

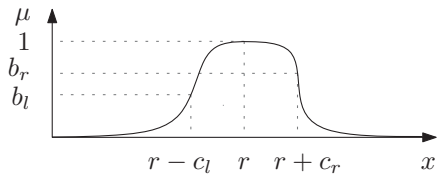

Figure 1: Normalised parametric membership function (1).

The parameters of this membership functions may be chosen based upon expert knowledge on the one hand, and automatically be computed [1] from a set of learning data on the other hand.[1] Both options benefit from the interpretability of these parameters.

A probably unique advantage of this function concept is that a multivariate membership function—based upon a conjunction of one-dimensional sets using a compensatory n-fold Hamacher intersection—may also be obtained in *parametric* form [1]. The n-fold operator is given by (2). The resulting multidimensional membership function is, for a simplified case of symmetric left- and right-hand branches, given by (3). Additionally (and omitted here for brevity), the class space may optionally be rotated in the underlying feature space for each class individually, leading to $(n-1)$ further rotation angle parameters, which can be obtained from a principal component analysis of the learning data. Fig. 2 depicts two examples of membership functions in a two-dimensional feature space.

$$\cap^{n}_{Ham}\,\mu_i = \frac{1}{\dfrac{1}{n}\displaystyle\sum_{i=1}^{n}\frac{1}{\mu_i}} \tag{2}$$

[1] The parameters of (1) are computed from data as follows: Firstly, the modal point r is being calculated by averaging the object values. The left- and right-hand side extents $c_{l/r}$ are chosen such that all learning objects, augmented by a so-called elementary fuzziness, lie within these class borders. Finally, the shape parameters b and d parameters are—if not specified manually—being computed to best fit the dispersion of the data.

ISBN: 978-989-95079-6-8

$$\mu(\boldsymbol{x}) = \frac{a}{1 + \frac{1}{n}\sum_{i=1}^{n}\left(\frac{1}{b_i} - 1\right) \cdot \left|\frac{x_i - r_i}{c_i}\right|^{d_i}} \tag{3}$$

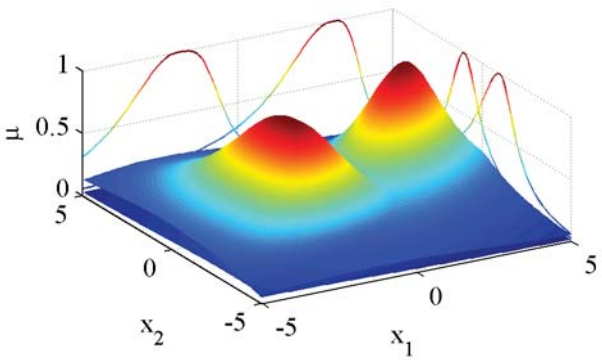

Figure 2: Two examples of two-dimensional fuzzy classes.

2.2 A Fuzzy Model for Time Series Patterns

The membership function concept introduced in section 2.1 forms the basis of a classifier model for multivariate time series sequences [2]. It allows to compute a continuous degree of similarity $\mu \in [0, 1]$ between a measured time series pattern and the fuzzy pattern model. Therefore pattern matching is being treated as a fuzzy classification task. The model described hereafter may be employed for equidistantly sampled univariate or multivariate time series.

Each point $\boldsymbol{x}(i)$ of a time series pattern (length: L sample points) is being described by a membership function $\mu_{P,i}(\boldsymbol{x})$, $\boldsymbol{x} \in \mathbb{R}^n$, $i = 1, \ldots, L$. This model therefore exhibits a soft tolerance towards noise and other sources of imprecision. To compare a time series sequence against the model, i. e. to classify a pattern given by L points $\boldsymbol{x}(1), \ldots, \boldsymbol{x}(L)$, the individual classification results of each point are combined to an overall degree of similarity $\mu \in [0, 1]$ by means of a fuzzy conjunction:

$$\mu = \mu_{P,1}(\boldsymbol{x}(1)) \cap \cdots \cap \mu_{P,L}(\boldsymbol{x}(L)) \tag{4}$$

If we recall the ideas of section 2.1 which led to the multivariate parametric membership function, it appears reasonable to reuse the same conjunction operator given by (2). In that manner, the overall classifier for the entire time series pattern could also be thought of as *one* fuzzy class created from the conjunction of $(L \cdot n)$ univariate fuzzy sets, forming an $(L \cdot n)$-dimensional membership function. Thusly classification of time series sequences would very well remain in line with the multivariate classification paradigm behind section 2.1. One key advantage of this model—especially in comparison to many *black box* models such as neural networks—is its support for partial classification, i. e. for the classification of any possible subsequence, simply by intersecting the underlying classification results for the sample points available. We will make use of this advantageous property later on.

Fig. 3 depicts an example of an univariate ($n = 1$) pattern (length $L = 286$ sample points) described by this fuzzy time series model, learned from a set of 14 instances of this pattern (*Coffee* dataset, available from [6]). By means of this figure we may also come to the interpretation of the pattern classifier as a corridor with soft boundaries. A measured pattern will, depending on its degree of similarity, more or less follow this corridor. The properties of the underlying membership function ensure that no pattern will be absolutely rejected ($\mu = 0$) by this classifier, thusly enabling a smooth, non-switching behaviour of the recognition system.

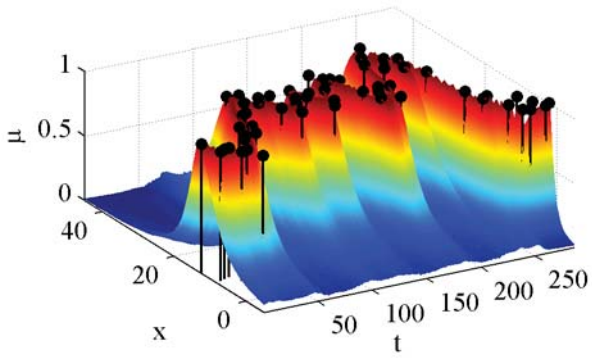

Figure 3: Fuzzy time series model along with a noisy pattern.

While the presented classifier aims at the recognition of recurring patterns that are similar in terms of absolute values, variations such as offsets or scaling may, at least to a certain extent, be covered by suitable preprocessing steps like normalisation. As in section 2.1, the time series pattern model may either be formulated based upon expert knowledge—eased by the interpretability of the individual parameters—or be result of a learning step using a set of pattern instances of the same phenomenon, employing the learning algorithm from section 2.1 for each point of the pattern. The latter is especially interesting in conjunction with clustering or motif mining algorithms. As there is no transform involved, the original properties of the pattern ensemble (energy content, statistics etc.) are mostly being preserved by this model. Furthermore, short-term forecasting of a time series with a partially elapsed pattern is made possible in a straightforward manner based upon the knowledge represented by the model.

3 Online Pattern Recognition

3.1 Task Description

The task of online pattern recognition—as we would like to understand it in the context of this work—can be described by means of Fig. 4. In a streaming univariate or multivariate time series $\boldsymbol{x}(t)$, we are looking for instances of a known pattern. *Online* pattern recognition firstly implies that an occurrence of the pattern has to be permanently expected. But in addition to that, we aim at detecting incompleted patterns, which would enable short-term predictions of the time series based on known patterns. For applications such as machine diagnosis, for instance, this facilitates preventive maintenance actions before a minor damage develops into a severe one.

At the current point in time t_{now} (as sketched in Fig. 4), the model containing the desired pattern has to be adjusted in its relative position τ such that the subsequence $\boldsymbol{x}([t_{\text{now}} - \tau] \ldots t_{\text{now}})$ optimally matches the partial model. τ then represents the time already elapsed in the pattern.

Summarisingly, an online pattern recognition system has to check if a pattern in a time series can be found at the current point in time, and if so, at which stage of development τ.

ISBN: 978-989-95079-6-8

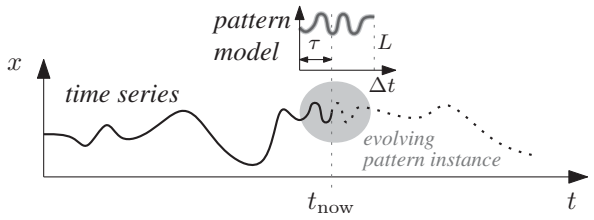

Figure 4: Online matching of evolving patterns.

3.2 Fuzzy Online Recognition

For reasons outlined above, we would like to treat the pattern matching problem as a fuzzy classification task, with time series subsequences (length τ, $\tau \leq L$) being input to a suitable classifier representing a pattern of length L. For each point in time t, this would yield classification results $\mu(t,\tau)$ for every possible value of τ. Semantically, $\mu(t_{\text{now}},\tau)$ represents the similarity of the time series subsequence $\boldsymbol{x}([t_{\text{now}}-\tau]\ldots t_{\text{now}})$ to the first part (length τ) of the pattern model/classifier.

In a truly fuzzy sense[2], *each* pattern would be found at *every* point in time in *all* possible stages of development τ, expressed by non-zero classification results $\mu(t,\tau) > 0\ \forall\tau$, even though $\mu(t,\tau)$ may, of course, be negligibly small. At any point in time t, fuzzy classification of evolving time series patterns therefore results in a *fuzzy set* $\mu(t,\tau)$—instead of just *one* truth value $\mu(t)$, as in a "conventional" fuzzy classification task, cf. Fig. 5. Representing the recognition result as a fuzzy set reflects the fuzziness of the recognition task. It is a joint fuzzy representation of the following information:

1. Could the pattern be found at the current point in time?
2. What is the pattern's state of development τ?

Both questions can—in real-world time series—not be answered precisely and unambigously. $\mu(t,\tau)$ commensurates with this vagueness. Furthermore, it may be interpreted as a fuzzy specification of τ, resembling the concept of fuzzy numbers.[3]

3.3 Representation as Fuzzy Automaton

In section 2.2, a suitable classifier model for patterns in equidistantly sampled time series has been introduced. As this model supports partial classification, it is well suited for the online pattern matching problem. In an online recognition system, however, obtaining $\mu(t,\tau)$ for every possible value of τ by classifying all respective subsequences $\boldsymbol{x}([t-\tau]\ldots t)$ would be a rather time-consuming procedure. More specifically, it appears incommensurate to recompute the whole fuzzy set $\mu(t,\tau)$ if only one new datum $\boldsymbol{x}(t)$ is being presented to the recognition system at time t. We therefore would like to reuse the classification result $\mu(t-1,\tau-1)$ of the subsequence

[2] As an unofficial definition, we would like to understand "true" fuzziness as a property of models and methods which do not (explicitely or implicitely) perform crisp decisions or cut-off operations. For instance, a "truly" fuzzy set has infinite support, thusly all elements x of the underlying universe of discourse belong to this set with $\mu(x) > 0$. As a counterexample, triangular fuzzy sets feature crisp and finite extents, and would therefore not be regarded as "truly" fuzzy models.

[3] Although not being a fuzzy number in the sense of Dubois and Prade [7], especially owing to the very likely multimodality, it matches the spirit of a fuzzy number as a fuzzified representation of a real-valued number (here: τ) quite well.

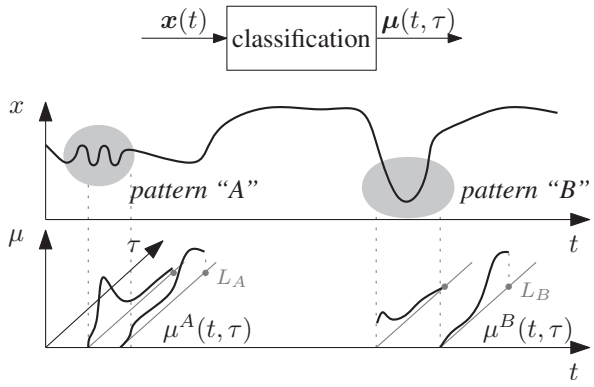

Figure 5: Fuzzy online recognition of two patterns "A" and "B" (length L_A and L_B). At each point in time t, the maximum truth values of the recognition results $\mu^{A/B}(t,\tau)$ w. r. t. τ point to the relative positions τ associated to the best match of the partially elapsed patterns. The fuzzy sets $\mu^{A/B}$ are shown at two different stages of development τ for each pattern.

$\boldsymbol{x}([(t-1)-(\tau-1)]\ldots t-1)$ when computing $\mu(t,\tau)$ for $\boldsymbol{x}([t-\tau]\ldots t)$.

For discrete time patterns of length L, the pattern recognition result $\mu(t,\tau)$ consists of L truth values ($\tau = 1,\ldots,L$). This result may be represented by means of a fuzzy state automaton [8], as sketched in Fig. 6. Being a fuzzy automaton, each state—corresponding to a certain value of τ—is active to a certain degree $\mu(t,\tau)$. At each point in time t, the automaton is triggered with a discrete event in the form of a new input value $\boldsymbol{x}(t)$, leading to new activation levels for each state. An activation level $\mu(t,\tau)$ depends on the current input value $\boldsymbol{x}(t)$ and the former activation level of the previous state:

$$\mu(t,\tau) = f(\mu(t-1,\tau-1),\boldsymbol{x}(t)) \tag{5}$$

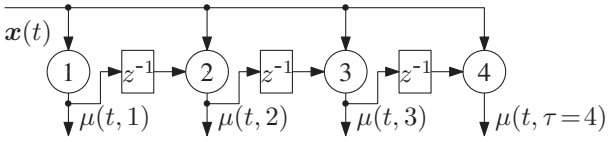

Figure 6: (Informal) fuzzy state automaton representation of a time series pattern recognition system, here for a pattern consisting of four sample points.

Recalling the internals of the time series pattern classifier from section 2.2, the overall classification result was gained from a compensatory Hamacher conjunction (cf. (4)) of individual classification results $\mu_{P,i}$ of time series sample points $\boldsymbol{x}_i$. Thusly $\mu(t-1,\tau-1)$ consists of a conjunction of $\tau-1$ truth values. $\mu(t,\tau)$ could therefore be obtained from a conjunction of $\mu(t-1,\tau-1)$ and the partial classification result $\mu_{P,\tau}(\boldsymbol{x}(t))$ for the τ^{th} point of the time series pattern. However, this conjunction should reflect the weight of the $\tau-1$ truth values that contributed to $\mu(t-1,\tau-1)$, so that $\mu_{P,\tau}(\boldsymbol{x}(t))$ does not outweigh all previous information. A suitable conjunction operator will be derived in the following section, which will enable us to rewrite (5) to such a weighted conjunction:

$$\mu(t,\tau) = \mu(t-1,\tau-1)\ {}^{(\tau-1)}\cap^{1}\ \mu_{P,\tau}(\boldsymbol{x}(t)) \tag{6}$$

ISBN: 978-989-95079-6-8

Equation (6) forms the basis for the mode of operation of the fuzzy automaton from Fig. 6, and will enable us to perform online recognition of time series patterns much more efficiently.

3.4 Weighted Compensatory Hamacher Conjunction

The compensatory Hamacher conjunction of n truth values μ_i $(i = 1, \ldots, n)$ has already been introduced in (2). By rearranging the components of (2) into two sets of truth values, we may formulate the compensatory Hamacher conjunction of $n = n_1 + n_2$ truth values as:

$$\begin{aligned}\mu_1 \cap \cdots \cap \mu_n &= \frac{1}{\frac{1}{n_1+n_2}\left(\sum_{i=1}^{n_1}\frac{1}{\mu_i} + \sum_{j=n_1+1}^{n}\frac{1}{\mu_j}\right)} \\ &= \frac{1}{\frac{1}{n_1+n_2}\left(\frac{n_1}{\mu_1 \cap \cdots \cap \mu_{n_1}} + \frac{n_2}{\mu_{n_1+1} \cap \cdots \cap \mu_n}\right)} \\ &= (\mu_1 \cap \cdots \cap \mu_{n_1})^{\,n_1 \cap^{n_2}}\ (\mu_{n_1+1} \cap \cdots \cap \mu_n)\end{aligned} \tag{7}$$

Based upon (7) we may now define the (n_a, n_b)-weighted compensatory Hamacher conjunction of two truth values μ_a and μ_b, which was in a similar manner also derived in [9]:

$$\mu_a \,^{n_a \cap^{n_b}}\ \mu_b = \frac{1}{\frac{1}{n_a+n_b}\left(\frac{n_a}{\mu_a} + \frac{n_b}{\mu_b}\right)} \tag{8}$$

Thusly it becomes possible to compute the conjunction of new truth values with existing conjunction results without having to store the individual truth values leading to the existing results and while exactly retaining the weight of each truth value that contributed to the overall result.

Finally, we may define the vectorial weighted conjunction of two equal-sized truth vectors $\boldsymbol{\mu}_a$ and $\boldsymbol{\mu}_b$ using weight vectors $\boldsymbol{n}_a$ and $\boldsymbol{n}_b$ containing the individual weights for the respective elements:

$$\boldsymbol{\mu}_a \,^{\mathbf{n_a} \cap^{\mathbf{n_b}}}\ \boldsymbol{\mu}_b = \begin{pmatrix} \vdots \\ \dfrac{1}{\frac{1}{n_{a,i}+n_{b,i}}\left(\frac{n_{a,i}}{\mu_{a,i}} + \frac{n_{b,i}}{\mu_{b,i}}\right)} \\ \vdots \end{pmatrix} \tag{9}$$

3.5 Update Equations for the Fuzzy Automaton

Recalling (6) and employing the weighted conjunction operator from (8), we may now formulate the update equation for each fuzzy state of the automaton representation of the recognition results $\mu(t, \tau)$ from section 3.3. Equation (6) holds for $\tau \geq 2$, as the first state of the automaton does not have a predecessor state to obtain $\mu(t-1, \tau-1)$. Since the weight of the non-existing zero-th state would be zero anyway, (6) can (for $\tau = 1$) be thought of to reduce to solely the classification result for the first sample point, cf. (10). All further results $\mu(t, \tau \geq 2)$ are computed by a weighted conjunction of antecedent recognition results and the classification results $\mu_{P,\tau}$ of the new sample point $\boldsymbol{x}(t)$ available at each point in time.

$$\mu(t, 1) = \mu_{P,1}(\boldsymbol{x}(t)) \tag{10}$$

To obtain a vectorial form of the update equations, we define $\boldsymbol{\mu}_P(t)$ as the vector containing the individual membership values of $\boldsymbol{x}(t)$ to all classes constituting the fuzzy time series pattern model, and $\boldsymbol{\mu}_\tau(t)$ as the state vector containing all levels of activation of the automaton, and thusly the overall pattern recognition results:

$$\boldsymbol{\mu}_P(\boldsymbol{x}(t)) = \begin{pmatrix} \mu_{P,1}(\boldsymbol{x}(t)) \\ \vdots \\ \mu_{P,L}(\boldsymbol{x}(t)) \end{pmatrix} \tag{11}$$

$$\boldsymbol{\mu}_\tau(t) = \begin{pmatrix} \mu_{\tau,1}(t) \\ \vdots \\ \mu_{\tau,L}(t) \end{pmatrix} = \begin{pmatrix} \mu(\tau, 1) \\ \vdots \\ \mu(\tau, L) \end{pmatrix} \tag{12}$$

Summarisingly, the recursive update equation for the recognition result (the fuzzy set $\mu(t, \tau)$) or its vectorial representation $\boldsymbol{\mu}_\tau(t)$ can be condensed from (5), (6) and (9) to (13):

$$\begin{aligned}\boldsymbol{\mu}_\tau(t) &= f(\boldsymbol{\mu}_\tau(t-1)), \boldsymbol{\mu}_P(\boldsymbol{x}(t))) \\ &= \left(\begin{pmatrix}1\\ \mathbf{0}\end{pmatrix} + \begin{pmatrix}\mathbf{0}^T & 0\\ \boldsymbol{I} & \mathbf{0}\end{pmatrix} \cdot \boldsymbol{\mu}_\tau(t-1)\right)^{\,\mathbf{n}_\tau \cap \mathbf{1}}\ \boldsymbol{\mu}_P(\boldsymbol{x}(t))\end{aligned} \tag{13}$$

$$\boldsymbol{n}_\tau = \begin{pmatrix} 0 \\ 1 \\ \vdots \\ L-1 \end{pmatrix} \tag{14}$$

Incorporating the weight vector $\boldsymbol{n}_\tau$, this finally results in:

$$\boldsymbol{\mu}_\tau(t) = \begin{pmatrix} \dfrac{1}{\frac{1}{1}\cdot\left(\frac{0}{1} + \frac{1}{\mu_{P,1}(\boldsymbol{x}(t))}\right)} \\ \vdots \\ 1 \\ \dfrac{1}{\frac{1}{i}\cdot\left(\frac{i-1}{\mu_{\tau,i-1}(t-1)} + \frac{1}{\mu_{P,i}(\boldsymbol{x}(t))}\right)} \\ \vdots \\ 1 \\ \dfrac{1}{\frac{1}{L}\cdot\left(\frac{L-1}{\mu_{\tau,L-1}(t-1)} + \frac{1}{\mu_{P,L}(\boldsymbol{x}(t))}\right)} \end{pmatrix} \tag{15}$$

Apart from the $(L-1)$ weighted conjunctions of truth values that are required at each time step, the online recognition of a (partially elapsed) fuzzy pattern therefore does not require more underlying classification steps and computations of $\mu_{P,\tau}$ than would be needed just for the fuzzy classification and recognition of only completed patterns in streaming time series.

4 Post-Processing Recognition Results

4.1 Windowing of $\mu(t, \tau)$

The fuzzy set $\mu(t, \tau)$—describing the recognition results of a pattern found at the current point in time t in all possible stages of development τ—is a rather complex result containing a wealth of information. In many cases it will thusly have to be narrowed down to particularly interesting or relevant parts. In addition to that, shorter subsequences of the pattern will be found more often in a time series than the whole pattern. This results in a tendency to relatively often obtain high degrees

ISBN: 978-989-95079-6-8

of similary $\mu(t,\tau)$ for small values of τ, which will later on diminish if the time series does not develop further into an instance of the pattern. For longer patterns, a user will therefore always have to gauge and find a trade-off between the necessity of detecting patterns at an early stage of development τ (with a higher risk of a false or premature recognition result) and the importance of a reliable recognition result (which can ultimately only be achieved at the end of an evolving pattern). This trade-off cannot be universally formulated in a crisp manner, and neither does it seem advisable to do so.

These considerations lead us to the idea of letting the user of the recognition system focus on certain stages development τ of a pattern in a soft manner, such that the recognition system only reports matches of the evolving pattern for values of τ falling within certain (fuzzy) boundaries. Subsequently, we will call these boundaries the *fuzzy window of interest for* τ. We will represent this window of interest by means of a fuzzy set $\mu_w(\tau)$ defined over all possible values of τ, with $\mu_w(\tau) \to 0$ indicating low interest in a recognition result for this particular value of τ, and $\mu_w(\tau) \to 1$ indicating high interest.

To obtain a *windowed* pattern recognition result $\tilde{\mu}(t,\tau)$, the window of interest $\mu_w(\tau)$ and the recognition result $\mu(t,\tau)$ are combined as in (16) by a conjunction[4] of the two fuzzy sets. Semantically, this corresponds to a coincidence of a pattern being found at a certain stage of development and the user's subjective assessment of the importance of this particular stage.

$$\tilde{\mu}(t,\tau) = \mu(t,\tau) \cap \mu_w(\tau) \quad \forall\tau \tag{16}$$

Equation (16) in its general form includes some interesting special cases, such as the following: By definition, the truth values in $\mu(t,\tau)$ appear equally important to the user regardless of τ, so that higher values of μ will often be found for smaller values of τ, although the pattern has just begun to evolve. Following the windowing approach would also enable us to (for example: linearly) weigh a recognition result $\mu(t,\tau)$ according to the stage of development τ of the pattern by chosing a suitable $\mu_w(\tau)$. To achieve this, $\mu_w(\tau)$ has—in this special case—to be chosen as a fuzzy set with (linearly) increasing truth values, reaching $\mu_w(\tau = L) = 1$ at the end of the pattern (length L). If we, as an example, choose the algebraic product for the operator $\cap$ in (16), we would simply obtain (17) for a thusly weighted/windowed recognition result.

$$\tilde{\mu}_{linear}(t,\tau) = \mu(t,\tau) \cdot \frac{\tau}{L} \tag{17}$$

4.2 *Deriving Decisions*

In order to further process the (windowed) recognition results $\mu(t,\tau)$ or $\tilde{\mu}(t,\tau)$, e. g. when serving as a rationale for subsequent actions, it will often be necessary to come to a crisp decision regarding the similarity and stage of development of a pattern found in a time series. In these cases, the fuzzy set $\tilde{\mu}(t,\tau)$ has to be condensed to one or more crisp parameters.

Although many defuzzification methods for fuzzy sets are available [10], we would—for the sake of simplicity—like to restrict ourselves in this article to a maximum approach (first of maxima, FOM). The resulting crisp value τ^* from $\tilde{\mu}(t,\tau)$ points to the earliest stage of development of the pattern yielding the highest degree of similarity $\tilde{\mu}^*$ to the respective time series subsequence, both of which may be represented as a fuzzy singleton $\tilde{\mu}^*(t,\tau^*)$ for each point in time t.

5 Example

Fig. 7 shows a time series containing one instance of the pattern modelled and depicted in Fig. 3. For illustrative purposes, the instance has been highlighted, as the surrounding parts of the the time series are relatively similar in amplitude and shape.

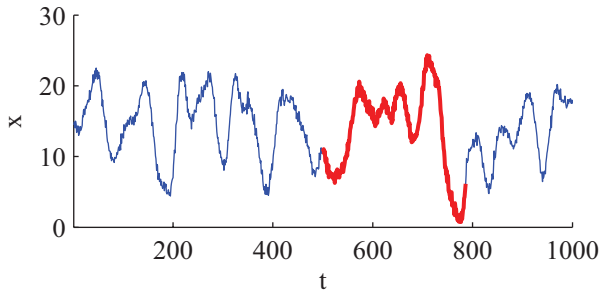

Figure 7: Univariate time series with a pattern instance.

Employing the fuzzy model from Fig. 3, we are now performing an online recognition of this pattern in the time series of Fig. 7. While advancing in time t through all points of the time series, the pattern is constantly being expected to be found in all[5] possible stages of development τ. The classification results for each point in time t—evolving fuzzy sets $\mu(t,\tau)$ defined over τ—are being shown in Fig. 8.

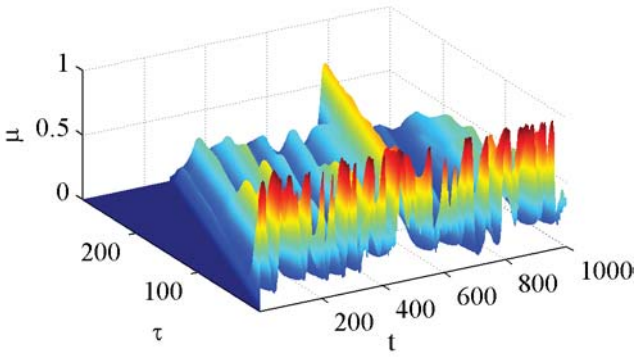

Figure 8: Results for an online recognition of the time series pattern of Fig. 3.

These recognition results $\mu(t,\tau)$ reveal high degrees of similarity of time series subsequences to the first part (i. e. small values of τ) of the pattern, and, in fact, it can be understood from Fig. 7 that the ascending first slope can (with slight variations) be found repeatedly throughout the time series. Apart from that, the progression of a detected instance is well visible in the course of $\mu(t,\tau)$. Only once a completed pattern is being found with distinctly high values for $\mu(t,\tau = L)$, which point to the pattern instance embedded in this time series.

To detect a pattern ahead of time ($\tau < L$), e. g. for forecasting purposes, the recognition result has to be well-founded, and therefore based upon a adequately large number of recognised

[4] As conjunction operator, a non-compensatory operator—such as all T-norm operators—should be chosen to ensure $\tilde{\mu}(t,\tau) \leq \mu(t,\tau)$.

[5] In the first part of the time series, the pattern may only be found at early stages of development $\tau < t$, i. e. $\mu(t,\tau > t) = 0$ must hold.

ISBN: 978-989-95079-6-8

sample points τ on the one hand, whilst τ being small enough to leave sufficient scope for actual forecasting. We will tackle both problems of "premature" pattern recognition and formulating a compromise for a suitable value of τ delivering usable recognition results by following the windowing approach for $\mu(t,\tau)$ presented in section 4.1. As an example, we would like to concentrate on recognition results for pattern instances being at least half-way, but not yet fully completed. Once again employing the unimodal parametric membership function from (1), we formulate a fuzzy window of interest $\mu_w(\tau)$ for this certain stage of the pattern's development, cf. Fig. 9.[6] Due to the fuzzy nature of the presented method, slight variations of $\mu_w(\tau)$ and its parameters will not alter the overall system behaviour and recognition results in a drastic, switching manner. This eases the design of $\mu_w(\tau)$, as no "critical" decisions have to be made when choosing its parameters.

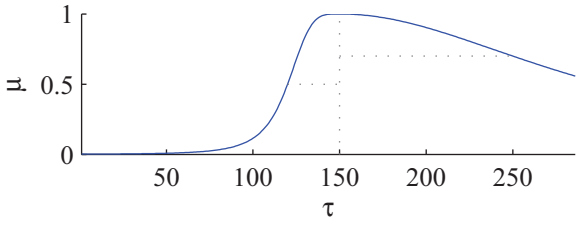

Figure 9: Fuzzy window of interest $\mu_w(\tau)$ for pattern recognition results $\mu(t,\tau)$ from Fig. 8.

For each t, the recognition result (fuzzy set) $\mu(t,\tau)$ was processed as given by (16) using a Hamacher product with $\mu_w(\tau)$. The windowed recognition results $\tilde{\mu}(t,\tau)$ are shown in Fig. 10. As a final step, a simple decision strategy was followed to generate crisp recognition results in singleton form for each point in time t. For each fuzzy set $\tilde{\mu}(t,\tau)$, the modal (maximum) value $\tilde{\mu}^*(t,\tau^*)$ was determined. Any result for τ^* with a corresponding truth value falling below a threshold $\tilde{\mu}^*(t,\tau^*) < 0.5$ was discarded. Results of this decision procedure are marked in Fig. 10. As can be seen in this figure, two candidate pattern instances are being identified at the desired stage of development τ, the first one of which vanishing quickly. The actual pattern instance embedded in the time series of Fig. 7 is being recognised reliably throughout the fuzzy window of interest.

6 Conclusions

This article dealt with the online recognition of patterns in multivariate time series. The vectorial recursive update equation for the recognition results derived in section 3.5 allows to obtain a fuzzy recognition result $\mu(t,\tau)$ for all possible stages of development τ of a pattern at almost the same computational cost as required for the fuzzy classification of only completed patterns. By formulating and applying a fuzzy window of interest, the recognition result $\mu(t,\tau)$ can be narrowed down to parts relevant for the respective application in a fuzzy manner. This also eases a subsequent crisp decision step.

Further work will concentrate on the application of the model and methods presented here to the recognition and prediction

[6] The parameter were chosen manually: $r = 150$, $b_l = 0.5$, $b_r = 0.7$, $c_l = 30$, $c_r = 100$, $d_l = 4$, $d_r = 2$. For $\tau < r$, $d_l = 4$ and $c_l = 30$ ensure a quick decrease of $\mu_w(\tau)$, whereas the right-hand side parameters b_r, c_r, d_r provide a gentle decrease of μ_w for $\tau > r$.

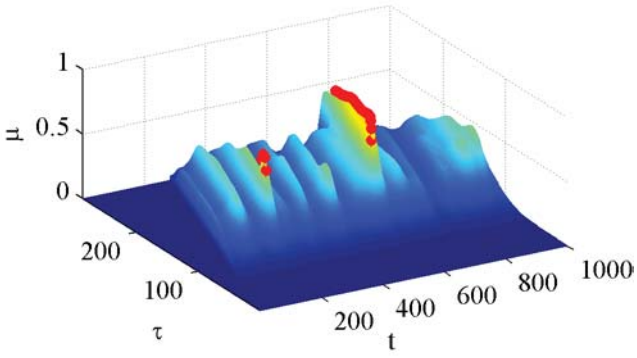

Figure 10: Windowed recognition results $\tilde{\mu}(t,\tau)$. Singleton results $\tilde{\mu}^*(t,\tau^*)$ of the decision procedure are marked with dots (slightly increased for better visibility).

of recurring patterns in energy load time series. Besides that, an enhancement of the decision procedure appears promising. A desirable goal would be a *fuzzy* decision process delivering *parametric* fuzzy information for the stage of development of a detected pattern. This could be more directly employed in subsequent (e. g. prediction) steps without discarding the fuzziness always inherent in a real-world recognition result.

The Collapsing Method: Does the Direction of Collapse Affect Accuracy?

Sarah Greenfield, Francisco Chiclana, Robert John[1]

1. Centre for Computational Intelligence, School of Computing, De Montfort University, Leicester LE1 9BH, UK
Email: {sarahg, chiclana, rij}@dmu.ac.uk

Abstract— *The Greenfield-Chiclana Collapsing Defuzzifier comes in many variants, depending on the order of slice collapse. The accuracy of the fundamental variants of forward, backward, inward and outward, and the composite variants of forward-backward and outward right-left is compared experimentally for the discretised interval type-2 fuzzy set.*

Keywords— Centroid, Collapsing, Defuzzification, Interval Type-2 Fuzzy Set, Representative Embedded Set.

1 Introduction

A fuzzy inferencing system (FIS) is a computerised system that uses fuzzy sets and rules to support decision making. *Type-2* FISs are being developed for an increasing number of applications such as [1], [2], [3]. There are five main stages to any FIS: fuzzification, antecedent computation, implication, aggregation and defuzzification. In the case of a type-2 FIS (where at least one fuzzy set is type-2), defuzzification consists of two parts — type-reduction and defuzzification proper, as shown in figure 1. Type-reduction is the procedure by which a type-2 fuzzy set is converted to a type-1 fuzzy set, known as the type-reduced set (TRS). The TRS is then easily defuzzified to give a crisp number.

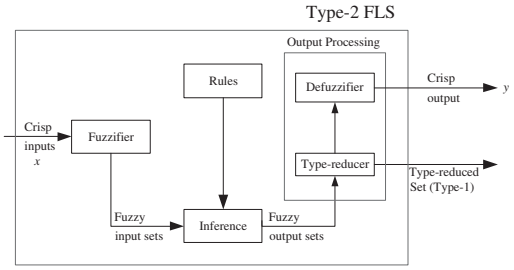

Figure 1: Type-2 FIS (from Mendel [4]).

The type-reduction stage of type-2 defuzzification is problematic owing to its computational complexity. This is the type-reduction algorithm originally described by Mendel ([4], pages 248-252):

1. All possible type-2 embedded sets ([4], definition 3-10, page 98) are enumerated.
2. For each embedded set the minimum secondary membership grade is found.
3. For each embedded set the domain value of the type-1 centroid of the type-2 embedded set is calculated.
4. For each embedded set the secondary grade is paired with the domain value to produce a set of ordered pairs (x,z). It is possible that for some values of x there will be more than one corresponding value of z.
5. For each domain value, the maximum secondary grade is selected. This creates a set of ordered pairs $(x,zMax)$ such that there is a one-to-one correspondence between x and $zMax$. This completes the type-reduction of the type-2 set to the type-1 TRS.

The resultant TRS, as with any type-1 fuzzy set, is readily defuzzified by finding its centroid.

Thus type-reduction involves the processing of *all* the embedded sets within the type-2 set. This is why we term the procedure 'exhaustive defuzzification'. Embedded sets are very numerous. For instance, when a prototype type-2 FIS performed an inference using sets which had been discretised into 51 slices across both the x and y-axes, the number of embedded sets in the aggregated set was calculated to be in the order of 2.9×10^{63}. Though individually easily processed, embedded sets in their totality give rise to a processing bottleneck simply by virtue of their high cardinality. Consequently, exhaustive defuzzification is an impractical technique.

A computationally simpler alternative to the exhaustive method is the *Greenfield-Chiclana Collapsing Defuzzifier*, introduced in [5]. This technique converts an interval type-2 fuzzy set into a type-1 fuzzy set which approximates to the *representative embedded set (RES)*, whose defuzzified value is equal to that of the original type-2 set. As a type-1 set, the RES may then be defuzzified straightforwardly.

In this paper we build on the work reported in [5]. The next section covers assumptions and definitions; section 3 presents an overview of the collapsing defuzzifier, after which section 4 introduces the theme of this article, the notion that *there are variants of the collapsing method.* Sections 5 and 6 are concerned with finding experimentally the most accurate variant.

2 Preliminaries

2.1 Assumptions

Discretisation The work presented here is concerned only with defuzzification of *discretised* type-2 fuzzy sets.

Interval Type-2 Fuzzy Set This paper is concerned with the *interval* type-2 fuzzy set.

Centroid Method of Defuzzification It is assumed that the centroid method of defuzzification ([6], page 336) is used.

2.2 Definitions

Definition 1 (Degree of Discretisation) *The* degree of discretisation *of a discretised fuzzy set is the separation of the slices.*

ISBN: 978-989-95079-6-8

Scalar Cardinality For type-1 fuzzy sets, Klir and Folger ([7], p17) define scalar cardinality as follows:

Definition 2 (Scalar Cardinality) *The* scalar cardinality *of a fuzzy set A defined on a finite universal set X is the summation of the membership grades of all the elements of X in A. Thus,*

$$| A |= \sum_{x \in X} \mu_A(x). \qquad ([7], p17)$$

To distinguish scalar cardinality from cardinality in the classical sense, we adopt the '$\| \|$' symbol for scalar cardinality.

3 Overview of the Collapsing Method

An interval type-2 set may be regarded as a blurred type-1 set. The collapsing method is a technique for deriving a type-1 fuzzy set from a type-2 fuzzy set, and may be thought of as a reversal of blurring. The type-1 set's membership function is calculated so that its defuzzified value approximates that of the type-2 fuzzy set. It is a simple matter to defuzzify the type-1 set, and to do so would be to find the defuzzified value of the original type-2 fuzzy set. The collapsing process approximates the output of the type-reducer followed by the type-1 defuzzifier, and in so doing reduces the computational complexity of type-2 defuzzification. We term this special type-1 set the *'representative embedded set approximation (RESA)'*. (Full details of the collapsing algorithm, including proof of the

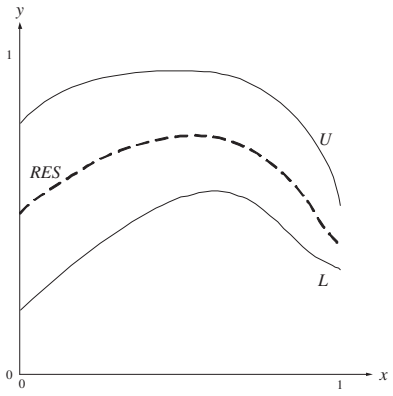

Figure 2: A Representative Embedded Set.

associated theorem, may be found at [5].) We formally state the Simple[1] Representative Embedded Set Approximation:

Theorem 1 (Simple Representative Embedded Set Approx.) *The membership function of the* embedded set *R derived by dynamically collapsing slices of a discretised type-2 interval fuzzy set $\tilde{F}$, having lower membership function L, and upper membership function U, is:*

$$\mu_R(x_i) = \mu_L(x_i) + r_i$$

with

$$r_i = \frac{\left(\|L\| + \sum_{j=1}^{i-1} r_j\right) b_i}{2\left(\|L\| + \sum_{j=1}^{i-1} r_j\right) + b_i}, \qquad (1)$$

and $b_i = \mu_U(x_i) - \mu_L(x_i)$, $r_0 = 0$.

This is an iterative formula. Collapsing proceeds vertical slice by vertical slice. The first slice is collapsed, the first y-value of the RESA calculated, the next slice is collapsed and the second y-value of the RESA calculated, and so on until all the slices have been collapsed. In this formula each b_i is the blur for vertical slice i, i.e. the difference between the upper membership function and the lower membership function for slice i. Each r_i is the amount by which the y-value of L must be increased to give the y-value of the RESA R.

4 Variants of the Collapsing Method

As we have seen, equation (1) is the formula for collapsing. This is in fact *a version* of collapsing — the most intuitive variant, whereby the slices are collapsed in the order of increasing domain value ($x = 0$ to $x = 1$). We term this *collapsing forward*. However slice collapse may be performed in any slice order giving slightly different RESAs. If the domain of the interval type-2 fuzzy set is discretised into s vertical slices, the number of permutations of these slices is $s!$ ([8], page 139). Therefore there must be $s!$ RESAs obtainable by varying the order of slice collapse. The question this piece of research addresses is, "Does the order in which the slices are collapsed affect the accuracy of the method?"

There are four fundamental variants, which we term *forward*, *backward*, *outward* and *inward*. Inward and outward may each be approached in two different ways. For the inward variant, slice collapse might start from the left or from the right. For the outward variant, the first slice is in the middle[2], but the second slice may be to the right or to the left. Added to these, there are composite variants, such as *forward-backward*, which is the mean of the defuzzified values found by collapsing forward and collapsing backward.

5 Experimental Comparison

5.1 Test Sets

We chose to test defuzzification in isolation from the rest of an FIS, on specially created test sets. Our methodology was to run different collapsing variants against each other to see which gave the most accurate results.

Symmetric Horizontal Test Set The lower membership function is the line $y = 0.2$; the upper membership function the line $y = 0.8$. The shape of this test set may be described as a horizontal stripe. The symmetry of this set tells us that its defuzzified value is 0.5.

Symmetric Triangular Test Set This is a normal test set. The lower and upper membership functions are both triangular in shape, both with vertices at $(0.4, 1)$. The symmetry of this set reveals its defuzzified value to be 0.4.

Asymmetric Gaussian Test Set This test set was deliberately designed to be asymmetrical, and hence a more realistic simulation of an FIS aggregated set. Both the lower and upper membership functions are Gaussian. As this set has no symmetry, exhaustive defuzzification (section 1) had to be employed to determine the actual defuzzified value, which, as

[1] In [5], we used the term 'simple' to describe an interval set in which each vertical slice consists of only two points, corresponding to L and U. The term is redundant in the context of this paper.

[2] We always employ an odd number of slices, giving a determinate middle slice.

ISBN: 978-989-95079-6-8

would be expected, varies slightly with the degree of discretisation.

5.2 Test Strategy

A preliminary set of tests was performed on the fundamental variants: forward, backward, inward, outward, and the composite variant forward-backward. As will be reported in the next section, the outward variant outperformed the others. This led on to further tests to discover the most accurate version of collapsing outward.

For the Gaussian test set, the only way of knowing its defuzzified value was to employ exhaustive defuzzification (section 1). This procedure only works properly for 21 slices or under. In contrast, the horizontal and triangular test sets reveal their defuzzified values by symmetry, so the number of slices used can be much higher, allowing finer discretisation.

6 Results and Conclusion

6.1 Preliminary Tests

Table 1 gives the results for the horizontal test set; table 2 gives the associated errors. Table 3 shows the triangular test set results, and table 4 the errors. The defuzzification results for the Gaussian test set are shown in table 5, with the errors in table 6. For all three test sets, the best performing variant was outward, followed by inward, then forward and backward. For the symmetrical sets (horizontal and triangular), the errors of collapsing forward were equal and opposite to those of collapsing backward. Therefore in these cases we would expect collapsing forward-backward to give exact results. This has been confirmed by experiments. For the Gaussian test set, backward performed more poorly than forward. In this case the composite of forward-backward performed worse than forward, though better than backward.

6.2 Further Tests

The outward variant may be performed in two ways, outward right and outward left (section 4). Collapsing right-left is the mean of collapsing right and collapsing left. The results and associated errors for the three versions of the outward variant as applied to the three test sets are shown in tables 7 to 9.

For the symmetrical horizontal test set, outward right and outward left gave rise to equal but opposite errors. For the composite outward right-left, these errors cancelled to zero.

The triangular test set, though symmetrical, is not placed symmetrically about $x = 0.5$. The errors of collapsing right and collapsing left were of equal sign and either equal or very close in quantity. When the errors were not equal, those of outward left were marginally smaller than those of outward right. Unsurprisingly, the performance of the composite of outward right-left fell between that of outward right and outward left.

For the Gaussian test set, the errors were all of negative sign. At all degrees of discretisation, outward left gave the best results, outward right the poorest, and outward right-left came in between.

For two of the three test sets outward left outperformed outward right. Our conjecture is that the position of the centroid is an important factor affecting which performs better out of outward right and outward left. This topic requires further research using a wider range of test sets, but for now we conclude that the optimum strategy is the composite outward right-left.

6.3 Why is Outward the Most Accurate Variant?

This explanation is based on the symmetrical horizontal test set. As each slice is collapsed, $\|L\| + \sum_{j=1}^{j=i-1} r_j$ in both the numerator and denominator of the collapsing formula (equation (1)) increases, which means that as the collapse progresses, the r_i for each collapsed slice i is a closer approximation to $\frac{1}{2}b_i$, i.e. half the 'blur' term. Thus with every successive collapsed slice, the RESA tends towards the midline of L and U, as shown in figure 3 for the forward and backward variants.

For the symmetrical horizontal test set, we take the RES to be the midline of L and U for two reasons. Firstly, by symmetry we would expect the RES to be a horizontal line. Secondly, as the number of slices is increased (either as the collapse progresses, or as the degree of discretisation is made finer), the RESA gets closer to the midline of L and U.

Therefore, as the slices are collapsed, the RESA approaches the RES. This means that the earlier slices in the RESA deviate more from the RES than the later ones. To get the best results, the collapse need to proceed symmetrically. Both the inward and outward variants meet this criterion; the inaccuracies are distributed symmetrically. However the greatest inaccuracy is associated with the first collapsed slice. To achieve maximum accuracy, the ideal place for this first slice to be positioned is centrally, as the effect on the defuzzified value obtained is then minimal. For this reason outward (figure 4) gives a more accurate defuzzified values than inward. We would expect the same reasoning to apply to all type-2 fuzzy test sets. However further investigation, using radically contrasting test sets, is planned.

Abstract—*The use of hierarchical taxonomies to organise information (or sets of objects) is essential to the semantic web and is also fundamental to many aspects of web 2.0. In most cases, the seemingly crisp granulation of a taxonomy disguises the fact that categories are based on loosely defined concepts which are better modelled by allowing graded membership. Fuzzy categories may also arise when integrating information from multiple sources which do not conform to precisely the same taxonomy definitions. Knowledge of relations between categories can be summarised by association rules. In this paper, we outline a new method to calculate fuzzy confidences for association rules between fuzzy categories from different hierarchies. We illustrate with examples drawn from a system that integrates information from web-based sources.*

Keywords— fuzzy association rules, fuzzy data mining, fuzzy hierarchies, soft semantic web, mass assignment.

1 Introduction

The semantic web [1] is a co-ordinated attempt to develop "*common formats for integration and combination of data drawn from diverse sources*"* whilst Web2.0 is an emergent trend involving changes in web use, including user participation, content sharing, collaboration, etc. Both rely heavily on hierarchical taxonomies as a fundamental mechanism for information organisation. In the case of the semantic web, ontologies provide a formal definition of terms, relations, constraints, etc. as well as their correspondence to objects in the real world. For example, an ontology for wine retailers would define terms such as grape type, vintage, region, descriptions of flavour, etc. Web documents using these terms can be processed by machines, knowing that the "meaning" is defined by the ontology. The use of "tags" from the ontology enables automated reasoning as well as assisting human understanding.

In the case of Web 2.0, tagging and categorisation also play a central role. Photo and video sharing sites, wikis, blogs, and large parts of e-commerce rely on hierarchical categorisation of content. This may be implicit rather than explicit - a tag such as *sport* can encompass *athletics*, *swimming*, *football*, etc - but the hierarchical nature is unarguable. Rather than relying on formal, agreed ontologies, the meaning of a tag is essentially defined by the user who adds the tag, and a degree of shared understanding is necessary for the system to work.

The ability to categorise and summarise data is a key feature of human intelligence, enabling us to group multiple entities together into an (approximately) uniform whole and represent / reason about the group as a single concept. Many familiar ways to access information such as books, libraries, computer file structures, the web and other networks provide evidence that hierarchical categorisation is an efficient way to organise and access information.

There is rarely a single unique hierarchy - instead, a person chooses the most appropriate way to split up data according to their expertise / background knowledge and the problem at hand. For example, Fig 1 shows two possible divisions of customers. Here, as in most real-world hierarchies, groups of entities (or conceptual categories) are loosely defined, able to admit elements according to some scale of membership rather than according to an absolute yes/no test - indicating that fuzzy set theory [2] is appropriate.

An association exists when the extensions of two concepts overlap significantly, as indicated in Fig 1 by the directed link. Association rules (in their crisp form) are a well-established technique for knowledge discovery in databases,

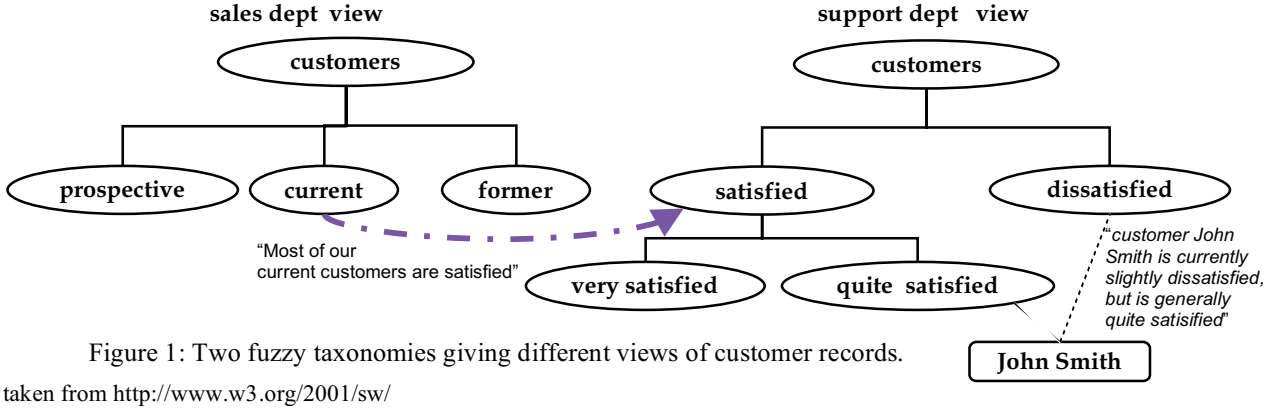

Figure 1: Two fuzzy taxonomies giving different views of customer records.

* taken from http://www.w3.org/2001/sw/

ISBN: 978-989-95079-6-8

enabling "interesting" relations to be discovered. There have been a number of proposals to develop fuzzy association rules, that is to discover the degree of association between fuzzy categories. Some of our recent work has used mass assignment theory [3-5] to find a point valued association strength between fuzzy categories [6], later extended to an interval-valued version [7]. In common with other work on fuzzy association rules, most of our previous work assumes there is a crisp value for the rule confidence.

The main contribution of this paper is a novel mass assignment-based method for calculating a *fuzzy* confidence in associations between fuzzy categories. It relies on a new method of converting fuzzy relations to mass assignments and a membership function for fuzzy confidence related to the movement of mass needed to produce that confidence value. The minimum and maximum values for the confidence can be found quickly, and memberships calculated based on the corresponding mass assignments. A full version, including proofs, will appear subsequently [8].

2 Background

The Smart Queries and Adaptive Data (SQuAD) project is concerned with adding structure (tags) to data and refining approximate knowledge from this data. It aims to assist in the extraction of useful information from diverse sources of semi-structured text data and consists of four main components:

- approximate fuzzy grammars [9] to tag small text fragments.
- SOFT (Structured Object Fusion Toolkit) [10] to help determine that entities from different sources are the same (a process also known as instance-matching, entity resolution)
- iPHI (intelligent Personal Hierarchies of Information) [11, 12] which aims to combine and integrate multiple sources of information and to configure access to the information based on an individual's personal categories.
- TRACK (Time-varying Relations in Approximately Categorised Knowledge). [7] The previous three processes leave us with a collection of objects organised into fuzzy categories, where the taxonomic structure reflects a view of the underlying data. Insight can be gained by considering relations between fuzzy categories, particularly from different category hierarchies. Of particular interest is the change over time in the degree of association between fuzzy categories - for example, in Fig 1, an executive in charge of the company would be interested to know whether the set of current customers (in the sales department's categorisation) is mostly the same as the fuzzy set of satisfied customers (in the support department's categorisation) and how the relation has changed over recent time, over the medium term and over the long term - particularly if there have been significant changes such as company practice, number/nature of competitors, etc during any of these periods.

2.1 Fuzzy Sets - the Conjunctive Interpretation

Many authors (e.g. [13]) have proposed fuzzy sets to model uncertain values in databases and knowledge based applications. The standard (disjunctive) interpretation of a fuzzy set in this context is as a possibility distribution - a single valued attribute which is not known exactly.

The conjunctive interpretation of a fuzzy set occurs when the attribute can have multiple values. These values are not repeated so it is a set, not a multi-set. For example, a person may be able to speak several languages; we could model this as a fuzzy set of languages, where membership would depend on the degree of fluency. This is formally a relation rather than a function on the underlying sets. We distinguish between the conjunctive interpretation - modelled by a monadic fuzzy relation – and the disjunctive interpretation – modelled by a possibility distribution by using the notation

$$F(a) = \{x/\mu(x) \mid x \in U\}$$

to denote a single valued attribute F of some object a (i.e. a possibility distribution over a universe U) and

$$R(a) = [x/\chi(x) \mid x \in U]$$

to denote a multi-valued attribute (relation). Fuzzy categories represent the latter case, since we have multiple values that satisfy the predicate to a greater or lesser degree.

2.2 Extending Association Rules to Fuzzy Categories

In creating association rules within transaction databases (e.g. [14], see also [15] for a clear overview), the standard approach is to consider a table in which columns correspond to items and each row is a transaction. A cell contains 1 if the item was bought, and 0 otherwise. The aim of association rule mining is to find links between disjoint subsets of items – for example, do customers generally buy biscuits and cheese when buying beer and wine? These disjoint subsets represent categories, as described earlier.

Let I denote the set of items, so that any transaction can be represented as $tr \subseteq I$, and consider X, the set of all transactions (strictly speaking, X is a multi-set but can be made into a set by adding a unique identifier to each transaction). We also specify two categories (itemsets) s and t, which are non-empty, non-overlapping subsets of I,

$$t \subset I \qquad s \subset I \quad \text{where} \quad s \cap t = \varnothing$$

and the sets of transactions containing s and t

$$S = \{x | x \in X \wedge s \subseteq x\}$$

$$T = \{x | x \in X \wedge t \subseteq x\}$$

An association rule is of the form $s \Rightarrow t$ and is interpreted as stating that when the items in s appear in a transaction, it is likely that the items in t will also appear i.e. it is not an implication in the formal logical sense. A slight abuse of notation allows us to use $S \Rightarrow T$ or $s \Rightarrow t$ as the rule.

Most authors use two measures to assess the significance of association rules. The support of a rule $s \Rightarrow t$ is the number (or relative number) of transactions in which both s and t appear, and the confidence of the rule is an estimate (based on the samples) of the conditional probability of t being contained in a transaction given that it contains s

$$Support(s,t) = |S \cap T| \qquad (1)$$

$$Conf(s,t) = \frac{|S \in T|}{|S|} \qquad (2)$$

Typically a threshold is chosen for the support, so that only frequently occurring sets of items s and t are considered; a second threshold filters out rules of low confidence.

ISBN: 978-989-95079-6-8

name	sales	salary
a	100	1000
b	80	400
c	50	800
d	20	700

good sales	*high salary*	*confidence*
sales≥80	*high≥400*	1
sales≥50	*high≥500*	0.667
sales>50	*high>500*	0.5
sales≥50	*high>800*	0.333

Figure 2 : A simple database of names (*a, b, c, d*), sales and salaries (top) and (bottom) confidences for the rule *good sales => high salary* arising from different crisp definitions of the terms *good sales* and *high salary*

For example, consider a database of sales employees, salaries and sales figures. A mining task might be to find out whether the good sales figures are achieved by the highly paid employees. Given the database table in Fig 2, we can obtain rule confidences ranging from 1/3 up to 1 by different crisp definitions of "*good sales*" and "*high salary*".. Although this is a contrived example, such sensitivity to the cut-off points adopted for crisp definitions is a good indication that a fuzzy approach is more in line with human understanding of the categories.

Various approaches to fuzzifying association rules have been proposed e.g. [15-17]. The standard extension to the fuzzy case is to treat the sets *S, T* as fuzzy and find the intersection and cardinality using a t-norm and sigma-count respectively.

$$Conf(S,T) = \frac{\in \mu_{S \cap T}(x)}{\in \mu_S(x)} \qquad (3)$$

In the example of Fig 2, a fuzzy approach would categorise employees according to simple membership functions for *good sales* (S) and *high salary* (T), which could lead to

$S = [a/1, b/0.8, c/0.5, d/0.2]$

and

$T = [a/1, b/0.4, c/0.8, d/0.7]$

and confidence 0.72 for the association $S=>T$ using (3).

As pointed out by [15], using min and the sigma count for cardinality can be unsatisfactory because it does not distinguish between several tuples with low memberships and few tuples with high memberships - for example,

$S = [x_1/1]$

$T = [x_2/1]$

leads to *Conf(S, T) = 0* but

$S_1 = [x_1/1, x_2/0.01, x_3/0.01, \ldots, x_{1000}/0.01]$

$T_1 = [x_1/0.01, x_2/1, x_3/0.01, \ldots, x_{1000}/0.01]$

leads to

$$Conf(S_1,T_1) = \frac{1000 \in 0.01}{1 + 999 \in 0.01} \in 0.91$$

which is extremely high for two almost disjoint sets (this example originally appeared in [18]). Using a fuzzy cardinality (i.e. a fuzzy set over the possible cardinality values) is also potentially problematic since the result is a possibility distribution over rational numbers, and the extension principle [19] gives a wider bound than it should, due to neglect of interactions between the numerator and denominator in Eq 2. For example, given

$S = [x1/1, x2/0.8]$

$T = [x1/1, x2/0.4].$

the fuzzy cardinalities are

$|S \cap T| = \{1/1, 2/0.4\}$,

$|S| = \{1/1, 2/0.8\}$

leading (by the extension principle) to a confidence of

$\{0.5/0.8, 1/1, 2/0.4\}$,

clearly incorrect as the confidence cannot be greater than 1.

2.3 Fuzzy Relations as Mass Assignments

As with previous work [6, 7] we start from the fact that a relation represents a conjunctive set of ordered *n*-tuples i.e. a conjunction of *n* ground clauses. For example, if *U* is the set of dice values then we could define a (crisp) predicate *differBy4or5* on $U \times U$ as the set of pairs

[(1,6), (1,5), (2,6), (5,1), (6,1), (6, 2)]

This is a conjunctive set, in that each pair satisfies the predicate. In a similar way, a fuzzy relation represents a set of *n*-tuples that satisfy a predicate to some degree. Thus *differByLargeAmount* could be represented by

[(1,6)/1, (1,5)/0.6, (2,6)/0.6, (5,1)/0.6, (6,1)/1, (6,2)/0.6]

The interpretation is not that a single pair satisfies this predicate, but that one set of pairs satisfies it (out of several possible sets of pairs).

A mass assignment [3-5] on a universe *U* is a distribution over the power set of *U*. Here, the mass assignment is on possible *relations* :

$R_1 = [(1,6),(6,1)]$

$R_2 = [(1,6),(1,5),(2,6),(5,1),(6,1),(6,2)]$

$m = \{\{R_1\} : 0.4, \{R_1, R_2\} : 0.6\}$

This is equivalent to treating the fuzzy relation as a fuzzy set of crisp relations:

$differByLargeAmount = \{R1/1, R2/0.6\}$

Similarly, a monadic fuzzy predicate *largeValue* defines a set of 1-tuples such as [6/1, 5/0.8, 4/0.3] which is written as a fuzzy set of crisp monadic relations:

$largeValue = \{[6]/1, [6,5]/0.8, [6,5,4]/0.3\}$

and has the mass assignment

$m_{largeValue} = \{\{[6]\} : 0.2, \{[6],[6,5]\} : 0.5, \{[6],[6,5],[6,5,4]\} : 0.3\}$

Our subsequent studies [7] show that this approach can sometimes overestimate the difference between full and nearly-full membership, which can lead to unreasonably large intervals calculated for the confidence of association rules. For example, under this interpretation, the monadic fuzzy relation $S = [a/1\ b/0.98]$ has the mass assignment

$m_S = \{\{[a]\} : 0.02, \{[a],[a,b]\} : 0.98\}$

ISBN: 978-989-95079-6-8

The normal mass assignment interpretation allows us to redistribute the mass on {*[a], [a,b]*} to either of the relations *[a]* or *[a,b]* which leads to the family of distributions:

$S = [a] : 1\text{-}x \quad , \quad [a,b] : x \quad$ where $0 \le x \le 0.98$

This flexibility in re-assigning mass means that for a source

$S = [a/1\ b/0.98]$ and target relation $T = [a/1\ b/0.98\ c/0.02]$

we get an interval [0.51, 1] which is surprisingly wide considering the two relations are so similar. NB this behaviour arises mostly in contrived cases, smaller intervals are calculated in the vast majority of "real" association rules that have arisen in our experimental studies such as [7].

2.4 Alternative Interpretation of Relations as Mass Assignments

The approach discussed above, which we will refer to as an open world approach, treats partial membership of a tuple x in a relation R (i.e. $0 < \cap_R(x) < 1$) as an upper bound for the mass that can be assigned to any set of tuples including x. This leads to a wide range of mass distributions that can be derived from the fuzzy relation R.

In the open world approach, for any tuple x where $\cap_R(x)<1$, the total mass that can be assigned to relations containing x is given by

$$0 \le \sum_{\substack{t=[x1,\ldots,xn] \\ x \in t}} m(t) \le \chi_R(x)$$

In the *largeValue* example above, consider the element $x=5$, which has $\cap_R(x) = 0.8$; the relations containing 5 are [5, 6] and [4, 5, 6] and we have

$$0 \le m_{largeValue}([5,6]) + m_{largeValue}([4,5,6]) \le 0.8$$

This gives a considerable degree of flexibility in assigning mass. The alternative interpretation used here - the closed world approach - regards partial membership of a tuple x in a relation R (i.e. $0 < \cap_R(x) < 1$) as *strictly equal* to the total mass assigned to the sets of tuples which include x, i.e.

$$\sum_{\substack{t=[x1,\ldots,xn] \\ x \in t}} m(t) = \cap_R(x)$$

This means there is no flexibility in the range of mass distributions that can be derived from the fuzzy relation R. However, there is flexibility in the mass assignments when R is combined with an assignment corresponding to another relation, for example in calculating association confidences as described later.

Under this interpretation, the monadic fuzzy relation *largeValue* discussed above has

$$m_{largeValue} = \{[6]:0.2,\ [6,5]:0.5,\ [6,5,4]:0.3\}$$

and clearly

$$m_{largeValue}([5,6]) + m_{largeValue}([4,5,6]) = 0.8$$

2.5 Closed world Mass-based Association Rules

For a source category

$$S = \left[x_1/\chi_S(x_1),\ x_2/\chi_S(x_2),\ldots,\ x_{|S|}/\chi_S(x_{|S|})\right]$$

and a target category

$$T = \left[x_1/\chi_T(x_1),\ x_2/\chi_T(x_2),\ldots,\ x_{|T|}/\chi_T(x_{|T|})\right]$$

we can define the corresponding mass assignments as follows. Let the set of distinct memberships in S be

$$\Lambda_S = \left\{\chi_S^{(1)}, \chi_S^{(2)}, \ldots, \chi_S^{(n_S)}\right\}$$

where

$$\chi_S^{(1)} > \chi_S^{(2)} > \ldots > \chi_S^{(n_S)}$$

and $n_S \le |S|$

Let

$$S_i = \left\{\left[x \,\middle|\, \chi_S(x) \ge \chi_S^{(i)}\right]\right\}$$

Then the mass assignment corresponding to S is

$$\left\{S_i : m_S(S_i)\right\}, \quad 1 \le i \le n_S$$

where

$$m_S(S_k) = \chi_S^{(k)} - \chi_S^{(k+1)} \qquad (7)$$

and we define

$$\chi_S^{(i)} = 0 \quad if \quad i > n_S$$

For example, the fuzzy category

$S = [a/1,\ b/0.8,\ c/0.5,\ d/0.2]$

has the corresponding mass assignment

$$M_S = \{[a]:0.2,\quad [a,b]:0.3,\quad [a,b,c]:0.3,\quad [a,b,c,d]:0.2\}$$

We can now calculate the confidence in the association between the categories S and T using mass assignment theory. In general, this is not a unique value as we are free to move mass (consistently) between the cells corresponding to S_i and T_j for each i, j.

For two mass assignments

$$M_S = \left\{S_i : m_S(S_i)\right\}, \quad 1 \le i \le n_S$$

$$M_T = \left\{T_j : m_T(T_j)\right\}, \quad 1 \le j \le n_T$$

the composite mass assignment is

$$M = M_S \oplus M_T = \left\{X : m(X)\right\}$$

where m is specified by the composite mass allocation function, subject to

$$\sum_{j=1}^{n_T} m_{ij} = m_S(S_i) \qquad \sum_{i=1}^{n_S} m_{ij} = m_T(T_j)$$

This can be visualised using a mass tableau (see [3]) as shown in Fig 3. Each row (column) represents a relation of the source (target) mass assignment. We label the rows $S_1, S_2, \ldots S_{nS}$ and columns $T_1, T_2, \ldots T_{nT}$, and assign mass m_{ij} to cell *(i, j)* subject to row and column constraints. The confidence in the association rule is given by

$$conf(M) = \frac{\sum_{i,j}\left(m_{ij} \times |S_i \cap T_j|\right)}{\sum_{i=1}^{n_S}\left(\sum_{j}^{n_T} m_{ij} \times |S_i|\right)} = \frac{n}{d}$$

$$where \quad n = \sum_{i,j}\left(m_{ij} \times |S_i \cap T_j|\right)$$

$$d = \sum_{i=1}^{n_S}\left(\sum_{j}^{n_T} m_{ij} \times |S_i|\right) = \sum_{i=1}^{n_S} |S_i| \times m_S^{(i)} \qquad (7)$$

ISBN: 978-989-95079-6-8

Clearly $n \geq 0$, $d > 0$ and d is a constant for a given source relation S, irrespective of T and M.
For example consider the fuzzy categories

$S = [a/1, b/0.8, c/0.5, d/0.2]$ and

$T = [a/1, b/0.4, c/0.8, d/0.7]$

One notable assignment is the least prejudiced distribution, obtained by taking the product of source and target masses for each cell as shown in Fig 3. This corresponds to the minimum entropy combination of the two mass assignments.

		0.2 [a]	0.1 [ac]	0.3 [acd]	0.4 [abcd]
0.2	[a]	[a] 0.04	[a] 0.02	[a] 0.06	[a] 0.08
0.3	[ab]	[a] 0.06	[a] 0.03	[a] 0.09	[ab] 0.12
0.3	[abc]	[a] 0.06	[ac] 0.03	[ac] 0.09	[abc] 0.12
0.2	[abcd]	[a] 0.04	[ac] 0.02	[acd] 0.06	[abcd] 0.08

Figure 3: mass tableau, showing intersections $S_i \in T_j$ and the least prejudiced mass distribution. The corresponding point valued rule confidence is 1.86 / 2.5 = 0.744

It is possible to show [8] that maximum rule confidence is obtained by moving mass towards the diagonal (top left to bottom right) and that minimum confidence is obtained by moving mass towards the bottom left - top right diagonal, as illustrated in figs 4 and 5.

		0.2 [a]	0.1 [ac]	0.3 [acd]	0.4 [abcd]
0.2	[a]	[a] 0.2	[a] 0	[a] 0	[a] 0
0.3	[ab]	[a] 0	[a] 0.1	[a] 0.2	[ab] 0
0.3	[abc]	[a] 0	[ac] 0	[ac] 0.1	[abc] 0.2
0.2	[abcd]	[a] 0	[ac] 0	[acd] 0	[abcd] 0.2

Figure 4 : mass tableau, showing intersections $S_i \in T_j$ and the mass distribution leading to minimum rule confidence 2.1 / 2.5 = 0.84

		0.2 [a]	0.1 [ac]	0.3 [acd]	0.4 [abcd]
0.2	[a]	[a] 0	[a] 0	[a] 0	[a] 0.2
0.3	[ab]	[a] 0	[a] 0.1	[a] 0.1	[ab] 0.2
0.3	[abc]	[a] 0	[ac] 0.1	[ac] 0.2	[abc] 0
0.2	[abcd]	[a] 0.2	[ac] 0	[acd] 0	[abcd] 0

Figure 5 : mass tableau, showing intersections $S_i \in T_j$ and the mass distribution leading to minimum rule confidence 1.5 / 2.5 = 0.6

2.6 Membership Function for Fuzzy Confidence

We define the membership function in terms of the mass which must be moved (relative to the least prejudiced distribution, where confidence has membership 1). Any other assignment of mass requires one or more elementary mass transfers relative to the LPD, and we are particularly interested in mass assignments corresponding to minimum and maximum confidence, M^{MIN} and M^{MAX}. We define a fuzzy interval C representing the confidence such that

$$\mu_C(conf(M)) = 1 - \frac{pos(M^{LPD} - M)}{N}$$

where $$N = \max\left(pos(M^{\max} - M^{LPD}), pos(M^{\min} - M^{LPD})\right)$$

Because the membership varies linearly with the amount of mass moved, it is triangular and can be calculated quickly by considering the end points. We note that it is possible for the membership function to be discontinuous at one end (i.e. to drop abruptly to zero). Fig 6 shows the membership function for the fuzzy confidence in the *good sales - high salary* example, with the calculations shown in figs 3, 4, and 5.

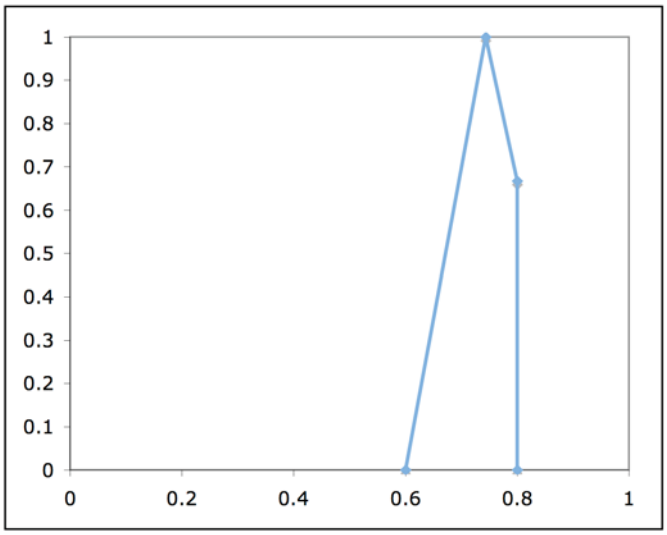

Figure 6 : Membership function for fuzzy confidence in the good sales - high salary example. Note the discontinuity at 0.8

3 Demonstrator Application

We have applied the algorithm to calculation of associations in an integrated taxonomic database of terrorist incidents, as described in [7]. Our primary source is the Worldwide Incidents Tracking System (WITS) [20] augmented by additional information from the MIPT Terrorism Knowledge Base (TKB) database[†]. WITS consists of incidents in which *"subnational or clandestine groups or individuals deliberately or recklessly attacked civilians or noncombatants (including military personnel and assets outside war zones and war-like settings)"*. We are not concerned with the correctness or otherwise of this definition, and treat the data simply as a testbed for SQuAD .

Once data has been integrated and categorised into the iPHI hierarchies, the methods outlined in this paper and [20]

[†] TKB ceased operation on 31 March 2008 and is now part of Global Terrorism Database (GTD) at www.start.umd.edu/data/gtd/

ISBN: 978-989-95079-6-8

have been applied to find significant associations between categories in different hierarchies (e.g. *geographic region*, *weapon type, perpetrator, casualty level* etc). Since the data is not static, we cannot assume that significant associations remain significant – indeed, valuable insight arises from changes in association levels relative to other associations, and trends in the strength of an association. 15,900 incidents between January 2005 and January 2006 were analysed.

Various associations can be extracted by consideration of fuzzy categories in different taxonomies. Although the vast majority of results from [7] led to reasonable intervals, there were a few cases in which intervals were quite large. As can be seen from Fig 7, much smaller intervals were obtained under the closed world method. The interval for closed world rules indicates the extremes of the fuzzy association confidence, with a symmetric triangular membership function (possibly truncated on one side). The interval for open world calculations has membership 1 throughout.

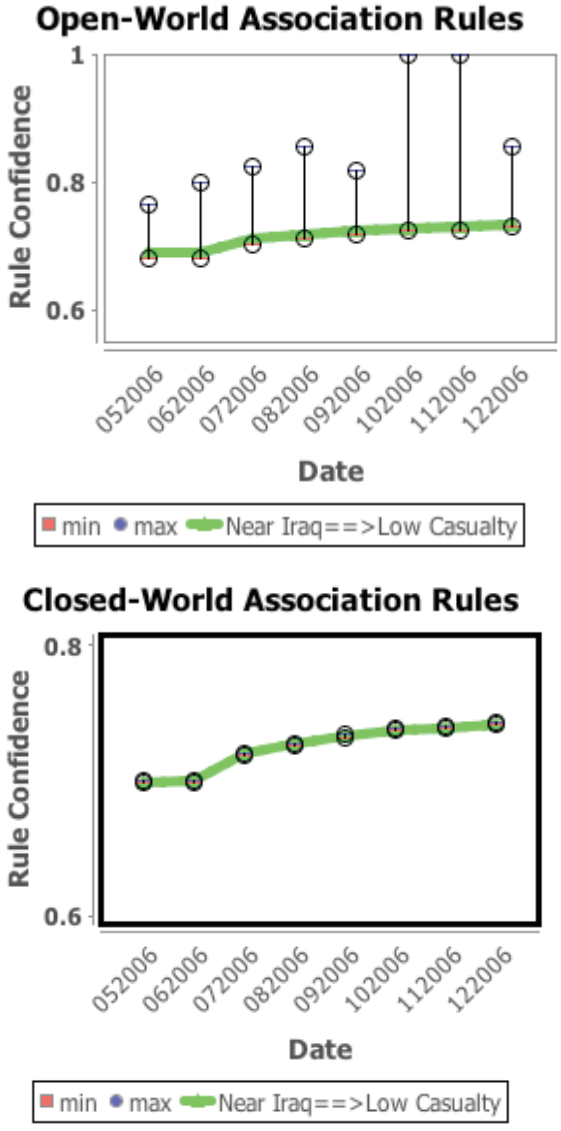

Figure 7 : Confidence intervals and point values for associations between the fuzzy categories *in/near Iraq* and *Medium casualty levels*. The fuzzy confidence (closed world) gives a much tighter interval than the open world calculation

4 Summary and Future Work

We have described a new method for calculating the confidence in an association rule between two (or more) fuzzy categories, based on mass assignment theory and yielding a fuzzy interval within which the confidence must lie. Combined with the point value confidence described in previous work, this enables us to order and plot association strengths with an indication of the degree of uncertainty.

Abstract— *Fuzzy logic has a considerable success in the area of applications. However, this active growth in the implementation in applied electronic devices has not always been accompanied by a discussion about the theoretical grounds underlying those uses. This paper deals with some theoretical aspects that seem convenient to discuss for the purpose of clarifying the status of fuzzy logic, to get into its true nature and to appoint its achievements and limits. In order to carry out this goal, the paper is organized around three questions: 1) Fuzzy logic, is it a logic or a techno-logic?; 2) How fuzzy is fuzzy computing?; 3) Are there fuzzy objects?*

Keywords— Fuzziness, fuzzy computation, fuzzy objects, philosophy of soft computing, vagueness.

1 Introduction

Borderline cases are initially addressed by Ch. S. Peirce in 1902 [1]. In 1923, B. Russell positioned vagueness as an interesting subject in the philosophy arena [2]. Later, Hempel and Copi dealt with vagueness in separate articles published in the journal *Philosophy of Science* [3, 4]. Up till them, vague language was not considered a central topic for the analytic tradition, a school of thought characterized by an emphasis on clarity and argument, achieved by formal logic and analysis of language. M. Black introduced in 1937 [5] the 'consistency-profiles' as a way to represent the meaning of a vague predicate, defined by the standard use that a community make of it. Consistency-profiles are represented by curves, showing the degree of consistency in the application of a word to an object or concept. The notion involves three characteristics present in the modern forms to represent vagueness: the user of a language, a situation in which the user is trying to apply a symbol to an object and a way to represent the consistency of this application through a logic formalism.

Among the modern initiatives to deal with the formal representation of vagueness, understood as imprecision, the most successful has been Zadeh's fuzzy logic [6]. Fuzzy logic enables to symbolize vague propositions and to manage approximate inferences in a suitable way. As a result, it has had a tremendous growth, supported mainly by the success of their applications. However this active growth in the area of applications has not always been accompanied by a reflection on the theoretical grounds involved in the use of the underlying tool. As an applied logic it was not surprising that, in the beginning, Zadeh claimed that *"clearly the problems, the aims and the concerns of fuzzy logic are substantially different from those which animate the traditional logical systems. Thus, axiomatization, decidability, completeness, consistency, proof procedures and other issues which occupy the center of the stage in such systems are, at best, of peripheral importance in fuzzy logic"* [6, p.151]. And perhaps the same could be said of the metatheoretical discussions. In this paper we will deal with some theoretical problems that we believe that they are important for the purpose of clarifying the status of fuzzy logic, to get into its true nature and to draw its achievements and limits. The fundamental issues considered here take the form of three questions that, in turn, will name the next three sections of this work.

2 Fuzzy logic, in its true nature, is it a logic or rather than a *techno*-logic?

The reflection about the logical statute of fuzzy logic is involved with two traditional topics in Philosophy:

i. The classification of sciences.

ii. The fundamentation of sciences.

The classification of sciences is frequently revised in function of new emergent branches of knowledge, forcing to modify standard taxonomies. In the field of deductive sciences, fuzzy logic came as a new discipline that questioned some of the classical principles, prompting a debate about the nature of the logic and provoking a discussion about the status of the deviant logics, among which fuzzy logic was included [7].

Since its birth, fuzzy logic was valued in different ways by engineers (applied scientists) and by mathematicians (theoretical thinkers). Due to the success of the applications, fuzzy logic was welcomed in Engineering Schools. Nevertheless, it also caused rejection among mathematicians because, during a long time, it was a matter under construction, provisional and tentative.

Engineers use fuzzy logic according, at least, three criteria:

- Fuzzy logic allows us to represent complex scenarios that involve uncertainty using few rules. In the same vein, it permits to manage approximate inferences reaching good and quite stable solutions to the pretended conclusions.
- Although fuzzy logic is a (precise) logic about imprecision, it manages outputs that provides enough information to make good decisions. As Popper says: *"Although clarity is valuable in itself, exactness or precision is not: there can be no point in trying to be more precise than our problem demands"* [8, p.28]. So, in presence of imprecision, alternatives to the classical bivalent logic should be suggested.
- Systems with incorporated fuzzy rules are quite robust. Fuzzy logic admits a tolerance fringe between positive and negative outputs, although it is difficult to supply *a priori* guaranties about the stability of a fuzzy controller.

ISBN: 978-989-95079-6-8

These points agree with the Zadeh's *dictum*, known as 'Principle of Incompatibility': *"Stated informally, the essence of this principle is that as the complexity of a system increases, our ability to make a precise and yet significant statements about its behavior diminishes until a threshold is reached beyond which precision and significance (or relevance) become almost mutually exclusive characteristics"* [9, p. 28].

In summary, from the applied sciences point of view, as engineering, fuzzy logic is a useful discipline. Its success are the achievements of its applications and any further evidence is not requested about the logical properties of the formal tool. For engineers, fuzzy logic is a techno-logic, i.e., a logic to be implemented in electronic machines.

But beyond applications, fuzzy logic is a kind of logic and, therefore, a branch of mathematics. Mathematics is a theoretical science, not an applied one and its currency are precision, rigor and proof. So, frequently, fuzzy logic was not welcomed in mathematical circles while it was used as an *ad hoc* tool for solving quite particular problems in a large extent and specially in early applications. This partial and temporary knowledge was not well received in the field of mathematics, accustomed to dealing with eternal truths. Attending to its provisional character, mathematicians think that fuzzy logic is not a logic, but a kind of formalism for managing specific problems that involves imprecision; fuzzy logic, they say, does not manage any rationality, even not that it say to grasp: the imprecise or vague reasoning.

Attending to classical logic, the Verificability Principle allows us to substitute a proposition by its truth value. But in the field of fuzzy logic, this unanimous correspondence is problematic. A vague predicate can be represented, in a reasonable way, by similar linguistic labels or fuzzy numbers. As a matter of degree, fuzzy meaning is grasped in an imprecise way; hence, some margins of tolerance should be admitted in order to represent it. Accordingly, in fuzzy logic it is not possible to forget the world and focus only in the proofs. We need to reconcile both of them. Any attempt to give a fuzzy logic axiomatic approach hits with the absence of the stability of truth, with the lack of a perfect truth. Therefore, for mathematicians, fuzzy logic is not a true logic.

From the point of view of the fundamentation of sciences, logic is a main part of the scientific method. The hypothetico-deductive system is considered, frequently, as the scientific method *par excellence*. From Aristotle, Science is strongly related to deductive reasoning. In [10], it is defined a deductive science as a set S of sentences that satisfies four conditions:

1. *Reality postulate*: Sentences of S are about a particular subject matter, about real entities.

2. *Truth postulate*: Each sentence of S is true.

3. *Deductive postulate*: If something can be deduced from a subset of S, then it is also a member of S –closure property under logical consequence.

4. *Evidence postulate*:

   (a) *Definability*: The sentences of S are built from a finite set of terms, which have a meaning immediately obvious.

   (b) *Axiomatizability*: The truth of every sentence of S can be inferred logically from a certain finite subset S_1 of S whose truth is also obvious.

Postulates 1 and 2 require comments. It is known that both mathematics and physics are scientific theories. But while mathematics is an ideal science, physics is an experimental one. So, the objects of mathematics are not real objects, but ideal entities. Therefore, their statements can be absolutely true; timeless true. This forces to not cast doubts about the postulate 3. The simplification of the reality and the idealism related to the mathematical thinking lead to not questioning the postulate 4. But empirical statements are about real entities, and material objects change and vary over time. So, postulate 2 –the *truth postulate*– is not immediately obvious. Sometimes empirical sentences are true, sometimes are partially true (true in a degree, true with a probability,...) but they are always temporarily true; that is, true in absence of falsation. Postulate 2 is known as the Principle of Bivalence and it was traditionally rejected in other applications which are different from the logic of mathematical entities.

In twentieth century, with the birth of artificial intelligence, a new way to see deductive sciences came. The logic is not only applied to specific languages, such as the mathematical language –crisp in nature–, or to regimented natural language –specified artificially–, but also to statements that verbalize normal situations related to ordinary life. So, the *Reality Postulate* was extended to any real entity, including these with ill-defined borders and the *Principle of Bivalence* was replaced by the *Principle of Valence* [11], which states that every proposition has a truth value, not fixing how many or which. The relaxation of principles 1 and 2 casts doubt on the fourth: in real life it is difficult to think about meanings or truths immediately obvious. More attention is demanded by the third principle. Fuzzy logic is a deductive logic that grasps imprecise consequences. As a logic, it aims to conclude deductively, but as a theory of imprecise consequences, calls for margins of tolerance or imprecise intervals of plausible conclusions. Whether fuzzy logic verifies, or not, the deductive postulate depends on how the meanings of vague sentences are represented, as well as the approach to combine them into complex propositions. For example, Trillas et al. showed that the unique way to obtain consequences in the Tarski's sense from the Zadeh's compositional rule of inference is using the bold t-norm if the rule is represented by the Reichenbach's conditional definition [12].

From the beginning until now, fuzzy logic has evolved dramatically. Today it is still a formal tool with successful applications, but also a logic that seeks its theoretical consolidation. In this goal highlights –among others– the contributions made by the Spanish school of fuzzy logic, particularly those made by Esteva & Godo and Trillas. Esteva & Godo deal with fuzzy logic as a symbolic logic developed in the spirit of classical logic (syntax, semantics, axiomatization, truth-preserving deduction, completeness, etc. both in propositional and predicate logic) [13]. Hajek and Novak et al. contributed too to credit fuzzy logic in this vein [14, 15]. Hence, their work was directed to confer credit to fuzzy logic as a kind of logic. Trillas has been from a long time devoted to evolve a fuzzy metatheory of fuzzy logic; so, he has contributed to develop fuzzy logic as a fuzzy theory [12]. All of them, helped to

ISBN: 978-989-95079-6-8

credit fuzzy logic as an area of interest in the contemporary scientific panorama.

Despite these developments, fuzzy logic needs to assume new challenges. In the field of applications is a truism the success of the fuzzy controllers in many household devices. But to avoid falling in auto-complacency, it would be desirable to develop applications where vagueness or imprecision are the main component of a complex system; e.g., implementing fuzzy logic into devices in order to summarize perceptions [16]. In the theoretical perspective, fuzzy logic needs to debate about the ways to represent the meaning of a vague proposition, how to justify one choice or another among the various alternatives. Its credibility will be critically linked to this task. Another job will be to mix fuzzy logic with others logics while imprecision in not the only characteristic of human language or human decision-making. Context, time, intentionality, beliefs and its corresponding logics are jointly relevant to model human reasoning and, therefore, to build electronic devices that simulate human behavior.

The new fuzzy logic proposed by Zadeh under bright titles as 'Computing with Words and Perceptions', 'Precisiated Natural Languages', 'Protoforms' and so on [17], should make progress in this regard. Until now we have ashy headlines but low content.

3 How fuzzy is fuzzy computing?

'Turing machine' (TM) is perhaps the main reference in computer science. So, it is said that any function is computable if it is Turing computable. If a problem is computable, it admits an algorithmic definition; i.e., its solution can be reached by a finite sequence of instructions that ends in a finite time.

A TM requires that:

- Each cell of the tape contains only a symbol, although there can be an infinite number of cells.
- States are finite and discrete: the machine is in one state or another, but never in two states at the same time or in no state.

According to the discrete nature of the alphabet and the states, the computation performed by a TM is linear and precise. But although the representation and the computation of a problem are bivalent in nature, the output may be trivalent: in effect, a TM computation can conclude in three different states:

- Final state or success: The problem is decidable and it has a solution.
- Non-final state or failure: The problem is decidable but it does not have solution.
- Loop state or auto-referential state: The machine computes indefinitely and never stop. The problem is indecidable and it does not have any solution. Hence, a TM may have not solution because it stops on a not final state or because it does not stop.

There are so many TM as problems can be putted in an algorithmic form. But a nice achievement of the theory of computation is that any TM admits to be simulated by a special one: the binary TM. A binary TM works as follows: any symbol or state is represented by binary digit or a set of binary digits. So, an instruction as $10 \longrightarrow 10001l$ denote that the machine is in the internal state *1*, reads *0* in the tape, change to the state *1000*, writes *1* and it moves the tape one step to the left. A binary TM can simulate any other specific TM; so, it is an universal computing machine.

At this point, we wish to emphasize the capability of the binary TM to simulate the behavior of any other TM. But the TM not only support be simulated. It is also an excellent simulator; in particular, mimic goods solutions to problems which was not designed to. For example, several TM working simultaneously can imitate a parallel computation, although the way in which TM process is sequential and not parallel.

Fuzzy TM goes back to the late 1960s, when Zadeh spoke about the notion of fuzzy algorithm [18]. Santos gave the formal description of a fuzzy algorithm by fuzzy variants of Turing machines, Markov algorithms and finite automata [19]. He established the fundamentals of the fuzzy language too. Fuzzy TM are linked to classical TM through the support and crisp part of a fuzzy set. Fuzzy algorithms were drawn to perform imprecise computations.

What is meant by imprecise computations? At least, two answers are possible:

- In a soft sense, imprecise computations refer to problems whose working process can be expressed in an algorithm form through imprecise instructions; that is, rules that are or are not completely satisfied, but only fulfilled at some extent. From this perspective, a typical imprecise computation is a cooking recipe: add a pinch of salt, cook quite slowly, serve very cold,...
- In a hard sense, imprecise computations should refer to a genuinely form to compute vague instructions. If so, there would be a new model of computing, but up till today, the TM is the only machine for computing. Afterwards, we come back to this topic.

Imprecise computations in a soft sense can be simulated by a TM. A fuzzy instruction, as "add a pinch of salt', can be represented by a generalized membership function. Fuzzy logic provides a fuzzy arithmetic for managing fuzzy commands. So, a TM with a fuzzy arithmetic module can operate fuzzy computations and output a final state of partial success; that is, a solution qualified by a degree. The appearance of this fuzzy output may be continuous and not discrete. Discrete outputs passing serially, one after the other, in a small temporary sequence, may emerge as a continuous appearance –cartoons are a god metaphor: snapshot sequences of static pictures seem to have movement by themselves.

In a soft sense, a fuzzy computation can be performed by a classical TM, at least, in two ways:

- Weighting the symbols of the tape alphabet.
- Qualifying the states with degrees of preference.

So, from a theoretical point of view, fuzzy computation is classical computation augmented with a module that operates with degrees. "Fuzzy" refers to data high level representation not to a form of computing. Therefore, there is not a new or genuine way of computation [20]. However, from an applied

ISBN: 978-989-95079-6-8

perspective, the important thing is not to valuate the nature of the process, but its outcome. Today there is an enormous amount of computational processes that simulate approximate solutions to interesting problems. Still having the TM as a substrate, all of them have a very realist appearance, as it is showed by the software that control the smoothness of a train brake or the camera that stabilizes the frame for taking a good picture show. From this point of view, fuzzy computation is a fact regardless if the true nature of the computational process is fuzzy or not.

As we have said before, if it is possible to get good simulations of fuzzy instructions using classical methods, would still be desirable a true fuzzy computer? The answer of this question leads to discuss the differences and analogies between the real and the artificial, between the authentic and the simulated, directing, ultimately, the old philosophical question of what is 'being'. But this inquiry is out the limits of this paper.

Computing in the traditional sense involves inputs with numbers and symbols that are crisp. However, human beings use words to solve daily problems that attend to fuzzy rules; so to speak, humans use words to make computations. In the last years, some new idea has being emerging in this field. Fuzzy logic is emphasized to play a key role in granular computing, the methodological base for computing with words and perceptions. So, while in classical theory a sensor records a temperature by a number (30 C^o), in fuzzy theory a device should to convert the numerical input in the name of a perception: its hot. According to Ying [21], the start point of models for computing with words is to deal with fuzzy finite-state and fuzzy pushdown automata through extending their inputs to be strings of fuzzy subsets of input an alphabet. However, a study about the correlation between the strings or words and the symbols as inputs has not taken place.

In the context of translating human perceptions to computational perceptions and in the frame of a practical application, Triviño et al. [16] developed a methodology to generate a linguistic summary from data provided by sensors. A chain of transducers perform this task. A 'transducer' is a kind of automata capable of translating perceptions between two levels of granularity. In the project of a Linguistic Fuzzy Transducer the following actions are involved:

- Representing the granular word of the input by its associated vector of linguistic state variables.
- Representing the granular word of the output by its associated vector of linguistic state variables.
- Defining a set of rules that describes the evolution of the system in order to reach the outputs as a function of the values of the inputs.
- Generating a generic representation of the system by the methodology of Zadeh's protoform.

Besides fuzzy computation, there are other initiatives to deal with imprecision. The most remarkable is quantum computing. In quantum physics, vagueness or imprecision take the form of indetermination. But quantum indetermination and linguistic vagueness or imprecision are quite different concepts in nature. So, today quantum computing does not seem an adequate model for imprecise computing. Despite the different nature of vagueness and indetermination, the *continuum* and not deterministic nature of quantum computing encouraged to find alternative models in the general area of imprecision. Although today TM is the computational tool *par excellence*, other emerging tools, impelled by the problem of imprecision, are coming. If they can be an alternative to the classical way of computation is still an enigma, as they are in a starting point.

4 Are there fuzzy objects?

As previously noted, in 1923 Bertrand Russell published a seminal paper about vagueness. In that article, he provided a starting point to introduce the vagueness as a topic of discussion in the field of the analytic philosophy, that attempt to clarify, by analysis, the meaning of statements and concepts. After Russell, other philosophers like Hempel, Black, Dummet or Fine wrote about this subject [22].

Russell discussed the role of vagueness in the language and wrote: *"Vagueness and precision alike are characteristics which can only belong to a representation, of which language is an example. The have to do with the relation between a representation and that which it represents. Apart from representation, whether cognitive or mechanical, there can be no such thing as vagueness or precision; things are what they are, and there is an end of it"*[2, p. 2]. So, vagueness is confined to the realm of the language and excluded as a property of the objects.

Saying that there are only vague sentences and not vague objects seems to be a truism. Objects are what they are. Only the way to access them by the language is imperfect or imprecise in nature. In the vein of positivism, some philosophers thought the opposite: so, the first Wittgenstein said in the *Tractatus* that sentences, if they are to mean anything, must mirror reality in the same way that a picture does. But even in natural sciences, words picture objects in different ways: in that task, some words are more vague that others.

So, we can say unequivocally that the Everest is higher than Mont Blanc. But is it is intrinsically imprecise where the Mont Blanc starts or which area encompasses. A cloud is too a typical case of object with fuzzy boundaries. Quantum mechanics brought a new field of examples of vague objects. The 'spin' is a fundamental property of atomic nuclei, hadrons, and elementary particles. 'Having a spin direction x' is a property clearly defined and it is possible to know exactly when a particle is or not in a given spin direction. Making an experiment we can identify a number of electrons that have this property and the result obtained will be the same if the experiment is repeated. Nevertheless, we cannot notice if the particles that had the property in the first experiment are the same as the second. The particles fall or not under the extension of the predicate 'Having a spin direction x', but it is impossible to fix the identity of the resulting set.

We can refer to vague objects from three points of view:

- Objects are well defined but there is not enough information or appropriate knowledge for grasping them precisely.
- Objects are well defined but it is not possible to know their true being.
- Objects are ill defined because we cannot observe them

ISBN: 978-989-95079-6-8

directly and the instruments to watch them distort irremediably their nature.

The first two points are related to the representation of reality through language. The third refers to the essential nature of the objects. We approach them in an inverted order.

The mental experiment of Schrödinger's cat provides a good example of essential vagueness: suppose a cat into a box. Suppose you cannot see in it and the cat cannot see out. Into the box there are a rock, a Geiger counter and a vial of poison. Now, the rock is slightly radiactive, with an exactly 50% chance of emiting a subatomic particle during an hour. If the rock emits a particle, the Geiger counter activates a device that breaks the vial of poison, killing the cat. Quantum mechanics suggests that after an hour the cat is simultaneously alive and dead, so it is an indeterminate or vague object.

From a philosophical point of view, an essentialist perspective is approached by G. Evans, who address the impossibility of vague objects in the frame of the Kripke's theory of rigid designators. A term is a rigid designator if it always designates the same object in any world where the object exists. Proper nouns are rigid designators. Like this, we can imagine a world where the name 'cat' do not refer to a domestic, hairy, medium size, enemy of the mice,..., animal, but we cannot imagine that the name 'Lotfi Aliasker Zadeh' do not refer to Lotfi Aliasker Zadeh. If a word denotes always to the same object in every possible world, we can say that there are a strong correspondence between the word and the object: when we are talking about something, we can say that the words replace objects and the words have an unambiguous and precise meaning. Evans uses this preconception for showing the impossibility of vague objects.

In a short paper published in *Mind* in 1978, he introduced the question about the existence of vague objects [23]. The underlying question posed under the title: *Can there be vague objects?* This question adress the possibility of a vague identity relationship when both sides of the equal sign are occupied by terms that are rigid designators. Evans answers 'no' arguing the following proof (see table 1): Denote ∇ 'indeterminate',

Table 1: Evans' Theorem.

(1)	$\nabla(a = b)$	$a = b$ is indeterminate	(assumption)
(2)	$\lambda x[\nabla(a = x)]b$	b is indeterminely equal to a	(from 1)
(3)	$\neg\nabla(a = a)$	$a = a$ is determinate	axiom
(4)	$\neg\lambda x[\nabla(x = b)]a$	a is not indeterminely equal to b	(from 3)
(5)	$a \neq b$	a is not equal to b	(from 2 and 4)

Evans' argument shows that there are not vague entities if the terms are rigid designators: briefly, if it is indeterminate that *a* is equal to *b* and it is determinate that *a* and *a* are equals, whatever *a* be, *a* and *b* differ at least in one property; so, are different. But the Evans' argument entails a mistake: as D. Lewis point out in [24], Evans' proof start attaching vagueness to the identity relation involving rigid designators. But the own proof demonstrates that the premise is false; therefore, the starting point of the argument was inadequate. Evans' argument shows the inconvenience to judge the imprecision in a small subset of the language –that of rigid designators–, and the mistake to extend this conclusion to the overall language.

In general, language is imprecise in nature and its formal approach, a matter of degree. Furthermore, some words are essentially vague. In the sequel, we analyse the second way in which an object can be vague, according to the bottom clasification. There are objects of which we know all that it is required for knowing their meaning, for attributing them a valuation, but, in some cases, we cannot do that in a unique way. A 'Bald man' or a 'heap of sand' are some examples.

Sorites or *Falakros* is a well-known paradox since Greek philosophers that comes from the use of predicates as 'bald' or 'heap' in the argumentation. To analyse a *Sorites* argument with a classical look leads to paradoxical and unacceptable conclusions. Note that baldness can be mainly referred in terms of hairs and their distribution, that is, in terms of numerable instances. So, a man with 0 hairs is absolutely bald and a man with 10^{10} hairs, not. But counting does not ever clarify the status of a vague predicate. Adding to every man that is bald one hair does not modify its attribute and preserve bald. But the key point is how many hairs are neccesary to change a man from bald to not bald. If you choose a number, I can select another very close to the previous and to claim the truth with the same legitimacy. There is not a bald object that determines, in a unanimous way, a unique use of the word 'bald', but only different uses depending on the context. Different uses mean diverse representations, leading to variations –between some margins– in the conclusions reached by argumentations. Trillas and Urtubey proposed a reasonably cut point that divide when a person is going to be more bald that not bald [25]. But following a kind of metatheoretical game and applying a type-*sorites* reasoning to it, the solution comes irremeably affected by high-order vagueness: the objection that emerge is why not suggest a very similar, but distinct, cut point, to the one supplied. So, it seems quite difficult to solve problems of vagueness with precise measures.

Finally, there are objects well defined but there is not enough information or appropriate knowledge for grasping them precisely; that is, objects that are imprecisely verbalized. Linguistic imprecision should be analysed with fuzzy armamentarium. Fuzzy logic provides tools for managing problems that involve imprecise statements or approximate reasoning. In the field of fuzzy logic, there is not a debate about what is a vague object but how to represent words with vague meaning. From some philosophical traditions (phenomenology, e.g.), an object is how we describe it using words in context. Objects are represented by words, and sentences are represented by logic. If objects have a crisp shape, perhaps precise sentences can designate them and classical membership functions should be employed to formalize them. If the objects have loose frontiers, the way to speak about them are vague in nature and generalized membership functions should be used.

For fuzzy logic there are vague objects as there are fuzzy representations of them. There is no other consideration about its true nature. Fuzzy logic is not a physical theory, but a formal one. So, it does not pretend to reveal the essential nature of the objects, but knowing how people verbalize and represent them in a manageable way in order to solve problems. For fuzzy logic, fuzzy objects are mental or physical objects acceded by sentences uttered in a culture or context that point out the consensus required for an adequate formalization.

Fuzzy logic repairs on linguistic vagueness, not vague objects, anything they that be. Therefore, words or predicates

ISBN: 978-989-95079-6-8

that are instead of the objects are the objective of fuzzy logic. So, its function is to be faithful to how that ordinary people describe reality trough language, generating models to catch the meaning of the predicates according their use in context, generalising solutions whenever possible, making hypothesis on its explanatory character and contrasting the reached conclusions with those awaited. This is a dialectical process, typical of experimental sciences. As a formal tool, fuzzy logic must pursue eternal truths –even imprecise truths–, but like an experimental one, facts must show that truth is obtained only in a degree.

In addition to pursuing affordable challenges, as providing models for a large number of vague sentences in real scenarios, fuzzy logic must address others questions that are still elusive. One of them is how to justify and to manage a suitable specification of the context, basic for representing, in an adequate way, the meaning of vague predicates. There are some formal theories of context, but seems too complex to be manageable or too simple to account the complexity of the meaning. Other challenge is how to summarize a complex perception, where attention is frequently directed to an issue, with a unique membership function. Those are applied inquiries that, however, also require a theoretical debate.

5 Final Remarks

Philosophical discussion about fuzzy logic and its applications is convenient. The popularity of fuzzy logic is based, in a large extent, on the success of its applications. Applications show the working face of a theory, but its consolidation and credit come through the development of a meta-theory, that shed light over its foundations and limits. More work should be done in this direction.

Although vagueness is treated from fuzzy logic mostly by the side of applications, theoretical studies are useful if shed intriguing doubts or suggest illuminating challenges to applied developments. Theory without applications is lame, but applications without theory are blind.

So, to justify the election of a membership function consistent with the true context of a used word or to argue about alternatives for combining atomic sentences into a composite one are tasks that will help to approach more credible solutions to problems every time more generals; so, to transfer credit to fuzzy logic as logic.

The discussion about alternatives to classical computation and the characteristic of a genuine fuzzy TM serve to distinguish the real and the imitated behavior. Also it is interesting to emphasize the simulation power of the classical TM to get fuzzy outputs managing approximate algorithms with crisp implementations.

Finally, to consider how we represent objects permits us to focus on tools as fuzzy logic that manage the meaning of the words that verbalize not only objects, but objects in context.

Abstract— *Web 2.0 is based on personalized access to imprecise and incomplete information from heterogeneous sources. In this paper we present a web-based system enabling preference-based search. We use modified Fagin's model of fuzzy preferences based on aggregation of attribute preferences. Aggregation is generated by user ranking of objects. Our contributions are twofold. First we present a formal model and implementation suitable for efficient preferential search. Second we provide several fuzzy measures to evaluate experimental results of our system.*

Keywords— web search, fuzzy logic, fuzzy systems, user preference

1 Introduction

From its birth in 1965, fuzzy logic has spread to many areas. It has influenced logic, databases, neural networks, expert systems, natural language processing and other fields of both theoretical and practical research. Fuzzy logic allows us to model imprecise, vague or uncertain information and to specify vague requirements. Any theory or application can possibly be fuzzified. However, we should first consider the purpose, especially in case of applications. The important question is how much fuzziness we really deal with and where it comes from.

In this paper we propose one such application of fuzzy logic: we use fuzzy sets to represent a notion of user preference in the process of web search. Web search tasks are recently changing from finding a document to solving specific problem for specific user. A typical problem is to buy some item online, make a flight reservation, find a transportation line, apply for a job. Most of these problems actually require searching for objects from some *domain* (e.g. flights, books, notebooks, job offers). The search depends on various attributes of objects (e.g. price, destination, date of departure, airlines and class in the domain of flights). Fulltext search often fails to support such tasks.

Therefore we search data from one arbitrary, but fixed domain. Data is extracted from heterogeneous sources on the web and stored in a standard database or ontology. Our extraction tool does not create fuzzy data. Although the formal model can be easily extended to handle fuzzy data, we focus on the situations where the main source of fuzziness is not in the data itself, but in the imprecise way of human thinking and specifying requirements. Most web users do not know precisely what they want to find, but they are able to distinguish between better and worse objects. Hence we allow users to rate objects and we use inductive learning tool [1] to adjust user preferences. But users also have an opportunity to specify their preferences precisely by means of a special graphical interface. The best objects can be retrieved with top-k threshold algorithm (see [2, 3]).

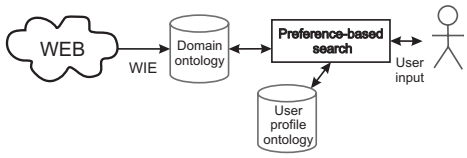

Figure 1: Overview of User-Dependent Search System.

This paper investigates how fuzzy logic can be used to make web search easier and more suitable for imprecise requirements. We compare our approach with other systems and formal models and point out the features necessary for Web 2.0 applications [4] – modeling vague preferences, dealing with huge amounts of data and ordering search results by degree of preference. We also analyze user data from our system with various measures of fuzzy similarity, equality, correlation and we compare the results.

2 Formal Models

Throughout the rest of this paper we will use the domain of job offers which is used also in the implementation. But the formal models described below are suitable for other domains as well. We tested the whole system or its parts in domain of cars, flats and investments.

Web search process is divided into two phases. The first phase is called *WIE* – web information extraction. Information is extracted from HTML pages, each of which contains data for a single object (job offer). Such pages are often generated by server side scripts, so that their structure and HTML tags are similar. The extraction tool [5] compares the page structure with *diff* algorithm and analyzes HTML tags with regular expressions. Differing parts of page sources contain relevant information, most often various attributes of domain objects. We use heuristics (like regular expression patterns for HTML structure) to avoid irrelevant information. Extracted crisp data is stored in domain ontology of job offers. Data repository is the only point that connects extraction phase with searching phase (see Fig. 1). Therefore it is easy to use other extraction tools or search in some existing standard database as well. It is also possible to have fuzzy domain data. Some extraction tools consider reliability of web sources, quality of source data or other conditions to determine fuzzy degree of extracted objects. Our formal model could be extended to consider this type of data as well. Full description of the extraction phase is beyond the scope of this paper, for more information see [6, 7, 5].

ISBN: 978-989-95079-6-8

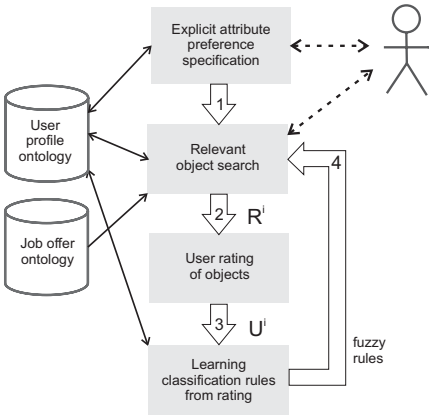

Figure 2: Flow Diagram of User-Dependent Search.

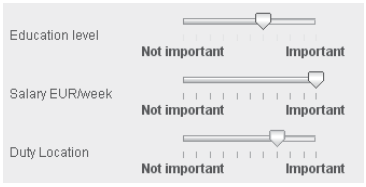

Figure 3: Interface for Attribute Importance.

The second phase, preference-based search, is detailed on Fig. 2. The task of job offer search can be repeated. The system reads user preferences (specified directly) or user feedback (previous search results rated in five-degree scale), updates stored preferences and finds new results. Every such *search cycle* provides more information about the user and helps the system to find more exact preferences.

In the rest of this section we will describe all phases of user-dependent search from Fig. 2 in more detail, together with underlying formal models. We especially emphasize the sources of fuzziness and their influence on the formal model.

2.1 Explicit Preference Specification

Current web portals often provide either a text field for fulltext search or some form to specify required attribute values. Job offer portals usually allow applicants to specify at least place, job position and contract type (i.e. permanent or temporary). But it is impossible to express things like "I prefer York to Birmingham" or "my decision depends on salary more than on location". Our system allows for vague user preferences and provides a suitable graphical interface.

First, the user is presented a list of all *attributes* from the domain of job offers that could influence his decision (like salary, benefits, required education level, required experience, place, job position, contract type, start date). The interface displays a slider marked with "Not important" and "Important" for each attribute (Fig. 3). User can drag the slider to specify how much he cares about the corresponding attribute. The settings from Fig. 3 will produce weighted average

$$@^U = \frac{6 \cdot \mu^U_{education\_level} + 10 \cdot \mu^U_{salary} + 7 \cdot \mu^U_{location}}{23}$$

Weighted averages and other types of aggregation will be described below.

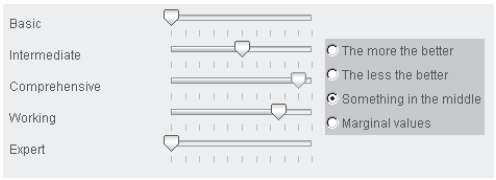

Figure 4: Interface for Attribute Preference.

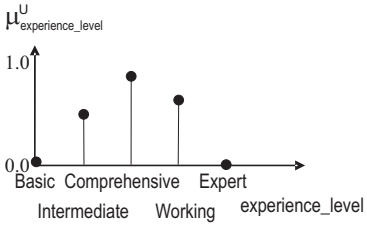

Figure 5: Preference to experience level, acquired from user input.

The next step is to specify preferred attribute values (only for attributes that are marked as "Important" to some non-zero degree). Now the graphical interface contains one slider for every attribute value. Fig. 4 shows the input interface for required experience level. The user prefers those job offers that require comprehensive experience (possibly because he has such experience in the profession).

Formally, user preference related to one particular attribute is a typical example of fuzzy subset. We consider a domain Δ of objects (job offers) and a finite set of domain attributes $\{A_1, \ldots, A_n\}$. Every attribute A_i is a function $A_i : \Delta \longrightarrow \Delta_{A_i}$, where Δ_{A_i} is a set of possible attribute values. Then *attribute preference* for user U and attribute A_i is defined as $\mu^U_{A_i} = \Delta_{A_i} \longrightarrow [0,1]$. Thus $\mu^U_{A_i}$ defines a fuzzy subset of Δ_{A_i}, which is usually a finite set with some natural element ordering.

Fuzzy set $\mu^U_{experience\_level}$ generated from user input on Fig. 4 is shown on Fig. 5. Job offers that require basic or expert experience are unacceptable, while job offers with comprehensive experience are the most preferred. Every attribute preference defines non-strict linear ordering of all objects based on their membership values. The ordering generated by the fuzzy set $\mu^U_{experience\_level}$ would not preserve original ordering of attribute values. Note that some distinct attribute values (e.g. basic and expert experience) have equal membership values. Such objects are *indiscernible* with respect to attribute $experience\_level$.

The most suitable membership functions to represent real user preferences are monotonic and trapezoidal. Some attributes are preferred similarly by all users (e.g. high salary is better than low), however, other attribute preferences may differ significantly (e.g. preference for required language level). These *preference types* can be seen on the right side of Fig. 4.

If we consider more than one attribute, we need to determine the final preference degree for every object, based on attribute preferences. User requirements are often conflicting so that the orderings are different, sometimes even reverse. Therefore we use *aggregation function* to acquire overall ordering. Aggregation function is n-ary monotone function $@^U : [0,1]^n \longrightarrow [0,1]$.

ISBN: 978-989-95079-6-8

Let us consider an object $x \in \Delta$ with attribute values $A_1(x), \ldots, A_n(x)$ and attribute preferences $\mu^U_{A_1}(A_1(x)) = p_1, \ldots, \mu^U_{A_n}(A_n(x)) = p_n$. The global preference degree of x will be $@^U(p_1, p_2, \ldots, p_n)$. A typical aggregation function is weighted average which reflects the idea that some attributes can be more important than the others. Our system acquires the weights from the interface shown on Fig. 3. We will describe other types of aggregation functions in Section 2.3.

2.2 Relevant Object Search

After storing user preferences the system proceeds to the next phase - relevant object search. It is a modification of Fagin's threshold algorithm [3] called *top-k* [2], based on the idea that users are interested only in a few best results from potentially huge dataset and that different users can have different attribute preferences.

Top-k uses a preprocessing phase to generate lists of objects ordered by attribute values. A typical structure for indexing is a B+ tree which allows us to follow records (attribute values) from highest to lowest or vice versa. User preference can define a different ordering of objects, but it can be simulated as well. If the user specified a trapezoidal membership function ("Something in the middle" preference), we start traversing values in both directions from the middle and we merge two non-increasing lists into one non-increasing list. Thus we gain a list of objects ordered from most preferred to least preferred. (The original threshold algorithm considered only one fixed ordering for each attribute.)

If our domain contains attributes $A_1, \ldots, A_n$, we prepare n ordered lists $L_1, \ldots, L_n$. Lists can be stored in heterogeneous repositories, or even acquired from web services. Top-k algorithm uses sorted access to the lists, reads attribute values and calculates preference values. One object can have different position in each ordered list, so some attribute values will be unknown in the meantime. After reading all attribute values of some object x, top-k algorithm calculates aggregation function to determine overall preference value of the object. A threshold value is determined to see if any object with some unknown values has a chance to be more preferred than x. If not, object x is written on the output.

This algorithm is very efficient for complex preferential search. The preprocessing phase causes that we can find k best objects without traversing the whole dataset. The output is an ordered list of k best objects (according to given preferences) together with overall preference values. Despite the fact that source data is crisp, we obtain fuzzy results similar to "object $x1$ is preferred by user U to degree $0,8$". This fuzziness originates from vague user preference representation and it is reflected in the results.

2.3 Learning Classification Rules from Ratings

Although the preference model is fuzzy, it is intended to represent real user preferences as precisely as possible. If they do not correspond, the user obtains different results, or results in wrong order. The graphical interface gives user a chance to rate the results in 5-degree scale (bad, poor, average, good, excellent) as can be seen on Fig. 6. Degrees can also be represented as percents, stars, smilies, etc. Then we use ordinal classification [8] to find a new aggregation function. As we showed in [9], it is sufficient to learn an aggregation function,

Figure 6: Interface to view and rate search results.

provided that types of attribute preferences did not change (e.g. from "The more the better" to "The less the better"). The new aggregation function has a form of *fuzzy rules*.

Fuzzy rules are well-known from fuzzy controllers [10], fuzzy inference systems [11] and many other application areas. A fuzzy rule consists of antecedent and consequent. *Antecedent* is typically a (fuzzy) conjunction or disjunction of fuzzy condition clauses. *Consequent* can be some action (in case of fuzzy controllers) or a fuzzy predicate (in case of fuzzy inference systems).

controller rule: IF temperature IS cold THEN heater IS high

inference system rule: IF wind IS strong AND barometer IS falling THEN forecast IS bad

Different types of rules look syntactically similar, but they differ in the semantics of consequent. In the first case the consequent "heater IS high" means that the heater device will be *set* to high level. In the latter case the consequent "forecast IS bad" means that the variable forecast will be assigned a fuzzy value bad, but no physical action will take place. Condition clauses contain crisp variables (temperature, wind, barometer) and fuzzy sets (cold, strong, falling) in both cases. Connectives AND, OR are fuzzy t-norms and t-conorms, IF-THEN implications are also fuzzified. There is usually a larger set of rules which are processed, their outputs are combined (aggregated) in some way into a single fuzzy set. It is then defuzzified to determine crisp output value. The most common defuzzification method is *centroid calculation*, which returns the geometric center of area under the fuzzy membership function.

Our usage is more similar to fuzzy inference systems because we use fuzzy rules to find a preference value, not to control some electronic device. It is somewhat simplified to reflect our preference model. The following example shows a set of classification rules. We chose fuzzy rules as aggregation method because they are human-understandable and very close to natural way of thinking.

IF $\mu^U_{salary}(salary(x)) \geq 0.7$ AND $\mu^U_{place}(place(x)) \geq 0.6$ AND $\mu^U_{position}(position(x)) \geq 0.5$ THEN $good^U(x) \geq 0.8$

IF $\mu^U_{experience\_level}(experience\_level(x)) \geq 0.3$ AND $\mu^U_{salary}(salary(x)) \geq 0.6$ THEN $good^U(x) \geq 0.6$

It is easy to see some differences compared to fuzzy rules mentioned above. Our fuzzy rules are induced from a small set of rated objects, so they are more specific. Condition clause $\mu^U_{salary}(salary(x)) \geq 0.7$ can be written more intuitively as $salary(x)$ IS good ≥ 0.7. We use arbitrary fuzzy sets $\mu^U_{A_i}$ instead of linguistic variables like "cold".

ISBN: 978-989-95079-6-8

Our condition clauses use α-cut defuzzification and thus our conjunctions and implications are crisp. If object x satisfies the antecedent, then the aggregation function $good^U$ will be greater or equal to the value specified in the consequent. If some object satisfies more antecedents, we choose the greatest output value. If it does not satisfy any rule antecedent, the result will be set to 0. A set of rules makes up a monotone aggregation function. An object y with all attribute preference values greater or equal to object x will be "good" to greater or equal degree than x.

3 Implementation

The system for user-dependent web search is implemented and available on http://x64.ics.upjs.sk:8080/nazou/. It is a web application created in Java with Wicket[1] framework. Java servlets run under Tomcat application server. The server also supports Sesame[2] database to store both our ontologies, i.e. job offer ontology and user preference ontology (see Fig. 2). User preference ontology schema is fixed, while domain ontology is arbitrary (see [12, 9] for details).

The application is divided into relatively independent tools: top-k search, inductive learning, and user preference acquisition called UPreA. UPreA provides user preferences for other tools, processes user inputs and manages all changes in user profile. It communicates with Sesame database through Java API to store and update user information.

4 System and Model Evaluation

Our goal is to experiment with the implemented system and to find out if our model is a suitable representation of real user preferences. As our model is fuzzy, we are interested in fuzzy degree of correspondence between our results and some "ideal" results. Analysis of experiments is further complicated by the fact that user preferences are evolving in time and user inputs can be inconsistent.

We anticipate vague user preferences and therefore we use inductive learning to adjust the aggregation function. Our preferences define an ordering of all objects from the domain, while user ratings define another ordering of some small subset of objects. Fig. 2 shows orderings that are generated in search cycles: R^i is the ordering of search results and U^i is the ordering specified by user ratings. We explore the correspondence of R^i and U^i. If these orderings are similar, the user must have assigned higher ratings to objects from the front of the result list and therefore our preference model reflected real user preferences well. Throughout the rest of this section we assume that R^i and U^i are permutations of objects $\{o_1, \ldots, o_n\}$. Also note that results R^0 are retrieved with user-defined aggregation function (weighted average), while other results R^i, $i \geq 1$ are retrieved with aggregation (fuzzy rules) learned from previous ratings.

The main problem is how to determine the correspondence of two fuzzy subsets. We present several measures below and compare the results. We analyse how R^i corresponds with U^i in six successive search cycles. In fact, some users stopped searching after the first or the second cycle, so the number of analyzed ordered lists is slightly decreasing. Data for this analysis (search results R^i and user ratings U^i) comes from real users who tested the implemented system.

Table 1: Correlations of result ordering and user evaluation.

Cycle	0.	1.	2.	3.	4.	5.
τ-correlation	0.73	0.77	0.79	0,77	0,81	0,81
Result lists	174	134	102	53	26	15

Table 2: Weighted similarity of result ordering and user evaluation.

Cycle	0.	1.	2.	3.	4.	5.
similarity	0.53	0.41	0.39	0,56	0,61	0,64

4.1 Correlation of Orderings

The first possibility is Kendall τ-correlation coefficient [13]. It is defined as $\tau = \frac{n_c - n_d}{\frac{1}{2}n(n-1)} - 1$, where n_c is the number of concordant pairs and n_d is the number of discordant pairs in both ratings. A pair of elements is discordant if their order is reversed. We modified this formula to $\tau = \frac{2P}{\frac{1}{2}n(n-1)}$, so that results belong to interval $[0, 1]$ to conform with our fuzzy model. However, in this case only results above 0.5 mean a positive correlation.

Kendall τ-correlation originally deals with strictly ordered lists. However, in our case many objects from R^i or U^i can share the same fuzzy value. We distinguish ties according to the (strict) order in which they are presented to user. This order in fact depends on indexing methods used in top-k search.

4.2 Weighted order similarity

If the order of some objects change, τ-correlation decreases evenly, regardless of the position where the discordance arose. We can also assume that the position of discordance is important – discordance on the 1^{st} and the 2^{nd} position is more significant than discordance on the 8^{th} and the 9^{th} position. This idea is reflected in *weighted order similarity*. We choose a decreasing vector of weights such that differences between adjacent values are also decreasing, e.g. $w = \langle 20, 15, 11, 8, 6, 5, 4, 3, 2, 1\rangle$ for $n = 10$. Weighted order coefficient is defined as $\mathcal{W} = 1 - \sum_{j=1}^{n} \left| w_{p_j} - w_{q_j} \right|$ where p_j is a sequence number of R^i_j and q_j is a sequence number of U^i_j. Note that this coefficient does not consider all pairs of elements as τ-correlation, only the sequence number of the same element in both orderings.

4.3 Fuzzy Equality

Another suitable measure is *fuzzy equality* [14], which is stronger condition than similarity. In this case we consider fuzzy aggregation values $@^U$, not only orders. We define fuzzy equality of fuzzy sets μ_A, μ_B as: $\equiv^\bullet (\mu_A, \mu_B) = \inf_{x\in\Delta}\{\vee^\bullet(\rightarrow^\bullet (\mu_A, \mu_B), \rightarrow^\bullet (\mu_B, \mu_A))\}$. It means that μ_A, μ_B are equal if $\mu_A(x)$ implies $\mu_B(x)$ and vice versa, for all x from the domain. We can choose different types of fuzzy implication and conjunction, namely Łukasiewicz, Gödel and product. The universal quantifier is always represented as infimum for all elements from the domain.

Finally, we compare results of these fuzzy measures on Fig. 7. τ-correlation and weighted similarity seem to be the most

Table 3: Fuzzy equality of result ordering and user evaluation.

Cycle	0.	1.	2.	3.	4.	5.
$\equiv^{\bullet}_{L}$	0.19	0.41	0.32	0,35	0,42	0,42
$\equiv^{\bullet}_{G}$	0.23	0.22	0.14	0,20	0,22	0,24
$\equiv^{\bullet}_{p}$	0.17	0.28	0.16	0,23	0,31	0,27

Table 4: τ_R-correlation of result lists R^i, R^{i+1}.

i	0	1	2	3	4
$\lvert R^i \cap R^{i+1} \rvert$	4,50	6,21	5,95	4,88	5,52
$\tau_{\cap}$	0,65	0,80	0,76	0,63	0,76
τ_R	0,53	0,67	0,64	0,56	0,64

suitable measures. Fuzzy equalities impose too strict conditions on fuzzy values. We do not expect result lists and user ratings to be totally equal because we learn new preferences from their difference. Correlation increases most significantly between 1^{st} and 2^{nd} cycle where we start to use fuzzy rules. So experiments proved that fuzzy rules are suitable representation of user preference.

Another interesting point is that τ-correlation and weighted similarity have the same trends up to fifth cycle, while all fuzzy equalities have the same trends from second to fifth cycle. Łukasiewicz equality has the greatest results and Gödel equality has the smallest results because the corresponding fuzzy implications also have this feature.

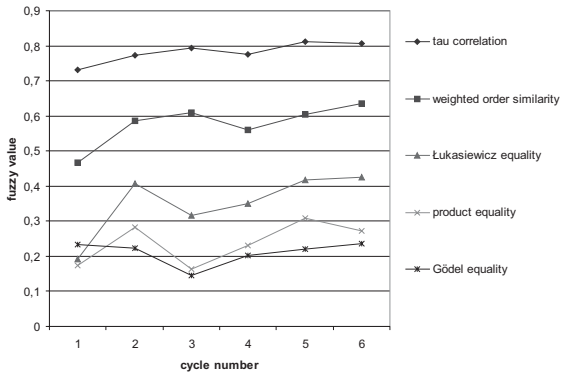

Figure 7: Comparison of different fuzzy measures.

4.4 Correlation of Subsequent Result Lists

We are also interested in the correlation of k-tuples R^i, R^{i+1}. If R^i and R^{i+1} have empty intersection, this correlation will be 0. In case of non-empty intersection, we can compute usual τ-correlation coefficient of the common elements $\tau_{\cap}$ and multiply the result with $\frac{\lvert R^i \cap R^{i+1} \rvert}{n}$. Thus we obtain τ_R. Average results for the first 5 cycles are shown in Table 4.

5 Related Work

In this section we present a short survey of similar preference models and searching methods. Many searching methods allow user to select desired attribute values, but they mostly produce a conjunctive query from user requirements. Our model is more general because aggregation functions are generalization of both (fuzzy) conjunctions and disjunctions.

A similar problem is addressed by *fuzzy multicriteria decision making* [15, 16]. It supports decision based on various attributes called *criteria*. Attribute preferences are usually represented as *fuzzy preference relations* – binary relations defined for every two-tuple of objects. Preference relation defines a degree to which one object is better than another object, based on the corresponding attribute. Other models of attribute preference mentioned in [16] are *utility functions* (identical with our fuzzy functions) and crisp *preference orderings* of objects. Aggregation is defined as *OWA operator* [17]. It is ordered weighted average associated with a normalized weight vector $w = (w_1, \ldots, w_n)^T$. Note that weight w_i is not connected with preference value of i^{th} attribute, but with i^{th} greatest preference value. This operator produces one "collective" preference relation from attribute preferences.

The *main difference* is that multicriteria decision is mainly designed for a small number of objects (alternatives). Each preference relation requires quadratic space w.r.t. number of objects. Decision making process consists of computing aggregated preference relation and transforming this relation to a global ranking of objects. Efficiency issues are left to implementations. Our model is closely connected with efficient top-k searching method which allows finding best objects without computing aggregation for all of them and sorting the results. Advantages of fuzzy multicriteria decision include support of sophisticated aggregation methods like Choquet integral and various modifications of OWA operator.

Another method to find interesting objects according to more attributes is based on *Skyline* [18]. Every attribute forms one dimension and every object is represented as a point in multi-dimensional space. Skyline is defined as a set of points which are not *dominated* by any other point (Pareto optimal), which means that no other point is equally good or better in all dimensions and strictly better at least in one dimension. A special Skyline clause can be integrated to relational database systems. Efficient methods of finding Skyline are proposed in [18, 19], including partitioning, indexing with B-trees and searching with top N algorithm (similar to top-k).

Compared to our system, Skyline produces a set of *unordered*, potentially interesting objects. Despite the similar searching methods, results can be different from our top-k results. First object o returned by top-k always belongs to Skyline set, but not necessarily the following objects, which can be in fact dominated by o, but still very close to it. Skyline also does not support attribute preferences other than simple "The more the better" or its reverse for ordinal attributes, thus it assumes the same attribute preferences for all users.

Another similar approach is *rank-aware querying* [20]. It uses general aggregation (scoring) functions to compute object ranking and returns a list of results ordered by ranking. Aggregations and new rank-join operators are integrated into relational database system. Rank-join operator performance is optimized by transforming a query into an execution plan and finding the most efficient plan. As in the case of Skyline operator, rank-aware querying does not support various attribute preferences or fuzzy rules. Simple preferences like "The less the better" can be simulated with scoring functions.

All-purpose fuzzy database system *FSQL Server* is proposed in [21]. It supports attribute preferences (called *linguistic labels*) for both ordered and unordered attribute do-

ISBN: 978-989-95079-6-8

mains. It is possible to define special fuzzy connectives to aggregate the results, but weighted average and fuzzy rules are not supported. In addition to fuzzy features needed in our system, FSQL supports fuzzy comparison, fuzzy constants, special values and α-cuts (fulfillment thresholds). FSQL is intended to support all common fuzzy features, while our system is designed for a single purpose of preferential web search.

From theoretical point of view, *rough set theory* [22] also has some common ideas with our model. It uses conditional attributes and decision attributes (similar to our user rating). Objects with the same attribute values belong to the same equivalence class and they are called *indiscernible* by those attributes. However, a set that contains one element from an equivalence class and does not contain another object from the same equivalence class, cannot be defined exactly (using only available attributes). Such set is called *rough set* and it can be defined with help of lower and upper approximation.

The main goal of rough set theory is to synthesize *decision rules* to determine the value of decision attribute from conditional attributes. The main difference is that a rough set *does not generate any ordering*, we can only distinguish objects inside the set from "boundary" objects.

6 Conclusions

Some approaches mentioned in the previous section are focused on theoretical support of decision process, some deal more with efficiency and optimization. We address both issues to achieve a clear-cut formal model and efficient implementation. Our main purpose is to enable user-specific web search in one arbitrary domain. All parts described in section 2 are important for personalized search: web information extraction, interface for explicit preference specification, top-k search, user rating and inductive learning. To the best of our knowledge, other fuzzy preference systems do not address all these phases to connect web and user.

So our approach has the following contributions:

- *Formal model* – fuzzy sets and aggregation as a model of user preference, suitable for preferential search.
- *Expressive power* – arbitrary fuzzy sets and fuzzy rules are strong tools to represent preferences.
- *Implementation* – web-based system implements specified functionality.
- *Model evaluation* – various fuzzy measures are used to analyze the results.

Multi-Goal Aggregation of Reduced Preference Relations Based on Fuzzy Interactions between Decision Goals

Rudolf Felix
F/L/S Fuzzy Logik Systeme GmbH, Joseph-von-Fraunhofer Straße 20, 44 227 Dortmund, Germany

Abstract– *Many aggregation operators like fuzzy integrals and similar require a preference relation as input. If the number of decision alternatives increases it becomes almost impossible to provide the exponentially increasing number of preference statements which are needed because a preference relation is defined upon the power set of the set of decision alternatives. If, as in many real world applications, the number of decision goals increases, it is also almost impossible to supervise the consistency of preference statements with respect to the interactions between the decision goals. In this paper it is discussed in which way a decision making approach based on interactions between goals is applied in order to use preference information that is not defined upon the power set of the set decision alternatives but simply on the decision set itself. Instead of defining the preferences upon the power set of the decision alternatives with respect to all the goals, for every decision goal the preference of the decision alternatives for this goal is defined upon the set of decision alternatives by a linear preference ranking of the decision alternatives. Consequences for both decision modeling based on classical preference relations and based on weighted sums are discussed.*

Keywords– Aggregation complexity, decision making, interactions between goals, reduced preference relation, weighted sum.

1 Introduction

Many decision making approaches are limited with respect to the management of complexity [4], [5], [8], [9], [10]. The consequence of this limitation is that these models are rather not applicable for real world problems. Many aggregation approaches require a preference relation as input. For more complex decision problems such preference relations are difficult to obtain because a preference relation is defined upon the power set of the set of the decision alternatives. If the number of decision alternatives increases it becomes almost impossible to provide the exponentially increasing number of preference statements needed. If additionally, as in many real world applications, the number of decision goals increases, it is almost impossible to supervise the consistency of preference statements with respect to the interactions between the decision goals. In this paper it is discussed in which way a decision making approach based on interactions between goals is adapted in order to aggregate in complex decision situations requiring only reduced linear preference information. The required input preference information is not defined upon the power set of the decision alternatives. Instead of this, for every single decision goal a linear preference ranking of the decision alternatives with respect to that goal is required. Of course, the single goal preference rankings may rank the decision alternatives in different way for different goals as the goals usually are partly conflicting. The presented aggregation approach ascertains for each pair of goals their conflicts (and correlations) by computing the so called interactions between the goals from the initial input single goal rankings. The only additional information needed when the interactions between the goals have been calculated is a linear importance information of each goal which is expressed in terms of goal priorities. The goal priorities are numbers of [0,1] and are comparable with a fuzzy measure that ranks not the decision alternatives but the decision goals itself with respect to their importance (priority).

It turned out that the decision making based on interactions between goals is less limited because the complexity of both the input information required and the aggregation process is not higher than polynomial. Since the model has successfully been applied to many real world problems [3] it clearly helped to manage many complex aggregation processes in which the number was varying between 50 and 100. The number of decision alternatives was in some applications even more than several thousands.

In the subsequent sections first for better readability of the paper we repeat a brief description of the decision making approach based on interactions between decision goals. Then we show how the approach is applied in order to work with single goal preference rankings and a statement with respect to classical preference based decision modeling is made. Subsequently it is discussed under which conditions decision models based on weighted sums help and how they are related to decision situations with interacting decision goals. Finally, the consequences of the results are discussed.

2 Decision Making based on Interactions between Goals

In the following it is shown how an explicit modeling of interaction between decision goals that are defined as fuzzy sets of decision alternatives helps to manage complexity of the decision making and aggregation. This modeling of the decision making and aggregation process significantly differs from the related approaches and the way they manage complex decision situations. First the notion of positive and negative impact sets is introduced. Then different types of interaction between goals are defined. After this it is shown how interactions between goals are used in order to aggregate pairs of goals to the so called local decision sets. Then it is described how the local decision sets are used for the aggregation of a final decision set. The complexity of the different steps is discussed.

2.1 Positive and Negative Impact Sets

Before we define interactions between goals as fuzzy relations, we introduce the notion of the positive impact set and the negative impact set of a goal. A more detailed discussion can be found in [1],[2] and [3].

Def. 1a) Let A be a non-empty and finite set of decision alternatives, G a non-empty and finite set of goals, $A \cap G$

ISBN: 978-989-95079-6-8

$=\emptyset, a \in A, g \in G, \delta \in (0,1]$. For each goal g we define the two fuzzy sets S_g and D_g each from A into [0, 1] by:

1. Positive impact function of the goal g: $S_g(a) := \delta$, if a affects g positively with degree δ, $S_g(a) := 0$ else.
2. Negative impact function of the goal g: $D_g(a) := \delta$, if a affects g negatively with degree δ, $D_g(a) := 0$ else.

Def. 1b) Let S_g and D_g be defined as in Def. 1a). S_g is called the positive impact set of g and D_g the negative impact set of g.

The set S_g contains alternatives with a positive impact on the goal g and δ is the degree of the positive impact. The set D_g contains alternatives with a negative impact on the goal g and δ is the degree of the negative impact.

2.2 Interactions between Goals

Let $P(A)$ be the set of all fuzzy subsets of A. Let X, Y ∈ $P(A)$, x and y the membership functions of X and Y respectively. Assume now that we have a binary fuzzy inclusion $I: P(A) \times P(A) \to [0,1]$ and a fuzzy non-inclusion $N: P(A) \times P(A) \to [0,1]$, such that $N(X,Y) := 1 - I(X,Y)$. In such a case the degree of inclusions and non-inclusions between the impact sets of two goals indicate the degree of the existence of interaction between these two goals. The higher the degree of inclusion between the positive impact sets of two goals, the more cooperative the interaction between them. The higher the degree of inclusion between the positive impact set of one goal and the negative impact set of the second, the more competitive the interaction. The non-inclusions are evaluated in a similar way. The higher the degree of non-inclusion between the positive impact sets of two goals, the less cooperative the interaction between them. The higher the degree of non-inclusion between the positive impact set of one goal and the negative impact set of the second, the less competitive the relationship. The pair (S_g, D_g) represents the whole known impact of alternatives on the goal g. Then S_g is the fuzzy set of alternatives which satisfy the goal g. D_g is the fuzzy set of alternatives which are rather not recommendable from the point of view of satisfying the goal g.

Based on the inclusion and non-inclusion between the impact sets of the goals as described above, 8 basic fuzzy types of interaction between goals are defined. The different types of interaction describe the spectrum from a high confluence between goals (analogy) to a strict competition (trade-off) [1].

Def. 2) Let S_{g_1}, D_{g_1}, S_{g_2} and D_{g_2} be fuzzy sets given by the corresponding membership functions as defined in Def. 1). For simplicity we write S_1 instead of S_{g_1} etc.. Let $g_1, g_2 \in G$ where G is a set of goals. *T* is a t-norm.

The fuzzy types of interaction between two goals are defined as relations which are fuzzy subsets of $G \times G$ as follows*:*

1. g_1 *is independent of* g_2*:* <=> $T(N(S_1,S_2), N(S_1,D_2), N(S_2,D_1), N(D_1,D_2))$
2. g_1 *assists* g_2*:* <=> $T(I(S_1 S_2), N(S_1,D_2))$
3. g_1 *cooperates with* g_2*:* <=> $T(I(S_1,S_2), N(S_1,D_2), N(S_2,D_1))$
4. g_1 *is analogous to* g_2*:* <=> $T(I(S_1,S_2), N(S_1,D_2), N(S_2,D_1), I(D_1,D_2))$
5. g_1 *hinders* g_2*:* <=> $T(N(S_1,S_2), I(S_1,D_2))$
6. g_1 *competes with* g_2*:* <=> $T(N(S_1,S_2), I(S_1,D_2), I(S_2,D_1))$
7. g_1 *is in trade-off to* g_2*:* <=> $T(N(S_1,S_2), I(S_1,D_2), I(S_2,D_1), N(D_1,D_2))$
8. g_1 *is unspecified dependent from* g_2*:* <=> $T(I(S_1,S_2), I(S_1,D_2), I(S_2,D_1), I(D_1,D_2))$

The interactions between goals are crucial for an adequate orientation during the decision making process because they reflect the way the goals depend on each other and describe the pros and cons of the decision alternatives with respect to the goals. For example, for cooperative goals a conjunctive aggregation is appropriate. If the goals are rather competitive, then an aggregation based on an exclusive disjunction is appropriate.

Note that the complexity of the calculation of every type of interaction between two goals is O(card(A) * card(A)) = O((card(A))^2) [4].

2.3 Two Goals Aggregation based on the Type of their Interaction

The assumption, that cooperative types of interaction between goals imply conjunctive aggregation and conflicting types of interaction between goals rather lead to exclusive disjunctive aggregation, is easy to accept from the intuitive point of view. It is also easy to accept that in case of independent or unspecified dependent goals a disjunctive aggregation is appropriate. For a more detailed formal discussion see for instance [1],[2]. Knowing the type of interaction between two goals means to recognize for which goals rather a conjunctive aggregation is appropriate and for which goals rather a disjunctive or even exclusively disjunctive aggregation is appropriate. This knowledge then in connection with information about goal priorities is used in order to apply interaction dependent aggregation policies which describe the way of aggregation for each type of interaction. The aggregation policies define which kind of aggregation operation is the appropriate one for each pair of goals. The aggregation of two goals gi and gj leads to the so called local decision set $L_{i,j.}$. For each pair of goals there is a local decision set $L_{i,j.} \in P(A)$, where A is the set of decision alternatives (see Def 1 a)) and P(A) the power set upon A. For conflicting goals, for instance, the following aggregation policy which deduces the appropriate decision set is given:

if (g_1 is in trade-off to g_2) and (g_1 is slightly more important than g_2) then $L_{1,2} := S_1 / D_2$.

In case of very similar goals (analogous or cooperative goals) the priority information even is not necessary:
if (g_1 cooperates with g_2) then $L_{1,2} := S_1 \cap S_2$ because $S_1 \cap S_2$ surely satisfies both goals.
if (g_1 is independent of g_2) then $L_{1,2} := S_1 \cup S_2$ because

ISBN: 978-989-95079-6-8

$S_1 \cup S_2$ surely do not interact neither positively nor negatively and we may and want to pursue both goals.

In this way for every pair of goals g_i and g_j, i,j ∈ {1,…,n} decision sets are aggregated. The importance of goals is expressed by the so called priorities. A priority of a goal g_i is a real number $P_i \in [0,1]$. The comparison of the priorities is modeled based on the linear ordering of the real interval [0,1]. The statements like g_i *slightly more important than* g_j are defined as linguistic labels that simply express the extend of the difference between P_i and P_j.

2.4 Multiple Goal Aggregation as Final Aggregation based on the Local Decision Sets

The next step of the aggregation process is the final aggregation. The final aggregation is performed based on a sorting procedure of all local decision sets $L_{i,j}$. Again the priority information is used to build a semi-linear hierarchy of the local decision sets by sorting them. The sorting process sorts the local decision sets with respect to the priorities of the goals. Subsequently an intersection set of all local decision sets is built. If this intersection set is empty then the intersection of all local decision sets except the last one in the hierarchy is built. If the resulting intersection set again is empty then the second last local decision set is excluded from the intersection process. The process iterates until the intersection is not empty (or more generally speaking until its fuzzy cardinality is big enough with respect to a given threshold). The first nonempty intersection in the iteration process is the final decision set and the membership values of this set give a ranking of the decision alternatives that is the result of the aggregation process (for more details see [2]).

2.5 Complexity Analysis of the Aggregation Process

As already discussed for instance in [4] the complexity of the aggregation process is $O((card(A))^2 * (card(G))^2)$ and the complexity of the information required for the description of both the positive and the negative impact functions is $O(card(A) * card(G))$.

3 Application of the Aggregation in Case of Reduced Preference Relations

In preference based decision making the input preference information has to be defined upon the power set of the decision alternatives [6]. This means that the complexity of the input information required is exponential with respect to the cardinality of the set of decision alternatives. This also means that the input information required is very difficult to obtain. Especially if the number of decision goals increases and the goals are partly conflicting the required preference information has to be multidimensional and the provider of the preference information has to express all the multidimensional interactions between the goals through the preference relation. With increasing number of goals and interactions between them the complexity of the required input preference relation possesses the same complexity as the decision problem itself. But, if the complexity of the required input is the same as the solution of the underlying decision problem itself then the subsequent aggregation of the input does not really help to solve the problem and is rather obsolete.

Therefore we propose to reduce the complexity of the input preference relation. Instead of requiring a preference relation defined upon the power set of the set of the decision alternatives which expresses the multidimensionality of the impacts of the decision alternatives on the goals for every single decision goal a linear preference ranking of the decision alternatives with respect to that goal is required. This means that for every goal a preference ranking defined on the set of decision alternatives is required instead of a ranking defined on the power set of the alternatives. The multidimensionality of the goals is then computed from all the single goal preference rankings using the concept of interactions between the goals as defined in section X.2.

In the sequent we extend the definition Def. 1. The extension defines how a single goal preference ranking defined on the set of the decision alternatives is transformed into positive and negative impact sets:

Def. 1c) Let A be a non-empty and finite set of decision alternatives, G a non-empty, finite set of goals as defined in Def. 1) a),

$A \cap G = \emptyset, a \in A, g \in G, \delta \in (0,1]$.

Let $>p_g$ be a preference ranking defined upon A with respect to *g* defining a total order upon A with respect to g, such that

$a_{i1} >p_g a_{i2} >p_g a_{i3} >p_g \ldots >p_g a_{im}$, where m=card(A) and $\forall a_{ij}, a_{ik} \in A, a_{ij} >p_g a_{ik} :\Leftrightarrow a_{ij}$ is preferred to a_{ik} with respect to the goal g. The preference relation $>p_g$ is called the *reduced single goal preference relation* of the goal g.

For simplicity, instead of $>p_g$ we also equivalently write RSPR of the goal g. All the RSPRs for all $g \in G$ are called the *reduced preference relation* RPR for the whole set of goals *G*. In order to avoid complete redundancy within the RPR we additionally define that the RSPRs of all the goals are different.

Let us assume that there is a decision situation with *n* decision goals where *n=card(G)* and *m* decision alternatives where *m=card(A)*. In the subsequent we propose an additional extension of the original definition Def. 1b with the aim to transform the single goal preference relations RSPR of every goals $g \in G$ into the positive and negative impact sets *Sg* and *Dg*:

Def. 1d) Let again A be a non-empty and finite set of decision alternatives, G a non-empty, finite set of goals as defined in Def. 1) a), $A \cap B \neq \emptyset$, $a_i \in A$, *m=card(*A*), g*∈G, i, c∈ {1, …, *m*}. For any goal g we obtain both the positive and the negative impact sets Sg and Dg by defining the values of δ according to Def. 1a) and 1b) as follows:

Def. 1d1) For the positive impact set:

$Sg(a_i)=\delta:=1/i$ iff $i \in [1,c-1]$,
$Sg(a_i)=\delta:=0$ iff $i \in [c,m]$.

Def. 1d2) For the negative impact set:

$Dg(a_i)=\delta:=0$ iff $i \in [1,c-1]$,
$Sg(a_i) = \delta:= 1/(m-i+1)$ iff $i \in [c, m]$.

Using the definition Def. 1d1 and Def. 1d2 for any goal g∈G we obtain a transformation of the RPR into positive

ISBN: 978-989-95079-6-8

and negative impact sets of all the goals and can evaluate the interactions of the goals using Def. 2 that are implied by the RPR.

Compared to classical preference based decision models this transformation helps to reduce the complexity of the input preference information required without losing modeling power for complex real world problems. The advantage is that using Def. 2. the interactions between goals that are implied by the RPR expose the incompatibilities and compatibilities that may be hidden in the RPR. The exposed incompatibilities and compatibilities are used adequately during the further calculation of the decision sets. Note that the exposition is calculated with a polynomial number of calculation steps with degree 2. The only additional information required from the decision maker is the priority information for each goal which has to be expressed as a weight with a value between 0 and 1. Many real world applications show that despite the reduced input complexity there is no substantial loss of decision quality [3].

*Statement 1***:** *In particular this means that it is not necessary to have classical preference relations defined upon the power set of the decision alternatives in order to handle complex decision problems with both positively and negatively interacting decision goals.*

Another interesting question is how the decision making based on interactions between decision goals is formally related to aggregation methods based on weighted sums. In order to investigate this we introduce the notion of r-consistency of RPRs and will consider the question under which conditions the weighted sum aggregation may be appropriate from the point of view of the application of the decision making based on interactions between goals if we have an RPR as input. For this we define the following:

Def.3) Given a discrete and finite set A of decision alternatives. Given a discrete and finite set G of goals. Let $r \in (0,1]$. The reduced preference relation RPR is called r-consistent :$\Leftrightarrow \exists\, c \in \{1, \ldots, m\}$, $m=card(A)$ such that $\forall\, (g_i, g_j) \in G \times G$, $i,j \in \{1, \ldots, n\}$, $n=card(G)$, (g_i *cooperates with* g_j) $\geq r$.

Let us now consider an important consequence of the interaction between goals using the notion of r-consistency. This notion will imply a condition under which an aggregation based on a weighted sum may lead to an appropriate final decision.

For this let us assume that the quite sophisticated final aggregation process of the iterative intersections as described in section 2.4 is replaced by the following rather intuitive straight forward consideration of how to obtain an optimal final decision.

Again let us identify the local decision sets $L_{i,j}$ obtained after the application of the local decision policies for each pair of goals (g_i, g_j) as the first type of decision subsets of the set of all decision alternatives A which, according to the decision model are expected to contain an optimal decision alternative a_k. Thus we define the set of sets

T1:= { $L_{i,j}$ | i ,j $\in$ {1, .. n}, $n=card(G)$} and expect that the optimal decision alternative has a positive membership in at least one of the sets of T1. Since we want to consider multiple goals we may also expect that an optimal decision alternative may have a positive membership in at least one of the intersections of pairs of the local $L_{i,j}$. Thus we define T2:= { $L_{k,l} \cap L_{p,q}$ | k,l,p,q $\in$ {1, .. n}, $n=card(G)$}. In order to simplify the subsequent explanation we concentrate on the crisp case and replace all membership values > 0 in all $L_{i,j}$, and $L_{k,l} \cap L_{p,q}$ by the membership value 1. Now we define the system of these crisp sets GDS as follows:

Def.4) GDS:={∅,T1,T2}, T1,T2 are the sets of crisp sets that we construct as described above by replacing all membership values > 0 in all $L_{i,j}$, and $L_{k,l} \cap L_{p,q}$ by the membership value 1.

With this definition we are able to formulate the following theorem that describes a property of the crisp GDS in the case that the underlying decision situation stems from a reduced preference relation RPR to which the decision model based on interactions between decision goals is applied. This property will enable us to relate this decision making to the calculation of optimal decisions by concepts based on weighted sums that are strongly connected with the notion of a matroid [7] and optimal decisions obtained by Greedy algorithms.

Theorem 1: If the reduced preference relation RPR is r-consistent then the system ($\mathcal{P}$*(A),GDS) is a matroid.*

Sketch of the Proof:

The proof will show that the following matroid conditions [7] hold: 1. $\emptyset \in$ GDS, 2. $X \subseteq Y$, $Y \in$ GDS $\Rightarrow X \in$ GDS and 3. $X,Y \in$ GDS card(X)<card(Y) $\Rightarrow \exists x \in Y \backslash X$ and $X \cup \{x\} \in$ GDS.

Ad1.: Holds by definition of GDS. Ad2.: If X is one of the $L_{i,j}$s then Y must be one of the another $L_{k,l}$ with $i \neq k$, $j \neq l$. If X is one of the $L_{k,l} \cap L_{p,q}$ then Y must be $L_{k,l}$ or $L_{k,l}$. Ad3.: This condition holds because the RPR is r-consistent and therefore we have $\forall$ k,l,p,q $\in$ {1, .. n}, $n=card(G)$, card($L_{i,j}$)=card($L_{k,l} \cap L_{p,q}$)=c.

With this result we obtain the following corollary that relates decision making based on interactions between decision goals to calculating optimal decisions by concepts based on weighted sums.

Corollary 1: If the reduced preference relation RPR is r-consistent then there exists a greedy algorithm based on the maximization of the weighted sum $\Sigma_{i \in \{1,\ldots,n\}, k \in \{1,\ldots,m\}} P_i * S_i(a_k)$, *where* S_i *is defined as in Def. 1d1 and* $a_k \in A$ *being a decision alternative,* $n=card(G)$, $m=card(A)$. P_i *is the priority of the goal* g_i *as used for the calculation of both the local and the global decision sets (see sections 4.3 and 4.4).*

Sketch of the Proof:

The proof is an immediate result from the Theorem 1 and the theory of matroids used in the field of combinatorial optimization [7].

4 Discussion of the Consequences

As already mentioned, this corollary relates the decision making based on interactions between decision goals to the calculation of optimal decisions by concepts based on weighted sums. It shows that weighted sums both as aggregation and optimization concept are rather appropriate if the goals or criteria are cooperative e.g. if they interact

ISBN: 978-989-95079-6-8

positively (or at least do not interact at all being independent). In contrast to this the decision making based on interactions between decision goals is more general and it reflects both positive and negative interactions between the goals. This is important in the context of real world decision making and optimization problems which usually possess partly conflicting goal structures. If the aggregation is performed by weighted sums, like for instance Choquet integrals, then one can suppose that the aggregation will only work if the choices to be made are free of conflicts. The hypothesis formulated in [6] postulating that there exists a preference relation on subsets of decision alternatives which is compatible with a weak order of decision alternatives belonging to different subsets of decision alternatives seems not to be that natural as postulated (especially in the field of optimization problems where partly contradicting goals are daily business).

Even if for a given application field the postulated preference relation exists, in case the number of decision alternatives increases it becomes almost impossible to provide the exponentially increasing number of required preference statements. If additionally, as in many real world applications, the number of decision goals increases, it is almost impossible for a human decision maker to keep all the interactions between the goals in mind and supervise the consistency of the preference statements with respect to the interactions between these decision goals. We see that the adapted decision making approach based on interactions between goals helps reducing the complexity of the required preference information without reducing neither the quality of the decision results [3] nor the complexity of decision situations that are modeled [4]: The required input preference information is not defined upon the power set of the decision alternatives. Instead of defining the required preferences upon the power set of the decision alternatives with respect to all the goals, for every decision goal the preference of the decision alternatives for this goal is defined upon the set of decision alternatives by a simple linearly ordered preference ranking of the decision alternatives (for each particular goal). This means that it is not necessary to require from the decision maker that he or she keeps in mind all the interactions between the goals. We are able to calculate the interactions as implication of linearly ordered single goal preference rankings by applying Def. 2. accordingly as shown in section 3. The only additional information that we require from the decision maker are assertions about the importance of the goals, namely again only a simple (linear) ordering of the so-called priorities of goals which are real numbers from the interval [0,1] and express for every goal its importance in a particular decision situation (see sections 2.3 and 2.4).

5 Conclusions

In this paper it is discussed in which way a decision making approach based on interactions between goals is applied in order to use preference information that is not defined upon the power set of the set decision alternatives but simply on the decision set itself. Instead of defining the preferences upon the power set of the decision alternatives with respect to all the goals, for every decision goal the preference of the decision alternatives for this goal is defined upon the set of decision alternatives by a linear preference ranking of the decision alternatives. Although the input complexity is reduced, the decision quality is not. Therefore we conclude that classical preference relations defined upon the power set of the decision alternatives are not necessary in order to adequately handle complex decision problems. We have also discussed in which way the decision model based on interaction between decision goals can be related to decision making methods based on weighted sums only. Through a link to the theory of matroids it is shown that the model is more general in the sense that an adequate aggregation is possible even if the goals are partly conflicting whereas weighted sums are in this kind of situations rather restricted.

Abstract— Real options are a typical framework in economics that involves uncertainty. Very often, in fact, managers have vague ideas about the future expected cash flows, the cost of the project and many other variables that are fundamental in the process decision among many investments. The calculation of the value function of real options can take advantage of a model of uncertainty that include stochastic processes and fuzzy numbers.

A special version of the multiple population differential evolution algorithm is designed to compute the level-cuts of the fuzzy extension of the multidimensional real valued function of fuzzy numbers in the resulting optimization problems.

We perform some computational experiments about the option to defer investment, that is an American call option on the present value of the completed expected cash flows with the exercise price equal to the required outlay. We show that fuzziness may help for a more profitable decision.

Keywords— Fuzzy Numbers, Parametric Representation, Real Options, Sensitivity Analysis.

1 Introduction

Nowadays the most suitable valuation methodology for corporate investment decisions is the real options theory (ROT) because it takes into account management's flexibility to adapt ongoing projects in response to uncertain conditions. Since Myers' ([7]) innovative idea of viewing firm's future investment opportunities as real options – that is, the right but not the obligation to undertake some business decision at a cost during a certain period of time -, a vast literature has developed, which elaborate both theoretical and empirical methods for quantifying the values of various real (call or put) options embedded in investment opportunities. Dixit and Pindyck ([3]) develop a systematic treatment of ROT, providing the fundamentals of this method and also emphasizing the market implications of such valuation of investment decisions under uncertainty. Trigeorgis ([12]) provides a classification of real options that maps different categories of investments into the space of different types of financial options.

The value of real options depends on some basic variables:(i) the underlying asset, which is the current value of (gross) expected future operating cash flows, (ii) the exercise price, which is the cost of the project; (iii) the time to expiration of the option, that is the time up to which the project can be undertaken (either finite or infinite); (iv) the standard deviation of the value of the underlying risky asset; (v) the risk-free rate of interest over the life of the option. All the above-mentioned variables are uncertain and therefore various stochastic models have been introduced in ROT to deal with the uncertainty surrounding most corporate decisions. In general expected future cash flows are assumed to evolve according to a geometric Brownian motion, but it often happens that reality is more complex than a normal distribution.

The imprecision associated with the subjective judgement and estimation of future cash flows, which is typical of management's project decisions, needs to be incorporated in the treatment of uncertainty. By introducing fuzzy numbers, we are able to capture the somewhat vague and imprecise ideas the manager possesses about the future expected cash flows, the profitability of the project, the costs of the project, etc. To the best of our knowledge, such an approach has never been discussed in the literature, with the exception of Carlsson and Fuller [1], that interpret the possibility of making an investment decision in terms of a European option, while we use an American option. In addition, we elaborate a computing methodology which is more general and we can represent the shape of the value functions.

The paper is organized as follows. In section 2 we present some basic elements of fuzzy theory which will be used in the numerical implementation of real option models. In section 3 we describe the introduction of fuzziness in real options and section 4 collects some of the computational experiments that have been performed in order to capture how and how much fuzziness affects the decision. Finally, section 5 concludes.

2 Fuzzy Numbers and Parametric Representation

Fuzzy numbers (more details in [4]) are a very powerful and flexible way to describe uncertainty or possibilistic values for given variables for which a precise quantification is not possible or one is interested in evaluating the effects of variations around a specified value. In fact a fuzzy number models the different specifications of intervals around a given precise value; it is defined, informally, as a "cascade" of intervals, which start with a given number $a \in \mathbb{R}$ and grow increasing to a final interval which gives the most uncertain set of possible values. The levels of the cascade are usually parametrized by a parameter $\alpha \in [0,1]$ which represents the so called membership value (or possibilistic degree) of a given interval, with the convention that $\alpha = 1$ corresponds to the possibly exact value (the core of the fuzzy number) while $\alpha = 0$ corresponds to the highest uncertainty (the support of the fuzzy number). With the same convention on α we can say that $1 - \alpha$ is the level of uncertainty of the corresponding interval.

ISBN: 978-989-95079-6-8

A wide class of fuzzy numbers with the core at $a \in \mathbb{R}$ is obtained by considering its membership function $\mu : \mathbb{R} \longrightarrow [0,1]$ such that, denoting $[a^-, a^+]$ the interval representing the support,

$$\mu(x) = \begin{cases} L(x) & if \quad a^- \leq x \leq a \\ R(x) & if \quad a \leq x \leq a^+ \\ 0 & otherwise \end{cases} \quad \text{for } x \in \mathbb{R} \tag{1}$$

where $L(x)$ is the left branch, an increasing function with $L(a^-) = 0$, $L(a) = 1$ and $R(x)$ is the right branch, a decreasing function with $R(a) = 1$, $R(a^+) = 0$. A fuzzy number obtained by the form (1) is called LR-fuzzy number (with usual notation $u = \langle a^-, a, a^+ \rangle_{L,R}$).

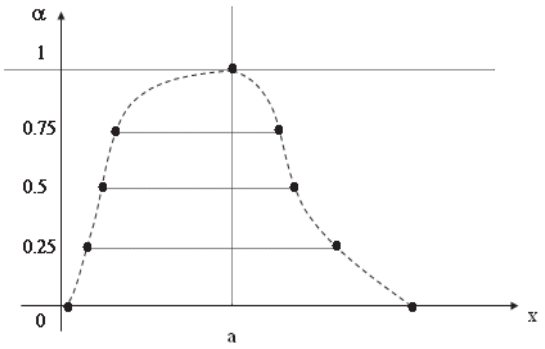

Figure 1: A fuzzy number as a "cascade" of intervals representing increasing uncertainty around the given value a.

For values of $\alpha \in]0,1]$, the $\alpha - cut$ is defined to be the compact interval $[u]_\alpha = \{x | \mu(x) \geq \alpha\}$ and the support is $[u]_0 = cl\{x | \mu(x) > 0\}$ ($cl(A)$ is the closure of set A). The *level-cuts* of a fuzzy number are "nested" closed intervals and this property is the basis for the LU representation (L for lower, U for upper).

Definition 1 *An LU-fuzzy quantity (number or interval) u is completely determined by any pair $u = (u^-, u^+)$ of functions $u^-, u^+ : [0,1] \longrightarrow \mathbb{R}$, defining the end-points of the $\alpha - cuts$, satisfying the three conditions:(i) $u^- : \alpha \longrightarrow u^-_\alpha \in \mathbb{R}$ is a bounded monotonic nondecreasing left-continuous function $\forall \alpha \in]0,1]$ and right-continuous for $\alpha = 0$;(ii) $u^+ : \alpha \longrightarrow u^+_\alpha \in \mathbb{R}$ is a bounded monotonic nonincreasing left-continuous function $\forall \alpha \in]0,1]$ and right-continuous for $\alpha = 0$;(iii) $u^-_\alpha \leq u^+_\alpha \ \forall \alpha \in [0,1]$. In particular, the $\alpha - cuts$ of a fuzzy number or interval are nonempty, compact intervals of the form $[u]_\alpha = [u^-_\alpha, u^+_\alpha] \subset \mathbb{R}$.*

The support of u is the interval $[u^-_0, u^+_0]$ and the core is $[u^-_1, u^+_1]$. We refer to the functions $u^-_{(.)}$ and $u^+_{(.)}$ as the lower and upper branches on u, respectively. The membership function can be written as $\mu_u(x) = \sup\{\alpha | x \in [u^-_\alpha, u^+_\alpha]\}$, where the left branch is the increasing inverse of $u^-_{(.)}$ on $[u^-_0, u^-_1]$ and the right is the decreasing inverse of $u^+_{(.)}$ on $[u^+_1, u^+_0]$.

To model the monotonic branches u^-_α and u^-_α we start with an increasing shape function p such that $p(0) = 0$ and $p(1) = 1$ and a decreasing function q such that $q(0) = 1$ and $q(1) = 0$, with the four numbers $u^-_0 \leq u^-_1 \leq u^+_1 \leq u^+_0$ defining the support $[u^-_0, u^+_0]$ and the core $[u^-_1, u^+_1]$ and we define

$$\begin{aligned} u^-_\alpha &= u^-_1 - (u^-_1 - u^-_0)p(\alpha) \text{ and} \\ u^+_\alpha &= u^+_1 - (u^+_1 - u^+_0)q(\alpha) \text{ for all } \alpha \in [0,1]\,. \end{aligned} \tag{2}$$

The two shape functions p and q, as suggested in [11], are selected in a family of parametrized monotonic functions where the parameters are related to the first derivatives of p and q in 0 and 1; there are many ways to define p and q as illustrated in [9]. For each decomposition we require (in the differentiable case) $4(N+1)$ parameters $u = (\alpha_i; u^-_i, \delta u^-_i, u^+_i, \delta u^+_i)_{i=0,1,...,N}$ satisfying the following conditions:

$$\begin{aligned} u^-_0 &\leq u^-_1 \leq ... \leq u^-_N \leq u^+_N \leq u^+_{N-1} \leq ... \leq u^+_0 \\ \delta u^-_i &\geq 0, \delta u^+_i \leq 0. \end{aligned} \tag{3}$$

and on each sub-interval $[\alpha_{i-1}, \alpha_i]$ we use the data $u^-_{i-1} \leq u^-_i \leq u^+_i \leq u^+_{i-1}$ and the slopes $\delta u^-_{i-1}, \delta u^-_i \geq 0$ and $\delta u^+_{i-1}, \delta u^+_i \leq 0$.

The simplest representation is obtained on the trivial decomposition of the interval $[0,1]$, with $N = 1$ (without internal points) and $\alpha_0 = 0, \alpha_1 = 1$. In this simple case, u can be represented by a vector of 8 components

$$u = (u^-_0, \delta u^-_0, u^+_0, \delta u^+_0; u^-_1, \delta u^-_1, u^+_1, \delta u^+_1). \tag{4}$$

In the search for the value of a real option, the fundamental step is the computation of fuzzy-valued functions. Given a function $y = f(x_1, x_2, ..., x_n)$ of n real (crisp) variables $x_1, x_2, ..., x_n$, its fuzzy extension is obtained to evaluate the effect of uncertainty on the x_j modelled by the corresponding fuzzy number u_j. If $v = f(u_1, u_2, ..., u_n)$ denotes the fuzzy extension of a continuous function f in n variables, then for each level α the resulting interval $[v^-_\alpha, v^+_\alpha]$ represents the propagation of uncertainty from x_j to y. In particular, if the uncertainty on the original variables is modelled by fuzzy numbers, the obtained v is yet a fuzzy number starting from a single value (at level $\alpha = 1$) to the most uncertain interval (at level $\alpha = 0$).

It is well known that the fuzzy extension of f to normal upper semicontinuous fuzzy intervals (with compact support) has the level-cutting property, i.e. the $\alpha - cuts$ $[v^-_\alpha, v^+_\alpha]$ of v are the images of the $\alpha - cuts$ of $(u_1, u_2, ..., u_n)$ and are obtained by solving the box-constrained optimization problems $(EP)_\alpha$:

$$\begin{cases} v^-_\alpha = \min \left\{ f(x_1, ..., x_n) | x_k \in [u^-_{k,\alpha}, u^+_{k,\alpha}],\ k = 1, ..., n \right\} \\ v^+_\alpha = \max \left\{ f(x_1, ..., x_n) | x_k \in [u^-_{k,\alpha}, u^+_{k,\alpha}],\ k = 1, ..., n \right\}. \end{cases} \tag{5}$$

With the exception of simple elementary cases for which the optimization problems above can be solved analytically, the direct application of *(EP)* may be difficult and computationally expensive. Usually, the $\alpha - cuts$ $[v^-_\alpha, v^+_\alpha]$ of v are computed at a prefixed given number of values α_j of interest (say from 10 to 100 points) and the membership function is approximated pointwise. As we will see, an advantage of the LU-parametrization is to obtain the extended fuzzy numbers $v = f(u_1, u_2, ..., u_n)$ in the same parametric form as for $u_1, u_2, ..., u_n$ with a possible important reduction in the computational effort and with a good approximation. As for the

ISBN: 978-989-95079-6-8

fuzzy numbers, we will consider the fuzzy extension of multivariate differentiable functions $f : \mathbb{R}^n \to \mathbb{R}$.

For a vector of n fuzzy numbers $u = (u_1, u_2, ..., u_n)$ let

$$u_k = (u^-_{k,i}, \delta u^-_{k,i}, u^+_{k,i}, \delta u^+_{k,i})_{i=0,1,...,N} \text{ for } k = 1, 2, ..., n$$

be the LU representation of the $k-th$ component. Let $v = f(u_1, u_2, ..., u_n)$ and $v = (v^-_i, \delta v^-_i, v^+_i, \delta v^+_i)_{i=0,1,...,N}$ be its LU representation; the $\alpha - cuts$ of v are obtained by solving the box-constrained optimization problems (5). For each $\alpha = \alpha_i$, $i = 0, 1, ..., N$ the $\min$ and the $\max$ (5) can occur either at a point whose components $x_{k,i}$ are internal to the corresponding intervals $[u^-_{k,i}, u^+_{k,i}]$ or are coincident with one of the extreme values; denote by $\widehat{x}^-_i = (\widehat{x}^-_{1,i}, ..., \widehat{x}^-_{n,i})$ and $\widehat{x}^+_i = (\widehat{x}^+_{1,i}, ..., \widehat{x}^+_{n,i})$ the points where the $\min$ and the $\max$ take place; then

$$v^-_i = f(\widehat{x}^-_{1,i}, \widehat{x}^-_{2,i}, ..., \widehat{x}^-_{n,i}) \text{ and } v^+_i = f(\widehat{x}^+_{1,i}, \widehat{x}^+_{2,i}, ..., \widehat{x}^+_{n,i}) \tag{6}$$

and the slopes δv^-_i, δv^+_i are computed (as f is differentiable) by

$$\begin{aligned} \delta v^-_i &= \sum_{\substack{k=1 \\ \widehat{x}^-_{k,i} = u^-_{k,i}}}^{n} f'^-_k \delta u^-_{k,i} + \sum_{\substack{k=1 \\ \widehat{x}^-_{k,i} = u^0_{k,i}}}^{n} f'^-_k \delta u^+_{k,i} \\ \delta v^+_i &= \sum_{\substack{k=1 \\ \widehat{x}^0_{k,i} = u^-_{k,i}}}^{n} f'^+_k \delta u^-_{k,i} + \sum_{\substack{k=1 \\ \widehat{x}^0_{k,i} = u^0_{k,i}}}^{n} f'^+_k \delta u^+_{k,i} \end{aligned} \tag{7}$$

where $f'^-_k = \frac{\partial f(\widehat{x}^-_{1,i}, .., \widehat{x}^-_{n,i})}{\partial x_k}$ and $f'^+_k = \frac{\partial f(\widehat{x}^0_{1,i}, .., \widehat{x}^0_{n,i})}{\partial x_k}$.To solve the optimization problems (5), we use an implementation of a multiple population differential evolution algorithm extensively described and analyzed in [10].

The *option to defer investment* is an American call option on the present value of the completed expected cash flows with the exercise price being equal to the required outlay. A project that can be postponed allows learning more about potential project outcomes before making a commitment. A seminal contribution on the option to defer is McDonald and Siegel [6] where the optimal time to invest and an explicit formula for the value of the option to invest are derived for an irreversible project whose net profits follow a geometric Brownian motion.

A firm is supposed to consider the following investment opportunity: at any time t the firm can pay some estimated cost K to install an investment project whose expected future net cash flows conditional on undertaking the project have an estimated present value Π. The installation of such project is irreversible. Let Π follow a geometric Brownian motion of the form:

$$d\Pi = \Pi(\mu dt + \sigma dW_t) \tag{8}$$

where $\mu < r$ is the appreciation rate, r is the risk-free interest rate and σ is the volatility ($\mu \in R, \sigma > 0$) and W is a standard Wiener process. For simplicity, let us assume that the time to expiration of this investment opportunity is infinite, which facilitates the derivation of a closed-form solution. If $V = V(\Pi)$ is the option value then it holds:

$$\frac{1}{2}\sigma^2 \Pi^2 V''(\Pi) + \mu \Pi V'(\Pi) - rV = 0$$

for $\Pi < \Pi^*$ with the initial condition $V(0) = 0$ and smooth-pasting $V(\Pi^*) = \Pi^* - K, V'(\Pi^*) = 1$. The solution is

$$\begin{cases} \Pi^* = K \frac{\phi}{\phi - 1} \\ V(\Pi) = (\Pi^* - K)\left(\frac{\Pi}{\Pi^*}\right)^{\phi} \end{cases} \tag{9}$$

with $\phi = \frac{1}{2} - \frac{\mu}{\sigma^2} + \left(\left(\frac{\mu}{\sigma^2} - \frac{1}{2}\right)^2 + \frac{2r}{\sigma^2}\right)^{\frac{1}{2}} > 1$.

In our methodology fuzziness is present in three steps. The estimated present value Π of future net cash flows of the project follows the stochastic differential equation (8) and we model the uncertainty of its parameters across intervals of values. The intervals are built with differentiated levels of uncertainty; given a crisp value, the levels produce a shape that can be characterized by asymmetries or nonlinearities depending on subjective beliefs and available information of the decision maker. It follows that fuzzy parameters play the lead role in a sensitivity analysis that starts gradually from a null variation to the greatest variation of the uncertainty consistent with data. In particular W_t remains a standard Brownian motion (the theory and applications of fuzzy set-valued stochastic differential equations has received recently several significant contributions from the seminal paper of Feng [5]).

Fuzziness comes out also in the valuation function of the option (obtained with the extension principle) that depends not only on Π, σ and μ but also on r and K, which we assume to be fuzzy too.

Finally, fuzziness affects the crucial value Π^*: as soon as Π reaches the threshold value Π^*, the firm finds it optimal to invest (case of the option to defer investment) or disinvest and liquidate (case of the option to abandon). Thus, the decision is based on the threshold value, which depends on all the parameters of the model. In the valuation method based on fuzzy variables, $\{\Pi_t, t \geq 0\}$ is assumed to be a fuzzy stochastic process, which is specified by the following membership function

$$\mu_{\Pi_t(\omega)}(x) = max\{1 - \mid (x - \widehat{\Pi}_t(\omega))/\beta_t(\omega) \mid, 0\},$$

that is, the fuzzy random variable Π_t is of the triangular type, with centre $\widehat{\Pi}_t(\omega)$, and left-width and right-width $\beta(\omega)$. The assumption of fuzziness is related to the manager's subjective belief about the future profitability of the project. The choice of a triangle-type shape is not restrictive at all and is introduced for simplicity only. Observe that the fuzziness in the process increases as $\beta(\omega)$ becomes bigger. The α-cuts of $\Pi_t(\omega)(x)$ are $\Pi^{\pm}_{t,\alpha}(\omega) = \left[\Pi^-_{t,\alpha}(\omega), \Pi^+_{t,\alpha}(\omega)\right] = \left[\widehat{\Pi}_t(\omega) - (1-\alpha)\beta(\omega), \widehat{\Pi}_t(\omega) + (1-\alpha)\beta(\omega)\right]$. It is also reasonable to assume that K is a fuzzy number. In the case of an option to defer, K is the estimated liquidation value of the firm's stock of capital and is affected by depreciation, fluctuating market evaluation and taxation regimes. In the case of an option to abandon, K denotes the investment cost and has many components which can change during the waiting period, due to various unpredictable circumstances.

ISBN: 978-989-95079-6-8

The extension principle is then applied to obtain the fuzzy Π^* and $V(\Pi^*)$ from the exact solutions given in equation (9). In the formulae (6)-(7) the vector $\widehat{x}_i$ is equal to $(\widehat{\mu}_i, \widehat{\sigma}_i, \widehat{r}_i, \widehat{K}_i)$ and some of the partial derivatives that define the slopes of the representation are nothing else than the first order Greeks, in particular, $\frac{\partial f(\widehat{\mu}_i,\widehat{\sigma}_i,\widehat{r}_i,\widehat{K}_i)}{\partial \sigma}$ is the Vega and $\frac{\partial f(\widehat{\mu}_i,\widehat{\sigma}_i,\widehat{r}_i,\widehat{K}_i)}{\partial r}$ is the Rho.

The degree of the uncertainty and the way in which it is spread from the model, play a central role in the analysis of the real option. The nonlinearities entering in the definition of $V(\Pi)$ in (9) are the main cause of such effects and they can propagate or contract uncertainty. It is very important to perceive the magnitude and the type of these effects. In particular we are interested in the analysis of how the various kinds of uncertainties inserted into the parameters will produce the corresponding uncertainties in Π^*, $V^* = V(\Pi^*)$, Π^{**} and $V^{**} = V(\Pi^{**})$.

As soon as information (on μ, σ, r, K) is modelled by fuzzy numbers, Π^* and V^* also become fuzzy and are represented by $\alpha - cuts$ $\left[\Pi_\alpha^{*^-}, \Pi_\alpha^{*^0}\right]$ and $\left[V_\alpha^{*^-}, V_\alpha^{*^0}\right]$ for all degrees of possibility α. The maximal uncertainty corresponds to the supports at $\alpha = 0$, given by the intervals $\left[\Pi_0^{*^-}, \Pi_0^{*^0}\right]$ and $\left[V_0^{*^-}, V_0^{*^0}\right]$ for Π^* and V^* respectively.

Due to the nonlinearity of Π^* and V^*, the $\alpha - cuts$ are not necessarily symmetric and, for a given uncertainty on the input values μ, σ, r and K, they have different left and right variations. Let $\widehat{\Pi}^*$ and $\widehat{V}^*$ denote the values of Π_α^* and V_α^* corresponding to $\alpha = 1$. It is immediate to argue that V^* is symmetric if and only if $\Delta V_\alpha^{*^0} = \Delta V_\alpha^{*^-}, \forall \alpha \in [0, 1[$ where

$$\Delta V_\alpha^{*^0} = V_\alpha^{*^0} - \widehat{V}^*, \quad \Delta V_\alpha^{*^-} = \widehat{V}^* - V_\alpha^{*^-}.$$

The quantity $\Delta V_\alpha^{*^0}$ represents the possible increase in $\widehat{V}^*$ due to uncertainty and analogously, $\Delta V_\alpha^{*^-}$ measures the possible decrease. The same argument can be applied to Π_α^* and $\widehat{\Pi}^*$, defining the quantities $\Delta\Pi_\alpha^{*^0} = \Pi_\alpha^{*^0} - \widehat{\Pi}^*$ and $\Delta\Pi_\alpha^{*^-} = \widehat{\Pi}^* - \Pi_\alpha^{*^-}$.

. 6 f d gl kHkdf e HcRngRhdl Re ki

We test the fuzziness effect in the option to defer investment by running several computational experiments; the fuzzy version of the indicated parameters (say θ) are obtained as triangular symmetric fuzzy numbers, centered at the crisp values and with the support being the interval $[\theta - 0.1\theta, \theta + 0.1\theta]$, corresponding to a symmetric uncertainty of 10% of the value of the parameter. To analyze the effect of the uncertainty on the output variables, we give the plots of their membership functions and the tables including the values for $\alpha - levels$ with $\alpha = 1$ (the crisp level), $\alpha = 0.75$, $\alpha = 0.5$, $\alpha = 0.25$, $\alpha = 0$ (corresponding to the uncertainty of 10% in the parameters).

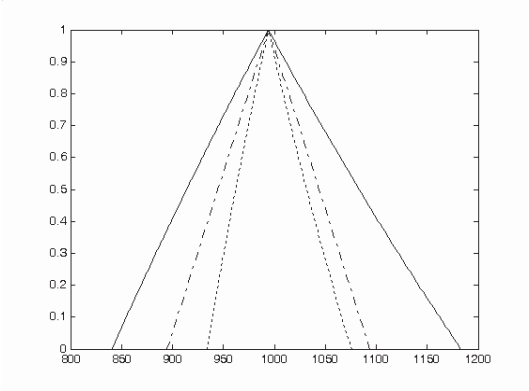
The robustness of the fuzzy model for the option to defer investment is tested with three sets of real data that we call, for short, Data1, Data2 and Data3, referring to three different industrial sectors. *Data1* refers to an investment decision in the human genome sciences project (HGSI) whose data are taken from the Human Genome project database (details in http://www.ornl.gov/sci/ techresources/ Human_Genome/ home.shtml). *Data2* refers to an investment decision in a big infrastructure, that is the Eurotunnel project (details in [2]). *Data3* deals with the case of an investment in new capacity in the public-utility sector, i.e. the electricity market (details in [8]). The values of the parameters μ, σ, r and K are the following:

	: HkH(	: HkH)	: HkH-
μ	0.01	0.025	0.03
σ	0.048	0.183	0.173
r	0.044	0.06	0.08
K	704.9	8865	600

In figures concerning the behavior of Π^* we report the three different cases that we will denote as: *Allfuzzy* (straight line) when the parameters μ, σ, r and K are fuzzy, *Kcrisp* (dotted line) when μ, σ, r are fuzzy and K is crisp and finally *Kfuzzy* (dashed line) when μ, σ, r are crisp and K is the unique source of uncertainty.

4.0.1 Results for Data1

Figure 2 shows that, as expected, the greatest uncertainty in Π^* occurs in the Allfuzzy case, when all the fuzzy quantities are considered to be fuzzy; but it is interesting to observe that in the Kcrisp case (dotted line) the generated uncertainty is less then in the Kfuzzy case (dashed line), i.e. the uncertainty in the values of only K produces more uncertainty on Π^* then the uncertainty in the values of μ, σ and r.



D5l1 hR) 4 Π^* for Data1

Table 1, Table 2 and Table 3 report values of the $\alpha - cut$ for Data1 in the Allfuzzy, Kcrisp and Kfuzzy case respectively.

Table 1

α	Π^-	Π^+
1.0	994.28	994.28
0.75	953.16	1037.56
0.5	913.97	1083.26
0.25	876.50	1131.69
0	840.58	1183.25

Table 2

Π^-	Π^+
994.28	994.28
977.60	1012.25
962.07	1031.67
947.56	1052.74
933.98	1075.68

Table 3

α	Π^-	Π^+
1.0	994.28	994.28
0.75	969.43	1019.14
0.5	944.57	1043.99
0.25	919.71	1068.86
0	894.86	1093.71

ISBN: 978-989-95079-6-8

Observe that in the Kfuzzy case (Table 3) the threshold value Π^* displays a symmetric shape in all analyzed projects because Π^* depends linearly on K. In the Allfuzzy and Kcrisp cases, instead, we can observe an asymmetric pattern, due to the nonlinear dependence of Π^* with respect to the other variables.

At level 0.5 the average values are 998.615 in Allfuzzy and 996.87 in Kcrisp, which are larger than the crisp value 994.28. Since on average the fuzzy threshold value is larger then without fuzziness, just considering the crisp value the decision to invest would be too early. Figure 3 shows the graphical behavior of the fuzzy function $V(\Pi)$ in the Allfuzzy case; the little crosses point the optimal values of Π corresponding to the levels of Π^* for $\alpha = 0, 0.25, 0.5, 0.75, 1$.

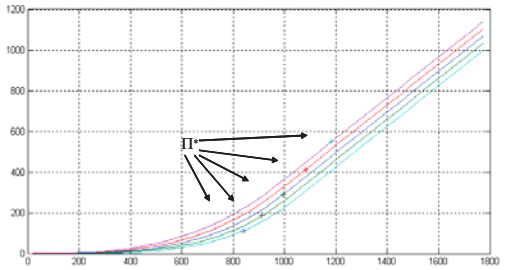


Figure 4: Data1 when parameters μ, σ, r and K are fuzzy.

It is evident that fuzziness implies a certain degree of freedom in the choice of Π^*. Figure 4 illustrates $V(\Pi)$ as a fuzzy function (a sequence of fuzzy numbers).

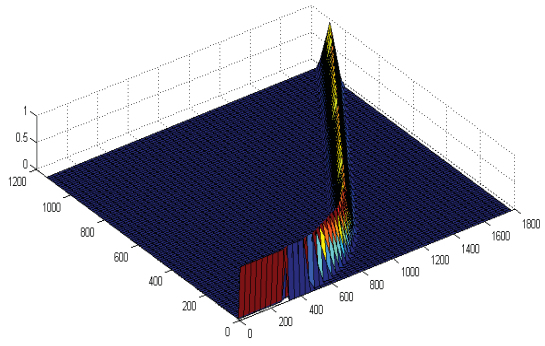

Figure 5: $V(\Pi)$ in the Allfuzzy case

4.0.2 *Results for Data2*

Figure 5 shows the behavior of Π^* in the three different cases: again the biggest uncertainty occurs in the Allfuzzy case, when all the quantities are fuzzy; but we observe that in the Kcrisp case (dotted line), when μ, σ, r are the sources of uncertainty and K is the unique crisp value, the uncertainty in Π^* is bigger then in the Kfuzzy case, i.e. the same level of uncertainty in K produces less uncertainty on Π^* then the uncertainty in the other parameters. With respect to Data1, there is here an inversion.

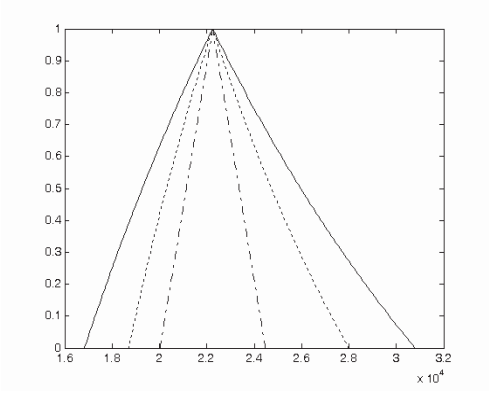

Figure 6: Π^* for Test 2

Table 4 and Table 5 report the values of the $\alpha - cut$ of Π^* in the Allfuzzy and Kcrisp case for Data2.

Table 4:

α	Π^-	Π^+
1.0	22249.62	22249.62
0.75	20686.18	23997.55
0.5	19277.60	25967.74
0.25	18000.33	28209.16
0	16835.43	30786.48

Table 5:

α	Π^-	Π^+
1.0	22249.62	22249.62
0.75	21216.59	23412.24
0.5	20292.21	24731.18
0.25	19459.82	26241.08
0	18706.04	27987.71

If we compute again the average values at level 0.5, they are 22622.67 in Allfuzzy and 22511.695 in Kcrisp, which are larger than the crisp value 22249.62. It follows that in the Data2 project it is confirmed the suggestion to wait for the decision to invest.

4.0.3 *Results for Data3*

The last project we consider for an option to defer investment is Data3; the relative values of Π^* are reported in Figure 6:

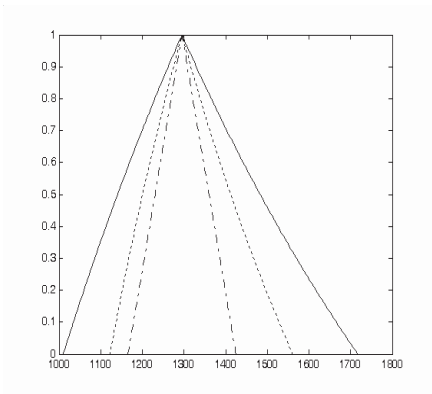

Figure 7: Π^* for Test4

ISBN: 978-989-95079-6-8

Table 6, Table 7 report values of the $\alpha - cut$ for Data3 in the Allfuzzy and Kcrisp case respectively.

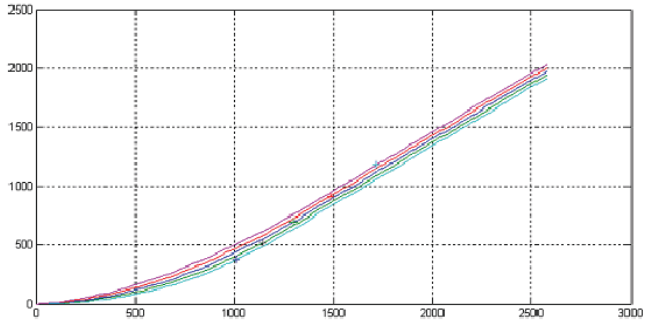
The graphical representation of $V(\Pi)$ in Allfuzzy case is in Figure 7.



D5l1 hR34 Data3 in the Allfuzzy case

Some further considerations concerning the $\alpha - cut$ values in all the data set enable us to state that our model allows us to describe how the investment decision is actually affected by a perceived increase in "fuzziness". For a pessimistic (optimistic) firm an increase in fuzziness decreases (increases) the perceived value of the project in comparison with the crisp value. On average - for most decision makers- an increase in fuzziness has a positive impact on the investment opportunity, i.e. it increases the perceived value of the project. As a consequence, the decision to invest is delayed in comparison with the absence of fuzziness. However, for pessimistic decision-makers imprecise information about the project value becomes available over time, which makes waiting with investment less valuable. Thus, for pessimistic firms higher fuzziness erodes the subjective value of the investment opportunity. Notice that this result is in keeping with the literature on real options and ambiguity aversion it contrasts with the impact of volatility in the standard real option theory.

1 6feNlilfei

The powerful contribution of fuzzy modelling can be shown in many fields and, especially in human sciences like economics, it can provide rigorous models (a detailed motivation of its use is in Zadeh [13]). In tis paper, we model the uncertainty involved in real options theory through fuzzy numbers represented in the LU model; when including fuzziness, the decision rule moves away from the original one and the choice to delay or not the investment becomes a key feature of the fuzzy model.

Our model allows us to quantify how the threshold values change with fuzzy parameters. Practically, we solve the investment/disinvestment decision in terms of a problem of fuzzy stopping time - that is, a fuzzification of the classical optimal stopping time - and our computation experiments provide the sensitivity analysis of the decision variable with respect to the relevant parameters. Our main results are that the decision to invest is delayed in comparison with the case of absence of fuzziness, the decision to disinvest is anticipated in a fuzzy environment. The fuzzy model we use provides the set of values within which the decision is taken by the manager. Our empirical validation, which is based on case studies from real world, seems to confirm the validity of the model and to open up further ways of research in finance in a fuzzy environment.

Abstract—*Classes issued of evolving systems are dynamic and their characteristics vary over the time. Assigning a pattern to a class is achieved using a classifier. Therefore, the classifier parameters must be adapted online in order to take into account the temporal changes in the classes' characteristics. This adaptation is based only on the recent and useful information carried out by the new incoming classified patterns. In this paper, we propose to develop the classification method Fuzzy Pattern Matching (FPM) to be operant in the case of dynamic classes. This development is based on the use of an incremental algorithm to follow the accumulated gradual temporal changes of classes' characteristics after the classification of each new pattern. When these changes reach a suitable predefined threshold, the classifier parameters are adapted online using the recent and representative patterns.*

Keywords— Classification, dynamic patterns, evolving systems, pattern recognition.

1 Introduction

Dynamic systems evolve between different normal or faulting functioning modes in the course of time. In statistical Pattern Recognition (PR) [12, 9], observations about system functioning modes are divided into groups of similar patterns, called classes, using an unsupervised learning method [10, 4] or human experience. These patterns, with their class assignments, constitute the learning set. They are represented by a set of *d* features, or attributes, so they can be viewed as *d*-dimensional features vectors, or points, in the feature space. A supervised learning method [9, 16] uses the learning set to build a classifier that best separates the different classes in order to minimize the misclassification error. The model of each class can be represented by a membership function which determines the membership value of a pattern to a class. Then, new incoming patterns are assigned to the class for which they have the maximum membership value. In supervised learning methods, the membership function can be generated using Probability Density Function (PDF) estimation based methods or heuristic based ones.

Patterns describing the system functioning can be static or dynamic. A static pattern is represented by a point in the feature space while a dynamic pattern is represented by a multidimensional trajectory. In this case, the feature space has an added dimension which is the time [3]. Classes can also be static or dynamic. Static classes are represented by restricted areas formed by similar static patterns in the feature space. Hence, the way in which patterns occur is irrelevant to their membership values. Therefore, the classifier's parameters remain unchanged with the time. However, data issued from evolving processes are non stationary. In this case, classes become dynamic and their characteristics change in the course of time. Thus, the classes' membership functions must be adapted to take into account these temporal changes. This requires an adaptive classifier with a mechanism for adjusting its parameters over the time. Hence, some of the new incoming points reinforce and confirm the information contained in the previous data, but the other ones could bring new information (creation, drift, fusion, splitting of classes, etc.). This new information could concern a change in operating conditions, development of a fault or simply more significant changes in the process dynamic.

The general principle of dynamic PR methods [14, 3, 7, 13] is to observe the change of some statistical properties of classes, in order to decide in which state the system is: unchanged, gradually changed or completely changed. Thus, the classifier parameters, i.e. the membership functions, will be respectively unchanged, slightly adapted, or relearned from scratch.

In the literature, the membership functions are generally adapted using two approaches [2, 3, 14]. The first one acts directly on the classifier parameters, by substituting or adding some recent and representative patterns to the learning set [3, 14], according to the state in which the system is. This adaptation is based only on the most recent batch of patterns selected by one of the two following methods. The first method uses a time window, with a fixed or a variable size, which permits to reduce or limit the growing size of the database by accepting the *n* most recent patterns [14, 17]. The size of the time window must be well-chosen to obtain a compromise between a fast adaptation and a sufficient number of representative patterns. The second method is based on the use of a template containing a fixed number of selected patterns according to their age and usefulness [11]. Nevertheless, it is subjective and difficult to estimate the utility of patterns. The second approach to adapt the membership functions is based on the use of evolving neural networks [1, 2, 7]. In [2], a potential function based on the distance between data points is defined for the new points. The first data point potential is considered as equal to 1 and it establishes the first neuron (or rule) which is considered as the prototype (or centre) of the first cluster. Then, the next new data points may possess a potential close or greater than the one of the prototype neuron. This point can reinforce or confirm the information contained in the previous ones, or if the point is more informative than the data used as prototype, a new neuron (new rule) is added. In [1], the neural network is based on a multiprototype Gaussian modeling of non convex classes. The activation

ISBN: 978-989-95079-6-8

function of each hidden neuron determines the membership degree of an observation to one prototype of a class. With the first acquisition, the network is initialized there is creation of the first prototype constituting the first class. The prototype is parameterized by its centre and an initial covariance matrix. Then, according to the membership degree of new acquisitions, the prototype (the hidden neuron) can be adapted, eliminated or a new prototype can be created.

Dynamic classification methods are used to solve several real problems. The application of [3] concerns the credit-scoring which aims to decide whether a new customer is a good or a bad risk according to changes in his consumption. In [1], the authors aim to detect and to follow up the progressive evolution of the functioning mode from normal to faulty one of a thermal regulator. This evolution is due to the age of the system's components or to other temporal factors in its environment. In [13], the author looks to estimate a ratio between the number of good parts in a completed batch of microelectronic chips and the number of parts obtained from the same batch if there is no default. Due to high complexity and variability of modern microelectronics manufacturing industry, this ratio is affected daily by hundreds of material-related, equipment-related and human-related factors. In [7], dynamic traffic data streams are treated in order to reduce the waiting time of drivers at the road intersections.

We use the classification method Incremental Fuzzy Pattern Matching (IFPM) [15] which is an incremental version of FPM [6]. The membership functions are based on the estimation of the marginal class probability density functions using histograms. Then, the membership functions are adapted incrementally after the classification of each new pattern. IFPM provides good result in the case of static classes based on static patterns. This method is simple and has a low and constant classification time according to the size of the database. However, IFPM has no mechanism to forget the no more useful patterns.

In this paper, we propose to develop IFPM to be operant in the case of dynamic classes. This development is called Dynamic FPM (DFPM). The paper is structured as follows. The two first parts are devoted respectively to the functioning of IFPM and DFPM. In the third part, the limits of IFPM and results of DFPM are presented in the case of dynamic classes. The last part concludes the paper and presents the perspectives of our future work.

2 Incremental Fuzzy Pattern Matching

2.1 Principle

The functioning of Incremental FPM (IFPM) involves the learning, the classification, and the incremental update phases.

2.1.1 Learning phase

Let X_i be the set of learning points belonging to the class C_i. Each class C_i contains N_i points, or patterns, in the feature space, $\Re^d$, formed by d attributes. X is the learning set, containing N points x belonging to C classes, so $X = \bigcup_{i=1}^{C} X_i$. The learning phase consists in building, based on X, a decision rule characterized by a set of membership functions. These latter are based on histograms allowing to estimate the conditional probability density of each class C_i according to each attribute j. The number h of bins b_k, $k \in \{1,2,..., h\}$ of a histogram is determined experimentally. The choice of h conditions the performances of IFPM. The lower $\min^j$ and upper $\max^j$ borders of each attribute are determined manually by an expert. In the case of dynamic classes, these borders must be well defined to contain all patterns of the classes' evolutions. This constitutes a shortcome of IFPM when the classes are dynamic. The width Δ^j of a bin according to the attribute j is defined by:

$$\Delta^j = \frac{(\max^j - \min^j)}{h} \tag{1}$$

The histogram or the distribution of probability $\{p_i^j(b_{ik}^j), i \in \{1,2,...,c\}, j \in \{1,2,...,d\}, k \in \{1,2,...,h\}\}$ for the class C_i according to the attribute j is determined by calculating the probability $p_i^j(b_{ik}^j)$ of each bin b_{ik}^j:

$$p_i^j(b_{ik}^j) = \frac{n_{ik}^j}{N_i} \tag{2}$$

where n_{ik}^j is the number of learning points of the class C_i which are located in the bin b_{ik}^j and N_i is the total number of points of the class C_i. Then, the resulting distribution of probability is transformed into a distribution of possibility $\{\pi_i^j(b_{ik}^j), i \in \{1,2,...,c\},\ j \in \{1,2,...,d\}, k \in \{1,2,...,h\}\}$ by using the transformation of Dubois and Prade [8]:

$$\pi_i^j(b_{ik}^j) = \sum_{z=1}^{h} \min(\ p_i^j(b_{iz}^j),\ p_i^j(b_{ik}^j)) \tag{3}$$

The possibility measure has the advantage to take into account the imprecision and the uncertainty contained in the data [8]. Finally, the density of possibility Π_i^j of the class C_i according to the attribute j is obtained by a linear interpolation of the bins centers of the histogram of possibility.

2.1.2 Classification phase

A pattern x is assigned to a known class C_i using the following three steps:

- determination of the membership possibility value π_i^j of x^j to each class C_i according to each attribute j. This possibility is obtained by projection of x^j on the density Π_i^j of each class C_i according to each attribute j (Fig. 1).

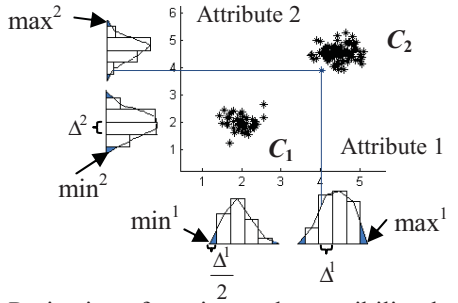

Figure 1: Projection of a point on the possibility densities. Δ^1 and Δ^2 are the bins' widths according respectively to attributes 1 and 2.

ISBN: 978-989-95079-6-8

- fusion, for each class C_i, of all membership possibility values $\pi_i^1, \pi_i^2, ..., \pi_i^d$ by the aggregation operator "minimum". The result of this fusion represents the membership possibility π_i of x to each class C_i,
- classification of the point x to the class for which it has the highest membership value.

2.1.3 *Incremental update phase*

Each new classified pattern carries information about the temporal changes of the class' characteristics. In order to take into account this new information, the membership functions must be relearned after the classification of each new pattern. An incremental learning algorithm is proposed in [15] to relearn the membership functions based on the most recently classified pattern in such a way that the previous learned information is reused. When a new point is classified in the class C_i, the number of points belonging to this class becomes $N_i + 1$, so the probability of each bin changes. If the point is located in the bin b_{ik}^j, the new probability $p_i'^j(b_{ik}^j)$ of this bin is [15]:

$$p_i'^j(b_{ik}^j) = \frac{n_{ik}^j}{N_i} \times \frac{N_i}{N_i+1} + \frac{1}{N_i+1} = p_i^j(b_{ik}^j) \times \frac{N_i}{N_i+1} + \frac{1}{N_i+1} \quad (4)$$

For each other bin, the new probability is:

$$p_i'^j(b_{iz}^j) = \frac{n_{iz}^j}{N_i} \times \frac{N_i}{N_i+1} = p_i^j(b_{iz}^j) \times \frac{N_i}{N_i+1}, z=1...h \ \& \ z \neq k \quad (5)$$

Using (4) and (5), the probability histograms can be updated after the classification of a new point without the need to recalculate them. We just need to know in which bin the new point is located. The histogram of possibility is then calculated by (3). IFPM has been developed to deal with data represented in a feature space of correlated attributes as the case of XOR database [5]. In the next part, the improvements realized on IFPM are presented.

3 Dynamic Fuzzy Pattern Matching

We have called Dynamic Fuzzy Pattern Matching (DFPM) the improved version of IFPM. DFPM integrates a mechanism to adjust the classifier's parameters when serious changes in the classes' characteristics are detected during a growing time window. The size of the time window depends of the application's dynamic. The next subsections detail the two phases of DFPM's functioning.

3.1 *Detection phase*

In the detection phase, three indicators are used to monitor the temporal changes of a system. The first indicator is a measure evaluating the bins' usefulness. This indicator is based on the accumulated temporal changes which have occurred in the probability distributions during a variable time sliding window. It considers the number of new points located in each bin of the probability histograms, as well as its initial probability before the assignment of the new pattern(s). Let $\Delta T = t_w - t_s$ be the growing size of the time window at the present time t_w. This time window starts at the instant t_s. Let $\{p_i^j(b_{ik}^j), k \in \{1,2,..., h\}\}$ be the probability histogram for the class C_i according to the attribute j at the instant t_s. The probability of each bin is calculated by (2). Let ΔN_i be the number of new classified points in the class C_i and let Δn_{ik}^j be the number of new points located in the bin b_{ik}^j at the present time t_w. The new probability of this bin is calculated by:

$$p_i'^j(b_{ik}^j) = \frac{n_{ik}^j + \Delta n_{ik}^j}{N_i + \Delta N_i} \quad (6)$$

where n_{ik}^j and N_i are respectively the number of points of the class C_i located in the bin b_{ik}^j and the total number of points of the class C_i before the classification of the new pattern(s). The accumulated temporal changes for each bin are evaluated as the difference between the bin's probabilities at the present time $p_i'^j(b_{ik}^j)$ and at the beginning $p_i^j(b_{ik}^j)$ of the growing time window:

$$\Delta p_i^j(b_{ik}^j) = p_i'^j(b_{ik}^j) - p_i^j(b_{ik}^j) = \frac{N_i.\Delta n_{ik}^j - n_{ik}^j.\Delta N_i}{N_i.(N_i + \Delta N_i)} \quad (7)$$

We define the usefulness measure as a gradual measure, $I_i^j(b_{ik}^j) : \{1,2,...,h\} \rightarrow [-1,1]$ for each bin b_{ik}^j of each class C_i according to each attribute j. This measure evaluates the usefulness of each bin based on the accumulated temporal changes in the probability distributions defined by (7):

$$I_i^j(b_{ik}^j) = \begin{cases} \dfrac{p_i'^j(b_{ik}^j) - p_i^j(b_{ik}^j)}{p_i^j(b_{ik}^j)} \in [-1,0] \ if \ \Delta p_i^j(b_{ik}^j) < 0 \\ \dfrac{p_i'^j(b_{ik}^j) - p_i^j(b_{ik}^j)}{p_i'^j(b_{ik}^j)} \in [0,1] \ if \ \Delta p_i^j(b_{ik}^j) > 0 \end{cases} \quad (8)$$

This measure is calculated after the classification of each new classified point. When the value of this indicator is negative for one bin, it indicates a decrease of its usefulness. This decrease is due to the fact that no new classified points, or just a few ones, are located in this bin. On the contrary, the positive values indicate an increase of the bin's usefulness due to the assignment of many new points in the bin, according to its initial value. It is interesting to take into account the old or initial probabilities. Indeed, if there is no important change in the probability distribution, it is normal that the bin with the highest probability receives more new points than the others. If most of the new classified points are located in the bins which possess a small initial probability, this indicates a serious change in the probability distribution and thus their usefulness indicators must have a more important positive value.

To detect an evolution, a second indicator, which is a residual, is calculated based on the usefulness' measure of all histograms' bins according to all attributes. The goal of this residual is to provide one indicator for each class, which evaluates the temporal accumulative changes in the probability distributions of this class. This residual is sensitive for these changes. Two thresholds *th*1 and *th*2 predefined by an expert according to the system dynamic are used to determine the size ΔT of the time window. The value of this residual is updated and compared after each pattern assignment to *th*1 and *th*2. If the residual value is

ISBN: 978-989-95079-6-8

inferior to *th*1, then no serious change in the class' characteristics is yet started. As long as the residual is inferior to *th*1, the measure of usefulness is based on the difference between the current bin probability and the one of the previous classified pattern. If the residual value is superior to *th*1 and inferior to *th*2, a serious change has begun to occur. The time window starts at this moment, $t=t_s$, and patterns are stored in a block, called the evolution block. During this window, the measure of usefulness is calculated using (8). Patterns are stored in the evolution block until the residual value reaches *th*2. At this moment the growing time window reaches its final size $t_w=t_f$. This residual is defined for each class C_i as follows:

$$0 \le R_i = \max\left(\frac{\sum_{k=1}^{h}\left|I_i^j(b_{ik}^j)\right|}{h}\right) \le 1, j \in \{1,..,d\} \quad (9)$$

When the residual value reaches *th2*, a serious change can be decided in a class so the classifier parameters (densities of possibility) must be adapted using only the patterns stored in the evolution block. The old patterns which have become obsolete are forgotten and an online update of the classifier's parameters can then be performed.

3.2 Adaptation phase

This phase consists in the adaptation of the probability histograms and the update of the lower and upper attributes' borders as well as the number of bins *h*. Indeed, in IFPM, these latter are defined initially using (1) and they remain unchanged. For dynamic classes, it is not realistic to define static attributes' borders. Thus, in DFPM these borders will be updated online with the classification of new points. If a new classified point involves the creation of a bin for a histogram, then a bin is added to the histogram according to this attribute so that *h* is incremented and the histograms' borders are updated:

$$\begin{cases} x^j < \min^j - \frac{\Delta^j}{2} \Rightarrow \min'^j = \min^j - \Delta^j \\ x^j > \max^j + \frac{\Delta^j}{2} \Rightarrow \max'^j = \max^j + \Delta^j \end{cases} \quad (10)$$

$$h' = h + 1 \quad (11)$$

The value of Δ^j is defined initially by (1). With this update *h* can be different according to each attribute. The adaptation of probability histograms is achieved using an incremental approach. Let $\left\{p_i^j(b_{ik}^j), k \in \{1,2,...,h\}\right\}$ be the probability histogram for the class C_i according to the attribute *j*. When the residual value of a class reaches *th*2, old patterns are deleted and only the new patterns of the evolution block are considered. So, the value of probability for each bin is calculated incrementally by:

$$p_i''^j(b_{ik}^j) = \frac{\Delta n_{ik}^j}{\Delta N_i} = \left(\frac{n_{ik}^j + \Delta n_{ik}^j}{N_i + \Delta N_i} - \frac{n_{ik}^j}{N_i} \times \frac{N_i}{N_i + \Delta N_i}\right) \times \frac{N_i + \Delta N_i}{\Delta N_i}$$

$$p_i''^j(b_{ik}^j) = \left(p_i'^j(b_{ik}^j) - (p_i^j(b_{ik}^j) \times \frac{N_i}{N_i + \Delta N_i})\right) \times \frac{N_i + \Delta N_i}{\Delta N_i}, k \in \{1,..h\} \quad (12)$$

This incremental adaptation permits to follow the evolution of classes online with a constant and low classification time. Then, the histogram of possibility is calculated using (3).
Fig. 2 illustrates the functioning phases of DFPM.

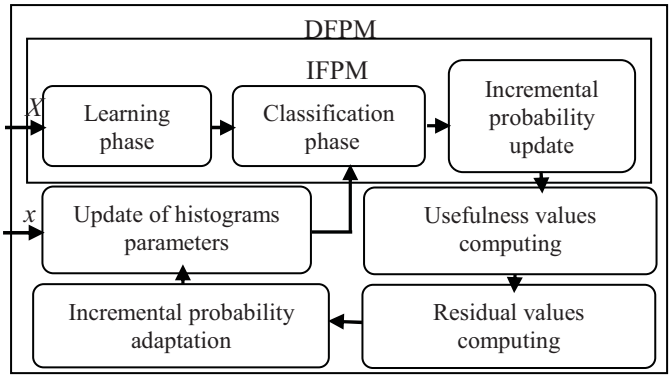

Figure 2: Functioning phases of DFPM.

4 Results with dynamic classes

Classes become dynamic if at least one of their characteristics changes with the time. For the sake of simplicity we have used a set of simulations described in a two dimension space. The obtained results can be extended for higher dimensions. The generated datasets follow a normal distribution of two independent variables (mean and standard deviation). We suppose that one unit of time corresponds to the classification of one point. This hypothesis is verified since DFPM has a constant and low classification time.

4.1 Class drift

Figure 3 shows a drift of a class in the course of time. The drift database has been created as follows:
- t=0: the possibility densities are already learned using 100 labeled patterns. The mean values of these data points are μ^1=3 and μ^2=3 (Fig. 3.a).
- t=1 to 100: 100 new incoming patterns, possessing the same initial class' characteristics (mean and standard deviation) occur in the class; thus there is no evolution or drift.
- t=101 to 200: a sudden change takes place in the class' mean values μ^j according to each attribute *j*, $j \in \{1,2\}$. This sudden change is followed by a slow drift of the mean value according to each attribute (Fig. 3.b):

$$\begin{cases} \mu^{1'}(t) = \mu^1 + 2 + \frac{4 \times (t-100)}{100} \\ \mu^{2'}(t) = \mu^2 + 2 + \frac{2 \times (t-100)}{100} \end{cases} \quad 101 \le t \le 200 \quad (13)$$

- t=201 to 300: 100 new patterns with the same characteristics as the ones of the drifted class occur. Fig 3.c presents the 0.1 membership level curve expected for the final drifted class. This curve contains all the points which have a membership possibility value to the class greater or equal to 0.1.

ISBN: 978-989-95079-6-8

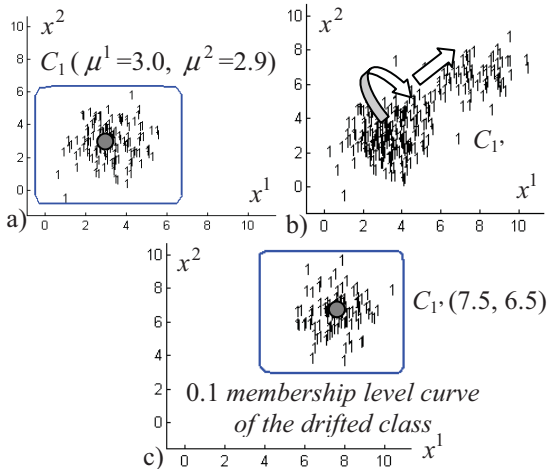

Figure 3: Evolution of the drift for the class C_1. The mean values of the class are presented before and after evolution between parentheses.

Fig. 4 presents the 0.1 membership level curve obtained by IFPM at the end of the class' drift ($t = 200$). We suppose here that each attribute borders were correctly determined in order to include the class drift.

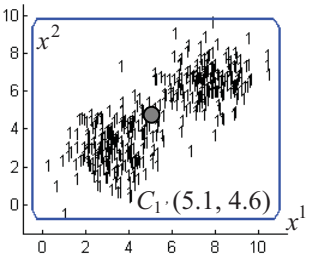

Figure 4: Classification of all patterns of the drifted class by IFPM.

All the patterns classified by IFPM are considered representative. Thus, the membership function, represented by the 0.1 membership level curve in Fig. 4, is not adapted to the drifted class with its new means values (see Fig. 3.c). This is due to the fact that all patterns were considered without eliminating any old and useless pattern.

The DFPM method is evaluated on the same drift of a class generated by (14). The residual values obtained progressively after the classification of each pattern in the class are represented in Fig. 5.

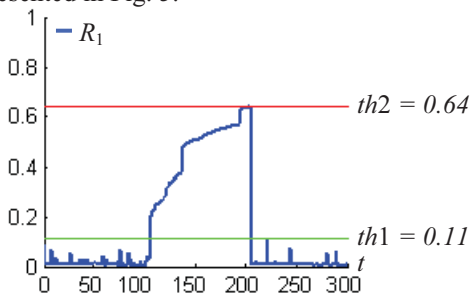

Figure 5: Residual values obtained by DFPM for the class drift.

Based on Fig. 5, we can conclude:

- between t=1 and t=100, the class' evolution has not yet begun.
- at t=105, the evolution of the class is detected. To detect this evolution the *th1* must be equal to 0.11.
- at t=204, the class drift is finished. To detect the end of this class drift the second threshold *th*2 must be equal to 0.64.
- finally, between t=205 and t=300 no evolution is observed so the residual values are small for the latest patterns and the class is stable. These patterns are classified in the class as usual.

Fig. 6 permits to see the membership level curve obtained by DFPM just before the evolution (Fig. 6.a) and the final result of classification after evolution when the adaptation of the histograms was realized (Fig. 6.b).

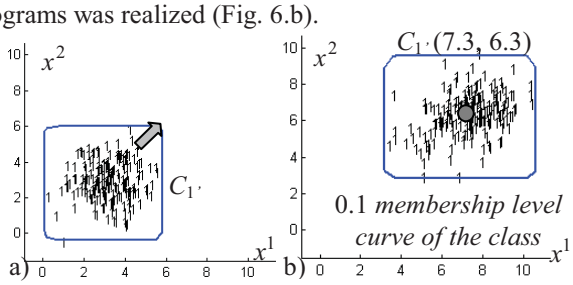

Figure 6: 0.1 membership level curve obtained by DFPM before evolution and after classification of all patterns.

The drift of the class has been well detected for both attributes. The classifier has been adapted with the representative patterns. However, the thresholds *th*1 and *th*2 must be well determined. A too big or too small *th*1 value leads to lose some representative patterns or to keep some obsolete ones, while a too big or a too small *th*2 value leads to detect too late or too early the class evolution.

The mean values of the class obtained by DFPM are close to those expected, contrary to those obtained by IFPM (Fig. 4). However, some patterns which represent the connection between the old class and the evolved one are still in the final class obtained by DFPM.

4.2 Rotation of class

The rotation of a class is presented in Fig. 7. The standard deviations of the class according to the two attributes are initiated at σ_1 =4 and σ_2 =0.25. The possibility densities are already learned using 150 learning patterns of the class (Fig. 7.a). Then, new incoming points evolve, between t=1 and t=150, to achieve a rotation of the class (Fig. 7.b).

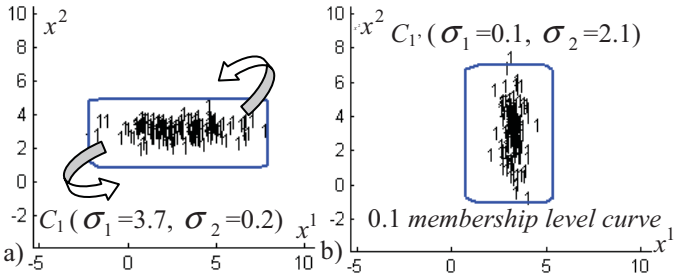

Figure 7: Rotation of the class C_1.

These changes are generated for the class according to each attribute j, $j \in \{1,2\}$, by:

$$\left.\begin{aligned} \mu_1^{1'} &= \mu_1^1 \times \sqrt{\frac{\sigma_2 \times t}{150}} \\ \mu_1^{2'} &= \mu_1^2 \times \sqrt{\frac{\sigma_1 \times t}{150}} \end{aligned}\right\} \quad 1 \le t \le 150 \qquad (14)$$

Fig. 8 presents the 0.1 membership level curve obtained by IFPM after the rotation of the class (t=150).

ISBN: 978-989-95079-6-8

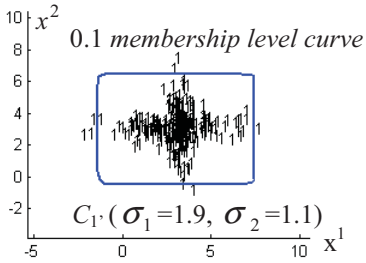

Figure 8: Final classification result obtained by IFPM for the patterns of the rotation's case.

All patterns have been classified in the class, but IFPM has not detected the rotation of the class. The membership level function is not adapted and useless patterns are still in the class. With DFPM, the residual values obtained after the classification of each pattern in the class are represented in Fig. 9.

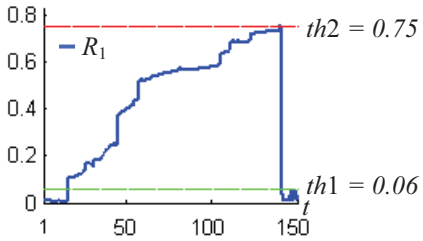

Figure 9: Residual values obtained by DFPM for the rotation of the class.

Based on Fig. 9, we can conclude that the use of $th1$=0.06 and $th2$=0.75 leads to well detect the class rotation.
Fig. 10 presents the membership level curve obtained by DFPM after classification of the evolving patterns when the adaptation of the histograms was realized.

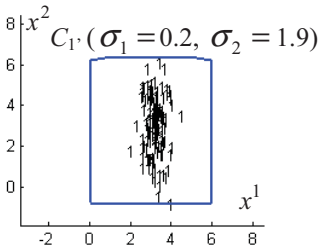

Figure 10: Classification result obtained by DFPM after adaptation of the class.

The classifier has been adapted with all representative patterns detected since the start of the class rotation. The new conserved useful patterns are the only patterns used to calculate the membership function. The resulting class corresponds well to the expected one, contrary to the class obtained by IFPM (Fig. 8).

5 Conclusions

In this paper, the Incremental version of the classification method Fuzzy Pattern Matching (IFPM) has been developed to discriminate dynamic classes. This development, called Dynamic FPM (DFPM), follows online the accumulated gradual changes in classes' probability distributions after the classification of each new pattern. Bins' usefulness values are calculated for each class and attribute. Based on these usefulness values, a residual value is calculated for each class in order to follow the evolution of each class. Then, the classes histograms are adapted in an incremental manner using the recent and useful patterns. This adaptation is achieved when the residual value reaches a suitable threshold according to the system dynamic. The DFPM method will be applied on two real applications. The first one concerns the following of a treatment's evolution for hemiplegic's patient according to its response to a medical treatment. The second application is a folding metal system which evolves from a normal mode to a faulty one according to temporal changes in the characteristics of the system and to the wear of its tools.

Abstract— *The setting of formal concept analysis presupposes the existence of a relation between objects and properties. Knowing that an unspecified object has a given property induces a formal possibility distribution that models the set of objects known to possess this property. This view expressed in a recent work by the authors of the present paper, has led to introduce the set-valued counterpart to the four set functions evaluating potential or actual, possibility or necessity that underlie bipolar possibility theory, and to study associated notions. This framework puts formal concept analysis in a new, enlarged perspective, further explored in this article. The "actual (or guaranteed) possibility" function induces the usual Galois connexion that defines the notion of a concept as the pair of its extent and its intent. A new Galois connexion, based on the necessity measure, partitions the relation in "orthogonal" subsets of objects having distinct properties. Besides, the formal similarity between the notion of division in relational algebra and the "actual possibility" function leads to define the fuzzy set of objects having* most *properties in a set, and other related notions induced by fuzzy extensions of division. Generally speaking, the possibilistic view of formal concept analysis still applies when properties are a matter of degree, as discussed in the paper. Lastly, cases where the object / property relation is incomplete due to missing information, or more generally pervaded with possibilistic uncertainty is also discussed.*

Keywords— possibility theory; formal concept analysis.

1 Introduction

Formal concept analysis [1] exploits the duality between objects and properties in a lattice theory setting, which has led to an original and practical view of the notion of a formal concept with application in data mining. A concept is then a pair made of a set of objects and a set of properties that are in mutual correspondence. These two sets are the extent and of the intent of the concept respectively. In this framework, properties are *binary*, and *complete* information is assumed about the relation linking objects and properties.

Fuzzy set theory [2] has emphasized the idea that properties are not always all-or-nothing notions, but are rather often a matter of degree. This has led to an extension of the original formal concept analysis setting by allowing intermediate truth values for the propositions "object x has property y" [3]. However, complete information is still assumed. Namely, for any pair (object, property), it it is known to what degree the object has the property. Besides, fuzzy sets have also been the starting point for the development of a new approach for the representation of uncertainty, named possibility theory [4, 5]. Fuzzy sets then have a disjunctive reading and represent states of incomplete information, i.e. (soft) restrictions on the mutually exclusive possible values of a single-valued variable.

The authors of the present paper have recently advocated the interest of a possibilistic reading of formal concept analysis where the possibility theory set-functions are shown to be meaningful in formal concept analysis [6]. Under this view, the set of objects known to possess a given property plays the role of a formal possibility distribution that restricts the possible value (identity) of an unspecified object only described as having the given property. This leads to an enlarged setting that we continue to investigate in this paper. Besides, this enlarged setting can be itself extended either by allowing properties to be non-Boolean, or by considering that the relation between objects and properties may be incompletely known.

The next section provides the background on a possibility theory-inspired view of formal concept analysis. Four basic operators that are the counterparts of the four basic set-functions in bipolar possibility theory are introduced, leading to consider another Galois connexion distinct from the usual one that gives birth to the notion of concept. Section 3 briefly describes the extension of the enlarged setting to fuzzy properties, i.e., when the relation linking objects and properties becomes fuzzy. Section 4 relates the operator underlying classical formal concept analysis and the notions of division (and quotient) in relational algebra. This provides a basis for defining the fuzzy set of objects having $most$ properties in a set (where $most$ is a fuzzy quantifier) and other related notions. Section 5 deals with the situation where information is incomplete or uncertain. Due to the lack of space, the paper only outlines new ideas, without developing them.

2 A possibility theory view of concept analysis

A formal information system is viewed here as a binary relation R between a set Obj of objects and a set $Prop$ of Boolean properties. Some authors speak of 'attribute' instead of 'property'. As we shall see in Section 5, this distinction only matters for attributes with non-binary domains. R is called *context* in formal concept analysis. If $X \subseteq Obj$, $\overline{X}$ is its complement $Obj \setminus X$. The notation $(x, y) \in R$ means that object x has property y. $R(x) = \{y \in Prop | (x, y) \in R\}$ is the set of properties of object x. Similarly, $R^{-1}(y) = \{x \in Obj | (x, y) \in R\}$ is the set of objects having property y. Its characteristic function induces a two-valued possibility distribution π:

$$\forall x \in Obj, \quad \pi(x) = \begin{cases} 1 & \text{if } x \in R^{-1}(y) \\ 0 & \text{otherwise,} \end{cases}$$

Intuitively speaking, if all we know about an unknown object is that it has property y then this object may be any x such that $\pi(x) = 1$ in context R. Thus, the relation R for a particular property y plays the role of a possibility distribution π encoding a set of possible values for x.

ISBN: 978-989-95079-6-8

2.1 Possibility theory

In possibility theory [5], two "measures" are associated with a possibility distribution π defined on a universe U as the characteristic (membership) function of a fuzzy set E representing the available information (in the above case $U = Obj$, and $E = R^{-1}(y)$ is an ordinary subset of U). Namely

i) a possibility measure Π (or "potential possibility"):

$$\Pi(A) = \max_{x \in A} \pi(x).$$

It estimates to what extent event A is *consistent with* the information represented by π. $\Pi(A \cup B) = \max(\Pi(A), \Pi(B))$ is the characteristic property of possibility measures [4].

ii) a dual measure of necessity N, expressing that an event is all the more necessarily (certainly) true as the opposite event is more impossible. N thus reflects an "actual necessity":

$$N(A) = 1 - \Pi(\overline{A}) = 1 - \max_{x \notin A} \pi(x),$$

where $\overline{A} = U \setminus A$. $N(A)$ estimates to what extent event A is *implied* by the information E represented by π (inasmuch as this information entails that any realization of $\overline{A}$ is more or less impossible). Necessity measures are characterized by the decomposability property $N(A \cap B) = \min(N(A), N(B))$.

Π and N are based on the $maximum$ of π over A and $\overline{A}$ respectively; two other set-functions [5] use the $minimum$:

iii) a measure of "actual (or guaranteed) possibility"

$$\Delta(A) = \min_{x \in A} \pi(x),$$

which estimates to what extent all elements in A are possible. Δ can be also termed "$sufficiency\ measure$" since $\Delta(A) = 1$ is enough for ensuring that all realizations of A are actually possible. Clearly, $\Delta \leq \Pi$. Note also that $\Delta(A)$ and $N(A)$ are unrelated. $\Delta(A \cup B) = \min(\Delta(A), \Delta(B))$ is the characteristic property of guaranteed possibility measures.

iv) a dual measure of "potential necessity or certainty"

$$\nabla(A) = 1 - \Delta(\overline{A}) = 1 - \min_{x \notin A}(\pi(x))$$

which estimates to what extent there exists at least one value in the complement of A that has a zero (or more generally a low) degree of possibility. This is clearly a $necessary$ condition for having "$x \in A$" somewhat certain. Property $\nabla(A \cap B) = \max(\nabla(A), \nabla(B))$ characterizes these measures.

2.2 An enlarged formal concept analysis setting

These four set functions make sense in the formal concept analysis. Namely, four remarkable sets can be defined:

$$R^{\Pi}(X) = \{y \in Prop | R^{-1}(y) \cap X \neq \emptyset\}$$
$$R^{N}(X) = \{y \in Prop | R^{-1}(y) \subseteq X\}$$
$$R^{\Delta}(X) = \{y \in Prop | R^{-1}(y) \supseteq X\}$$
$$R^{\nabla}(X) = \{y \in Prop | R^{-1}(y) \cup X \neq Obj\}$$

whose respective characteristic functions are $\Pi(X)$, $N(X)$, $\Delta(X)$, and $\nabla(X)$. Their meanings are as follows w. r. t. a subset of objects X in context R.

- $R^{\Pi}(X)$ is the set of properties that are associated with at least one object in X. Formally, we have

$$R^{\Pi}(X) = \cup_{x \in X} R(x).$$

$R^{\Pi}(X)$ is such that any object that satisfies one of them is possibly in X. In other words, if an object has none of the properties in $R^{\Pi}(X)$ then it cannot belong to X. Moreover, we have $R^{\Pi}(X_1 \cup X_2) = R^{\Pi}(X_1) \cup R^{\Pi}(X_2)$.

- $R^{N}(X)$ is the set of properties s. t. any object that satisfies one of them is necessarily in X. Having any property in $R^{N}(X)$ is a sufficient condition for belonging to X, and $R^{N}(X) = \overline{R^{\Pi}(\overline{X})} = Prop \setminus R^{\Pi}(\overline{X})$. Thus,

$$R^{N}(X) = \cap_{x \notin X} \overline{R(x)}.$$

and $R^{N}(X_1 \cap X_2) = R^{N}(X_1) \cap R^{N}(X_2)$.

- $R^{\Delta}(X)$, set of properties shared by all objects in X is

$$R^{\Delta}(X) = \cap_{x \in X} R(x).$$

In other words, satisfying all properties in $R^{\Delta}(X)$ is a necessary condition for an object to belong to X. $R^{\Delta}(X)$ is a partial conceptual characterization of objects in X: objects in X should have all the properties of $R^{\Delta}(X)$ and may have some others (that are not shared by all objects in X). It is worth noticing that $\overline{R^{\Pi}(X)}$ provides a negative conceptual characterization of objects in X since it gathers all the properties that are never satisfied by any object in X. Besides, it can be checked that $R^{N}(X) \cap R^{\Delta}(X)$ is the set of properties possessed by all objects in X and only by them. Moreover, we have $R^{\Delta}(X_1 \cup X_2) = R^{\Delta}(X_1) \cap R^{\Delta}(X_2)$.

- Note that $R^{\nabla}(X) = \overline{R^{\Delta}(\overline{X})} = Prop \setminus R^{\Delta}(\overline{X})$. Thus $R^{\nabla}(X)$ is the set of properties in $Prop$ that are not satisfied by at least one object in $\overline{X}$, i.e. $R^{\nabla}(X)$ is the set of properties that some object in $\overline{X}$ misses. In other words, in context R, for any property in $R^{\nabla}(X)$, there exists at least one object outside X that misses it. We have

$$R^{\nabla}(X) = \cup_{x \notin X} \overline{R(x)}.$$

and the following decomposability property holds $R^{\nabla}(X_1 \cap X_2) = R^{\nabla}(X_1) \cup R^{\nabla}(X_2)$.

Note that $R^{\Pi}(X)$ and $R^{N}(X)$ get larger when X increases, while $R^{\Delta}(X)$ and $R^{\nabla}(X)$ get smaller. The four modal-like operators R^{Π}, R^{N}, R^{Δ}, and R^{∇} have been considered by Düntsch and Orlowska [7] in the Boolean algebra setting, where R^{Δ} is called *sufficiency* operator, and its representation capabilities are studied. Taking inspiration as the previous authors from rough sets [8], Yao [9] also lays bare these four subsets. In both cases, the four operators were introduced without any mention of possibility theory.

Results in possibility theory have their counterparts in the enlarged formal concept analysis setting, as, e.g., [6]: If R^{-1} is s. t. $\forall y \in Prop, R^{-1}(y) \neq \emptyset$ and $R^{-1}(y) \neq Obj$, then

$$\forall X \subseteq Obj, \quad R^{N}(X) \cup R^{\Delta}(X) \subseteq R^{\Pi}(X) \cap R^{\nabla}(X). \quad (1)$$

Assuming that the property y is non trivial with respect to the set of objects Obj, i.e. $R^{-1}(y) \neq \emptyset$ (at least one object has property y) and $R^{-1}(y) \neq Obj$ (at least one object has not property y), then the four sets $R^{\Pi}(X)$, $R^{\Delta}(X)$, $R^{N}(X)$,

$R^{\nabla}(X)$ are necessary and sufficient for describing (and distinguishing between) the seven relative possible positions of X and $R^{-1}(y)$, as shown in Table 1, where 1 (resp. 0) stands for $y \in A$ (resp $y \notin A$) where A is the set $R^{*}(X)$ associated to the column (and $*$ is Π, Δ, N, or ∇). Note that the 9 = 16 - 7 remaining binary 4-tuples are ruled out by the constraints induced by (1), namely $R^{N}(X) \subseteq R^{\Pi}(X)$, $R^{\Delta}(X) \subseteq R^{\Pi}(X)$, $R^{\Delta}(X) \subseteq R^{\nabla}(X)$, $R^{N}(X) \subseteq R^{\nabla}(X)$. For instance, the "trivial" cases $R^{-1}(y) = \emptyset$ and $R^{-1}(y) = Obj$ (ruled out by the constraints) would be captured by distinct 4-tuples in Table 1, namely $(0 \quad 0 \quad 1 \quad 1)$ and $(1 \quad 1 \quad 0 \quad 0)$ respectively.

The above characterization of remarkable sets of properties w. r. t. a set of objects can be easily adapted for defining the corresponding sets of objects associated to a set of properties $Y \in Prop$: namely $R^{-1\Pi}(Y)$, $R^{-1N}(Y)$, $R^{-1\Delta}(Y)$, and $R^{-1\nabla}(Y)$. Their definitions can be easily obtained by swapping R and R^{-1} and exchanging the roles of the sets Obj and $Prop$. Namely,

$$R^{-1\Pi}(Y) = \{x \in Obj | R(x) \cap Y \neq \emptyset\} = \cup_{y \in Y} R^{-1}(y)$$
$$R^{-1N}(Y) = \{x \in Obj | R(x) \subseteq Y\} = \cap_{y \notin Y} \overline{R^{-1}(y)}$$
$$R^{-1\Delta}(Y) = \{x \in Obj | R(x) \supseteq Y\} = \cap_{y \in Y} R^{-1}(y)$$
$$R^{-1\nabla}(Y) = \{x \in Obj | R(x) \cup Y \neq Obj\} = \cup_{y \notin Y} \overline{R^{-1}(y)}.$$

Remark The above operators can be combined together. For instance, consider an object x_0. Let $R(x_0)$ be the set of its (known) properties. Compute $R^{-1\Delta}(R(x_0))$, the set of objects that share these properties. Then get $R^{\Pi}(R^{-1\Delta}(R(x_0)))$, which is the set of properties that are associated with at least one object sharing the properties of x_0. Viewing the table $Obj \times Prop$ as the information pertaining to a repertory of cases, and x_0 as a partially known extra object (not in Obj) for which one tries to guess other properties, the expression $R^{\Pi}(R^{-1\Delta}(R(x_0)))$ may be viewed as the result of a *case-based reasoning* procedure, i.e. a set of potential properties that x_0 may also have. Besides, its subset $R^{N}(R^{-1\Delta}(R(x_0)))$ is the set of properties that alone characterize the objects sharing the properties of x_0. Thus, if one of the properties in $R^{N}(R^{-1\Delta}(R(x_0)))$ is not already among the known properties of x_0, it may be considered as a serious candidate property for x_0.

2.3 Galois connexions

In formal concept analysis, the pair of set valued functions R^{Δ} and $R^{-1\Delta}$ induces a Galois connexion [10] between 2^{Obj} and 2^{Prop}. Then, a *formal concept* is a pair (X, Y) such that $X = \{x \in Obj | R(x) \supseteq Y\}$ and $Y = \{y \in Prop | R^{-1}(y) \supseteq X\}$, i.e. such that $X = R^{-1\Delta}(Y)$ and $Y = R^{\Delta}(X)$, X is called its *extent* and Y its *intent*. In other words, in a formal concept (X, Y), Y is the set of properties shared by all the objects in X, and X is the set of objects that possess all the properties in Y. Then $X \times Y \subseteq R$, i.e. $\forall x \in X, \forall y \in Y, (x, y) \in R$. A formal concept is a maximal pair that satisfies the latter condition (where maximality is taken in the sense of set inclusion).

Putting formal concept analysis in the perspective of possibility theory, it becomes then natural to also consider
- the pairs (X, Y) s. t. $X = R^{-1\Pi}(Y)$ and $Y = R^{\Pi}(X)$;
- the pairs (X, Y) s. t. t $X = R^{-1N}(Y)$ and $Y = R^{N}(X)$;
- the pairs (X, Y) s. t. $X = R^{-1\nabla}(Y)$ and $Y = R^{\nabla}(X)$.

First, observe that $X = R^{-1\nabla}(Y)$ and $Y = R^{\nabla}(X)$ holds if and only if $\overline{X} = R^{-1\Delta}(\overline{Y})$ and $\overline{Y} = R^{\Delta}(\overline{X})$ holds, i.e., if $(\overline{X}, \overline{Y})$ is a formal concept, due to the duality between operators R^{Δ} and R^{∇}. Similarly, $X = R^{-1\Pi}(Y)$ and $Y = R^{\Pi}(X)$ holds if and only if $\overline{X} = R^{-1N}(\overline{Y})$ and $\overline{Y} = R^{N}(\overline{X})$ holds. But, it can be easily seen that a pair (X, Y) such that $X = R^{-1N}(Y)$ and $Y = R^{N}(X)$, i.e. such that $X = \{x \in Obj | R(x) \subseteq Y\}$ and $Y = \{y \in Prop | R^{-1}(y) \subseteq X\}$ is not generallly a formal concept, as now exemplified. This Galois connexion has been introduced by [11] on a formal basis, but its practical meaning was apparently not really discussed.

Example 1 *We consider an example of relation R described by the table of Figure 2. This relation defines the links between eight objects $Obj = \{1, 2, 3, 4, 5, 6, 7, 8\}$ and nine properties $Prop = \{a, b, c, d, e, f, g, h, i\}$. There is a "×" in the cell corresponding to an object x and to a property y if the object x has property y, in other words the "×"s describe the relation R (or context). An empty cell corresponds to the fact that $(x, y) \notin R$, i.e., it is known that object x has not property y. It can be checked that the pairs $(\{1, 2, 3, 4\}, \{g, h, i\})$, $(\{5, 6, 7, 8\}, \{a, b, c, d, e, f\})$ are pairs (X, Y) such that $X = R^{-1N}(Y)$ and $Y = R^{N}(X)$. These two pairs are not formal concepts. They are disjoint w. r. t. both Obj and $Prop$. Examples of formal concepts are $(\{2, 3, 4\}, \{g, h\})$, $(\{6, 7, 8\}, \{a, c, d\})$, or $(\{5, 6, 7, 8\}, \{a, d\})$. Note that these latter examples are here obtained by considering appropriate subsets in the previous pairs.*

Figure 3: R': relation R modified

is such that all the objects in X possess *at least one* property in Y and the properties in Y are only (possibly) possessed by the objects in X. While the intent of a formal concept is a *conjunction* of properties, the pairs (X, Y) forming an "N-block" correspond to sets of objects defined through *disjunctions* of properties. Finding such pairs, which may not exist, aims at decomposing the relation R into independent blocks without object or property in common, as in the Figure 2 example. When such a decomposition no longer holds, as in Figure 3, pairs (X, Y) such that $X = R^{-1N}(Y)$ and $Y = R^N(X)$ no longer exist, except for the trivial pair (Obj, $Prop$), as shown in the next example.

Example 2 *Let us now consider a modified version of relation R, say R′, depicted in the table of Figure 3, where object 4 has also the additional property d now. Then it can be checked that we still have* $R'^N(\{1,2,3,4\}) = \{g,h,i\}$*, but* $R'^{-1N}(\{g,h,i\}) = \{1,2,3\}$*, since* $R'(4) = \{d,g,h,i\} \not\subseteq \{g,h,i\}$*. Similary,* $R'^{-1N}(\{a,b,c,d,e,f\}) = \{5,6,7,8\}$*, but* $R'^N(\{5,6,7,8\}) = \{a,b,c,e,f\}$ *since* $R'^{-1}(d) = \{4,5,6,7,8\} \not\subseteq \{5,6,7,8\}$*. Thus the pairs* $(\{1,2,3,4\},\{g,h,i\})$*,* $(\{5,6,7,8\},\{a,b,c,d,e,f\})$ *are no longer pairs* (X, Y) *such that* $X = R'^{-1N}(Y)$ *and* $Y = R'^N(X)$ *in the new context R'.*

3 Handling fuzzy properties in the new setting

In the previous section, properties were supposed to be Boolean. Hence, when an object satisfies a property, it fully satisfies it: there is no intermediary degree of satisfaction since the property is not gradual. Thus, the relation linking objects and properties was all-or-nothing. When properties become a matter of intensity, i.e., when an object may have a property to some degree, the relation R between objects and properties becomes fuzzy. However, when relaxing the Booleanity assumption, we still assume that we have complete information. Namely, it is known to what extent α object x has property y for any pair (x, y), which is denoted $\mu_R(x, y) = \alpha$. Then, $\mu_{R^{-1}(y)}(x) = \alpha$ denotes the fact that object x satisfies property y at degree α where $\mu_{R^{-1}(y)}$ is the membership function of the fuzzy set of objects that constitutes the extension of $R^{-1}(y)$. Such an extension to standard concept analysis (based on the operator called here Δ) has been studied by Belohlavek [3]; see also [12].

Then, the four operators introduced in the previous section easily extend to the case where relation R is fuzzy. Namely,

$$\begin{array}{llll} \mu_{R^\Pi(X)}(y) & = \Pi_y(X) & = \max_{x\in X} & \mu_{R^{-1}(y)}(x) \\ \mu_{R^N(X)}(y) & = N_y(X) & = \min_{x\notin X} & 1-\mu_{R^{-1}(y)}(x) \\ \mu_{R^\Delta(X)}(y) & = \Delta_y(X) & = \min_{x\in X} & \mu_{R^{-1}(y)}(x) \\ \mu_{R^\nabla(X)}(y) & = \nabla_y(X) & = \max_{x\notin X} & 1-\mu_{R^{-1}(y)}(x) \end{array}$$

where Π_y, N_y, Δ_y and ∇_y are respectively potential possibility, actual necessity, actual possibility, and potential necessity measures, based on the gradual possibility distribution $\pi = \mu_{R^{-1}(y)}$. They thus enjoy the corresponding characteristic decomposability properties of these respective measures.

The following results are straightforward:

- $\mu_{R^N(X)}(y) = 1 - \mu_{R^\Pi(\overline{X})}(y)$;
- $\mu_{R^\nabla(X)}(y) = 1 - \mu_{R^\Delta(\overline{X})}(y)$
- if $\mu_{R^\Pi(X)}(y) = \alpha$ then $\exists x \in X, \mu_R(x, y) = \alpha$ and $\forall x \in X, \mu_R(x, y) \leq \alpha$
- if $\mu_{R^N(X)}(y) = \alpha$ then $\mu_R(x, y) > 1 - \alpha \Rightarrow x \in X$
- if $\mu_{R^\Delta(X)}(y) = \alpha$ then $x \in X \Rightarrow \mu_R(x, y) \geq \alpha$
- if $\mu_{R^\nabla(X)}(y) = \alpha$ then $\exists x \notin X, \mu_R(x, y) = 1 - \alpha$ and $\forall x \notin X, \mu_R(x, y) \geq 1 - \alpha$

The first two results extend duality relations to the graded case. The other ones express the meaning of each fuzzy set. Thus a property belongs to $R^\Pi(X)$ to degree α inasmuch as objects in X possess this property to at most degree α. Then $h(R^\Pi(X)) = \max_{y\in Y} \mu_{R^\Pi(X)}(y) = 0$ means that no object in X possesses a property in Y to any extent. A property belongs to $R^N(X)$ to degree α if any object possessing this property to a degree greater than $1 - \alpha$ necessarily belongs to X. In particular, any object possessing this property to some positive degree belongs to X, if $\alpha = 1$. A property belongs all the more to $R^\Delta(X)$ as any object in X possesses this property to a greater degree. Lastly, $\hbar(R^\nabla(X)) = \min_{y\in Y} \mu_{R^\nabla(X)}(y) = \alpha$ means that for any property y in Y objects outside X possess this property to at most to degree $1 - \alpha$. In particular, if $\hbar(R^\nabla(X)) = 1$, for any property in Y there exists an object outside X that misses it.

Moreover, we have the following counterpart to (1):

Proposition 1 *If* $R^{-1}(y)$ *is such that for* $y \in Prop$*,* $h(\mu_{R^{-1}(y)}) = 1$ *and* $\hbar(\mu_{R^{-1}(y)}) = 0$*, then*

$$\forall X \subseteq Obj, \quad \max(N_y(X), \Delta_y(X)) \leq \min(\Pi_y(X), \nabla_y(X)).$$

Lastly, it is clear that when nesting the operators as in the Remark at the end of Section 2.2, or when extending Galois connexions when R is fuzzy, we are led to extend again the above definitions to cases where X and Y become fuzzy sets themselves. From a possibility theory point of view, this means defining generalized measures for fuzzy events. Depending on the properties we want to preserve, several choices are possible here (see on this point [13], especially pages 51–64), which would lead to different extensions for the four operators. Choosing the appropriate extensions depends on the intended use and interpretation of the definition we want to generalize. We leave these questions for further research.

4 Generalized quotient and fuzzy quantifiers

In a relational database, given an ordered set of attributes $\mathbf{A} = \{\mathcal{A}^1, ..., \mathcal{A}^n\}$, information is stored in a relational table $\mathcal{R}$ where each column corresponds to an attribute, and a row to an object belonging to *Obj*. Thus a cell in such a relational table corresponds to the value of an attribute for an object. Any row in the relational table $\mathcal{R}$ is also called a 'tuple'. A 'tuple' is thus an ordered set of attribute values pertaining to an object. Let $\mathcal{T}u(\mathcal{R})$ denote the set of tuples in $\mathcal{R}$. Quotients are relational algebra operations that aim at finding out the subrelational table $\mathcal{R} \div \mathcal{S}$ of a finite relational table $\mathcal{R}$, containing subtuples of $\mathcal{R}$ that have for complements in $\mathcal{R}$ *all* the tuples of a relational table $\mathcal{S}$. The quotient operation is defined by

Definition 1 *Relational quotient.*

$$\mathcal{R} \div \mathcal{S} = \{t, \forall s \in \mathcal{T}u(\mathcal{S}), (t, s) \in \mathcal{T}u(\mathcal{R})\}$$

where s denotes a tuple of $\mathcal{S}$ and t a subtuple of $\mathcal{R}$ such that (t, s) is a tuple of $\mathcal{R}$.

The definition of $R^{\Delta}(X)$ can be viewed as a particular case of such a division. Indeed $R^{\Delta}(X) = \{y \in Prop | R^{-1}(y) \supseteq X\} = \{y \in Prop | \forall x \in X, (x, y) \in R\}$. Besides, a relation $R \subseteq Prop \times Obj$ can be viewed as equivalent to a 2-attribute relational table $\mathcal{R}$ with $\mathbf{A} = \{Object - name, Property - name\}$, where (x, y) (resp. (y, x)) is a tuple in $\mathcal{R}$ (resp. $\mathcal{R}^{-1}$) if and only if $(x, y) \in R$. Then, it becomes clear that $R^{\Delta}(X) = \mathcal{R}^{-1} \div \mathcal{X}$, where $\mathcal{X}$ is the one-attribute relational table containing the object names. Similarly, $R^{-1\Delta}(Y) = \mathcal{R} \div \mathcal{Y}$ ($\mathcal{Y}$ is the one-attribute relational table associated to Y).

The fuzzy extensions of the basic operationsR^{Δ}, $R^{-1\Delta}$, which underly formal concept analysis, can thus be related to fuzzy division operations in fuzzy relational databases where tuples are weighted [14, 15]. As we shall see, this also provides a way for introducing fuzzily quantified conjunctions in order to require that tuples in R are associated with "at least k", or more generally '*most*' objects in X , rather than *all* elements in X as in formal concept analysis basic operations. In the following, we discuss these extensions in the setting of formal concept analysis.

First, the definition of $R^{\Delta}(X)$ extended to the case where R becomes fuzzy, as given in the previous section, namely $\mu_{R^{\Delta}(X)}(y) = min_{x \in X} \mu_{R^{-1}(y)}(x)$, is the exact counterpart to the fuzzy division $\mu_{\mathcal{R}^{-1} \div \mathcal{X}}(y) = \min_{x \in \mathcal{T}u(\mathcal{X})} \mu_R(x, y)$, for all pair (y, x) in $\mathcal{T}u(\mathcal{R}^{-1})$, when R is a fuzzy relation and X remains a classical set. The definition of a fuzzy division in fuzzy relation databases includes the more general case where X is also a fuzzy set. This can be done as well here, choosing an appropriate type of inclusion between fuzzy sets, i.e. an implication connective $\rightarrow$ in the expression:

$$\mu_{R^{\Delta}(X)}(y) = \min_{x \in Obj} \mu_X(x) \rightarrow \mu_{R^{-1}(y)}(x)$$

in relation with the intended meaning of having X fuzzy. For instance, taking Gödel implication ($a \rightarrow b = 1$ if $a \leq b$, and $a \rightarrow b = b$ if $a > b$) amounts to seeing $\mu_X(x)$'s as a significance threshold to which $\mu_R(x, y)$ is compared, while using Dienes implication ($a \rightarrow b = \max(1 - a, b)$) would be more in agreement with the idea of viewing $\mu_X(x)$ as a level of priority of x, just requiring the inclusion of important objects in $R^{-1}(y)$ (indeed the less important x, the greater $(1 - \mu_X(x))$, and the smaller the impact of x on the global evaluation, even when x totally fails to have property y (see [14, 15] for details).

Having both a fuzzy relation R and a fuzzy set X of objects may sound unrealistic in practice. In formal concept analysis, it is the starting point for natural weakening of the quantifier 'for all' into "at least k", or even into 'most'. The idea is to require that "at least k" (or more generally 'most') objects in X are the important objects that are the most in relation R with property y.

Let I be a fuzzy constraint on integers, defined by a membership function of the form: $\mu_I(0) = 1$and$\mu_I(i) \geq \mu_I(i+1)$. For instance, "at least k objects are important" is represented by $\mu_I(i) = 1$ if $0 \leq i \leq k$ and $\mu_I(i) = 0$ for $i \geq k + 1, n$ where $n = |X|$. Let us reorder the $\mu_{R^{-1}(y)}(x_k)$'s decreasingly, so that objects (x_k)'s that are more in relation R with y are the most important ones:

$$\mu_{R^{-1}(y)}(x_{\sigma(1)}) \geq \mu_{R^{-1}(y)}(x_{\sigma(2)}) \geq ... \geq \mu_{R^{-1}(y)}(x_{\sigma(n)}).$$

Then the extent to which property y is possessed by 'at least k' objects in X can be computed as

$$\mu_{R^{\Delta}(X),I}(y) = \min_i \ \max(\mu_{R^{-1}(y)}(x_{\sigma(i)}), 1 - \mu_I(i)),$$

I being defined as above. This expression, which involves an absolute fuzzy quantifier, may be easily modified in order to introduce relative quantifiers Q like 'most', having an increasing membership function in $[0, 1]$, by changing $1 - \mu_I(i + 1)$ into $\mu_Q(i/n)$ for $i = 0, n - 1$ and $\mu_Q(1) = 1$. It gives

$$\mu_{R^{\Delta}(X),Q}(y) = \min_i \ \max(\mu_{R^{-1}(y)}(x_{\sigma(i)}), \mu_Q(\frac{i-1}{n})).$$

Clearly, if Q means 'all', $\mu_Q(t) = 0$ for $t < 1$, then the above expression reduces to $\mu_{R^{\Delta}(X)}(y) = \min_{x \in X} \ \mu_{R^{-1}(y)}(x)$.

5 Incomplete and uncertain information

Until now, it has been assumed that we have *complete* information about the existing links between properties in $Prop$ and objects in Obj. Namely, $(x, y) \in R$ means that object x satisfies property y and $(x, y) \notin R$ means that object x does not satisfy property y, rather than "we do not know if $(x, y) \in R$ or not". Clearly, this assumption may be relaxed, while Boolean properties are still assumed: One may consider that there are pairs (x, y) for which it is not known at all if x has property y or not. This case has been considered in [16]. Information may be also uncertain, i.e., we are certain at level α that x has property y, or at level β that x has not property y.

In the most general case, properties are non Boolean (i.e. $\mu_R(x, y)$ is supposed to belong to $[0, 1]$), but the extent $\mu_R(x, y)$ to which an object x has a property y may be only fuzzily known under the form of a possibility distribution $\pi_{\mu_R}^{(x,y)}$ on $[0, 1]$ that restricts its possible values. Then one may not be even sure in general that some property y is possessed by an object x at least at some degree α). Since the information about $\mu_R(x, y)$ is now represented by a fuzzy set (on $[0, 1]$), and the four measures introduced in Section 3

ISBN: 978-989-95079-6-8

$\mu_{R^{\Pi}(X)}(y) = \Pi_y(X)$, $\mu_{R^{N}(X)}(y) = N_y(X)$, $\mu_{R^{\Delta}(X)}(y) = \Delta_y(X)$, $\mu_{R^{\nabla}(X)}(y) = \nabla_y(X)$ can themselves only be known under the form of induced possibility distributions (using the fuzzy set extension principle [2]). Let us take the example of $\mu_{R^{\Pi}(X)}(y) = \Pi_y(X) = \max_{x \in X} \mu_R(x, y)$. The induced possibility distribution is given by

$\pi_{\Pi_y(X)}(t) = \max_{i:\max_i t_i = t} \min_{x_i \in X} \pi_{\mu_R}^{(x_i,y)}(t_i)$ i.e.
$\pi_{\Pi_y(X)}(t) =$
$\max_i \min(\pi_{\mu_R}^{(x_i,y)}(t), \min_{j \neq i}(\max_{t_j \leq t} \pi_{\mu_R}^{(x_j,y)}(t_j))$.
Such a computation may be heavy in practice, but one may at least compute an upper bound of the possibility that a property y is associated to an object x with a degree equal to α, as $\pi^*_{\Pi_y(X)}(\alpha) = \max_{x \in X} \pi_{\mu_R}^{(x,y)}(\alpha)$. One may also compute the degree of membership of property y to the fuzzy set of properties that are possibly associated with at least one object in X at least to a degree ρ as $\Pi_{y,\rho}(X) = \max_{x \in X} \max_{\{t | t \geq \rho\}} \pi_{\mu_R}^{(x,y)}(t)$.

A maybe more promising approach for dealing with incomplete information in formal concept analysis is to first slightly modify the setting we start with by accommodating directly many-valued attributes instead of binary ones. We now outline this idea. Indeed when attribute domains are two-valued, they only give birth to a binary property (and its negation), while any non empty subset of a many-valued attribute domain (different from the domain itself) defines a non-trivial property. Take the example of the *color* attribute with domain $\{black, red, yellow, blue, green, ...\}$, $red\ or\ green$, or $red\ or\ yellow\ or\ blue$ are (imprecise) properties, beside the basic colors $black$, red, etc. Let Y now denote a set of attributes y, $dom(y)$ be the domain of y, P_y denote a non-empty subset of $dom(y)$. Let $\Gamma_y(x)$ represent the available information about the value of attribute y for object x. It is assumed that $\Gamma_y(x) \subseteq dom(y)$. Information is imprecise if $\Gamma_y(x)$ is not a singleton. For the moment, we suppose that information may be incomplete but not uncertain. $\Gamma_y(x) = \varnothing$ means that y does not apply to x, and $\Gamma_y(x) = dom(y)$ means that the value of y is unknown for x. $\Gamma_y(x) \neq \varnothing$ is now assumed.

Then $R^{-1N}(P_y) = \{x | \Gamma_y(x) \subseteq P_y\}$ is the set of objects that (certainly) have property P_y w. r. t. attribute y. Three other similar sets can be defined by reversing $\subseteq$, or replacing it by non-empty intersection, or non-covering union conditions, in the spirit of the basic definitions of Section 2. Let $R^{-1N\bigstar}$ be the relation that expresses that *certainly* objects have some (maybe imprecise) properties; it is defined on $X \times \cup_{y \in Y} \mathcal{P}(y)$, where $\mathcal{P}(y)$ denote the power set of $dom(y)$. Since $(\mathcal{P}(y), \subseteq)$ is a Boolean lattice, $(x, P_y) \in R^{-1N\bigstar}$ entails $(x, P'_y) \in R^{-1N\bigstar}$ as soon as $P_y \subseteq P'_y$ (if an object is red, it is also $red\ or\ green$). Clearly, $\{x | (x, red\ or\ green) \in R^{-1N\bigstar}\} = \{x | \Gamma_{color}(x) = red\} \cup \{x | \Gamma_{color}(x) = green\} \cup \{x | \Gamma_{color}(x) = red\ or\ green\}$. Moreover, we can also find out if there are only *possibly* $red\ or\ green$ objects, e.g. those that are known to be $red\ or\ blue$. If not, it means that there is no completion of the knowledge that can alter the extension of the set of $red\ or\ green$ objects in our example. More generally, we can look for concepts associated with sufficiently imprecise properties that remain stable under any knowledge completion. This can be extended to gradual uncertain knowledge by working with the α-cuts of the $\Gamma_y(x)$'s, i.e. pieces of information that are $(1-\alpha)$-certain. These are lines for further research.

6 Concluding remarks

Starting with a possibility-theoretic reading of concept analysis, we have reintroduced four operators, that enable us to describe all the different possible relations between a set of objects and a set of properties. Apart from retrieving the Galois connexion defining formal concepts, another Galois connexion based on the "actual necessity" operator is laid bare for decomposing the relation into independent blocks. The proposed setting extends to graded properties, leading to two kinds of Galois connected pair of fuzzy sets, whose meaning must be laid bare. Besides, the formal similarity between the actual possibility operator and relational algebra division operation, suggests a relaxation of the definition of concepts, computing the extent to which a property is *highly* possessed by *most* objects in a set. Lastly, extensions of the formal concept analysis setting to incomplete or uncertain information have been outlined. It is clear that many pending issues remain, such as e.g. the use of rough set reducts in this setting.

***Abstract*—**

In this work we study the behaviour of a Fuzzy Rule Based Classification System, and its relationship to a certain data complexity measures family. As Fuzzy Rule Based Classification System we have selected a recent proposal called Positive Definite Fuzzy Classifier, which is a Fuzzy System that uses Support Vector Machines for its training, obtaining accurate results and a low number of rules.

We have examined several data complexity metrics of separability of classes *over a wide range of data sets built from real data, and try to extract behaviour patterns from the results for this learning method. Using these data complexity measures and the accuracy results of the Positive Definite Fuzzy Classifier, we have built a rule set which describes both good or bad behaviours of this Fuzzy Rule Based Classification System.*

These rules use different values of such data complexity measures as antecedents, so we aim to predict the behaviour of the method from the data set complexity metrics prior to its application. Therefore, the rule set could characterise the domains of competence of this particular Fuzzy Rule Based Classification System.

***Keywords*—** Classification, Data complexity, Fuzzy Rule Based Systems, Support Vector Machines

1 Introduction

Fuzzy Rule Based Classification Systems (FRBCSs) [12, 14] are a very useful tool in the ambit of Data Mining, since they are capable of building a linguistic model clearly interpretable by human beings. There is a vast literature in the field of FRBCSs [14], which is very active at this time [9, 1, 16, 13].

The prediction capabilities of classifiers are strongly dependent on the problem's characteristics. An emergent field, that uses a set of complexity measures applied to the problem to describe its difficulty, has recently arisen. These measures quantify particular aspects of the problem which are considered complicated to the classification task [11]. Studies of data complexity metrics applied to particular classification's algorithms can be found in [11, 4, 3, 19].

In this work we are interested in analysing the relationship between FRBCSs and the complexity measures, considering a case of study using the Positive Definite Fuzzy Classifier (PDFC) proposed by Chen and Wang [5]. In particular we consider one type of data complexity measures based on the separability of classes.

To perform this study, we have created several binary classification data sets from real world problems, 438 ones, and computed the value of 3 metrics proposed by Ho and Basu [10]. We have analysed the intervals of the complexity measures values related to the created data sets, in which PDFC method performs well or badly, and then formulated a rule for such intervals. The rules try to describe the ranges where some information and conclusions about the behaviour of PDFC method can be stated.

This contribution is organised as follows. In Section 2 we describe the FRBCS we have used. In Section 3 the considered complexity measures are described. In Section 4 we include the experimental set-up, the results obtained and the rules extracted, along with their analysis. Finally, in Section 5 some concluding remarks are made.

2 Preliminaries: Fuzzy Rule Based Classification System

Any classification problem consists of l training patterns $x_p = (x_{p1}, \ldots, x_{pn})$, $p = 1, 2, \ldots, l$ from M classes where x_{pi} is the ith attribute value ($i = 1, 2, \ldots, n$) of the p-th training pattern.

Let us consider a two-class classification problem of assigning class label $y \in \{+1, -1\}$ to input feature vector x_p. In this work we consider the additive FRBCSs with constant `THEN`-parts.

As learning method we use the PDFC method [5], which uses a Support Vector Machine (SVM) approach to build up the model. In the following two Subsections, first we include the fuzzy inference model and a complete description of the PDFC algorithm.

2.1 Fuzzy Inference Model: PDFC Method

Consider a fuzzy model with m fuzzy rules of the form:

$$\text{Rule } j: \text{ If } A_j^1 \text{ AND } A_j^2 \text{ AND } \ldots \text{ AND } A_j^n \text{ THEN } b_j \qquad (1)$$

where A_j^k is a fuzzy set with membership function $a_j^k : \mathbb{R} \to [0, 1]$, $j = 1, \ldots, m$, $k = 1, \ldots, n$, $b_j \in \mathbb{R}$. If we choose product as the fuzzy conjunction operator, addition for fuzzy rule aggregation, and center of area defuzzification, then the model becomes a special form of the Takagi-Sugeno fuzzy model, and the input output mapping, $\mathcal{F} : \mathbb{R}^n \to \mathbb{R}$, of the model is defined as

$$\mathcal{F}(x_p) = \frac{\sum_{j=1}^{m} b_j \prod_{k=1}^{n} a_j^k(x_k)}{\sum_{j=1}^{m} \prod_{k=1}^{n} a_j^k(x_k)}. \qquad (2)$$

Equation (2) could not be well-defined on $\mathbb{R}$ if $\sum_{j=1}^{m} \prod_{k=1}^{n} a_j^k(x_k) = 0$ for some $x_p \in \mathbb{R}^n$, which could happen if the input space is not wholly covered by fuzzy rule "patches". To fix this problem, we add a fuzzy rule so that the

ISBN: 978-989-95079-6-8

denominator $\sum_{j=1}^{m}\prod_{k=1}^{n}a_j^k(x_k) > 0$ for all $x_p \in \mathbb{R}$. Thus the following rule is added:

$$\text{Rule } 0: \text{ If } A_j^1 \text{ AND } A_j^2 \text{ AND } \ldots \text{ AND } A_j^n \text{ THEN } b_0 \quad (3)$$

where $b_0 \in \mathbb{R}$, the membership functions $a_0^k(x_k) \equiv 1$ for $k = 1, \ldots, n$ and any $x_p \in \mathbb{R}^n$. Consequently, the input output mapping becomes

$$\mathcal{F}(x_p) = \frac{b_0 + \sum_{j=1}^{m} b_j \prod_{k=1}^{n} a_j^k(x_k)}{1 + \sum_{j=1}^{m}\prod_{k=1}^{n} a_j^k(x_k)}. \quad (4)$$

A classifier associates class labels with input features, i.e., it is essentially a mapping from the input space to the set of class labels. In binary case, thresholding is one of the simplest ways to transform $\mathcal{F}(x_p)$ to class labels $+1$ or -1.

Considering the FRBCS with $m+1$ fuzzy rules where Rule 0 is given by (3), then the system induces a binary fuzzy classifier, f , with decision rule

$$f(x_p) = \text{sign}(\mathcal{F}(x_p) + t) \quad (5)$$

where $t \in \mathbb{R}$ is a threshold. We can assume $t = 0$ without loss of generality.

The membership functions for a binary fuzzy classifier defined above could be any function from $\mathbb{R}$ to $[0, 1]$. We narrow our interests to a class of membership functions, $a_j^k : \mathbb{R} \to [0, 1]$, $j = 1, \ldots, m$, which are generated from a reference function a^k through location transformation [8], and the classifiers defined on them. In [5] well-known types of reference functions can be found, like the symmetric triangle and the gaussian function.

As consequence of the presented formulation, the decision rule of our binary fuzzy classifier can be written as:

$$f(x_p) = \text{sign}\left(\sum_{j=1}^{m} b_j K(x_p, z_j) + b_0\right) \quad (6)$$

where $z_j = [z_j^1, z_j^2, \ldots, z_j^n]^T \in \mathbb{R}$ contains the location parameters of a_j^k. $K : \mathbb{R}^n \times \mathbb{R}^n \to [0, 1]$ is a translation invariant kernel defined as

$$K(x_p, z_j) = \prod_{k=1}^{n} a^k(x_p^k - z_j^k) \quad (7)$$

which is actually a Mercer Kernel [6], if it has nonnegative Fourier transform. Again, from [5] some Mercer kernels can be built using the reference functions mentioned above.

Thus, the decision rule of a binary fuzzy classifier is

$$f(x_p) = \text{sign}\left(b_0 + \sum_{j=1}^{m} b_j \prod_{k=1}^{n} a_j^k(x_p^k)\right) \quad (8)$$

2.2 Learning method: SVM approach to build PDFC

Here, we assume that the reference functions are predetermined. So the remaining question is how to find a set of fuzzy rules ($\{z_1, \ldots, z_m\}$ and $\{b_0, \ldots, b_m\}$) from the given training so that the PDFC method has good generalization.

As given in (7), for a PDFC, a Mercer kernel can be constructed from the positive definite reference functions. The kernel implicitly defines a nonlinear mapping Φ that maps $\mathbb{X}$ into a kernel-induced feature space $\mathbb{F}$. Theorem 3.12 in [5] states that the decision rule of a PDFC can be viewed as a hyperplane in $\mathbb{F}$. It is well-known that the SVM algorithm finds a separating hyperplane with good generalization by reducing the empirical risk and, at the same time, controlling the hyperplane margin [21]. Thus we can use the SVM algorithm to find an optimal hyperplane in $\mathbb{F}$. Once we get such a hyperplane, fuzzy rules can be easily extracted. The whole procedure is described by the following algorithm 1.

Algorithm 1 SVM learning for PDFC

INPUTS: Positive definite reference functions $a^k(x_p)$ associated with n input variables, and a set of training samples
OUTPUTS: A set of fuzzy rules parameterized by z_j, b_j, and m. z_j contains the location parameters of the `IF`-part membership functions of the jth fuzzy rule, b_j is the `THEN`-part constant of the jth fuzzy rule, and $m+1$ is the number of fuzzy rules.
Steps:
1 Construct a Mercer kernel, K, from the given positivedefinite reference functions according to (7).
2 Construct an SVM to get a decision rule of the form

$$f(x) = sign\left(\sum_{i \in S} y_i \alpha_i K(x, x_i) + b\right),$$

being S the index set of the support vectors:
2.1 Assign some positive number to the cost C, and solve the quadratic program defined by the proper SVM to get the Lagrange multipliers α_i.
2.2 Find b (details can be found in, for example, [18]).
2.3 Extracting fuzzy rules from the decision rule of the SVM:
$b0 \leftarrow b$
$j \leftarrow 1$
for $i = 1$ **to** l **do**
  if $\alpha_i > 0$ **then**
    $z_j \leftarrow x_i$
    $b_j \leftarrow y_i \alpha_i$
    $j \leftarrow j + 1$
  end if
end for
$m \leftarrow j - 1$

In our study, we have considered the parameters values recommended by the authors. They are summarized as follows:

- $C = 100$ (weight of the classification error)
- $d = 0.25$ (parameter used by the reference functions)
- Type of reference functions: Gaussian

3 Data Complexity Measures Based on the Separability of Classes

In this section we describe the three metrics we have used in this contribution, with their correspondent acronym.

For our study, we will examine three measures of separability of classes from [10] which offer information for the PDFC method. They are described next.

- **N1**: fraction of points on class boundary. This method constructs a class-blind minimum spanning tree over the entire data set, and counts the number of points incident to an edge going across the two classes. The fraction of

ISBN: 978-989-95079-6-8

such points over all points in the data set is used as a measure. For two heavily interleaved classes, a majority of points are located next to the class boundary. However, the same can be true for a sparsely sampled linearly separable problem with margins narrower than the distances between points of the same class.

- **N2**: ratio of average intra/inter class Nearest Neighbour (NN) distance. For each input instance x_p, we calculate the distance to its nearest neighbour within the class (intraDist(x_p)) and the distance to nearest neighbour of any other class (interDist(x_p)). Then, the result is the ratio of the sum of the intra-class distances to the sum of the inter-class distances for each input example, i.e.,

$$N2 = \frac{\sum_{i=0}^{m} intraDist(x_i)}{\sum_{i=0}^{m} interDist(x_i)},$$

where m is the number of examples in the data set. This metric compares the within-class spread with the distances to the nearest neighbours of other classes. Low values of this metric suggest that the examples of the same class lay closely in the feature space. Large values indicate that the examples of the same class are disperse. It is sensitive to the classes of the closest neighbours to a point, and also to the difference in magnitude of the between-class distances and that of the within-class distances.

- **N3**: error rate of 1-NN classifier. This is simply the error rate of a nearest-neighbour classifier measured with the training set. The error rate is estimated by the leave-one-out method. The measure denotes how close the examples of different classes are. Low values of this metric indicate that there is a large gap in the class boundary.

4 Experimental Study: Analysis of the PDFC with Data Complexity Measures

In this Section we analyse the obtained results for the PDFC method. First, in Subsection 4.1 we present the experimental framework, with the data sets generation method, accuracy validation scheme, and the global average results of the PDFC method. Next we determine several rules based on PDFC's behaviour in Subsection 4.2. Finally we analyse the collective evaluation of the set of rules in Subsection 4.3.

4.1 Experimental Framework: Data Sets Generation

We evaluate the PDFC method on a set of 438 binary classification problems. These problems are generated from pairwise combinations of the classes of 20 problems from the University of California, Irvine (UCI) repository [2]. These are *iris, wine, new-thyroid, solar-flare, led7digit, zoo, yeast, tae, balanced, car, contraceptive, ecoli, hayes-roth, shuttle, australian, pima, monks, bupa, glass, haberman* and *vehicle*.

In order to do that, first we take each data set and extract the examples belonging to each class. Then we construct a new data set with the combination of the examples from two different classes. This will result in a new data set with only 2 classes and the examples which have two such classes as output. We perform this process for every possible pairwise combination of classes. However, if an obtained data set with this procedure proves to be linearly-separable, we discard it (since we could classify it with a linear classifier with no error). The complexity measure L1 from [10] indicates if a problem is linearly-separable if its value is zero, so every data set with a L1 value of zero will be discarded.

This method for generating binary data sets is limited by the proper combinatorics, and we can only obtain over 200 new data sets with the original 20 data sets with this first approach. In order to obtain more data sets, we group the classes two by two, that is, we create a new binary data set, and each of its two classes are the combination of two original classes each. For this second approach we have used *ecoli*, *glass* and *flare* data sets, since they have a high number of class labels. Again, those data sets with a L1 value of zero are discarded.

In order to measure the PDFC performance, we have applied a 10-fcv validation scheme. In Table 1 we show the global Training and Test accuracy obtained by the PDFC method.

Table 1: Global Average PDFC Training and Test Accuracy

PDFC Global % Accuracy Training	94.06%
PDFC Global % Accuracy Test	91.22%

4.2 Determination of Rules Based on the PDFC Behaviour

In the following we present the results of the execution over the 438 data sets summarized in Figures 1 to 3.

Table 3: Rules with one metric obtained from the intervals

Id.	Rule	Support	%Training	Training Diff.	% Test	Test Diff.
R1+	If N1[X] $<$ 0.089 then *good behaviour*	33.11%	99.09%	4.91%	98.15%	6.55%
R2+	If 0 $<$ N3[X] $<$ 0.047 then *good behaviour*	28.31%	98.92%	4.86%	97.70%	6.48%
R1-	If N1[X] $\geq$ 0.25 then *bad behaviour*	25.57%	84.64%	-9.42%	79.01%	-12.21%
R2-	If N2[X] $>$ 0.5196 then *bad behaviour*	24.89%	86.14%	-7.92%	80.88%	-10.34%
R3-	If N3[X] $>$ 0.175 then *bad behaviour*	19.41%	82.64%	-11.42%	76.77%	-14.45%

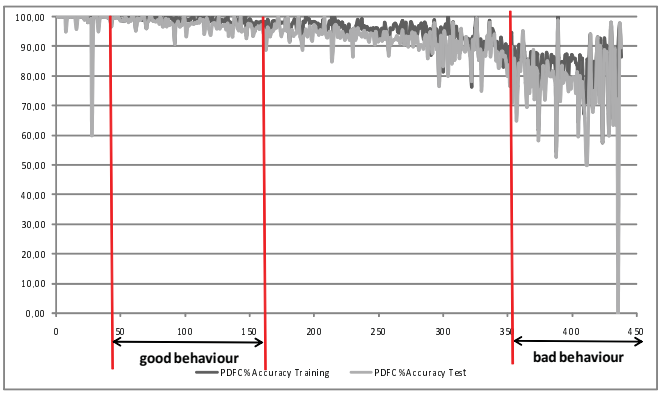

Figure 3: PDFC accuracy in Training/Test sorted by N3

axis we represent the data sets, not the complexity measure value, and the Y axis depicts the accuracy obtained both in training and test. The reason to do so is to give each data set the same space in the graphic representation. For those measures where we can find different *ad-hoc* intervals which present *good* or *bad behaviour* of the PDFC, we use a vertical line to delimit the interval of the region of interest.

- We understand for *good behaviour* an average high test accuracy in the interval, as well as the absence of over-fitting.
- By *bad behaviour* we refer to the presence of over-fitting and/or average low test accuracy in the interval.

In Table 2 we have summarized the intervals found ad-hoc from Figures 1 to 3.

Table 2: Significant intervals

Interval	PDFC Behaviour
$N1 < 0.089$	*good behaviour*
$0 < N3 < 0.047$	*good behaviour*
$N1 \geq 0.25$	*bad behaviour*
$N2 > 0.5196$	*bad behaviour*
$N3 > 0.175$	*bad behaviour*

From these ad-hoc intervals we construct several rules that model the performance of the FRBCS we have used. In Table 3 we have summarized the rules derived from Table 2. Given a particular data set X, we get the complexity measure of X with the notation $CM[X]$. Table 3 is organised with the following columns.

- The first column corresponds to the identifier of the rule for further references.
- The "Rule'" column presents the rule itself.
- The third column "Support" presents the percentage of data sets which verifies the antecedent of the rule.
- The column "% Training" shows the average accuracy in training of all the examples which are covered by the rule.
- The column "Training Diff." contains the difference between the training accuracy of the rule and the training accuracy across all 438 data sets.
- The column "% Test" shows the average accuracy in test of all the examples which are covered by the rule.
- The column "Test Diff." contains the difference between the test accuracy of the rule and the test accuracy across all 438 data sets.

As we can see in Table 3, the positive rules (denoted with a "+" symbol in their identifier) always show a positive difference with the global average, both in training and test accuracy. The negative ones (with a "-" symbol in their identifier) verify the opposite case. The support of the rules shows us that we can characterize a wide range of data sets and obtain significant differences in accuracy.

From this set of rules we can state that a low N1 value results in a good behaviour of the PDFC method. A low N3 value obtains the same results. In the other hand, a high value in the N1 metric produces a bad behaviour of the PDFC considered in our analysis. A high N3 value will also produce a bad behaviour of the PDFC method. With similar outcome, if N2 presents a high value, the PDFC method will obtain bad behaviour.

Although we have obtained some interesting rules, we can extend our study by considering the combination of these complexity metrics in order to obtain more precise and descriptive rules.

4.3 Collective Evaluation of the Set of Rules

The objective of this section is to analyse the good rules jointly, and the bad rules together as well. Thus we can arrive at a more general description, with wider support, of the behaviour of the PDFC with these joint rules. We perform the disjunctive combination of all the positive rules to obtain a single rule, and all the negative ones, so we obtain another rule.

ISBN: 978-989-95079-6-8

Table 4: Disjunction Rules from all simple rules

Id.	Rule	Support	%Training	Training Diff.	% Test	Test Diff.
PRD	If R1+ or R2+ then *good behaviour*	37.44%	98.99%	4.93%	97.90%	6.68%
NRD	If R1- or R2- or R3- then *bad behaviour*	31.51%	86.23%	-7.83%	81.24%	-9.98%
not characterised	If not PRD and not NRD then *good behaviour*	31.05%	96.06%	2.00%	93.27%	2.05%

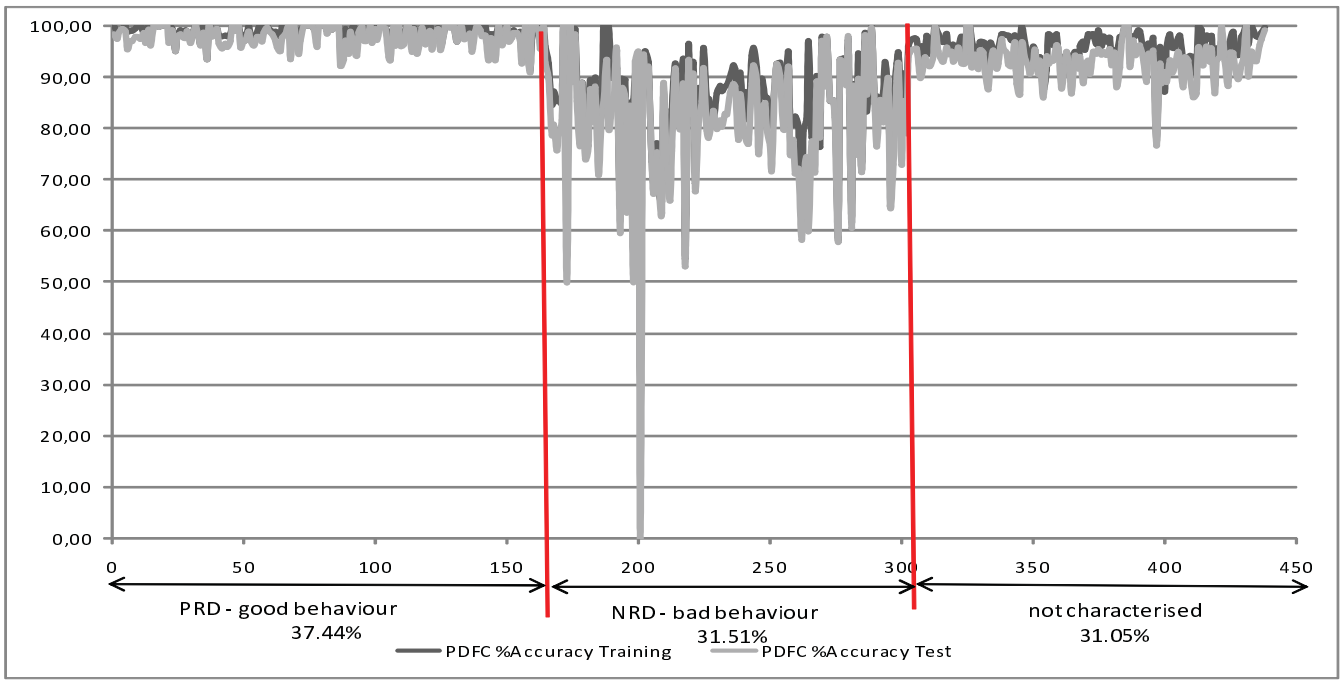

Figure 4: Three blocks representation for PRD, NRD and not covered data sets for PDFC

The new disjunctive rule will be activated if any of the component rules' antecedents are verified. In Table 4 we summarize both disjunctions, and a third rule representing those data sets which are not charaterised by either disjunction rules.

From the collective rules we can observe that the support has been increased from the single rules both for the Positive Rule Disjunction (PRD) and Negative Rule Disjunction (NRD). In the other hand, the Test and Training Accuracy Differences are similar to the single rules from Table 3. Since there are no data sets in PRD and NRD simultaneously, we can consider three blocks of data sets with their respective support, as depicted in Figure 4 (with no particular data set order within each block):

- The first block (the left-side one) represents the data sets covered by the PRD rule. They are the data sets recognized as being those in which the PDFC has good accuracy.
- The second block (the middle one) plots the data sets for the rule NRD, which are bad data sets for the PDFC method considered.
- The third and last block (the right-side one) contains the unclassified data sets by the previous two rules.

We can see that almost the 70% of the analysed data sets are covered by these two rules, and hence the *good behaviour* and *bad behaviour* consequents represent well the accuracy of PDFC methods.

5 Concluding Remarks

We have performed a study over a set of binary data sets with the PDFC method. We have computed some data complexity measures for the data sets in order to obtain intervals of such metrics in which the method's performance is significantly good or bad. We have constructed descriptive rules, and studied the interaction between the intervals and the proper rules.

We have obtained two rules which are simple and precise to describe both good and bad performance of the PDFC. Furthermore, we present the possibility of determining which data sets PDFC would performs well or badly prior to their execution, using the Data Complexity measures.

We must point out that this is a particular study for one specific method, the PDFC. On the other hand, this work presents a new challenge that could be extended to other FRBCSs, to analyse their domains of competence, and to develop new measures which could give more information on the behaviours of FRBCSs for pattern recognition.

Abstract—*In this paper we tackle the issue of generating Mamdani fuzzy rule-based systems with optimal trade-offs between complexity and accuracy by using a multi-objective genetic algorithm, which concurrently learns rule base, granularity of the input and output partitions and membership function parameters. To this aim, we exploit a chromosome composed of three parts, which codify, respectively, the rule base, and, for each variable, the number of fuzzy sets and the parameters of a piecewise linear transformation of the membership functions. We show the encouraging results obtained on a real world regression problem.*

Keywords— Accuracy-Interpretability Trade-off, Granularity Learning, Mamdani Fuzzy-Rule-Based Systems, Multi-objective Evolutionary Algorithms, Piecewise Linear Transformation.

1 Introduction

In the last years, the problem of finding the right trade-off between interpretability and accuracy of Mamdani fuzzy rule-based systems (MFRBSs) [1] has arisen a growing interest in the fuzzy community [2]. To this aim, Multi-Objective Evolutionary Algorithms (MOEAs) have been extensively used for tuning or learning the data base (DB) and the rule base (RB) of the MFRBSs [3][4]. All these approaches generate approximated Pareto fronts with non-dominated solutions in the interpretability-accuracy space. For example, in [5], authors use a predefined DB and evolve only the RB, while in [6] the membership function (MF) parameters are adapted to a specific context exploiting a predefined RB. Furthermore, in [7] and [8] the tuning of the DB is performed together with a rule selection.

The ideal approach would be to learn concurrently DB and RB. So far, only approximations of this ideal approach have been proposed such as to learn simultaneously the overall RB and, for the DB, only the MF parameters [9][10] or the granularities of the uniform partitions defined on the input and output variables [11][12].

On the other hand, both granularity and MF parameters are a critical factor in MFRBS generation [6][13], since both affect accuracy and interpretability. Indeed, the former fixes an upper bound to the number of rules in the MFRBS and the latter adapts the meaning of the linguistic values to the specific application context.

In this paper, we propose a multi-objective evolutionary approach to generate MFRBSs with different trade-offs between complexity and accuracy. The main novelty of our approach is that the RB, the granularity of the input and output partitions and the MF parameters of each fuzzy set are learnt concurrently during the evolutionary process. To deal with RBs defined on different granularities, we exploit the concept of virtual RBs introduced in [12]. Further, the learning of the MF parameters is performed by using a piecewise linear transformation [14][15], which allows us to obtain a high modelling capability with a limited number of parameters.

Chromosomes are composed of three parts, which codify the RB, and, for each linguistic variable, the number of fuzzy sets and the parameters of the piecewise linear transformation, respectively. In the evolutionary process, we adopt the mating operators proposed in [5] for the fist part of the chromosome, and standard crossover and mutation operators for the second and third parts, respectively.

Our approach has been tested on a real world regression problem, with nine input variables, and has provided Pareto fronts with solutions characterized by better trade-offs between accuracy and complexity than solutions belonging to Pareto fronts generated by learning only the rule base with a fixed DB, and concurrently the rule base and the MF parameters with fixed granularities, respectively.

2 Mamdani Fuzzy Systems

Let $\mathbf{X} = \{X_1, ..., X_f, ..., X_F\}$ be the set of input variables and X_{F+1} be the output variable. Let $U_f (f = 1, ..., F+1)$ be the universe of the f^{th} variable. Let $P_f = \{A_{f,1}, ..., A_{f,T_f}\}$ be a fuzzy partition of T_f fuzzy sets on variable X_f. An MFRBS is composed of *M* rules expressed as:

$$R_m: \text{IF } X_1 \textbf{ is } A_{1,j_{m,1}} \text{ AND } \ldots \text{ AND } X_F \textbf{ is } A_{F,j_{m,F}} \text{ THEN } X_{F+1} \textbf{ is } A_{F+1,j_{m,F+1}} \quad (m = 1, ..., M) \qquad (1)$$

where $j_{m,f} \in [1, T_f]$ identifies the index of the fuzzy set (among the T_f fuzzy sets of partition P_f), which has been selected for X_f in rule R_m.

To take the "don't care" condition into account [16] a new fuzzy set $A_{f,0}$ $(f = 1, ..., F)$ is added to all the F input partitions P_f. This fuzzy set is characterized by a membership function equal to 1 on the overall universe.

The terms $A_{f,0}$ allow generating rules which contain only a

ISBN: 978-989-95079-6-8

subset of the input variables. It follows that $j_{m,f} \in [0, T_f]$, $f = 1,..., F$, and $j_{m,F+1} \in [1, T_{F+1}]$.

An MFRBS can be completely described by the following matrix $J \in \mathbb{N}^{M \times (F+1)}$

$$J = \begin{bmatrix} j_{1,1} & \cdots & j_{1,F} & j_{1,F+1} \\ \cdots & \cdots & \cdots & \cdots \\ j_{m,1} & \cdots & j_{m,F} & j_{m,F+1} \\ \cdots & \cdots & \cdots & \cdots \\ j_{M,1} & \cdots & j_{M,F} & j_{M,F+1} \end{bmatrix}$$

where the generic element (m, f) indicates that fuzzy set $A_{f,j_{m,f}}$ has been selected for variable X_f in rule R_m.

We adopt the product and the weighted average method as AND logical operator and defuzzification method, respectively.

Given a set of *N* input observations $\mathbf{x}_n = [x_{n,1},..., x_{n,F}]$, with $x_{n,f} \in \Re$, and the set of the corresponding outputs $x_{n,F+1} \in \Re$, $n = 1,..., N$, we apply a multi-objective evolutionary algorithm which produces a set of MFRBSs with different trade-offs between accuracy and complexity by learning simultaneously the RB, the granularity of the partitions of each variable and the MF parameters. The choice of the appropriate trade-off between accuracy and complexity depends on the particular application.

3 Granularity and MF Parameter Learning

3.1 Granularity Learning

To determine simultaneously the granularity of partitions and the RB in the evolutionary process is not an easy task since the RB depends on the number of fuzzy sets used to partition the variables. In [12] we have introduced the concept of *virtual RB*. A virtual RB is composed of rules defined by considering the variables partitioned with a user-defined maximum number $T_{\max}$ of fuzzy sets (*virtual partition*). All the mating operators are applied to virtual RBs: the actual granularity is used only in the computation of the fitness. In practice, we generate virtual RBs and assess their quality using each time different "lens" depending on the actual number of fuzzy sets used to partition the single variables. Thus, we do not worry about the actual granularity in applying crossover and mutation operators.

To map the virtual RB defined on variables uniformly partitioned with $T_{\max}$ fuzzy sets into a concrete RB defined on variables uniformly partitioned with T_f fuzzy sets, we adopt a mapping strategy. Let X_f **is** $\hat{A}_{f,h}$, $h \in [0, T_{\max}]$, be a generic fuzzy proposition defined in a rule of the virtual RB. Then, the proposition will be mapped to X_f **is** $\tilde{A}_{f,s}$, with $s \in [0, T_f]$, where $\tilde{A}_{f,s}$ is the fuzzy set more similar to $\hat{A}_{f,h}$ among the T_f fuzzy sets $\hat{A}_{f,j}$ defined on X_f. For the sake of simplicity, we have trivially considered as similarity measure the distance between the centroids of the two fuzzy sets. If there are two fuzzy sets in $\tilde{P}_f = \{\tilde{A}_{f,1},..., \tilde{A}_{f,T_f}\}$ with centroids at the same distance from the centroid of $\hat{A}_{f,h}$, we choose randomly one of the two fuzzy sets.

Note that different rules of the virtual RB can be mapped to equal rules in the concrete RB. This occurs because distinct fuzzy sets defined on the partitions used in the virtual RB can be mapped to the same fuzzy set defined on the partitions used in the concrete RB. In the case of equal rules, only one of these rules is considered in the concrete RB. The original different rules are, however, maintained in the virtual RB. Indeed, when the virtual RB will be interpreted by using different "lens", all these rules can again be meaningful and contribute to increase the accuracy of the MFRBS. Thus, the concept of virtual RB allows us to explore the search space and concurrently exploiting the optimal solutions achieved during the evolutionary process.

3.2 MF Parameter Learning

We approach the problem of learning the MF parameters by using a piecewise linear transformation [14][15]. The transformation is described in Fig. 1 for a generic variable X_f. In the following, we assume that the interval ranges of the original and transformed variables are identical. Further, we consider triangular fuzzy sets $A_{f,j}$ defined by the tuple $(a_{f,j}, b_{f,j}, c_{f,j})$, where $a_{f,j}$ and $c_{f,j}$ correspond to the left and right extremes of the support of $A_{f,j}$, and $b_{f,j}$ to the core. Finally, given a generic partition $P_f = \{A_{f,1},..., A_{f,T_f}\}$, we assume that, for $j = 2 \ldots T_f - 1$, $b_{f,j} = c_{f,j-1}$ and $b_{f,j} = a_{f,j+1}$, and $a_{f,1} = b_{f,1}$ and $b_{f,T_f} = c_{f,T_f}$.

Before passing the input value x_f to the MFRBS, we apply the transformation $t(x_f)$. Thus, we have that:

$$A_{f,j}(x_f) = \tilde{A}_{f,j}(t(x_f)) = \tilde{A}_{f,j}(\tilde{x}_f)$$

where $\tilde{A}_{f,j}$ and $A_{f,j}$ are two generic fuzzy sets from the uniform and non-uniform fuzzy partitions, respectively. In those regions where *t* has a high value of the derivative (high slope of the lines), the fuzzy sets $A_{f,j}$ are narrower; otherwise, the fuzzy sets $A_{f,j}$ are wider.

As observed in [14], the transformation *t* must be non-decreasing. Further, the fuzzy sets $A_{f,j}$ of the non-uniform fuzzy partition induced by the transformation *t* are not necessarily of triangular shape. This could bring to fuzzy partitions difficultly interpretable. To preserve the shape of the MFs, we force the change of slopes in *t* to coincide with the cores of the fuzzy sets in the partitions.

Let $b_{f,1},..., b_{f,T_f}$ and $\tilde{b}_{f,1},..., \tilde{b}_{f,T_f}$ be the cores of $A_{f,1},..., A_{f,T_f}$ and $\tilde{A}_{f,1},..., \tilde{A}_{f,T_f}$, respectively. Transformation *t* can be defined as:

$$t(x_f) = \frac{\tilde{b}_{f,j} - \tilde{b}_{f,j-1}}{b_{f,j} - b_{f,j-1}}(x_f - b_{f,j-1}) + \tilde{b}_{f,j-1}, \quad b_{f,j-1} \le x_f < b_{f,j},$$

with *j*=2…T_f.

Once fixed the granularity of the partitions, $\tilde{b}_{f,1},..., \tilde{b}_{f,T_f}$ are fixed and therefore known. Further, $b_{f,1}$ and b_{f,T_f} coincide

ISBN: 978-989-95079-6-8

with the extremes of the universe U_f of X_f. Thus, $t(x_f)$ depends on T_f –2 parameters, that is, $t(x_f; b_{f,2},...,b_{f,T_f-1})$. Once fixed $b_{f,2},...,b_{f,T_f-1}$, the partition $P_f = \{A_{f,1},...,A_{f,T_f}\}$ can be obtained simply by transforming the three points $(\tilde{a}_{f,j}, \tilde{b}_{f,j}, \tilde{c}_{f,j})$, which describe the generic fuzzy set $\tilde{A}_{f,j}$, into $(a_{f,j}, b_{f,j}, c_{f,j})$ applying $t^{-1}(\tilde{x}_f)$.

We define the piecewise linear transformation on the maximum granularity. When we reduce the granularity, to maintain the original shape of the MFs, we do not apply the piecewise linear transformation to all the points of the universe, but only to the three points, which define the generic triangular MF. In practice, we transform $(\tilde{a}_{f,j}, \tilde{b}_{f,j}, \tilde{c}_{f,j})$ into $(a_{f,j}, b_{f,j}, c_{f,j})$ by applying $t^{-1}(\tilde{x}_f)$. Fig. 2 shows an example of this transformation for granularity 5 by using the piecewise linear transformation in Fig. 1, defined with granularity 7.

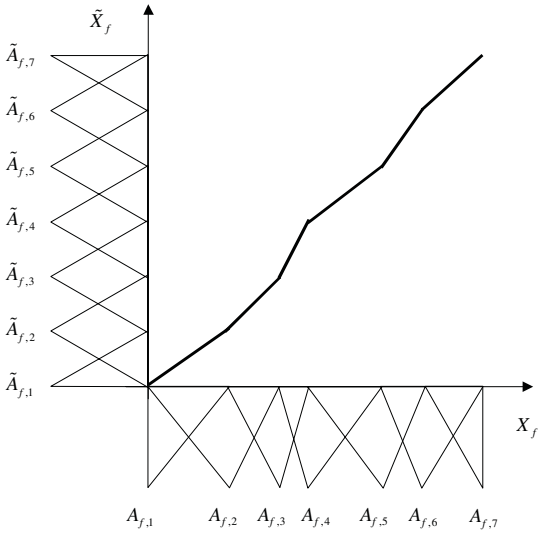

Figure 1: An example of piecewise linear transformation.

4 The Multi-Objective Evolutionary Approach

4.1 Chromosome coding

Each solution is codified by a chromosome C composed of three parts (C_1, C_2, C_3), which define the virtual RB, and the granularities and the piecewise linear transformations of all the variables, respectively. In particular, C_1 encodes the virtual RB by considering that each variable X_f is uniformly partitioned by using $T_{\max}$ fuzzy sets, that is, $P_f = \{A_{f,1},...,A_{f,T_{\max}}\}$. As described in [5], C_1 is composed of $M \cdot (F+1)$ natural numbers where M is the number of rules currently present in the virtual RB. The RB (defined as *concrete RB*) used to compute the fitness is obtained by means of the mapping strategy using the actual granularities fixed by C_2.

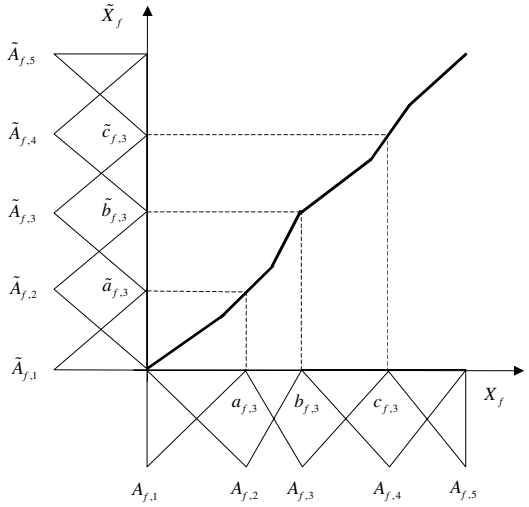

Figure 2: An example of piecewise linear transformation with granularity different from $T_{\max}$.

C_2 is a vector containing $F+1$ natural numbers: the f^{th} element of the vector contains the number $T_f \in [2, T_{\max}]$ of fuzzy sets which partition the linguistic variable X_f. $T_{\max}$ is fixed by the user and is the same for all the linguistic variables.

C_3 is a vector containing $F+1$ vectors of $T_{\max}-2$ real numbers: the f^{th} vector contains the $[b_{f,2},...,b_{f,T_{\max}-1}]$ points which define the piecewise linear transformation for the linguistic variable X_f. To preclude that the piecewise linear transformation can become decreasing, we force $b_{f,j}$ to vary in $\left[\tilde{b}_{f,j} - \frac{\tilde{b}_{f,j} - \tilde{b}_{f,j-1}}{2}, \tilde{b}_{f,j} + \frac{\tilde{b}_{f,j+1} - \tilde{b}_{f,j}}{2}\right]$, $\forall j \in [2, T_{\max}-1]$.

Each chromosome is associated with a bi-dimensional objective vector. The first element of the vector measures the complexity of the MFRBS as the number of propositions used in the antecedents of the rules contained in the concrete RB (the number of antecedents may be different, as explained in the next subsection, between the virtual and concrete RBs). The second element assesses the accuracy as the half of the mean square error (MSE) between the output of the MFRBS and the expected output.

4.2 Genetic operators

In order to generate the offspring populations, we exploit both crossover and mutation. We apply separately the one-point crossover to C_1 and C_2 and the BLX-α crossover, with α = 0.5, to C_3. Let s_1 and s_2 be two selected parent chromosomes. The common gene for C_1 is chosen by extracting randomly a number in $[M_{\min}, \rho_{\min}]$, where $M_{\min}$ is the minimum number of rules, which must be present in a rule base, and $\rho_{\min}$ is the minimum number of rules in s_1 and s_2. The common gene for C_2 is extracted randomly in $[1, F+1]$.

ISBN: 978-989-95079-6-8

As regards mutation, we apply two mutation operators for C_1. The first operator adds γ rules to the virtual RB, where γ is randomly chosen in $[1, \gamma_{\max}]$. The upper bound $\gamma_{\max}$ is fixed by the user. If $\gamma + M > M_{\max}$, then $\gamma = M_{\max} - M$. For each rule R_m added to the chromosome, we generate a random number $v \in [1, F]$, which indicates the number of input variables used in the antecedent of the rule. Then, we generate v natural random numbers between 1 and F to determine the input variables which compose the antecedent part of the rule. Finally, for each selected input variable f, we generate a random natural number $j_{m,f}$ between 1 and $T_{\max}$, which determines the fuzzy set $A_{f,j_{m,f}}$ to be used in the antecedent of rule R_m in the virtual RB. To select the consequent fuzzy set $A_{F+1,j_{m,F+1}}$, a random number between 1 and $T_{\max}$ is generated.

The second mutation operator randomly changes δ elements of the matrix J associated with the virtual RB. The number δ is randomly generated in $[1, \delta_{\max}]$. The upper bound $\delta_{\max}$ is fixed by the user. For each element to be modified, a number is randomly generated in [0, $T_{\max}$].

The mutation applied to C_2 randomly chooses a gene $f \in [1, F+1]$ and changes the value of this gene by randomly adding or subtracting 1. If the new value is lower than 2 and larger than $T_{\max}$, then mutation is not applied.

The mutation applied to C_3 first chooses randomly a variable $f \in [1, F+1]$, then extracts a random value $j \in [2, T_{\max} - 1]$ and changes the value of $b_{f,j}$ to a random value in the allowed interval $\left[\tilde{b}_{f,j} - \frac{\tilde{b}_{f,j} - \tilde{b}_{f,j-1}}{2}, \tilde{b}_{f,j} + \frac{\tilde{b}_{f,j+1} - \tilde{b}_{f,j}}{2}\right]$.

We experimentally verified that these mating operators ensure a good balancing between exploration and exploitation, thus allowing the multi-objective evolutionary algorithm described in the next subsection to create good approximations of the Pareto fronts.

4.3 Multi-objective evolutionary algorithm

We adopted the (2+2)M-PAES proposed in [5]. Unlike classical (2+2)PAES, which uses only mutation to generate new candidate solutions, (2+2)M-PAES exploits both crossover and mutation. Further, in (2+2)M-PAES, current solutions are randomly extracted at each iteration rather than maintained until they are not replaced by solutions with particular characteristics.

Fig. 3 shows a pseudo-code which describes the application scheme of the different operators to generate the offspring solutions o_1 and o_2 from the selected parents s_1 and s_2. Note that P_{c1}, P_{c2} and P_{c3} represent the probabilities of applying the crossover operator on C_1, C_2 and C_3, respectively. Similarly, P_{m1}, P_{m2} and P_{m3} represent the probabilities of applying the mutation operator on C_1, C_2 and C_3, respectively, and P_{add} and P_{inc} represent the probabilities of adding rules and of increasing the granularity of the selected variable, respectively. In Fig. 3 we also report the values of the probabilities we used in our experimentations.

At the beginning, we generate two solutions s_1 and s_2. The genes of C_2 in both the solutions are set to the maximum value $T_{\max}$, while the genes of C_1 and C_3 are randomly generated. At each iteration, the application of crossover and mutation operators produces two new candidate solutions from the current solutions s_1 and s_2. These candidate solutions are added to the archive only if they are dominated by no solution contained in the archive; possible solutions in the archive dominated by the candidate solutions are removed. Typically, the size of the archive is fixed at the beginning of the execution of the (2+2)M-PAES. In this case, when the archive is full and a new solution z has to be added to the archive, if z dominates no solution in the archive, then we insert z into the archive and remove the solution (possibly z itself) that belongs to the region with the highest crowding degree [5]. If the region contains more than one solution, then, the solution to be removed is randomly chosen.

5 Experimental results

We tested our approach on a real world regression problem provided by the Bilkent University Function Approximation Repository [17]. The dataset contains the weather data of Ankara, a Turkish town, collected from 01/01/1994 to 28/05/1998. Here, the goal is to predict the mean temperature from the values of nine weather features, namely *max temperature*, *min temperature*, *dewpoint*, *precipitation*, *sea level pressure*, *standard pressure visibility*, *wind speed*, and *max wind speed*. The dataset contains 1609 instances of these features and corresponding mean temperatures. In order to asses the reliability of our approach, we performed a five-fold cross-validation and executed six trials, with different seeds, for each fold. We set $T_{\max}=5$, $M_{\min}=5$, $M_{\max}=30$, $\gamma_{\max}=5$, $\delta_{\max}=5$, the maximum number of evaluations to 300000 and the archive size to 64.

To assess the advantages of learning concurrently RB, granularities of partitions and MF parameters, we compared the results achieved by our approach with the ones obtained by applying the (2+2)M-PAES to learn only rules, that is, using only the first part of the chromosome and fixing the number of fuzzy sets in all partitions to $T_{\max}$, and to learn concurrently the RB and the MF parameters, using only the first and third parts of the chromosome with fixed granularities. We denote these two approaches as PAES-RB and PAES-SF, respectively, while the proposed approach is denoted as PAES-SFG.

Figures 4 and 5 show the average Pareto fronts achieved by the three algorithms on the training and test sets, respectively. The average Pareto front consists of the average values of the twenty most accurate solutions of each of the thirty Pareto front approximations (at least twenty solutions were always generated in all the trials for both datasets). In practice, the average Pareto fronts are obtained as follows. First, the solutions in the Pareto front approximations produced in each of the thirty trials are ordered for increasing MSE values. Then, only the twenty solutions with the lowest MSEs are retained for each Pareto front approximation. Finally, the average values, on the thirty Pareto front approximations, of complexity and MSE for these twenty solutions are computed. The choice of considering only the twenty solutions with the lowest MSEs was motivated by the observation that the other solutions are in general characterized by quite high MSEs which make these solutions impractical.

We note that the average Pareto front generated by PAES-SFG outperforms the other two average Pareto fronts both on the training and on the test sets. This proves that learning concurrently the RB, the granularities of the input and output partitions and the membership parameters allows generating FRBSs with better trade-offs between accuracy and complexity than the other two MOEAs used for comparison.

In Table 1 we show the average results corresponding to three representative points of the average Pareto fronts: the first (the most accurate), the median and the last (the least accurate) point. We refer to these average values as First, Median and Last, respectively. It is interesting to observe that the average MSEs of the most accurate solutions generated by PAES-SFG are 47% and 68%, and 33% and 56% lower than the corresponding solutions in the Pareto fronts generated by PAES-SF and PAES-RB with comparable complexity on the training and test sets, respectively.

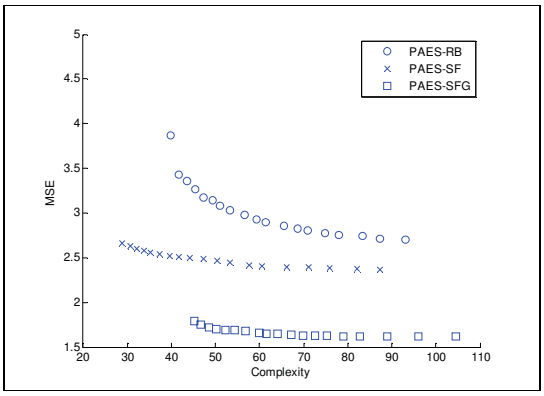

Figure 4. Average Pareto fronts on training set.

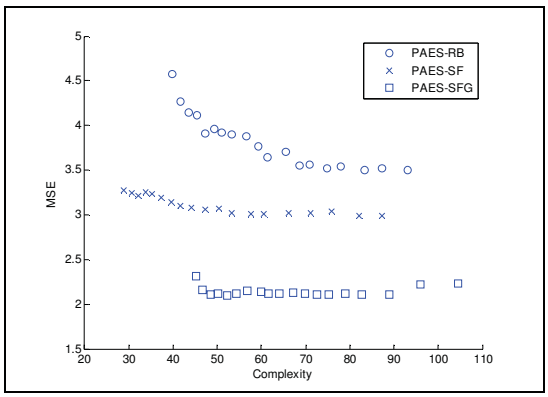

Figure 5. Average Pareto fronts on test set.

Table 1. Results obtained on three representative points of the average Pareto fronts

	MSE_{Tr}	MSE_{Ts}	Complexity	# Rules
	PAES-RB			
First	2.70±1.27	3.50±1.90	93.20±19.99	28.30±2.65
Median	2.93±1.40	3.77±2.17	59.33±17.02	22.80±4.48
Last	3.87±3.08	4.58±3.43	39.80±16.36	17.67±5.00
	PAES-SF			
First	2.36±1.60	2.99±2.18	87.23±17.33	24.20±4.24
Median	2.49±1.71	3.06±2.21	47.30±14.11	17.23±4.08
Last	2.66±1.88	3.28±2.51	28.80±11.10	12.97±3.69
	PAES-SFG			
First	1.61±0.34	2.24±1.11	104.53±27.86	25.77±4.59
Median	1.64±0.35	2.12±0.62	64.13±21.15	20.97±4.81
Last	1.79±0.62	2.31±1.11	45.10±15.76	17.33±4.19

Finally, Figures 6 and 7 show an example of complete Pareto fronts generated by the three algorithms in a single trial on the training and test sets, respectively. We have plotted only the solutions of the final archive with the MSEs lower than 5, since the other solutions in the archive are characterized by quite high MSEs and tend to visually flatten the plot. On the

ISBN: 978-989-95079-6-8

other hand, these solutions, though characterized by very low complexity, are not very interesting due to the high MSEs. We observe that the approximated Pareto fronts obtained by PAES-SFG are wide and quite dense. Further, except for some solutions in the low complexity zone, all the solutions in the Pareto front generated by PAES-SFG dominate the solutions at the same complexity of the other two fronts.

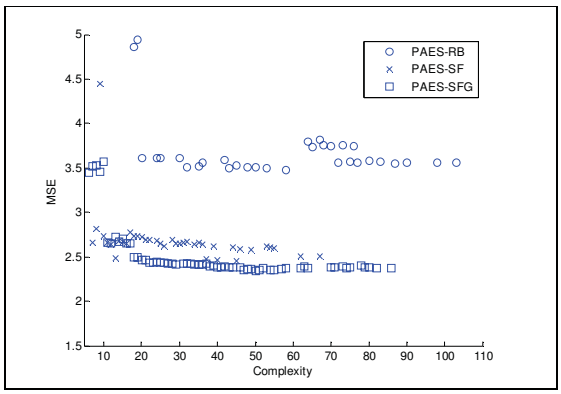

Figure 7. Examples of complete Pareto fronts on test set.

6 Conclusions

In this paper we have proposed a multi-objective evolutionary algorithm to generate a set of Mamdani rule-based fuzzy systems with optimal trade-offs between accuracy and complexity. We have exploited a modified version of the well known (2+2)PAES where the chromosome consists of three parts which codify the RB, and, for each variable, the number of fuzzy sets and the parameters of a piecewise linear transformation of the membership functions, respectively. To manage the dependence between granularity, and rule and membership parameters definition, we have adopted the following solution: the RB coded in the chromosome and the piecewise linear transformation are always defined on linguistic variables partitioned with a fixed maximum number of fuzzy sets. Only when accuracy and complexity have to be evaluated, the RB is actualized by using the real number of fuzzy sets determined by the second part of the chromosome and the DB by computing the corresponding piecewise linear transformation of the fuzzy sets. This approach has proved to be very efficient and effective, allowing both a good exploitation of the solutions and an accurate exploration of the search space.

The algorithm has been tested on a real world regression problem and has provided Pareto fronts with solutions characterized by better trade-offs between accuracy and complexity than solutions belonging to Pareto fronts generated by learning only the RB with a fixed BD, and concurrently the RB and the MF parameters with fixed granularities, respectively.

Abstract— *Fuzzy Databases have been a fertile research area that has produced a wide variety of remarkable solutions for the storage and manipulation of imperfect information. Proposals can be found in the three most relevant data models: relational, object-oriented, and object-relational. Query capabilities have been especially studied in the context of the relational data model, while in object models many problems continue being a matter of research. In this paper, we focus on the resolution of "division queries" (in its relational sense) in an object oriented data model. As we will see, the presence of fuzzily described objects in the database make necessary to use suitable operators that take into account the resemblance that governs the comparison in the underlying reference universe. We also analyze the role of cardinality in this kind of queries.*

Keywords— Division, Quotient, Fuzzy, Object-Oriented, Object-Relational, Database.

1 Introduction

Fuzzy Set Theory[1] has proved to be an adequate tool in handling real world data when they are affected by imperfections of very different kinds. The application of this theory in order to extend conventional databases has led to the development of fuzzy database systems.

Object-oriented and object-relational database management systems allow the representation of schema when complex relationships make the use of Codd's relational model difficult. The object-oriented data model is more powerful from a modeling point of view, because it incorporates important features such as inheritance and encapsulation. As it was the case with the relational data model in the past, many researchers have recently tried to improve object orientation with the help of fuzzy concepts. As a result, fuzzy object-oriented database models (FOODBM) have appeared [2, 3, 4].

In [5, 6] a framework is presented which allows programmers to handle imprecision in the description of objects. An object-relational implementation of this model can be found in [7].

In this paper, we focus on the study of operators that can be used to solve a special kind of queries in fuzzy object-oriented databases: those queries that, in the relational context, are known as fuzzy divisions. Fuzzy division queries in the relational data model has been deeply studied during the last decades: from the initial works of Dubois et al.[8] till the last works of Bosc et al.[9], the interested reader can find a wide survey of remarkable proposals(e.g. [10, 11, 12]).

This work analyzes how to solve this kind of queries over a fuzzy object model, where the equality is substituted by resemblance as the basis of comparisons. Due to this fact, we have to suitably soften the division operator, so that resemblance can be appropriately taken into account.

The paper is organized as follows: section 2 briefly introduces the fuzzy object-oriented data model that is the basis of our proposal; section 3 describes the type of queries we want to solve in an object-oriented context; section 4 analyzes the problem of considering the resemblance when computing the inclusion associated to division queries; section 5 analyzes the role that the cardinality of the involved sets plays in the resolution of the query; finally, some conclusions are outlined in section 6.

2 A fuzzy object-oriented model

As we have previously mentioned in the introduction, this paper is devoted to the problem of how to solve division queries in a fuzzy object model like the one introduced in [13]. We briefly present in this section a summary of its main characteristics.

As in any object model, the state of an object is equated with a set of attribute values according to its class description. The approach described in [13] considers different types of attribute values in order to give support to the representation of fuzzily described objects. Together with the *precise* values, objects, and *crisp* collections of any conventional object-oriented data model, the fuzzy model permits to use more powerful values, as imprecise labels and fuzzy collections, in order to deal with imprecision in the state of the object.

Fig. 1 shows a description of different types of attribute values that we consider in our approach. That is, the object state can be composed by:

- Precise values: This category of values involves all the classical basic classes that usually appear in an object-oriented data model (e.g. numerical classes, string classes, etc.). Values in these domains are easily represented and compared using conventional built-in data types and the classical set of relational operators.
- Imprecise values: The case of imprecise (atomic) values is a bit more complex. In many cases, linguistic labels[14, 15, 16] are associated to this kind of values, but different types of imprecise values must be considered according to their semantics.
- Objects: the attribute value may be a reference to another object (constituting what is called a complex object).
- Collections: the attribute may be conformed by a set of values or, even, by a set of objects. Imprecision in this kind of attributes may appear at two levels:

ISBN: 978-989-95079-6-8

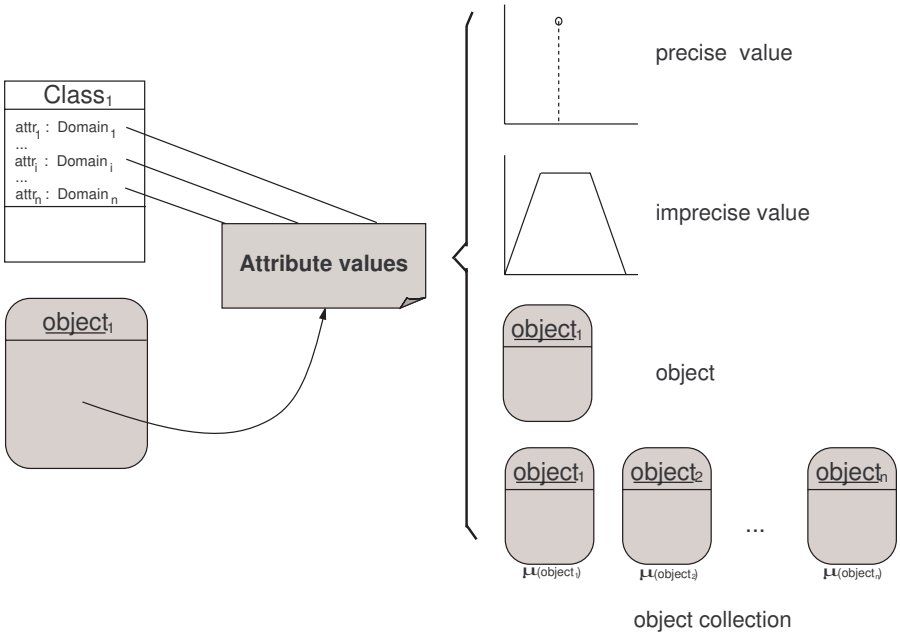

Figure 1: Different kinds of attribute values

– The set may be fuzzy. The semantics of membership degrees depends on the problem, but, in collections, the fuzzy set is considered to be conjunctive. For example, the set of languages a person can speak may be fuzzy if we take into account the degree of command for every language.
– The elements of the set may be fuzzy values or, in general, fuzzily described objects. For example, we can have a set of fuzzily described students.

An example of a fuzzy set of fuzzily described objects may be the collection of friends of a given person, if we use a degree to measure the friendship relation and the friends are described by means of fuzzy attribute values.

2.1 Generalization of equality

We do not only need a representation of fuzzily described objects in our model but also a way to manage this kind of objects. This includes a basic capability to compare the state of two objects belonging to a given class.

With fuzzily described objects like the ones presented in the previous paragraphs, this comparison has to be performed by a process which consists of two steps:

- computing degrees of resemblance for pairs of attribute values, and
- aggregating these resemblance degrees to obtain a general degree of object resemblance.

That is, if o_1 and o_2 are two objects belonging to class C which is characterized by type T_C whose structural component Str_C is an attribute set $\{x_1, x_2, \ldots, x_n\}$, then our goal is to find a resemblance degree between o_1 and o_2 by the aggregation of resemblance degrees of the pairs $(o_1.x_i, o_2.x_i)$.

$S_{x_i}(o_1, o_2)$ will stand for the resemblance degree observed between the x_i attribute values for objects o_1 and o_2, and $S(o_1, o_2)$ is the aggregated resemblance degree we want to calculate.

In this process, not all attributes need to have the same importance: each attribute x_i has an associated weight $p_{x_i} \in [0, 1]$ that represents its relative importance in the final decision.

Figure 2 summarizes the process of calculating resemblance degrees. In order to compare objects o_1 and o_2, we first compare their attribute values and obtain partial compatibility degrees $S_{x_i}(o_1, o_2)$. Then, we aggregate them to obtain a global resemblance opinion $S(o_1, o_2)$ according to the attribute importance established in the class.

As can be observed, the comparison of two objects involves a recursive procedure. For the sake of space, we omit here the operators for base cases and the analysis of the recursive aggregation procedure used in our model. Interested readers can found a detailed description in [17].

3 Division queries in fuzzy object-oriented databases

Codd defined a set of eight basic operators for his relational model. Some of them are implemented directly in SQL, but some other require particular implementation to fit into the SQL language. Relational division is one of the eight basic operations in Codd's relational algebra[18] that has these requirements.

Suppose that we have two relations t_a and t_b whose schema are, respectively, $T_A(X, Y)$ and $T_B(Y')$, where Y and Y' are compatible attributes. The division $t_a \div t_b$ obtains a new relation t_d with schema $T_D(X)$ and with the following set of tuples:

$$\{a | a \in domain(X) \wedge (\forall b, (b \in t_b) \rightarrow (< a, b > \in t_a)\} \quad (1)$$

Assume now that T_A and T_B are fuzzy relations, i.e., that their tuples are weighted by a number between 0 and 1. That

ISBN: 978-989-95079-6-8

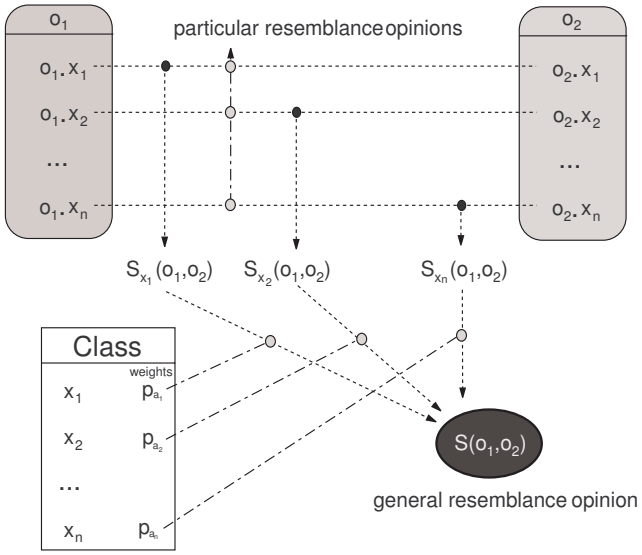

Figure 2: Obtaining the compatibility between two objects.

is, each tuple of t_a is affected by a membership degree, $\mu_{t_a}(< a, b >) \in [0, 1]$ and, similarly, each tuple of t_b has its corresponding $\mu_{t_b}(< b >) \in [0, 1]$.

The membership degree of the tuples of the division result can be obtained as follows [8]:

$$\mu_{t_d}(a) = inf_b\{\mu_{t_b}(b) \rightarrow \mu_{t_a}(a, b)\} \quad (2)$$

In the case of an object-oriented model, we have to consider (in the more general case) that attribute values are objects. Figure 3 depicts the tables with the new situation in an object-oriented context.

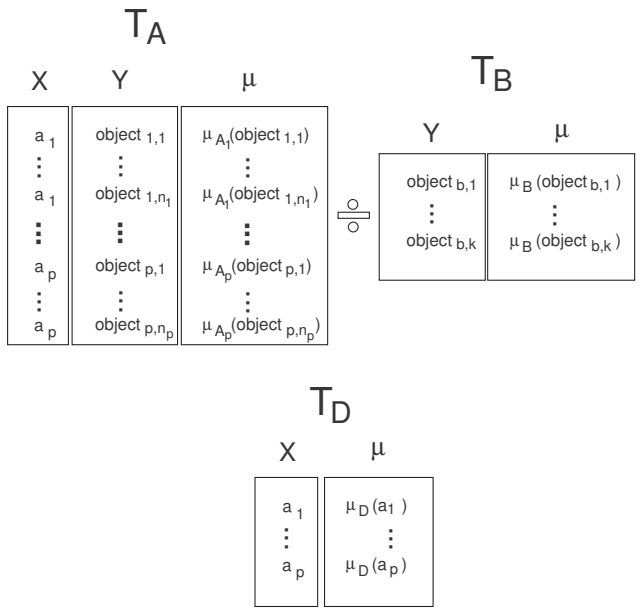

Figure 3: Tables involved in the division

Moreover, as in an object-oriented model attribute values do not necessarily have to be atomic, table T_A (and, similarly T_B) could have the schema showed in Fig. 4.

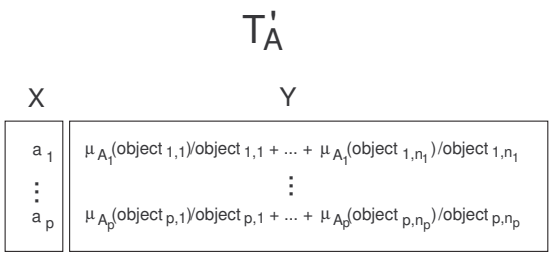

Figure 4: Object-oriented version of T_A

In any case, whatever the schema version of dividend and divisor tables are, the solution for division queries entails the resolution of the inclusion problem described in Fig. 5. Next sections are devoted to analyze this inclusion problem.

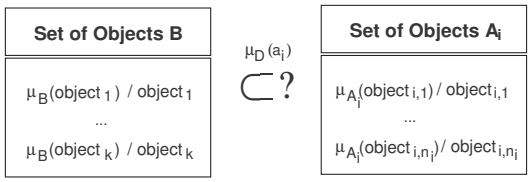

Figure 5: An inclusion problem

4 Two resemblance-based approaches

According to the previous paragraphs, in order to solve division queries in object-oriented models, we need to perform suitable computations of the above mentioned inclusion operator.

To compute the inclusion between any couple of fuzzy sets of objects (like in Fig. 5), we need to generalize the fuzzy inclusion operators, taking into account that the objects of the set may be fuzzily described.

Several proposals for the calculus of this inclusion degree can be found in the literature. In [19] the inclusion degree between two fuzzy sets A and B is calculated as follows:

$$N(B|A) = \min_{u \in U}\{I(\mu_A(u), \mu_B(u))\}, \quad (3)$$

where I stands for an implication operator, and μ_X is the membership function that describes the fuzzy set X. This degree coincides with the fuzzy division operator described in (2). The implication operator can be chosen in accordance to the properties we want the inclusion degree to fulfil [8, 10].

Nevertheless, independently of the chosen implication operator, this formulation supposes that both A and B are defined over a reference universe $\mathcal{U}$ made up of precise elements, where the classical equality is the basis of the comparisons. That is, the implication operator compares to what extent the presence of an element of the universe $\mathcal{U}$ in A forces its presence in B (i.e. we compare the membership degrees of the *same* object to both sets).

However, in the context of fuzzy databases, it frequently happens that the elements of the universe $\mathcal{U}$ are imprecise objects among which classical equality cannot be applied (as we

ISBN: 978-989-95079-6-8

commented in section 2. Instead, a similarity or a (more relaxed) resemblance relationship must be used. That is, for a given element in the set A, it is not clear which element of B has to be taken in order to compare the membership degrees.

In our example of object databases, the objects of the two set of Fig. 5 may be defined with imprecision and two *apparently* different objects (from the identity point of view) may be the *same* one (from the value equality point of view).

That is, if the reference universe $\mathcal{U}$ is formed by fuzzily described elements, a generalized version of (3) that takes into account resemblance among the involved objects must be used. We can consider two distinct ways of doing that, namely, making resemblance acts as a limit of the implication or making resemblance acts as a limit of membership to A_i.

4.1 Resemblance as a limit of the implication

If the reference universe $\mathcal{U}$ is formed by fuzzily described elements, (3) can be generalized as follows [20]:

Definition 1 (Resemblance driven inclusion degree) *Let A and B be two fuzzy sets defined over a finite reference universe $\mathcal{U}$, S be a resemblance relation defined over the elements of $\mathcal{U}$, and $\otimes$ be a t-norm. The inclusion degree of B in A driven by the resemblance relation S is calculated as follows:*

$$\Theta_S(A|B) = \min_{x\in\mathcal{U}} \max_{y\in\mathcal{U}} \theta_{B,A,S}(x,y) \tag{4}$$

where

$$\theta_{B,A,S}(x,y) = \otimes(I(\mu_B(x),\mu_A(y)),\mu_S(x,y)) \tag{5}$$

In (3), the inclusion degree is calculated taking into account the element of $\mathcal{U}$ that fulfils in a lower degree the implication condition between the membership degrees of this element to both sets. In (4), since the membership degrees of similar (but not necessarily equal from the identity point of view) elements can be compared, we restrict the implication using the resemblance degree of the two elements. In summary, for each element that belongs with a certain degree to the set A, we look for a *quite similar* object in $\mathcal{U}$ that belongs to the set B with an equal or higher degree.

Consider the example of Fig. 6.

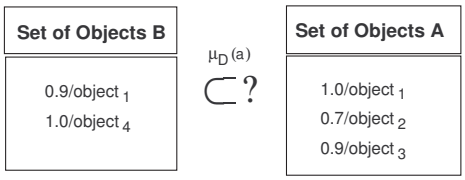

Figure 6: Example

In this example, $\{o_1, o_2, o_3, o_4\}$ is the reference universe $\mathcal{U}$ over which the resemblance relation S of table 1 is defined.

In this situation:

$\Theta_S(A|B)$= min {max {$\otimes$(I($\mu_B(o_1)$, $\mu_A(o_1)$), $\mu_S(o_1,o_1)$), ..., $\otimes$ (I($\mu_B(o_1)$, $\mu_A(o_4)$), $\mu_S(o_1,o_4)$)}, ..., max{$\otimes$(I($\mu_B(o_4)$, $\mu_A(o_1)$), $\mu_S(o_4,o_1)$), ..., $\otimes$(I($\mu_B(o_4)$, $\mu_A(o_4)$), $\mu_S(o_4,o_4)$)}}.

If we use the minimum as t-norm and (6) as implication operator, then:

$\Theta_S(A|B)$= min {max {1,0,0,0}, max {0,1,0,0}, max {0,0,1,0.7}, max {0,0,0.7,0}}= min{1,1,1,0.7}=0.7.

Table 1: Resemblance Relation

	o_1	o_2	o_3	o_4
o_1	1.0	0.0	0.0	0.0
o_2		1.0	0.0	0.0
o_3			1.0	0.7
o_4				1.0

$$I(x,y) = \begin{cases} 1, & \text{if } x \le y \\ y/x, & \text{otherwise} \end{cases} \tag{6}$$

4.2 Resemblance as a limit of relationship

As an alternative to the strategy used in the previous subsection, we can consider that the resemblance only restricts the membership degree of a certain object to the set A.

The assumption of this second version of flexible inclusion is to enlarge the set A into a superset A' obtained by composing A with the resemblance relation as suggested in [9]. The idea is to expand A in the sense that the objects of the reference class $\mathcal{U}$ *similar* to an object initially present in A, are added to A. This resemblance based tolerant inclusion can be defined as follows.

Definition 2 (Resemblance based tolerant inclusion degree) *Let A and B be two fuzzy sets defined over a finite reference universe $\mathcal{U}$, S be a resemblance relation defined over the elements of $\mathcal{U}$, and $\otimes$ be a t-norm. The tolerant inclusion degree of B in A according to the resemblance relation S is calculated as follows:*

$$\Psi_S(A|B) = \min_{x\in\mathcal{U}} \max_{y\in\mathcal{U}} \psi_{B,A,S}(x,y) \tag{7}$$

where

$$\psi_{B,A,S}(x,y) = I(\mu_B(x), \otimes(\mu_A(y),\mu_S(x,y)) \tag{8}$$

According to the example of Fig. 6 and the resemblance relation defined in Table 1:

$\Psi_S(A|B)$= min {max {I($\mu_B(o_1)$, $\otimes$($\mu_A(o_1)$,$\mu_S(o_1,o_1)$)), , ..., I($\mu_B(o_1)$, $\otimes$($\mu_A(o_4)$,$\mu_S(o_1,o_4)$))}, ..., max {I($\mu_B(o_4)$, $\otimes$($\mu_A(o_4)$,$\mu_S(o_4,o_1)$)), ...,I($\mu_B(o_4)$, $\otimes$($\mu_A(o_4)$,$\mu_S(o_4,o_4)$))}}.

If we use the minimum as t-norm and (6) as implication operator, then:

$\Psi_S(A|B)$= min {max {1,0,0,0}, max {1,1,1,1}, max {1,1,1,1}, max {0,0,0.7,0}}= min{1,1,1,0.7}=0.7.

4.3 Some notes on the two approaches

Although with our example, both flexible implementations of inclusion deliver the same value, normally the behaviour of these alternatives will differ.

An example where the second approach is more optimistic than the first one is described below.

Consider the naive example of Fig. 7.

In this example, $\{o_1, o_2\}$ is the reference universe $\mathcal{U}$ over which the resemblance relation S of table 2 is defined.

If we use the minimum as t-norm and (6) as implication operator, then:

$\Theta_S(A|B)$=0.6

$\Psi_S(A|B)$=1.0

ISBN: 978-989-95079-6-8

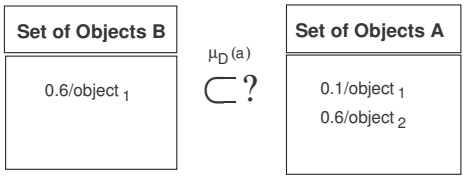

Figure 7: Example

Table 2: Resemblance Relation

	o_1	o_2
o_1	1.0	0.6
o_2		1.0

If we change the resemblance relation as in Table 3 and maintain the rest of data, then
$\Theta_S(A|B)$=0.9
$\Psi_S(A|B)$=1.0

Table 3: Resemblance Relation

	o_1	o_2
o_1	1.0	0.9
o_2		1.0

From a semantic point of view, with this configuration of the *Tolerant Inclusion*, in the computation of $\psi_{B,A,S}(x, y)$, the membership degree to A of a given object y bounds the needed resemblance between x and y. This effect can diminish if we use t-norms more restrictive than the minimum.

5 The role of cardinality

In order to finish our analysis of inclusion operators between fuzzy sets of fuzzily described objects, we now pay attention to cardinality, which may play a relevant role when computing the inclusion for two main reasons: On the first hand, if we soften the inclusion so that *similar* objects can fulfil the implication constraint, we have to be careful with the number of involved objects (the same object of A can be *matched* to more than one object of B); on the other hand, another point where the inclusion operators are able to be softened is to be tolerant with the number of objects of set B that we force to be included in A.

These two reasons lead us to new approaches to the inclusion operator which is supporting the division we want to solve.

5.1 Cardinality as a constraint of similarity

The use of resemblance relations instead of equality when computing inclusion degrees may make the obtained value be high, even if there is a great difference in terms of cardinality between the set of elements of B and the subset of elements of A matched to them during the computation of inclusion.

In some situations, cardinality may not be important. For example, imagine that A and B are two sets of *tools* and that we want to solve the question *Can a person do with tools of A all the tasks he can do with the tools of B?*. In this case, for each tool of B, we look for a tool of A with similar capabilities. In this context, it does not matter if the same tool of A is matched to more than one tool of B. That is, the number of *selected tools of A* is not relevant. However, if we need to assign this set of tools to a group of people that have to work independently, then, the number of *selected tools of A* is relevant and cardinality is important.

If we wish to distinguish between these situations, we need to weight the inclusion degree with a factor that takes into account the distance between the cardinalities of the fuzzy sets that are being compared.

Definition 3 (Cardinality Factor) *Let $\mathcal{U}$ be a reference universe. Let $|X|$ stands for the crisp cardinality of X. $CF : P(\mathcal{U}) \times P(\mathcal{U}) \to [0, 1]$ is a cardinality factor if:*

1. *If $|X| = |Y|$, $CF(X, Y) = 1$*
2. *If $|X| >= |Y|$, $CF(X, C) >= CF(Y, C)$*
3. *If $|X| >= |Y|$, $CF(C, Y) >= CF(C, X)$*

A simple example of CF is the following one:

$$CF(X,Y) = \begin{cases} 1, \text{ if } |X| >= |Y| \\ |X|/|Y|, \text{ otherwise} \end{cases} \quad (9)$$

This CF can be composed with a *relative fuzzy quantifier*[21] to adjust the behavior to the user needs.

Using (9) in the example of Fig. 8 and the resemblance relation of Table 4, we have:
$\Theta_S(A|B)$=1.0
$\Psi_S(A|B)$=1.0
but CF(matched elements of A,B)=0.5.

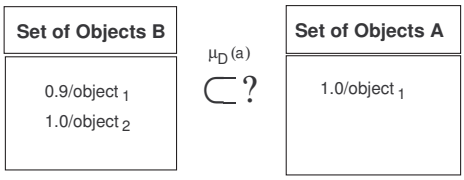

Figure 8: Example

Table 4: Resemblance Relation

	o_1	o_2
o_1	1.0	1.0
o_2		1.0

5.2 Cardinality as a relaxation of the inclusion

The other role cardinality can play in an inclusion operator is to soften the amount of elements of B that have to fulfil the inclusion relation. That is, with this kind of relaxation, the idea is to compute to what extent *almost all* elements of B are included in A. For example, in the case of tools, we want to solve the question *Can a person do with tools of A almost all the tasks he can do with the tools of B?*

There are many possible implementations of this idea in relation to what is called approximate division[8, 12]. One of the possible implementations of the corresponding approximate inclusion is to substitute the infimum in (3) by an OWA operator based on the desired *almost all* quantifier[22]. This way, we can adapt Θ and Ψ operators as follows.

ISBN: 978-989-95079-6-8

Definition 4 (Approximate Θ) *Let A and B be two fuzzy sets defined over a finite reference universe $\mathcal{U}$, S be a resemblance relation defined over the elements of $\mathcal{U}$, $\otimes$ be a t-norm, and $OWA_{\mathcal{Q}}$ an OWA operator induced by a regular non-decreasing quantifier $\mathcal{Q}$. The approximate inclusion degree of B in A driven by the resemblance relation S according to $OWA_{\mathcal{Q}}$ is calculated as follows:*

$$\Theta_{\mathcal{Q},S}(A|B) = OWA_{\mathcal{Q}}(\{\max_{y\in\mathcal{U}} \theta_{B,A,S}(x,y)\}_{x\in\mathcal{U}}) \qquad (10)$$

Definition 5 (Approximate Ψ) *Let A and B be two fuzzy sets defined over a finite reference universe $\mathcal{U}$, S be a resemblance relation defined over the elements of $\mathcal{U}$, $\otimes$ be a t-norm, and $\mathcal{Q}$ a relative fuzzy quantifier. The approximate tolerant inclusion degree of B in A based on the resemblance relation S according to $\mathcal{Q}$ is calculated as follows:*

$$\Psi_{\mathcal{Q},S}(A|B) = OWA_{\mathcal{Q}}(\{\max_{y\in\mathcal{U}} \psi_{B,A,S}(x,y)\}_{x\in\mathcal{U}}) \qquad (11)$$

6 Conclusions

In this paper, we have presented an approach to solve queries that are similar to the division queries of the relational data model but, now, in an object-oriented context. The fact that attribute values can be fuzzily described objects make us to extend the division operator by means of resemblance measures. We have considered two ways of incorporating such resemblance measures in the computation of inclusion, namely, restricting membership and restricting inclusion. Additionally, we have analyzed the role that cardinality can play in the division operator. Thus, we have considered to weight the inclusion operators with a cardinality factor that takes into account the number of elements of set A matched during the inclusion analysis. We have also propose two approximate inclusion operators based on the use of a quantifier for relaxing the division condition. With the described survey of operators, the user can semantically adapt the division operators to her/his needs in an object-oriented context.

Abstract—*In this paper, we present an evolutionary multiobjective learning model achieving positive synergy between the Inference System and the Rule Base in order to obtain simpler, more compact and still accurate linguistic fuzzy models by learning fuzzy inference operators together with Rule Base. The Multiobjective Evolutionary Algorithm proposed generates a set of Fuzzy Rule Based Systems with different trade-offs between interpretability and accuracy in linguistic fuzzy modeling, allowing the designers select the one that involves the most adequate equilibrium for the desired application.*

Keywords— Linguistic fuzzy modeling, interpretability-accuracy trade-off, Multiobjective genetic algorithms, adaptive Inference System, adaptive defuzzification, rule learning.

1 Introduction

The main objective in system modelling is to develop reliable and understandable models. Interpretability and accuracy are usually contradictory requirements in the design of linguistic fuzzy models (FMs). Recent research into genetic fuzzy systems has focused on methods aimed at generating Fuzzy Rule-Based Systems (FRBS) with an appropriate trade-off between accuracy and interpretability [1, 2].

Two important tasks in the design of a linguistic FM for a particular application are the derivation of the linguistic Rule Base (RB) and the setup of the Inference System and defuzzification method. In the framework of the trade-off between interpretability and accuracy in fuzzy modeling, adaptive Inference Systems and defuzzification methods have acquired greater importance [3, 4].

Recently, the use of Multiobjective Evolutionary Algorithms (MOEA) has been applied to improve the aforementioned trade-off between interpretability and accuracy of linguistic fuzzy systems [5, 6, 7, 8, 9, 10, 11]. Some of them obtain the complete Pareto (the set of non-dominated solutions with different trade-offs) by selecting or learning the set of rules which best represents the example data, i.e., improving the system accuracy and decreasing the FRBS complexity. In [7, 8, 11] the authors also propose tuning the membership functions together with the rule selection to obtain simpler yet still accurate linguistic FMs.

Following these ideas on the advantage of using parametric operators and MOEAs to improve the trade-off between interpretability and accuracy, in [9] we presented a MOEA capable of learning the fuzzy inference operators (including inference and defuzzification) and of performing rule selection for Mamdani linguistic fuzzy systems. The proposed model aimed to achieve a positive synergy, that is, cooperation between the fuzzy operators and the RB to improve accuracy while at the same time simplifying the RB to improve interpretability.

Our main objective in this work is to include a new and highly important element in the learning process, the complete RB. Thus, we propose a MOEA capable of generating a set of FRBS (each with a high degree of cooperation between the RB and the Inference System) with varying optimal trade-offs between accuracy and complexity, so as to obtain compact and accurate linguistic fuzzy models by learning fuzzy operators and RB.

To do this, Section 2 describes the parametric fuzzy operators, Section 3 shows the RB learning used in this work, Section 4 is devoted to describing the MOEA learning proposal, Section 5 develops an experimental study, and finally, Section 6 presents some concluding remarks.

2 Adaptive Fuzzy Operators

In this section we describe the adaptive Inference System as well as the adaptive defuzzification method used in our learning proposal.

2.1 Adaptive Inference System

Linguistic FRBSs for system modeling use IF - THEN rules of the following form:

$$R_i: \text{If } X_{i1} \text{ is } A_{i1} \text{ and } \ldots \text{ and } X_{im} \text{ is } A_{im} \text{ then } Y \text{ is } B_i$$

with i = 1 to N, where N stands for the number of rules of the RB, X_{i1} to X_{im} and Y for the input and output variables respectively, and A_{i1} to A_{im} and B_i for the involved antecedents and consequent labels, respectively.

The expression of the Compositional Rule of Inference in fuzzy modeling with punctual fuzzification is the following: $\mu_{B'}(y) = I(C(\mu_{A1}(x_1), \ldots, \mu_{Am}(x_m)), \mu_B(y))$, where $\mu_{B'}(\cdot)$ is the membership function of the inferred consequent, $I(\cdot)$ is the implication operator, $C(\cdot)$ is the conjunction operator, $\mu_{Ai}(x_i)$ are the values of the matching degree of each input of the system with the membership functions of the rule antecedents, and $\mu_B(\cdot)$ is the consequent of the rule.

ISBN: 978-989-95079-6-8

The two components, the conjunction (C(·)) and the implication operator (I(·)) are suitable for parametrization in order for the Inference System to be adapted. Our previous studies in [3] show that models based on the adaptive conjunction is a more valuable option than those based on the adaptive implication operator. Hence, we selected the adaptive conjunction in this study in order to insert parameters in the Inference System.

Taking into account the aforementioned studies in [3], we have selected the Dubois adaptive t-norm with a separate connector for every rule, the expression for which is shown in (1).

$$T_{Dubois}(x, y, \alpha) = \frac{x \cdot y}{Max(x, y, \alpha)}, \quad (0 \leq \alpha \leq 1) \qquad (1)$$

This adaptive t-norm showed the highest accuracy in previous studies, compared with Frank and Dombi t-norms and is more efficiently computed. The use of an adaptive t-norm for the antecedent connection seeks better performance than traditional t-norms. Dubois t-norm performs between minimum ($\alpha = 0$) and algebraic product ($\alpha = 1$).

2.2 Adaptive Defuzzification Interface

There are various tendencies in the development of adaptive defuzzification methods reported in the literature. These employ one or more parameters in their expression for modifying the behaviour of the defuzzifier or, in most cases, to achieve higher accuracy.

Following the studies developed in [13], in this work we consider applying the defuzzification function to the fuzzy set inferred by each rule (getting a characteristic value) and computing them by a weighted average operator, because of its fine performance, efficiency and easier implementation. This way of working is named FITA (First Infer, Then Aggregate) [12].

We also consider the use of a product functional term of the matching degree between the input variables and the rule antecedent fuzzy sets (h_i), $f(h_i) = h_i \cdot \beta_i$ where β_i corresponds to one parameter for each rule R_i, i=1 to N, in the RB, as it is more efficiently computed and obtains similar results to other functions [13]. The adaptive defuzzification formula selected is shown in (2).

$$y_0 = \frac{\sum_{i}^{N} h_i \cdot \beta_i \cdot V_i}{\sum_{i}^{N} h_i \cdot \beta_i}, \qquad (2)$$

where V_i represents a characteristic value of the fuzzy set inferred from rule R_i, the Maximum Value or the Gravity Center (GC), the latter being the one selected in this paper.

The product functional term with a different parameter for each rule has the effect of weighted rules. This value associated with the rule indicates the importance of that rule for the inference process.

3 Rule Base Learning

The linguistic RB learning used in this work is based on the ad-hoc data driven methodology named COR [14]. This methodology manages a set of consequent label sets (one per rule). Instead of selecting the consequent with the best performance in each subspace as usual (Wang and Mendel [15]), the COR methodology considers the possibility of using another consequent, different from the best, which allows the FRBS to be more accurate thanks to having a RB with best cooperation. For this purpose, COR performs a combinatorial search among the candidate rules looking for the set of consequents which globally achieves the best accuracy.

COR consists of two stages:

1) *Construction of the search space*—This obtains a set of candidate consequents for each rule.

2) *Selection of the most cooperative fuzzy rule set*—This performs a combinatorial search among these sets seeking the combination of consequents with the best global accuracy.

In order to perform this combinatorial search, an *explicit enumeration* or an *approximate search technique* can be considered. In this work, we use a search technique because it is effective and quick.

4 Rule Base and Inference System Cooperative Learning with Multiobjective Algorithms

This Section describes the evolutionary multiobjective model proposed in this work. As was previously mentioned, our objective is to obtain a set of fuzzy systems with different trade-offs between accuracy and interpretability, using adaptive inference and defuzzification, and Rule Base learning (including rule selection). To do this, we exploit two specific MOEAs considering a threefold coding scheme (coding of rules and coding of the parameters of the Inference Systems and Defuzzification). We adopted two of the most representative second generation MOEAs, SPEA2 [16] and NSGA-II [17], as two general purpose MOEAs for performing the cooperative adaptation of the fuzzy operators and fuzzy rule learning.

4.1 SPEA2 and NSGA-II

The SPEA2 algorithm [16] (*Strength Pareto Evolutionary Algorithm for Multiobjective Optimization*) is one of the most well-known techniques for solving multiobjective problems. It is characterized by the following two aspects: a *fitness* assignment strategy, which takes into account both dominating and dominated solutions for each individual, and a density function, estimated by employing the nearest neighbourhood, which guides the search more efficiently.

NSGA-II algorithm [17] is another of the most well-known and frequently-used MOEAs for general multi-objective optimization in the literature. It is a parameterless

ISBN: 978-989-95079-6-8

approach with several interesting principles: a binary tournament selection based on fast non-dominated sorting, an elitist strategy and a crowding distance method to estimate the diversity of a solution.

4.2 Questions related to the MOEAs.

The evolutionary model uses a chromosome with threefold coding scheme (C_C+C_D+C_R) where:

- C_C encodes the α_i parameters of the conjunction connective. They are N real coded parameters (genes), one for each rule, R_i ,of the linguistic RB. Each gene can take any value in the interval [0, 1], that is, between the minimum and the algebraic product. This is represented by the C_C part of the chromosome shown in Figure 1.

- C_D encodes the β_i parameters of the defuzzification. They are N real coded parameters, one for each rule, of the linguistic RB. Each gene can take any value in the interval [0, 10]. This interval has been selected according to the study developed in [13]. It allows attenuation as well as enhancement of the matching degree. This is represented by the real part C_D shown in Figure 1.

- C_R encodes the learning Rule Base. It is an integer string of N genes, each one representing a candidate rule consequent of the initial RB. Furthermore, depending on whether a rule is selected or not, the value '-1' is assigned to the corresponding gene. This is represented by the integer part of the chromosome shown in Figure 1.

The initial population is randomly initialized in the fuzzy operators part with the exception of a single chromosome:

- C_C with the N genes is initiated to 0 in order to make Dubois t-norm equivalent to Minimum t-norm initially.

- C_D also with the N genes is initiated to 1 with the objective of beginning like the standard WCOA method.

The initial population in the fuzzy rule part, C_R, is initialized following these two exceptions:

- A single chromosome with the N rules obtained by the WM-method [15], that is, with all the genes initialized to correspondent consequent.

- Default chromosomes randomly initiated with all rules activated. In this case, in order to achieve solutions with a high accuracy we should not lose rules that could present a positive cooperation once their FM parameters have been evolved. The best way to do this is to start with solutions that select all the possible rules. This favors a progressive extraction of bad rules (those that do not improve with the tuning of parameters).

The crossover operator employed by the fuzzy operators part is BLX-0.5 [18] while the one used for the rule learning part is HUX [19].

Finally, four offspring are generated by combining the two from the C_R part with the two from the operators part (the two best replace their parents). The mutation operator changes a gene value at random in the C_R and operators part (one in each part) with probability 0.2.

In this work, to obtain an optimal set of FRBS with different trade-offs, the fitness, based on the interpretability (using the number of rules) and the accuracy (using the error measure), must be minimized.

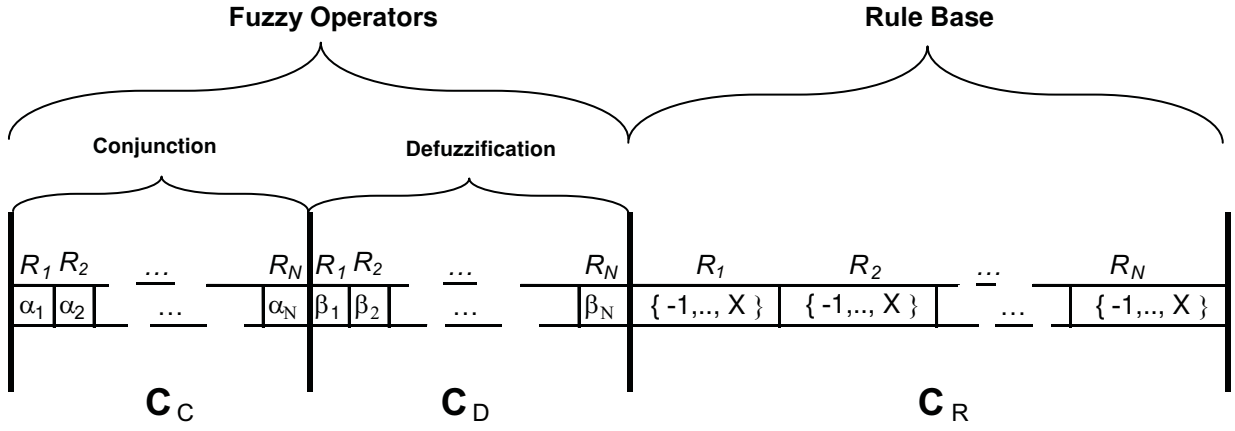

Fig. 1. Coding scheme for the MOEA with N rules

ISBN: 978-989-95079-6-8

5 Experimental Study

In order to analyse the practical behaviour of the proposed methods, we built several FMs in a real-world problem [20] of four input variables consisting in estimating the maintenance costs of medium voltage lines in a town. Methods considered for the experiments are briefly described in Table 1, where WM and COR methods are considered as reference. S denotes the methods that perform rule selection. If rule selection is performed after another method we give it a "+" denotation (eg. COR+S). However, if rule selection is performed jointly with another method we denote this in subscript (eg. COR_S). S–C–D means rule selection and fuzzy operators learning together. $SPEA2_{S\text{-}C\text{-}D}$, and $NSGA\text{-}II_{S\text{-}C\text{-}D}$ are the methods that learn the fuzzy operators and the rule selection together, while $SPEA2COR_{S\text{-}C\text{-}D}$ and $NSGA\text{-}IICOR_{S\text{-}C\text{-}D}$ are methods that also learn the RB as previously mentioned.

Table 1. Methods considered for comparisson

Ref.	Method	Description
[15]	WM	Wang & Mendel algorithm
[21]	WM + S	Wang & Mendel and then Rule Selection
[9]	WM + S–C–D	Wang & Mendel and then Rule Selection and Adaptive Fuzzy Operators
[14]	COR	COR
	COR + S	COR and then Rule Selection

[9]	$NSGA\text{-}II_{S\text{-}C\text{-}D}$	NSGA-II algorithm with Rule Selection and Adaptive Fuzzy Operators
-	$NSGA\text{-}IICOR_{S\text{-}C\text{-}D}$	NSGA-II algorithm with COR with Rule Selection and Adaptive Fuzzy Operators

5.1 Application Selected and Comparison Methodology

The application selected to test the evolutionary model is the aforementioned electrical distribution problem [20] that has a data set of 1059 cities with four input variables and a single output. The RB is composed of 65 linguistic rules achieved with the Wang and Mendel method [15]. The fuzzy partition used for inputs and output has 5 labels.

We considered a 5-fold cross-validation model, i.e., 5 random partitions of the data each with 20% (4 of them with 211 examples, and one of them with 212 examples), using the combination of 4 of them (80%) as training, and the remaining one as a test. We achieved a total of 30 trials for each evolutionary process, as the learning methods were run 6 times for each one of the data partitions. We show the average values of the medium square error (MSE) as a usual performance measure, computed considering the most accurate solution from each Pareto obtained with the multiobjective algorithm. This method of working was also employed in [9] in order to compare the single objective methods with the multiobjective ones based on considering the accuracy objective only, letting us see that the Pareto fronts are not only wide but also optimal, so similar solutions obtained with the WM + S–C–D or $COR_{S\text{–}C\text{–}D}$ must appear in the final Pareto. The MSE is computed with expression (3),

$$MSE\ (FM)_B = \frac{\frac{1}{2}\sum_{k=1}^{P}(y_k - FM(x_k))^2}{P} \qquad (3)$$

where *FM* denotes the fuzzy model the Inference System of which uses the Dubois t-norm as conjunction operator showed in expression (1), the inference operator is minimum t-norm, and the adaptive defuzzificación method is the one shown in expression (2). This measure uses a set of system evaluation data formed by P pairs of numerical data $Z_k = (x_k, y_k)$, k=1,..,P, with x_k being the values of the input variables, and y_k being the corresponding values of the associated output variables. The MOEAs population size was fixed at 200. The external population size of the $SPEA2_{S\text{-}C\text{-}D}$ and $SPEA2COR_{S\text{-}C\text{-}D}$ was 61.

5.2 Results and Analysis

To compare the results obtained we also used non-parametric tests, according to the recommendations made in [22]. The results obtained are shown in Table 2, where #R is the average number of rules, MSE_{tra} and MSE_{tst} are the average MSE for training and test respectively, and *Wilcoxon-test* is the result of applying a *Wilcoxon* signed-ranks test [23] (with 95% confidence), with the following interpretation: * represents the best average result (control algorithm); + means that the best result has better performance than that of the corresponding row, while sign (=) means it is similar to the best result. As we have mentioned, Demšar [20] recommends a set of simple, safe and robust non-parametric tests for statistical comparisons of algorithms, one of which is the Wilcoxon signed-ranks test [23]. This is analogous to the paired t-test in non-parametrical statistical procedures.

Table 2 only shows the best result for each MOEAs for accuracy. Analysing the results we can highlight the two following points:

- The learning of the RB allows remarkable improvement in accuracy: Looking at Table 2, we can observe that $SPEA2COR_{S\text{-}C\text{-}D}$ improves the accuracy of $SPEA2_{S\text{-}C\text{-}D}$ and $NSGA\text{-}IICOR_{S\text{-}C\text{-}D}$ improves $NSGA\text{-}II_{S\text{-}C\text{-}D}$. In spite of the fact that the number of rules shown in Table 2 is slightly larger, it must be taken into account that the results shown are the ones with the highest accuracy along the Pareto front. Looking at Table 3, we can observe similar values for accuracy in solutions with a lower number of rules from 40 to 32, so $NSGA\text{-}IICOR_{S\text{-}C\text{-}D}$ truly obtains better fuzzy systems (for accuracy and

ISBN: 978-989-95079-6-8

interpretability) than NSGA-II$_{S\text{-}C\text{-}D}$. Thus, the cooperation between the rules and the fuzzy operators improves the results of the evolutionary multiobjective proposal without rule learning.

- The solution with the best accuracy obtained with NSGA-II$_{COR_{S\text{-}C\text{-}D}}$ and SPEA2$_{COR_{S\text{-}C\text{-}D}}$ shows a similar accuracy to the single objective evolutionary model $COR_{S\text{–}C\text{–}D}$ (as shown in the non-parametric test) with a significant reduction in the number of rules, particularly for NSGA-II$_{COR_{S\text{-}C\text{-}D}}$. Consequently, the proposed method achieves more interpretable models with similar accuracy. We also notice that the best accuracy in Table 2 is obtained by the single objective model $COR_{S\text{–}C\text{–}D}$. The difference is small, but we can deduce that the evolutionary multiobjective methods are not achieving the most accurate solution. This fact suggested in [9] the design of more specific multiobjective algorithms in order to get even better solutions than the generic MOEAs SPEA2 and NSGA-II. Figure 2 shows the Pareto progress for each evolutionary algorithm (SPEA2$_{COR_{S\text{-}C\text{-}D}}$ and NSGA-II$_{COR_{S\text{-}C\text{-}D}}$) where we can observe the Pareto movement for each generation. Because to the adaptive fuzzy operators search space is large, we consider it may be necessary to focus the search process on the Pareto zone with highest accuracy, so that the same accuracy can be achieved as with single objective evolutionary algorithms based on accuracy.

6 Conclusions

In the framework of the trade-off between accuracy and interpretability, the use of MOEAs gives a set of solutions with different levels of conciliation between both features. In this work we have proposed a multiobjective evolutionary learning model where the adaptive fuzzy operator parameters are learnt together with the RB. This fact allows both elements to cooperate, improving the accuracy as well as the interpretability.

The results obtained have shown that the use of MOEAs can represent a way to obtain a set of FRBSs in a single run with optimal trade-off between accuracy and interpretability. In terms of future work, some improvements may be developed in order to guide the search towards the desired Pareto zone with higher accuracy (right and central zone) where the FRBSs obtained are perhaps more interesting in more applications.

By focusing the search process we can reduce the effort of the search, and a better precision in the non-dominated solutions can be obtained, because the search effort is concentrated on a reduced zone of the Pareto, such that the density of the obtained solutions is higher. An improvement could be a change in the MOEAs used or a change in the non-dominated definitions in order to give more weight to the objective of accuracy.

Abstract—*This paper investigates the potential information provided to the user by the uncertainty measures applied to the possibility distributions associated with the spatial units of an IKONOS satellite image, generated by two fuzzy classifiers, based, respectively, on the Nearest Neighbour Classifier and the Minimum Distance to Means Classifier. The deviation of the geographic unit characteristics from the prototype of the class to which the geographic unit is assigned is evaluated with the Un non-specificity uncertainty measures proposed by [1] and the exaggeration uncertainty measure proposed by [2]. The classifications were evaluated using accuracy and uncertainty indexes to determine their compatibility. Both classifications generated medium to high levels of uncertainty for almost all classes, and the global accuracy indexes computed were 70% for the Nearest Neighbour Classifier and 53% for the Minimum Distance to Means Classifier. The results show that similar conclusions can be obtained with accuracy and uncertainty indexes and the latter, along with the analysis of the possibility distributions, may be used as indicators of the classification performance and may therefore be very useful tools. Since the uncertainty indexes may be computed to all spatial units, the spatial distribution of the uncertainty was also analysed. It's visualization shows that regions where less reliability is expected present a great amount of detail that may be potentially useful to the user.*

Keywords—Accuracy assessment, Minimum Distance to Mean Classifier, Nearest Neighbour Classifier, Non-specificity measures, Remote Sensing Images, Uncertainty.

1 Introduction

Some classifiers used in Remote Sensing allow the assignment of each spatial unit (pixel or object) to several classes through the computation of degrees of possibility, probability or membership associated with each class, as opposed to the traditional classifiers where each spatial unit is only assigned to one class [3, 4, 5, 6]. This additional information may be interpreted as degrees of membership of the spatial unit to the classes, and in this case are usually referred to as soft classifiers [7]. Even though the use of soft classifiers is increasing, most applications still require a hard classification into disjoint classes of interest. For these cases, the spatial units may be assigned to the class presenting the larger degree of possibility or probability. The additional information provided by these degrees of possibility of probability may be used as indicators of the classifier difficulty to assign only one class to the spatial unit and, together with the application of uncertainty measures, may provide valuable information to the user [2, 8, 9, 10].

In [1] it is shown that, for a fuzzy classifier which assigns to each spatial unit degrees of membership or possibility associated with the classes, the non-specificity measures may be used to estimate the classification accuracy. They can therefore be a useful tool, since, on one hand, they can give an estimation of the classification accuracy prior to the final accuracy evaluation, enabling the classification improvement before the final classification accuracy is assessed (which is a time consuming and expensive process), and on the other hand enable the spatialization of the uncertainty [11]. In this paper a very high resolution image is classified with two fuzzy classifiers and the uncertainty measures (two non-specificity measures and an exaggeration measure) are applied to both classifications, to determine the usefulness of the information provided by them. A comparison between the information provided by the non-specificity measures and the producer's and user's accuracy indexes is made to determine their compatibility.

To evaluate the usefulness of the information provided by the spatialization of uncertainty, an approach similar to the one proposed by [2] is considered, where it is proposed that, when the spatial units are assigned to the best degree of similarity, errors of omission and commission are committed. The former occurs because, when assigning the spatial unit only to the best class, its similarity to the other classes is omitted. The latter occurs because, when the spatial unit is assigned to the best class and the degree of similarity to that class is smaller that one, a commission error is introduced, since a higher similarity is considered. To estimate omission errors [2] used an entropy measure. Since the Shannon entropy should only be applied to probability measures, the U_n uncertainty measure was used instead. To estimate the commission errors the measure of exaggeration proposed in [2] was used. The results are shown and conclusions drawn.

2 Data and methods

2.1 Data

The study was conducted in a rural area with a smooth topographic relief, situated in a transition zone between the

ISBN: 978-989-95079-6-8

centre and south of Portugal featuring diverse landscapes representing Mediterranean environments. The area is occupied mainly by agriculture, pastures, forest and agro-forestry areas where the dominant forest species in the region are eucalyptus, coniferous and cork trees. An image obtained by the IKONOS sensor was used, with a spatial resolution of respectively 1m in the panchromatic mode and 4m in the multi-spectral mode (XS) and a dimension of 11 884 m by 14 432m. The geometric correction of the multi-spectral image consisted of its orthorectification. The average quadratic error obtained for the geometric correction was 1.39 m, inferior to half the pixel size, which guarantees an accurate geo-referencing.

2.2 Classification

Two fuzzy classifiers were used in this application to obtain the elementary entities that are the basic units of landscape, like crown trees and parts of buildings, called Surface Elements (SE), to produce a Surface Elements Map (SEM). Both classifiers compute degrees of similarity [12] between the values observed at each spatial unit and a set of ideal values, which are, in this case, the spectral response observed in each spatial unit and what is considered to be the ideal characteristics of the class in terms of spectral values, respectively. Even though both classifiers use the same theoretical tools to derive the degrees of similarity, the definition of the ideal characteristics of each class is different for each of them.

The first classification method used is an object–oriented supervised Fuzzy classifier based on the Nearest Neighbor Classifier (FNNC) available on the software eCognition. In the supervised classification methods, a training set has to be chosen for each class. The spectral responses of the pixels inside this set are the signature files used to characterize each class. This classification method assigns to each pixel a degree of membership to each class, depending on the distance between its spectral response and the closest spectral response of the pixels used in the training set for each class (see Fig. 1).

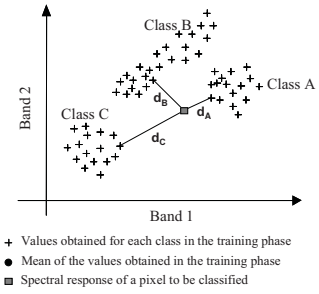

Figure 1: Nearest Neighbor Classifier.

The degrees of membership are computed using a membership function, where the ideal value, corresponding to a degree of membership equal to one, is obtained when the distance between the spectral response of the pixel to classify to the nearest reflectance value of the training set of the class is equal to zero (see Fig. 2).

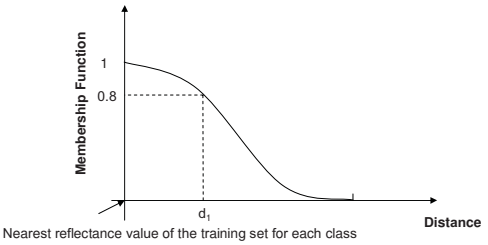

Figure 2: Membership function used in the fuzzy classifier based on the Nearest Neighbor Classifier.

The second classification method used is a pixel-based supervised Fuzzy classifier based on the underlying logic of Minimum-Distance-to-Means Classifier (FMDMC), available in the commercial software IDRISI. With this classification method, the image is classified based on the information contained in the signature files and a standard deviation unit (Z-score distance) introduced by the user. The fuzzy set membership is calculated based on a standardized Euclidean distance from each pixel reflectance, on each band, to the mean reflectance for each class signature (see Fig. 3), using a sigmoidal membership function (see Fig. 4).

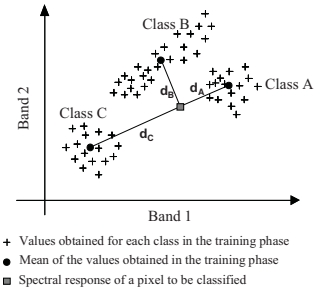

Figure 3: Minimum-Distance-to-Means Classifier.

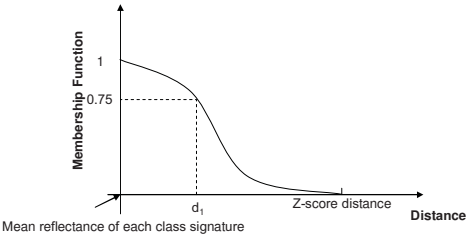

Figure 4: Membership function used in the fuzzy classifier based on the Minimum-Distance-to-Means Classifier

The underlying logic is that the mean of a signature represents the ideal point for the class, where fuzzy set membership is one. When distance increases, fuzzy set membership decreases, until it reaches the user-defined Z-score distance where fuzzy set membership decreases to zero. To determine the value to use for the standard deviation unit, the information of the training data set was used to study the spectral separability of the classes and determine their average separability measure.

The most representative surface elements of the study area are Eucalyptus Trees (ET), Coniferous Trees (CFT), Cork Trees (CKT), Shadows (S), Shallow Water (SW), Deep Water (DW), Herbaceous Vegetation (HV), Sparse Herbaceous Vegetation (SHV) and Non-Vegetated Area (NVA), and therefore these were the considered classes.

ISBN: 978-989-95079-6-8

2.3 Uncertainty measures

To evaluate the uncertainty of the possibilistic classifier the measures of nonspecificity were used. The uncertainty measure *NSp* proposed by [13] and given by

$$NSp(\Pi) = 1 - \sum_{i=1}^{n} \left[\Pi(x_i) - \Pi(x_{i+1}) \right] \frac{1}{i}$$

and a normalized version proposed by [1] of the U-uncertainty measure developed by [14], given by

$$U_n(\Pi) = \frac{[1 - \Pi(x_1)] \log_2 n + \sum_{i=2}^{n} [\Pi(x_i) - \Pi(x_{i+1})] \log_2 i}{\log_2 n}$$

In both equations Π is an ordered possibility distribution defined over a universal set X, that is, a possibility distribution such that $\Pi(x_1) \geq \Pi(x_2) \geq \ldots \geq \Pi(x_n)$, n is the number of elements of the universal set and $\Pi(x_{n+1})$ takes the value zero. A normalized version of the U-uncertainty measure was used to normalize the range of the measure, so that both non-specificity measures vary within the interval [0,1]. The non-specificity measures are appropriate to evaluate the uncertainty resulting from possibilistic classifications, since they quantify the ambiguity in specifying an exact solution [15, 16].

An additional uncertainty measure of exaggeration E, proposed by [2], was also used to quantify the commission errors at each spatial unit. This measure is given by

$$E = 1 - \Pi(x_1)$$

where $\Pi(x_1)$ is the largest degree of possibility.

2.4 Classification evaluation with the accuracy indexes

To evaluate the classifications accuracy a testing set was used. A random sampling of 900 pixels was selected considering the entire image scene. The sample unit was the pixel. The accuracy assessments was made with error matrixes, where the (i,j) entry is the number of pixels that is class i in the map and class j in the reference. The reference data were obtained from aerial images with larger resolution. The Global Accuracy was computed for both classifications. The User Accuracy (UA) and the Producer Accuracy (PA) indexes were also computed for all classes.

2.5 Comparison between uncertainty and accuracy indexes

To determine if the information given by the uncertainty measures may be used as indicators of the classifier's performance and if they are correlated with the results obtained with the classification quality assessment, two accuracy indexes were considered, namely the normalized user's and producer's accuracy; and one index for each uncertainty measure based on the mean, corresponding to the complement of the mean uncertainty per class ($I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$). Since high uncertainty values are expected to correspond to low accuracy values, and vice-versa, the complement of the uncertainty measures is considered to allow an easy comparison with the accuracy indexes. The correlation coefficient between the several accuracy and uncertainty indexes was also computed.

Even though uncertainty measures can be computed to the whole image, since the objective was to compare the results given by the uncertainty measures with the ones given by the error matrix, for this comparison only the sample pixels were used, so that the results were not influenced by the sample representativeness.

2.6 Spatial variation of uncertainty

Since there is a possibility distribution associated with all pixels or objects of the image, the uncertainty indexes may be computed for the whole image. This enables the visualization of the spatial distribution of uncertainty, and its spatial relation with the classes assigned to each spatial unit. As an estimator of the spatial units omission errors the U_n uncertainty measure was used, since it is more sensitive to dispersion than NSp (see [1]) and to estimate the commission errors the exaggeration E measure was used.

3 Results and discussion

3.1 Classification evaluation with accuracy indexes

The error matrix computed for the classification with the FNNC is presented in Fig. 5. The global accuracy obtained with this classification method was 70%.

	Error matrix of the classification with the fuzzy KNN									User's Accuracy (%)
	DW	SW	NVA	ET	S	HV	CKT	CFT	SHV	
DW	102									100.0
SW	3	92								96.8
NVA			76				2	1	8	87.4
ET				42	4	6	7	18	11	47.7
S	2				77		5			91.7
HV			2	1		90			7	90.0
CKT		1	11	8	18		50	6	26	41.7
CFT				3		43	10	42	9	39.3
SHV			23	3		22	16	3	73	52.1
Producer's Accuracy (%)	95.3	98.9	67.9	73.7	77.8	55.9	55.6	60.0	54.5	**69.77%**

Figure 5: Error matrix of the image classification with the method based on the Nearest Neighbour Classifier.

The error matrix shows that water classes (DW and SW) were well identified. Forestry species were often confused between each other and with other classes, such as Sparse Herbaceous Vegetation (SHV) and Herbaceous Vegetation (HV). Significant confusion was observed between Herbaceous Vegetation (HV) and Coniferous Trees (CFT). The class with the smaller value of PA is SHV (54.5%), which means it is the class with more omission error. And the class with smaller UA is CFT (39.3%) and therefore the class with more commission errors.

The global accuracy obtained with the classification with the FMDMC was 53% and the error matrix computed is presented in Fig. 6. The error matrix shows that Deep Water (DW) was the class best identified. Significant confusion was observed between Cork Trees (CKT), Eucalyptus Trees (ET) and Sparse Herbaceous Vegetation (SHV) and between ET and Coniferous Trees (CFT). The class with the smaller value of PA is SHV (14.8%), which means this is the class with more omission error. The pixels which are erroneously not included in this class are included mainly in the class Non Vegetated Areas (NVA), which is the class with smaller UA (27%) and therefore the class with more commission

ISBN: 978-989-95079-6-8

error, which receives pixels from all classes. These results show that this classifier presents great difficulty in classifying the class NVA.

	Error matrix of the classification with the fuzzy MDM									User's Accuracy (%)

3.2 Comparison between uncertainty and accuracy indexes

For the classification made with the FNNC, the uncertainty indexes $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$ along with the user's and producer's accuracy, ordered with increasing values of $I_{1-\overline{NSp}}$, are shown in Fig. 7.

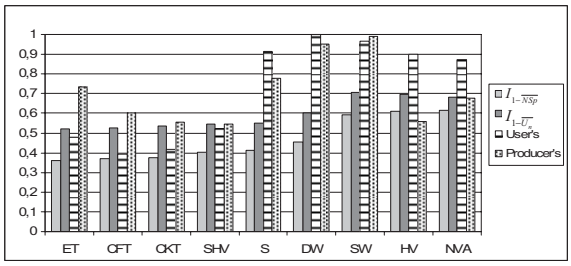

Figure 7: $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$ uncertainty indexes along with the user's and producer's accuracy of the classification based on the Nearest Neighbour Classifier.

It can be observed that for all classes the uncertainty indexes present low to medium values. To determine the reason for these relatively low values of certainty, the observation of the possibility distribution was made, and it was observed that the largest degree of possibility is in general very high, but also high levels of possibility are obtained for the second and sometimes even for the third classes, which explains the high levels of uncertainty (see Table 1). The analysis of the possibility distributions and the classes associated with the second degrees of possibility for the several points enable the identification of classes that might be easily confused, which are mainly the forest classes and SHV. Similar conclusions can be taken from the confusion matrix, with the exception that considerable confusion was also expected between CFT and HV, and this is not expected from the analysis of the degrees of possibility.

From this analysis, worst results are expected for the classes ET, CFT, CKT and SHV, which are exactly the classes with low levels of UA, $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$. This is an expected result, since in [1] it is shown that high correlation values are expected to occur between the uncertainty indexes and the UA. Similarly, the classes with higher values of $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$ are in general the ones presenting higher UA, except for the classes S and DW, which have slightly lower value of $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$.

Table 1: Mean values of the highest and second highest degrees of possibility of the possibility distributions associated with the sample points used to evaluate the accuracy of the classification with the FNNC, along with the most frequent second class.

Best class	$\overline{\Pi(x_1)}$	$\overline{\Pi(x_2)}$	Second class	% of pixels with the second class
SW	0.96	0.66	NVA	100
DW	0.99	0.87	NVA	51
NVA	0.84	0.37	SHV	52
ET	0.99	0.96	CKT	48
HV	0.93	0.55	SHV	50
SHV	0.94	0.83	CKT	52
CFT	0.98	0.94	ET	56
CKT	0.99	0.94	SHV	46
S	0.98	0.89	CKT	64

For the classification made with the FMDMC, the uncertainty indexes $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$ along with the user's and producer's accuracy, ordered with increasing values of $I_{1-\overline{NSp}}$, are shown in Fig. 8. It can be seen that the values of certainty given by both NSp and U_n are low to medium for all classes, presenting $I_{1-\overline{U_n}}$ slightly larger values than $I_{1-\overline{NSp}}$.

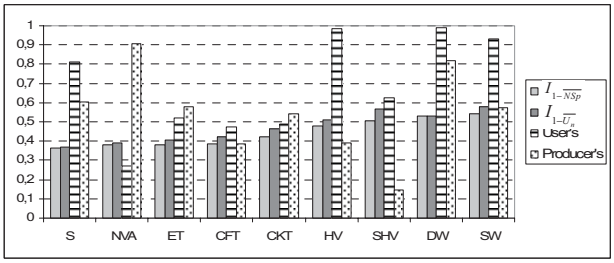

Figure 8: $I_{1-\overline{NSp}}$ and $I_{1-\overline{U_n}}$ uncertainty indexes along with the user's and producer's accuracy for the classification with the FMDMC.

To determine why such relatively high levels of uncertainty were obtained, an analysis of the possibility distributions was also made. This analysis showed that, for all classes, a high percentage of the pixels presented relatively low values for the highest degree of possibility, which explains the relatively low levels of certainty, and no point was classified with the highest degree of possibility equal to one (see Table 2). Further more, for all classes, the second highest degree of possibility for the great majority of testing sites was to the class Non Vegetated Areas (NVA) (except, of course, for the class NVA), in some cases with the degrees of possibility close to the higher degree, which means that there was great confusion between this class and all other classes.

ISBN: 978-989-95079-6-8

Table 2: Mean values of the highest and second highest degrees of possibility of the possibility distributions associated with the sample points used to evaluate the accuracy of the classification with the FMDMC, along with the most frequent second class.

Best class	$\overline{\Pi(x_1)}$	$\overline{\Pi(x_2)}$	Second class	% of pixels with the second class
SW	0.62	0.19	NVA	100
DW	0.53	0.003	NVA	26
NVA	0.41	0.07	HV	16
ET	0.48	0.14	NVA	88
HV	0.57	0.16	NVA	95
SHV	0.63	0.38	NVA	100
CFT	0.52	0.22	NVA	82
CKT	0.54	0.22	NVA	90
S	0.38	0.03	NVA	100

This indicates that one major problem of this classification was mainly due to the difficulty in discriminating NVA from the other classes. This same conclusion can be obtained from the accuracy analysis. The class NVA presents very different values for the user and producer accuracy, respectively 27% and 90%. This means that this class presents a very high percentage of commission errors, and therefore, a great amount of sites that should have been assigned to other classes were assigned to NVA, and were therefore absent from the other classes, such as SHV and HV, increasing their omission errors.

The information provided by the uncertainty measures is therefore in accordance with the one provided by the accuracy indexes, even though the analysis of the possibility distributions is necessary to reach the obtained conclusions.

The most evident discrepancies between the uncertainty and accuracy indexes obtained with the classification with the FMDMC are mainly for the class DW and S. These classes present higher values of accuracy, meaning that they were well identified according to the accuracy indexes, but considerably low levels of classification certainty, corresponding to lower values of the uncertainty indexes. This can be explained by the relatively low level of the first degree of possibility and the confusion between classes, which reinforces the assumption that uncertainty indexes capture the classifier difficulty in determining the correct class. Apparently some discrepancies occur between uncertainty and accuracy indexes for the SW and HV classes due to the fact that they present higher values of UA (93,1 and 98,5 respectively). However, the PA results are lower (57,4% and 38,9 % respectively) which reveal that these classes present higher omission errors and are in accordance with the lower values of $I_{1-\overline{U_n}}$ index. Two main aspects seem to be responsible for the results obtained with this classifier: 1) the larger degrees of possibility for each pixel are in general relatively low, which results in high uncertainty levels; 2) there is considerable confusion between all classes and the class NVA.

To explain the low degrees of possibility obtained with this classifier, a closer look to its classification approach is required. The computed degrees of possibility reflect the closeness of the spectral response of the testing set to an ideal value, which is the mean of the spectral responses obtained for the training set. The computed degrees of possibility are then obtained considering the distance between the spectral response at each testing site and that mean value, and therefore, if the obtained value is relatively distant from the mean, even if its spectral response is very close to some values obtained for the training set, a low degree of possibility will be assigned to it. This classifier and the obtained degrees of possibility, have therefore a limited capability to translate the information provided by the training set. For example, if a pixel has a spectral response equal to the spectral response of one of the pixels used in the training set, but which is relatively far from the mean, it will not have a degree of possibility of belonging to that class equal to one, as should be expected.

The fuzzy classifier based on the FNNC has a better behavior on this aspect, since it translates the information contained in the training set in a more reliable way. For example, all points with a spectral response equal to the spectral response of a point included in the training set will have a degree of possibility equal to one. Furthermore, if the spectral response of pixels is located inside the regions populated by the spectral responses of a particular class, high degrees of similarity are expected to occur to that class.

3.3 Spatial variation of uncertainty

Fig. 10 shows on a), b) and c) respectively an extract of the classification with the FNNC and the values of the U_n and E uncertainty measures. Fig. 10 d), e) and f) show the corresponding images obtained with the FMDMC.

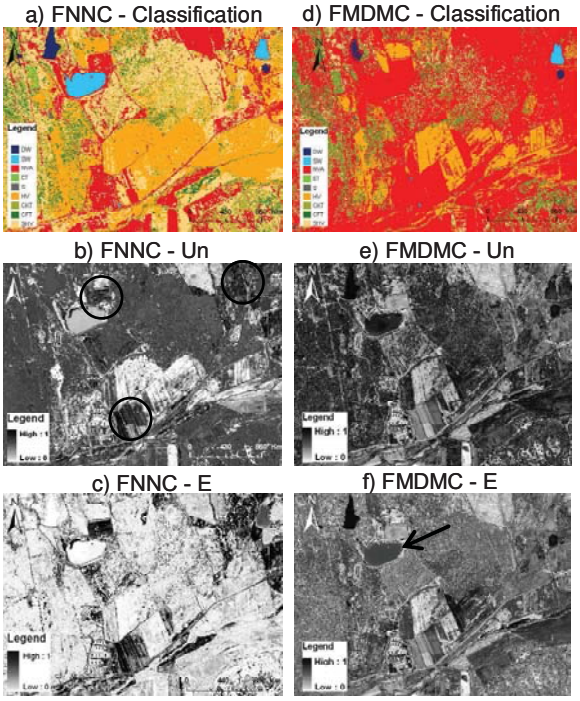

Figure 10: a), b) and c) show respectively the classification results, U_n and E uncertainty values obtained with the FNNC. Images d), e) and f) show the results corresponding to a), b) and c) obtained with the FMDMC.

It can be easily observed that the classification results are very different. Even though the accuracy evaluation and the

ISBN: 978-989-95079-6-8

uncertainty indexes already indicated that the classification with the FMDMC was worst, the visualization of the results clearly shows that it is bad. It can be seen that the FMDMC classified most of the image as NVA, while the FNNC manage to differentiate much more structures in the image.

Images shown in Fig. 10 b) and e) correspond to the spatial distribution of the U_n uncertainty measure of both classifications and may be used to illustrate the omission error committed when the pixel is assigned to the class corresponding to the largest degree of possibility. The regions with larger uncertainty are the ones where the degrees of possibility were more dispersed over other classes. Fig. 10b) shows that relatively large values of U_n were associated with regions that correspond to landscape units composed by different surface elements such as forest trees and Sparse Herbaceous Vegetation. Some region with higher U_n uncertainty can also be seen in the zones identified by the black circumferences. Fig. 10c) and f) show the commission errors, that is, the exaggeration committed when the best class is chosen. In general in Fig. 10c) low values are obtained for most of the image, higher values are mainly visible in some landscape boundaries and in the regions identified by the circumferences in Fig. 10b), which indicate, once again, that those regions may be problematic. Fig. 10f) shows that larger commission errors are obtained with the FMDMC than with the FNNC. One aspect clearly visible from Fig. 10e) and f) is that the spatial variation of uncertainty shows many structures invisible in the classification, such as the SW region shown in the region identified by the arrow.

4 Conclusions

The results obtained with the presented case study highlight that the classifiers FMDMC and FNNC presented possibility distributions with particular characteristics, which are a consequence of the method used to compute the degrees of possibility. The classification with the FNNC presented large possibility values for the best class, but also presented large values for the second and sometimes third class, and the classification with the FMDMC presented low values of the largest possibility. In both cases the presented characteristics increase uncertainty and are a signal of possible difficulties in the classification. In fact, neither of these classifications presented very good results, since Global Accuracies of only 70% and 53% were obtained.

It is also shown that when the classifications present relatively large and similar uncertainty values for all classes it is more difficult to take conclusions regarding the problematic classes only with these measures. Even though, an analysis of the possibility distributions may give valuable information. It is also very important to know how the degrees of possibility associated to the pixels are obtained, to understand what they represent.

In this study it was considered that the confusion matrix and the accuracy indexes were reliable, but in reality a human interpreted may have large difficulties in differentiating for example NVA from SHV, and this type of confusion between classes may influence greatly the accuracy indexes. In future analysis the uncertainty information present in the reference data, used to build the confusion matrixes, should be taken in consideration when comparing the results provided by the uncertainty and accuracy information.

The presented results also show that the spatialization of uncertainty may provide valuable information to the user. This will enable the identification of problematic regions, where the classification is probably less reliable. On the other hand, the spatial variation of uncertainty provides a great amount of information, which, if introduced in the classification itself, might be very useful.

On interval and fuzzy calculations of economic uncertainty

Hans Schjær-Jacobsen

Copenhagen University College of Engineering
15 Lautrupvang, DK-2850 Ballerup, Denmark
Email: hsj@ihk.dk

Abstract—*This paper emphasizes that numerically correct calculation of economic uncertainty with intervals and fuzzy numbers requires implementation of global optimization techniques in contrast to straightforward application of interval arithmetic. In general, the latter approach produces incorrect results in the sense that the degree of uncertainty is severely overestimated with the risk of improper decision making. This is demonstrated by a simple case from managerial economics as well as a cost estimation case from a real life railway reconstruction project.*

Keywords—Economic uncertainty, fuzzy numbers, intervals, possibility, probability.

1 Introduction

Criticism has been raised towards probability theory as being a too normative framework to take all the aspects of uncertain judgement into account, Dubois and Prade [1]. In this paper we will focus on alternative methods of modelling of economic uncertainty like the interval representation and the fuzzy number representation.

The interval representation, Moore [2], [3] is particularly well suited to a situation where the knowledge of an uncertain parameter is limited to knowing its minimum and maximum value whereas nothing else is known. Based upon a mathematical theory of interval analysis this approach has shown to be useful in keeping track of worst and best cases in economic analyses and thus contribute to improved decision processes, see e.g. Schjær-Jacobsen [4], [5]. The introduction of fuzzy sets supports the concept of possibility rather than probability and translates natural language expressions into the mathematical formalism of possibility measures. It is generally recognized that possibility is distinct from probability. Probabilities can be interpreted as relative frequencies or, more generally, uncertain knowledge or belief of a statistical nature. In contrast, possibility relates to the degree of feasibility and ease of attainment or imprecise knowledge. Particularly, this paper will deal with some computational aspects of uncertainty representation by intervals and fuzzy numbers. It will be demonstrated that correct results are obtained in the general case by applying global optimization. It is the author's experience that these aspects are widely neglected, probably due to lack of communication and interaction between professional communities each one advocating either concept.

2 A simple case from managerial economics

In order to demonstrate the principles of numerical modelling of uncertainty by intervals and fuzzy numbers presented in this paper we introduce a simple yet instructive referential case from managerial economics. Consider a company selling one product at price p and quantity q into a market. For the sake of simplicity we may assume fixed cost to be zero. The turnover TR is

$$TR = TR(p,q) = p \cdot q, \tag{1}$$

and the variable cost VC is given by

$$VC = VC(q) = 20 \cdot q. \tag{2}$$

Then the profit π is

$$\pi = \pi(p,q) = TR(p,q) - VC(q) = p \cdot q - 20 \cdot q. \tag{3}$$

We want to find the price p* and quantity q* that gives the maximum profit π^*. It is seen from (3) that the profit is a monotone function of q and p which means that no maximum of π exists unless variables are constrained. If for example $p \leq 65$ and $q \leq 450$, then $p^* = 65$, $q^* = 450$, and $\pi^* = 20.250$.

Next we suppose that price and quantity are interdependent variables due to market conditions. Assuming that they are connected by the demand function

$$p = p(q) = 100 - 0{,}1 \cdot q \tag{4}$$

we get for the turnover

$$TR = TR(p) = -10 \cdot p^2 + 1.000 \cdot p, \tag{5}$$

the variable cost

$$VC = VC(p) = -200 \cdot p + 20.000, \tag{6}$$

and the profit margin

$$\pi = \pi(p) = -10 \cdot p^2 + 1.200 \cdot p - 20.000. \tag{7}$$

The profit of (7) is maximized by the optimality criterion that marginal cost MC be equal to marginal turnover MR which gives the results

ISBN: 978-989-95079-6-8

$$p^* = 60,\ q^* = 400, \text{ and } \pi^* = 16.000. \quad (8)$$

In the following, we shall refer to the above examples for explanations of computational details and special features.

3 Uncertainty modelling using intervals

2.1 Basics of interval analysis

Following Moore [3] and Caprani, Madsen, and Nielsen [6] we define a real interval number as an ordered pair [a; b] of real numbers with $a \le b$. It may also be defined as an ordinary set of real numbers x such that $a \le x \le b$, or

$$[a; b] = \{x \mid a \le x \le b\}. \quad (9)$$

If the basic arithmetic operations addition, subtraction, multiplication, and division are denoted by the symbol #, we can define operations on two intervals $\mathbf{I}_1 = [a_1; b_1]$ and $\mathbf{I}_2 = [a_2; b_2]$ based on the set-theoretic formulation:

$$\mathbf{I}_1 \# \mathbf{I}_2 = \{x \# y \mid a_1 \le x \le b_1,\ a_2 \le y \le b_2\}. \quad (10)$$

For basic operations on the intervals $\mathbf{I}_1$ and $\mathbf{I}_2$ we get the resulting interval $\mathbf{I} = [a; b]$ by the formulas

$$\begin{aligned}
&\mathbf{I} = \mathbf{I}_1 + \mathbf{I}_2 = [a_1+a_2;\ b_1+b_2],\\
&\mathbf{I} = \mathbf{I}_1 - \mathbf{I}_2 = [a_1-b_2;\ b_1-a_2],\\
&\mathbf{I} = \mathbf{I}_1 \cdot \mathbf{I}_2 = [\min(a_1 \cdot a_2,\ a_1 \cdot b_2,\ b_1 \cdot a_2,\ b_1 \cdot b_2);\\
&\qquad \max(a_1 \cdot a_2,\ a_1 \cdot b_2,\ b_1 \cdot a_2,\ b_1 \cdot b_2)], \quad (11)\\
&\mathbf{I} = \mathbf{I}_1 / \mathbf{I}_2 = [\min(a_1/a_2,\ a_1/b_2,\ b_1/a_2,\ b_1/b_2);\\
&\qquad \max(a_1/a_2,\ a_1/b_2,\ b_1/a_2,\ b_1/b_2)],\ 0 \notin [a_2; b_2].
\end{aligned}$$

It can be shown that the four basic interval operations are inclusion monotonic, commutative, and associative. However, the distributive rule is not valid in general. Instead, the so-called sub-distributivity holds, but only for addition and multiplication [6]

$$\mathbf{I}_1 \cdot (\mathbf{I}_2 + \mathbf{I}_3) \subseteq \mathbf{I}_1 \cdot \mathbf{I}_2 + \mathbf{I}_1 \cdot \mathbf{I}_3. \quad (12)$$

From a rational real valued function F of n real valued variables

$$F = F(x_1, x_2, \ldots, x_n) \quad (13)$$

we can create the interval extension function as an interval function $\mathbf{F}^I$ of n intervals

$$\mathbf{F}^I = \mathbf{F}^I(\mathbf{I}_1, \mathbf{I}_2, \ldots, \mathbf{I}_n) \quad (14)$$

simply by replacing the real operators by interval operators and the real variables by intervals.

A rational function can be formulated in many ways whereas the same reformulations cannot be done for interval expressions due to the invalidity of the distributive rule. This implies that different formulations of a rational function will lead to different interval extension functions and thus to different interval results [6]. In the case of F being a monotonic function within the entire range of the input variables the minimum and maximum of $\mathbf{F}^I$ as an interval can simply be found among the function values F at the extreme points of the variables. In the general case of F being non-monotonic or variables appearing more then once, the calculation of $\mathbf{F}^I$ as an interval is non-trivial, which is demonstrated in the following example.

Example: Based on the real valued function $F = x \cdot (1 - x)$ the interval function $\mathbf{F}^I = \mathbf{I} \cdot (1 - \mathbf{I})$, $\mathbf{I} = [0; 1]$ is calculated. Straightforward application of formulas from (11) gives the result $\mathbf{F}^I = [0; 1]$ whereas the correct result is [0; 0,25].

In this paper the term "correct" is used to indicate the narrowest possible interval that can be calculated for an uncertain variable. Generally, to obtain this, iterative global optimization methods have to be used, see e.g. Hansen [7] and Kjøller *et al.* [8]. In order to obtain correct results (as in the above example) to an accuracy specified by the user, interval calculations in this paper are carried out using the Interval Solver 2000 program, Hyvönen and De Pascale [9], [10], as an add-in module to MS-Excel 2000. An overall absolute and relative precision of 10^{-6} has been applied.

Correct calculation of interval functions allows for strong statements about the uncertainties involved. *Firstly*, you can say that provided all uncertain input variables stay within their minimum and maximum values, the uncertain output function will stay within its minimum and maximum values. *Secondly*, the uncertain output function will not attain any value that is not a function value of some combination of the uncertain input values (within their minimum and maximum values).

2.2 Independent and interdependent variables

Independent variables using interval arithmetic

To calculate the uncertain profit we first use the formulas of interval arithmetic (11) by three different ways of calculation. As an example look at the independent and uncertain quantity and price

$$\mathbf{p} = [55; 65],\ \mathbf{q} = [350; 450], \quad (15)$$

Firstly, we use the turnover and variable cost as intermediate variables. By (1) we get for the uncertain turnover **TR** and by (2) for the uncertain variable cost **VC**

$$\begin{aligned}
&\mathbf{TR} = [55; 65] \cdot [350; 450] = [19.250; 29.250],\\
&\mathbf{VC} = 20 \cdot [350; 450] = [7.000; 9.000]. \quad (16)
\end{aligned}$$

Then by (3) we get for the uncertain profit

$$\boldsymbol{\pi} = \mathbf{TR} - \mathbf{VC} = [10.250; 22.250]. \quad (17)$$

However, the above calculation produces a too wide interval (17) for the profit. The reason for this is that in the expression (3) the variable q appears twice thus allowing the quantity q used to calculate **TR** to be different from the quantity used to calculate **VC**.

ISBN: 978-989-95079-6-8

Secondly, the rightmost form of (3) is used, giving

$$\boldsymbol{\pi} = [350; 450]\cdot[55; 65] - 20\cdot[350; 450] = [10.250; 22.250], \quad (18)$$

which is identical to (17) (and thus incorrect) because the arithmetic operations are identical.

Thirdly, (3) is rearranged before the interval calculations are carried out:

$$\pi = \pi(p,q) = q\cdot(p - 20). \quad (19)$$

We then get for the uncertain profit

$$\boldsymbol{\pi} = [350; 450]\cdot([55; 65] - 20) = [350; 450]\cdot[35; 45] = [12.250; 20.250], \quad (20)$$

which is a somewhat narrower interval than (17) and (18) because each variable is appearing only once in (19). Actually, (20) is the correct result. This can easily be verified simply by closer numerical inspection of the profit function (3) for various combinations of the variables p and q. The results are summarised in Table 1.

Independent variables using global optimization

Next, we calculate the uncertain profit by global optimization using Interval Solver 2000. With the same input variables (15) and intermediate variables **TR** and **VC** we get from (3)

$$\mathbf{TR} = [19.250; 29.250],\ \mathbf{VC} = [7.000; 9.000],\ \boldsymbol{\pi} = \mathbf{TR} - \mathbf{VC} = [10.250; 22.250], \quad (21)$$

which is identical to (17) and (18) for the same reason as mentioned above. With the same input variables and by way of formulas (18) and (19) we get the result

$$\mathbf{p} = [55; 65],\ \mathbf{q} = [350; 450],\ \boldsymbol{\pi} = [12.250; 20.250], \quad (22)$$

which is seen to be the correct result identical to (20). The results are summarised in Table 1.

Interdependent variables using interval arithmetic

To perform an uncertainty analysis around a given price p = 60 we set

$$\mathbf{p} = [55; 65]. \quad (23)$$

Obviously, since the quantity variable q can be eliminated by using the demand function (4), the number of variables is reduced from two to one, namely the price. Even in this simple case, as it turns out, the results obtained by interval arithmetic can be dramatically incorrect due to the fact that the profit function is now non-monotonic.

The profit is calculated in two different ways using interval arithmetic (11). *Firstly*, the profit is calculated by

Table 1. Summary of uncertainty analyses, independent price **p** = [55; 65] and quantity **q** = [350; 450]. Correct results shown in *italics*.

Calculation Method	$\boldsymbol{\pi} = \mathbf{TR} - \mathbf{VC}$	$\boldsymbol{\pi} = \mathbf{p}\cdot\mathbf{q} - 20\cdot\mathbf{q}$	$\boldsymbol{\pi} = \mathbf{q}\cdot(\mathbf{p} - 20)$
Interval Arithmetic	[10.250; 22.250]	[10.250; 22.250]	*[12.250; 20.250]*
Global Optimization	[10.250; 22.250]	*[12.250; 20.250]*	*[12.250; 20.250]*

intermediate variables **TR** and **VC** according to (5) and (6), respectively

$$\mathbf{TR} = -10\cdot[55; 65]^2 + 1.000\cdot[55; 65] = [12.750; 34.750] \quad (24)$$

and

$$\mathbf{VC} = -200\cdot[55; 65] + 20.000 = [7.000; 9.000], \quad (25)$$

which gives

$$\boldsymbol{\pi} = \mathbf{TR} - \mathbf{VC} = [3.750; 27.750]. \quad (26)$$

Secondly, the profit is calculated by the above formula

$$\boldsymbol{\pi} = -10\cdot\mathbf{p}^2 + 1.200\cdot\mathbf{p} - 20.000 \quad (27)$$

yielding

$$\boldsymbol{\pi} = -10\cdot[55; 65]^2 + 1.200\cdot[55; 65] - 20.000 = [3.750; 27.750]. \quad (28)$$

The results found above are identical but way out of order, since the correct result of the uncertain profit is [15.750; 16.000]. This is easily verified by closer numerical inspection of (7) with varying p.

Interdependent variables using global optimization

Global optimization is used to calculate the uncertain profit by means of (26) yielding [13.750; 17.750] and (27) yielding [15.750; 16.000]. It may be observed that correct results are produced in the latter case but not in the former, due to usage of intermediate variables **TR** and **VC**, which allows for a too wide resulting interval. The results are shown in Table 2.

Table 2. Summary of uncertainty analyses, interdependent price **p** = [55; 65] and quantity $\mathbf{q} = 1.000 - 10\cdot\mathbf{p}$. Correct result shown in *italics*.

Interval Arithmetic	[3.750; 27.750]	[3.750; 27.750]
Global Optimization	[13.750; 17.750]	*[15.750; 16.000]*

ISBN: 978-989-95079-6-8

The differences in Tables 1 and 2 between correct intervals and the more wide intervals are considerable. When an uncertain variable is appearing more than once, interval arithmetic will usually produce too wide results and global optimization must to be used. With non-monotonic functions, global optimization is necessary. In all cases, intermediate variables should be avoided, since both interval arithmetic and global optimization will produce incorrect results.

4 Uncertainty modelling using fuzzy numbers

4.1 Fuzzy numbers and intervals

A fuzzy set A in X where X is a space of points (objects) with a generic element of X denoted by x, i.e. X = {x}, is characterized by a membership function $f_A(x)$ which associates with each point in X a real number in the interval [0; 1]. The value of the membership function $f_A(x)$ at x represents the "grade of membership" of x in A. Thus the closer the value of $f_A(x)$ to unity, the higher the grade of membership of x in A. Note that when A is an ordinary set, i.e. non-fuzzy, the membership function can take only two values 0 and 1. In other words, a fuzzy set is a set of ordered pairs (x, $f_A(x)$)

$$A = \{(x, f_A(x)) \mid x \in X\}. \tag{34}$$

It is also useful to define the ordinary (non-fuzzy) set A_α as the α-cut of A:

$$A_\alpha = \{x \in X \mid f_A(x) \geq \alpha, 0 \leq \alpha \leq 1\}. \tag{35}$$

In this paper we are mainly interested in the concept of fuzzy numbers as a means of representing uncertain or fuzzy information, Dubois and Prade [11], [12]. In addition to the simplest fuzzy number, namely the interval, we also make use of the triangular fuzzy number, Chiu and Park [13], [a; c; b] where a ≤ c ≤ b, that can be defined by its membership function:

$$\begin{aligned} f(x) &= (x-a)/(c-a), && a \leq x \leq c, \\ &= (b-x)/(b-c), && c \leq x \leq b, \\ &= 0, && \text{otherwise.} \end{aligned} \tag{36}$$

Mathematical operations on triangular fuzzy numbers can be facilitated by introducing the left L(α) and right R(α) representation of a fuzzy triangular number $\mathbf{F}^T$, refer to the α-cut (35):

$$\begin{aligned} &\mathbf{F}^T = [L(\alpha); R(\alpha)], \text{ where} \\ &L(\alpha) = a + (c-a)\alpha \text{ and } R(\alpha) = b + (c-b)\alpha, \\ &\alpha \in [0, 1]. \end{aligned} \tag{37}$$

Observe that in this notation a fuzzy number is written as an interval with upper and lower bounds depending on α. This means that addition, subtraction, multiplication, and division can be carried out by using interval methods for all values of α. Likewise, for any triangular function, the resulting triangular functional values can be calculated and represented by L and R functions using interval methods for all values of α.

Example: Based on the real valued function F = x·(1 – x) calculate the corresponding fuzzy function with triangular argument [0; 0,5; 1]. Correct results have been calculated with global optimization and are shown in Table 3. From the results in Table 3 it can be seen that the function F has a maximum of 0,250 at x = 0,5 corresponding to α = 1. Also note that the R(α) function has been correctly calculated to 0,250 for all values of α.

To obtain simpler representations and reduce the number of calculations, triple and quadruple representations of fuzzy variables corresponding to α-cuts 0 and 1 in (35) may be used. In the above example the result then is [0; 0,25; 0,25], where the extreme function values is obtained by global optimization on the interval [0; 1] and the interior point is obtained by conventional calculation at x = 0,5.

4.2 Simple case with triangular fuzzy numbers

Next we calculate the simple case from Section 2 using profit function (3) with independent triangular fuzzy input parameters **p** = [55; 60; 65], **q** = [350; 400; 450] defined by (36). The resulting membership function is shown in Table 4 for different values of α. It is easily seen that the value α = 0 corresponds to the correct profit interval previously found and α = 1 corresponds to the single point calculation of the profit. This is one of the important features of the triangular fuzzy number representation of uncertainty: It is easily communicated and understood that the ordinary single point calculation is extended to an interval around the single point representing the uncertain value of the input variable. The resulting triangular fuzzy profit is interpreted as follows: With the given uncertain input variables, the most possible value of the profit is 16.000 and profits outside the interval [12.250; 20.250] are impossible.

Calculations have also been carried out with interdependent triangular fuzzy input price parameter corresponding to **p** = [55; 60; 65] and the profit function (7), the results are shown in Table 5. For all values of α the correct maximum profit of 16.000 has been found. No profit values outside the interval [15.750; 16.000] are possible given the uncertain price input variable **p**.

5 A railway reconstruction project

Consider the case of estimating the total cost incurred by a railway reconstruction project described by independent fuzzy input variables, namely 18 cost items $\mathbf{X}_1$,..., $\mathbf{X}_{18}$ and 3 correction factors $\mathbf{X}_{19}$,..., $\mathbf{X}_{21}$. This case has been treated previously by using the concept of imprecise stochastic variables, Schjær-Jacobsen [14]. The correction factors are introduced in order to account for overall influences not accounted for by the individual cost items. The total cost before corrections is the sum

$$\mathbf{Y}_1 = \mathbf{X}_1 + \mathbf{X}_2 + ... + \mathbf{X}_{18}. \quad (38)$$

The total cost after corrections $\mathbf{Y} = \mathbf{Y}(\mathbf{X})$ is a function of all 21 uncertain variables

$$\mathbf{Y} = (\mathbf{X}_1 + \mathbf{X}_2 + ... + \mathbf{X}_{18}) \cdot \mathbf{X}_{19} \cdot \mathbf{X}_{20} \cdot \mathbf{X}_{21}. \quad (39)$$

The uncertain input variables should be estimated by railway experts with relevant project experience. Subsequently, the total cost $\mathbf{Y}$ is calculated by means of global optimization. The total cost estimation results are shown in Table 6 in the case of triangular fuzzy input variables. The term "code" refers to the cost structure hierarchy. For example the item carrying code 0,00 is the sum of cost items at lower levels carrying the codes 0,10, 0,20, and 0,30. Thus the latter are input variables whereas the former is an output variable. The cost item carrying the code 10,00 is an input variable itself because it does not have cost items at lower levels involved. In Table 7 the membership function of total cost $\mathbf{Y}$ after corrections is shown.

For $\alpha = 1$ the single point calculation of 26.565 is shown corresponding to an ordinary calculation without uncertainty. This value is the most possible one and is attained when all input variables are attaining their most possible values. For $\alpha = 0$ the total cost after corrections is within the interval [23.842; 32.930] and any value outside this interval is impossible considering the uncertain input variables.

It should be mentioned here that comparative studies of approaches involving probabilistic methods (including Monte Carlo simulation), trapezoidal fuzzy numbers, and imprecise stochastic variables have been made in [14] and [15] and is further investigated in a research project concerning economic uncertainty in mega projects.

6 Conclusion

In order to calculate correct results with intervals and fuzzy numbers global optimization methods must be implemented in contrast to straightforward application of interval arithmetic. However, the experimental calculations reported in the paper also show that further care should be taken not to introduce intermediate variables, which may also result in excess width intervals. When calculating fuzzy extensions of non-monotonic functions global optimization must be used in order to produce correct results. Otherwise, additional and unnecessary uncertainty will arise eventually leading to wrong decisions.

The results of the paper indicate that correct calculations of intervals (and fuzzy number membership functions) allow for rather strong statements pertaining to economic uncertainties. For example, it can be said that provided all uncertain input variables stay within their limits the uncertain output variables will stay within their limits. Obviously, it is an advantage of the interval and triangular (and trapezoidal) fuzzy representation of uncertainty that the meaning is easily communicated and understood.

A method for locating the iliac crests based on the fuzzy Hough transform

Sergio Jaime-Castillo Juan Miguel Medina Antonio Garrido

Department of Computer Science and Artificial Intelligence, University of Granada
C/ Periodista Daniel Saucedo Aranda s/n, 18071 Granada, Spain
Email: {sjaime,medina,a.garrido}@decsai.ugr.es

Abstract— *In this paper we present a method based on the fuzzy Hough transform to locate the iliac crests in posteroanterior radiographs. Firstly, a Canny edge detector is applied to the X-ray images in order to obtain an edge map. Then, the fuzzy Hough transform is used in combination with several constraints extracted from our domain knowledge. At the bottom of the radiograph we search for two circular arcs, as we can represent the shape of the iliac crests by means of these curves. Locating the iliac crests can be useful for a later processing of the X-rays in order to obtain a fully automated segmentation of the whole spine.*

Keywords— Computer-aided diagnosis, fuzzy Hough transform, medical imaging, X-rays.

1 Introduction

Computer-aided diagnosis is increasing its importance in healthcare. This kind of systems can help physicians to perform routine tasks that require a long training and a great amount of time, and can provide more accurate and consistent measures that may improve the diagnostic process.

Modern medical imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) provide images of high quality which can help physicians enormously in diagnostic process. However, these techniques are usually expensive and give patients high doses of radiation. Therefore, they are not suitable for all diagnoses and, although X-rays do not provide as much quality as the other ones, they are widely used in diagnosis of many diseases.

Much research has been done to segment anatomical structures in CT and MRI. Nevertheless, X-rays have not been as widely studied as the other ones due to its lower quality. In our work we use X-ray images because they are extensively used in diagnosing scoliosis, which is the problem we are focused on.

Scoliosis is a three-dimensional deformation of the spine that produces vertebral rotation and crushing, and lateral curvature. It is typically classified as congenital (caused by vertebral anomalies present at birth), idiopathic (sub-classified as infantile, juvenile, adolescent or adult according to the time when the onset occurred) or as a secondary symptom of another condition, such as cerebral palsy, spinal muscular atrophy or due to a physical trauma.

Diagnosis of scoliosis is performed by calculating Cobb angle ([1]) manually on X-rays. Automatic measure of Cobb angle could improve diagnosis since it can provide more reliable and consistent measures. In order to assess Cobb angle automatically we need to segment the spine accurately and, as we will see afterwards, the proposed method can be useful to do so.

The iliac crest is the long and curved upper border of the wing of the ilium. According to a study performed by Render in [2], the line connecting the iliac crests intersects the spine at the level of the fourth lumbar vertebra or the interspace between the fourth and the fifth lumbar vertebra in 78.5% of cases, while the point of intersection was lower than the fourth lumbar vertebra in 17.8% and at the level of the interspace between the third and the fourth lumbar vertebra in 3.7%. We are interested in locating these anatomical structures as we can use them as a reference to initialise a segmentation algorithm that is intended to segment the whole spine. In the same way, this reference point will be useful to label the vertebrae found by the segmentation algorithm, since we can use the results of Render.

In this work, we have used full-length standing posteroanterior X-rays. The pictures were acquired from a PACS (Picture Archiving and Communication System) as DICOM (Digital Imaging and COmmunication in Medicine) files with 5700×2400 pixels of resolution. The problem with this kind of images is the presence of noise and distortions due to its acquisition process, that makes difficult to detect and identify the anatomical structures present in the X-rays accurately. Other important problems are poor contrast and low visibility of some details in the images. In order to deal with these problems, first of all we have to preprocess the images to obtain new ones with less quantity of noise and, as far as possible, better visibility than the initial ones.

The rest of the paper is organised as follows: in section 2 we describe the foundations and the operation of the fuzzy Hough transform. In section 3 we present our method for locating the iliac crests in posteroanterior radiographs and, in section 4, we discuss the results achieved by it. Finally, in section 5, we comment some aspects of our future work related to this paper.

2 The fuzzy Hough transform

The Hough transform (HT) was originally proposed as a technique to detect straight lines by Hough in 1962 ([3]). It was extended to detect general curves with known analytical expressions by Duda and Hart in [4] and, later, Ballard proposed a new extension in [5] to detect any curve although its expression was not known. In this work we use the fuzzy Hough transform (FHT), another extension of the original algorithm developed by Han *et al.* in [6].

A straight line can be represented as $\rho = x\cos\theta + y\sin\theta$, where θ is the angle of the vector from the origin to the closest point of the line, ρ is the lowest distance between the line and the origin and (x, y) are the coordinates of a point in the image space. In that way, a line is defined by these two parameters ρ

ISBN: 978-989-95079-6-8

and θ. Similarly, a circle and other curves can be represented by its parameters. The main goal of the algorithm is to detect shapes by checking which points in the edge map belong to the curve defined by a certain point in the parameter space. This is done by mapping the image space to the parameter space, where each point defines a different curve. By doing so we simplify the problem to locate a peak in an accumulator array.

In the original HT, the value at a point of the parameter space is the number of points in the image space that occur strictly on the shape defined by this point of the parameter space. There is no difference between a point being far from the ideal line or being just a little off it. Because of this, with the HT is difficult to detect approximate shapes that may appear in noisy environments due to the noise itself, or due to the not accurate edge detection performed by the feature detector. Fuzzy theory can help to deal with the detection of those approximate shapes.

We have assumed that we can represent the shape of the iliac crest by two circular arcs. However, the iliac crest is not exactly a circular arc, although it is close to. Because of this, the results obtained by applying the conventional HT to the X-rays are not accurate, so we propose the use of the FHT in order to achieve better results. In section 4 we make a comparison between both techniques based on the results achieved by them.

The main idea in the FHT is that each edge point contributes more or less to one point in the parameter space depending on its distance from the ideal curve defined by this point. To do this, once the accumulator is computed, Han *et al.* proposed to convolve it with the membership function

$$g(d) = \begin{cases} ke^{-d^2/\sigma^2} & if\ d < R \\ 0 & otherwise \end{cases} . \qquad (1)$$

As they proved, when the membership function of fuzzy points is defined as a circle the transforms of those points lying inside it is bounded in the parameter space by r, which is the radius of that membership function. That is true for straight lines and circles and, as we are considering circular arcs in such a way that they are particular instances of circles with some restrictions, we shall use this smoothing function.

In (1) k, σ and R are constants that are chosen empirically and d is the distance between the two points of the image considered. In our case, they are set as $k = 1$, $R = 3$ and $\sigma = 1.3$ in the experiments.

3 The proposed method to locate the iliac crest

In this section we present our method for automated detection of the iliac crest, based upon the fuzzy Hough transform. The method starts with the acquisition of the X-rays and finishes with the location of the iliac crests. Fig. 1 shows the operation of the method. It involves basically the search for circular arcs at the bottom of the radiograph, where the iliac crests are supposed to be, by means of the FHT.

As we have mentioned beforehand, a preprocessing stage is necessary to deal with noise and distortions present in the images. In this work we have used a combination of unsharp masking (UM), adaptive histogram equalisation and median filter to achieve images more suitable to be analysed by a computer vision system.

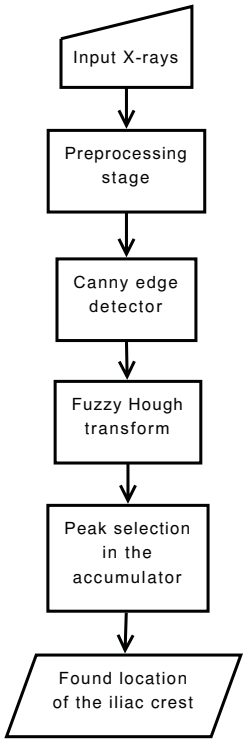

Figure 1: Flowchart of the proposed method to detect the iliac crest

Unsharp masking intends to improve the visibility of images by emphasising smoothed edges while the noise components are suppressed. The effect of the algorithm onto the images is edge sharpening, but usually it tends to reduce its contrast. Because of this, after the unsharp masking procedure we perform adaptive histogram equalisation to enhance it.

In unsharp masking, the high-frequency components of the image are extracted and then are added to the original image. First of all, a slightly blurred version I_{blur} of the image I_{orig} is obtained by convolving it with a Gaussian kernel and then is subtracted from I_{orig} to obtain I_{edge}. After that, I_{edge} is multiplied by a sharpness factor and the result, which contains the enhanced high-frequency components of the image, is then added to I_{orig}.

In our case, the unsharp masking is done by using

$$I_{sharp}(x,y) = I_{orig}(x,y) + 6 \cdot (I_{orig}(x,y) - I_{blur}(x,y)). \quad (2)$$

In (2) $I_{orig}(x,y)$ represents the original image and $I_{blur}(x,y)$ is a blurred version of the original image obtained by convolving $I_{orig}(x,y)$ with a Gaussian kernel of size 5×5 pixels and a variance of 5.

After the unsharp masking, we apply adaptive histogram equalisation to the image in order to enhance the contrast of the resultant image. Adaptive histogram equalisation divides the image into several regions and then distributes pixels values in each region of the image uniformly throughout the grey scale. It is performed in order to achieve a higher contrast for the images by means of the *adaptivehisteq* MATLAB function.

Finally, a median filter of size 11×11 pixels is applied to the image with the *medfilt2* MATLAB function to reduce the presence of impulse noise, naturally present in the X-rays.

ISBN: 978-989-95079-6-8

Once the image has been preprocessed, Canny edge detector is applied to it in order to obtain an edge map that will be used as a starting point for the FHT in the locating procedure. The Canny edge detector is one of the most widely used algorithms among all the features detectors. It was proposed by Canny in [7] in 1986. This method consists of several stages: first of all noise reduction is performed by means of a Gaussian filter; then it computes the gradient in every point of the image and discard those ones whose value is under a certain threshold; next, the pixels whose gradient magnitude is not maximum in the gradient direction are suppressed; finally a hysteresis thresholding is performed by using two thresholds to suppress spurious noisy pixels.

We have used the implementation available in MATLAB by means of the $edge$ function, and we have used the default parameters of the function.

In order to apply the FHT we need to identify the parameters that define the considered curve and the equation that relates them. A circular arc is defined by five parameters: the two coordinates of its centre, its radius, its orientation and its angular size. We could use the generalised Hough transform proposed in [5], but this would imply that we would have to use a five-dimensional accumulator. By doing so, the memory and computational requirements of the algorithm would rise enormously. Nevertheless, if we can fix one or more parameters, the requirements will remain reasonable.

In this case, after studying the characteristics of the iliac crests showed in the X-rays, we can assume that the radius of the circular arcs we use to represent them has to be between fifteen and forty pixels. We can also assume that an appropriate orientation for the circular arc could be 0 rad and a suitable angular size for it could be π rad. These assumptions we have made permit us to simplify the original problem reducing its computational requirements, which is one of the major drawbacks of the Hough transform. Instead of using a five-dimensional accumulator we can use a less computational expensive three-dimensional array.

In this work we have used a parametric representation of the circular arc, which allow us to use the parametric equation of the circle by restricting the permitted values for the parametric coordinate between 0 rad and π rad, instead of between 0 rad and 2π rad that we would use if we were searching for a whole circle. Moreover, the parametric representation facilitates the computation of the positions of the accumulator that have to be incremented. Thus, the equation used to describe the circular arc is

$$\begin{aligned} x(t) &= R \cdot \cos(t) + a \\ y(t) &= R \cdot \sin(t) + b \\ t &\in [0, \pi] \end{aligned} \tag{3}$$

where t is the parametric coordinate, R is the radius of the circular arc and (a, b) are the coordinates of the centre of the arc.

Next, we introduce the formal description of our implementation of the FHT:

1. Set the initial values of the accumulator A to 0.
2. For each edge point (x, y), do:
   (a) For each radius R between 15 and 40 pixels, do:
      i. For every $t \in [0, \pi]$, do:
         A. $a = x - R \cdot \cos(t)$
         B. $b = y - R \cdot \sin(t)$
         C. $A[a, b, R] = A[a, b, R] + 1$
3. Convolve the accumulator A with the smoothing function (1).

At this point we can apply the FHT, as we have just described it, to the edge map obtained in the previous step. By doing so, we get an accumulator array where the maximum values represent the most suitable arcs for the given image. We shall use the one hundred biggest ones of those peaks.

After the use of the FHT, several constraints coming from the domain knowledge are applied to the peaks found in the accumulator array to improve the performance of the algorithm.

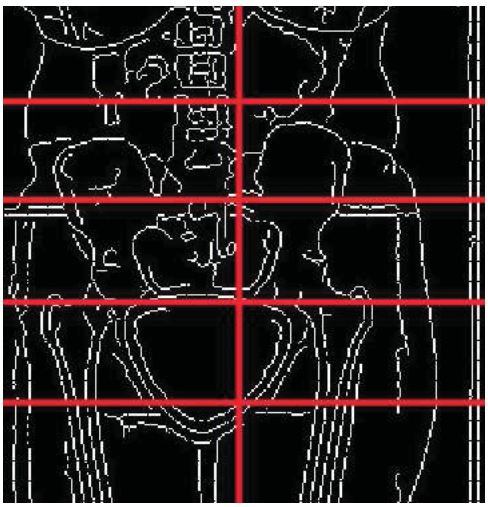

Figure 3: Canny edge map divided into regions to seek local maxima

We divide the lower part of the radiograph into two parts, and we seek the left iliac crest in the left half and the right iliac crest in the right half. Let us consider five regions of equal size within each considered division of the radiograph as we can see in Fig. 3. The search is performed separately in the left and in the right parts of the X-ray. In each region we search for the maximum local peak and record the parameters of the correspondent circular arc. Thus, we have ten local maxima, five for the left part and five for the right part, which represent ten circular arcs that are suitable locations for the iliac crests. We can make twenty five possible couples with those peaks by choosing one from the left and another one from the right.

We can assume that the locations of the left and the right iliac crests are, approximately, at the same height in the X-ray. Let us consider a tolerance factor of 15 pixels. In that case, we can discard those couples of peaks which do not satisfy this criterion. Finally, for the couples of peaks which satisfy the criterion, we add its values and we choose the one with the largest value. Thus, at the end we have a couple of peaks which corresponds to the location of the iliac crests obtained by the method. This process is called "peak selection in the accumulator" in Fig. 1.

We performed several experiments in order to choose the most appropriate values for the tolerance factor and the number of regions in terms of its performance.

(a) Only one iliac crest accurately located

(b) No iliac crest accurately located

Figure 4: Some examples which do not locate accurately the iliac crests

4 Results

In this section we discuss the results achieved by our method. We used a database with 45 X-ray images obtained from a PACS system in a local hospital. The images were in DICOM format with 5700×2400 pixels of resolution. Almost all the images were from patients suffering from scoliosis because we are focused on the study of this pathology by means of digital images. The resolution of the images was reduced to a tenth of its original one to reduce the time of processing before starting the location procedure. Experiments performed with several images suggest us that reduction in image size does not have a significant influence on the accuracy of our method.

It is important to remark that we are not interested in extract the exact shape of the iliac crest, but in the line drawn from the highest point of the left arc to the highest one of the right arc that, as we said beforehand, in an large number of cases will pass through the fourth lumbar vertebra or the interspace between the fourth and the fifth lumbar vertebrae. Therefore, accurate shape delimitation for the iliac crests is not essential.

The experiments we performed showed that in 28 out of 45 cases iliac crests were properly located, while in 3 images

ISBN: 978-989-95079-6-8

the method found the correct location for one iliac crest but failed to locate the another one. In Fig. 2 we can see some of the satisfactorily solved cases after performing the experiments. Moreover, Fig. 4 shows some cases that are not properly solved by our method.

The most important reasons that make our method fails in those cases are two: on the one hand, the presence of distortions in the area of the radiograph were the iliac crest is located, due to the position of the intestines which partially occlude it; on the other hand, the shape of some iliac crests is not completely round and this causes that our method fails because other rounder objects in the image, such as the femur heads, are located. In those cases other constraints should be included in our algorithm.

We also ran the same experiments using the method described here but using the standard HT instead of the FHT. Results obtained were satisfactory in 17 out of 45 images, whereas they were satisfactory for only one iliac crest in 14 out of 45. It is clear then that FHT can achieve better results in those images with a great presence of noise or in which the shapes sought are not clear.

5 Concluding remarks and future work

In this paper we have proposed a method for locating the iliac crests in X-ray images based on the fuzzy Hough transform. We can use the found location of the iliac crests to identify the fourth lumbar vertebra by drawing a line between the two crests and, that will be useful to initialise another algorithm designed to segment the spine. We are still working on improving accuracy and success rate of our method, as well as its efficiency, by incorporating additional constraints into the method.

It is important to remark that results achieved by means of FHT are clearly better than those obtained by standard HT. As shape of iliac crests is largely variable, it is difficult to find them by using a rigid template as HT does. For that reason FHT, which relaxes shape constraints by means of fuzzy logic, is more suitable in this problem.

Abstract— *The use of Linear Matrix Inequalities and Common Quadratic Lyapunov Functions is a powerful and commonplace tool for Takagi-Sugeno fuzzy controlled system analysis and synthesis. However, in practice, few practical and performing results are available when the subsystems exhibit different input matrices, because of the strong coupling between the subsystems/subcontrollers. In this paper, this coupling is demonstrated and a method is proposed which allows to synthesize, for a number of subsystems higher than 2, the local gains of a Parallel Distributed Controller. It is shown that the controller gains depend on the values of the input matrices and of the membership functions, and are thus able to relax classical stability conditions by embedding information on the fuzzy premises.*

Keywords— Fuzzy Control, Takagi-Sugeno Fuzzy Systems, Stability, Parallel Distributed Control.

1 Introduction

T-S fuzzy model is a fuzzy dynamic model which embeds a set of fuzzy rules in order to describe a global nonlinear system as a set of local linear models, these being smoothly connected by fuzzy membership functions [1]. As T-S fuzzy models are equivalent to polytopic linear models, systematic approaches to stability analysis and controller design can be developed using powerful conventional (linear and nonlinear) control theory with the help of optimization techniques such as Linear Matrix Inequalities solvers [2].

Control of T-S fuzzy system is most of the time achieved by the so-called Parallel Distributed Compensation method (PDC) for which the fuzzy controller shares the same fuzzy sets with the fuzzy model in the premise parts, and, thus, each control rule is distributively designed for the corresponding rule of a T-S fuzzy model. Since the consequent parts of T-S fuzzy models are described by linear state equations, linear control theory and corresponding stability tools can be used to design the fuzzy control local gains [3].

Among the mathematical tools used for assessing the stability of a T-S fuzzy system (with or without PDC control), the use of a Common Quadratic Lyapunov Function (CQLF) for all subsystems is the most popular, because it allows to derive easily explicit conditions [2] [4] [5]. It has been noted that Common Quadratic Lyapunov functions tend to be conservative, and even worse, might not exist for many complex highly nonlinear systems. Several works have allowed to relax stability conditions [4] [6] [7], and as an alternative, such tools as piecewise quadratic Lyapunov functions or fuzzy Lyapunov functions have been proposed (e.g. [8]). The drawbacks of these methods lie in the difficulty of synthesizing control gains - and not only analyze closed-loop stability with fixed controllers -, and that the results are quite independent of the membership functions, leading sometimes to poor overall performances. However, extended results have been obtained when considering additional bounds or shapes on membership functions considering linear consequents and PDC [9] [10] or nonlinear / non PDC controllers [11] [12] [13].

In short, there still remains a need for designing further tools to synthesize PDC control for T-S fuzzy systems, which appears to be very difficult when the input matrices of the systems of the fuzzy consequents are not identical or not proportional. In this case, the closed-loop system is not a parallel distribution of the individual closed-loop subsystems, because additional coupling terms appear, as the control gain designed for one subsystem is distributed over the remaining subsystems. Whereas most papers embed the general case, the examples are nearly always proposed for proportional or identical input matrices, or for a very limited number of input matrices.

When input matrices are different, it is not only necessary that all subsystems be stable, but also that any subsystem should be at least stable (or performing) under every other local controller, and, moreover, that all these closed-loop controlled subsystems should share a CQLF. A solution to this problem consists of solving a Riccati equation which has a positive definite solution that corresponds to a Lyapunov function, using some results from linear control theory [14]. In this case, the set of coupling terms is represented by a product of matrices involving a single uncertain matrix with a norm smaller than one, leading to a global Riccati equation [2].
Whereas this method is powerful and depends on the amplitude and variations of the membership functions, finding a global bounding matrix for the coupling terms is often not easy to work out, because these terms depend on the control gains themselves; in the case of control synthesis, when the gains are a priori unknown, this task can be impossible. The cancelation of such coupling terms has been tackled only for large-scale systems [15]. To sum up, practical and membership function-dependent of PDC control synthesis has not yet be performed when subsystems exhibit different input matrices as the explicit cancelation of coupling terms has not been proposed.

In this paper, the closed-loop T-S system under PDC control is rewritten in such a way that the cross-coupled terms are clearly

ISBN: 978-989-95079-6-8

seen as a weighted sum of the pairwise products involving the difference of two input matrices and their corresponding control gains. This allows, first, to determine easily a Riccati equation for each subsystem, which does not depend on the other subsystems control gains, and that takes the variation of fuzzy membership functions into account. Moreover, adding a little more conservativeness, allowing the control gains to be bounded, turns the stability conditions into a set of very simple Lyapunov equations, which might be a good help for control synthesis. Finally, it is shown that, when the number of subsystems is sufficient, the cross-coupled terms can be canceled by proposing nonlinear control gains.

2 Takagi-Sugeno fuzzy model and controller

2.1 Closed-loop model decomposition

The fuzzy model proposed by Takagi and Sugeno consists of a set of r fuzzy IF...THEN rules for which the consequents are linear models:

Plant Rule R_i: IF z_1 IS M_{i1} AND $\cdots$ AND z_g IS M_{ig} THEN $\dot{x} = A_i x + B_i u$;
where $x(t)$, $u(t)$ are state and input vectors, $z_i(t)$, M_{ij} are the premise variables and corresponding fuzzy rules, the final output of the fuzzy system being inferred as follows:

$$\dot{x} = \sum_{i=1}^{r} \mu_i \big(A_i x + B_i u\big), \tag{1}$$

where $\mu_i = \frac{\omega_i}{\sum_{i=1}^{r} \omega_i}$, ω_i is the grade of membership function of rule R_i.

For every subsystem S_i, a local controller can be defined as $u = K_i x$, where K_i is a control gain (possibly nonlinear). It is intuitive to build a fuzzy controller using a set of rules which share the same premises as the fuzzy model, hence distributing the local controllers within the global controllers according to their systems' weights.

Controller C_i: IF z_1 IS M_{i1} AND $\cdots$ AND z_g IS M_{ig} THEN $u = K_i x$, yielding:

$$u = \sum_{i=1}^{r} \mu_i K_i x. \tag{2}$$

Lemma 2.1. *Let the system $\dot{x} = \sum_{i=1}^{r} \mu_i (A_i x + B_i u)$ with PDC control $u = \sum_{i=1}^{r} \mu_i K_i x$ such that $A_i + B_i K_i = G_i$ and $\sum_{i=1}^{r} \mu_i \leq 1$, $\mu_i \geq 0$. The closed-loop system is:*

$$\dot{x} = \left(\sum_{i=1}^{r}\sum_{j=1}^{r} \mu_i \mu_j G_i + \sum_{i=1}^{r} A_i \Big(1 - \sum_{j=1}^{r} \mu_j\Big) + \sum_{i,j=1,j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i) \right) x. \tag{3}$$

Proof. One has

$$\dot{x} = \sum_{i=1}^{r} \mu_i \left(A_i x + B_i \sum_{j=1}^{r} \mu_j K_j x \right)$$
$$= \sum_{i=1}^{r} \mu_i \left(A_i + \mu_i B_i K_i + B_i \sum_{j=1,j\neq i}^{r} \mu_j K_j \right) x.$$
$$\dot{x} = \sum_{i=1}^{r} \left(\mu_i^2 G_i + \mu_i A_i (1 - \mu_i) + \mu_i B_i \sum_{j=1,j\neq i}^{r} \mu_j K_j \right) x.$$

Moreover,

$$\sum_{i=1}^{r} \mu_i B_i \sum_{j=1,j\neq i}^{r} \mu_j K_j = \sum_{i=1}^{r} \sum_{j=1,j\neq i}^{r} \mu_i \mu_j (G_i - A_i) + \sum_{i=1}^{r} \mu_i B_i \sum_{j=1,j\neq i}^{r} \mu_j K_j - \sum_{i=1}^{r} \sum_{j=1,j\neq i}^{r} \mu_i \mu_j B_i K_i.$$

In this equation, one can rearrange the two last sums into a sum of pairwise terms:

$$\sum_{i,j=1,j\neq i}^{r} \mu_j B_j \mu_i K_i + \mu_i B_i \mu_j K_j - \mu_i \mu_j B_i K_i - \mu_j \mu_i B_j K_j = \sum_{i,j=1,j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i).$$

Hence,

$$\sum_{i=1}^{r} \mu_i B_i \sum_{j=1,j\neq i}^{r} \mu_j K_j = \sum_{i=1}^{r} \sum_{j=1,j\neq i}^{r} \mu_i \mu_j (G_i - A_i) + \sum_{i,j=1,j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i).$$

One has now:

$$\dot{x} = \left(\sum_{i=1}^{r} \Big(\mu_i^2 G_i + \mu_i A_i (1 - \mu_i) \Big) + \sum_{i=1}^{r} \sum_{j=1,j\neq i}^{r} \mu_i \mu_j (G_i - A_i) + \sum_{i,j=1,j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i) \right) x.$$

As $\sum_{i=1}^{r} \mu_i^2 G_i + \sum_{i=1}^{r} \sum_{j=1,j\neq i}^{r} \mu_i \mu_j G_i = \sum_{i=1}^{r} \sum_{j=1}^{r} \mu_i \mu_j G_i$, and

$$\sum_{i=1}^{r} \mu_i A_i (1 - \mu_i) - \sum_{i=1}^{r} \sum_{j=1,j\neq i}^{r} \mu_i \mu_j A_i = \sum_{i=1}^{r} \mu_i A_i \Big(1 - \sum_{j=1}^{r} \mu_j\Big).$$

We demonstrate the final result:

$$\dot{x} = \left(\sum_{i=1}^{r}\sum_{j=1}^{r} \mu_i \mu_j G_i + \sum_{i=1}^{r} \mu_i A_i \Big(1 - \sum_{j=1}^{r} \mu_j\Big) + \sum_{i,j=1,j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i) \right) x.$$

□

ISBN: 978-989-95079-6-8

Remark: When $\sum_{i=1}^{r} \mu_i = 1$, formula (3) is reduced to:

$$\dot{x} = \left(\sum_{i=1}^{r} \mu_i G_i + \sum_{i,j=1, j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i) \right) x.$$

2.2 Global Stability Verification

It should be recalled that a Linear Matrix Inequality (LMI) is a set of equations which can be put under the form $F_O + F_1 x_1 + \cdots F_n x_n \prec 0$, where $F_i^T = F_i$. A matrix F is said negative definite, which is noted $F \prec 0$ if $\forall x \neq 0, x^T F x < 0$.
A Bilinear Matrix Inequality involves bilinear terms and cannot be solved in a straightformard way as LMIs are.

Theorem 2.2. *The system $\dot{x} = \sum_{i=1}^{r} \mu_i (A_i x + B_i u)$, under PDC control $u = \sum_{i=1}^{r} \mu_i K_i x$, such that $A_i + B_i K_i = G_i$ and $A_i + B_i K_j = G_{ij}$, is stable if there exists a common positive definite matrix P such that:*

$$\begin{array}{l} \forall\, i = 1 \cdots r, P G_i + G_i^T P \prec 0, \\ \forall\, i < j, P\left(G_{ij} + G_{ji}\right) + \left(G_{ij} + G_{ji}\right)^T P \prec 0. \end{array} \quad (4)$$

Remark: Theorem (2.2) allows the determination of both the Lyapunov matrix and the controller gain, using a change of variable $N_i = K_i P^{-1}$, when being replaced in the stability conditions, leads to a set of LMIs in N_i and in P, the PDC controller being provided by $K_i = N_i P$. The conservativeness of the result comes from several reasons: of course, the global system can be stable without sharing a Common Quadratic Lyapunov function. The conditions are independent of the membership functions, and those roughly mean that system *i* is considered to behave "well" with the corresponding local controller $u = K_i x$, but also with any other local controller $u = K_j x, j \neq i$. Of course, it cannot be expected that a system with a controller designed for another plant has a "good" behavior, and hence, the PDC controller is designed according to the "worst" case among the pairs {Plant *i*, Controller *j*}.

3 Coupling terms attenuation

Theorem 3.1. *[14] First, we consider the linear uncertain system for which $\dot{x} = A + \sum_{i=1}^{r} D_i \delta_i E_i, \|\delta_i\| \leq 1$, and the elements of δ are Lebesgue measurable. Then the positive-definite matrix P is a common Lyapunov matrix for this system if there exists r positive scalars η_i such that:*

$$PA + A^T P + \sum_{i=1}^{r} \eta_i P D_i D_i^T P + \eta_i^- 1 E_i^T E_i \prec 0,$$

or simply, if $\forall i, \eta_i = 1$

$$PA + A^T P + \sum_{i=1}^{r} P D_i D_i^T P + E_i^T E_i \prec 0. \quad (5)$$

Remark: This Theorem was applied first by Tanaka [2] and then by numerous authors to the whole coupling term. Whereas this method provides for a rather non-conservative solution, it is clear that finding individual uncertain matrices might be a tedious task, because the rate of variation and thus the bounds on the uncertain matrix depend on the control gains themselves. It can thus be applied to analyze an existing solution (the gains are fixed) but not for gain synthesis considering models/controllers coupling. The following Theorem proposes a different application of this method to every individual component of the coupling terms.

Theorem 3.2. *Consider the system $\dot{x} = \sum_{i=1}^{r} \mu_i (A_i x + B_i u)$, under PDC controller:*

$$\dot{x} = \left(\sum_{i=1}^{r} \mu_i G_i + \sum_{i,j=1, j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i) \right) x.$$

Let us suppose that: $\forall\, i$, there exists b_i such that:

$$\sum_{j/B_i \neq B_j} \mu_j (B_j - B_i) = b_i \delta_i, \text{ where } \|\delta_i\| \leq 1.$$

The matrices δ_i thus depend on membership functions and other input matrices μ_j and B_j; as μ_j may vary with time, δ_i is a matrix which may vary with time or with the state space x. The corresponding norm is the Euclidean norm.
The closed-loop system is quadratically stable if:

$$\forall\, i = 1 \cdots r, P G_i + G_i^T P + P b_i b_i^T P + K_i^T K_i \prec 0. \quad (6)$$

This can be turned into:

$$\forall\, i = 1 \cdots r, \begin{pmatrix} P G_i + G_i^T P & P b_i & K_i^T \\ b_i^T P & -I & 0 \\ K_i & 0 & -I \end{pmatrix} \prec 0. \quad (7)$$

Proof.

$$\begin{aligned} \dot{x} &= \sum_{i=1}^{r} \left(\mu_i G_i + \sum_{i,j=1, j\neq i}^{r} \mu_i \mu_j (B_i - B_j)(K_j - K_i) \right) x \\ &= \sum_{i=1}^{r} \mu_i \sum_{j=1, j\neq i}^{r} G_i + \mu_j (B_i - B_j) K_i. \end{aligned}$$

One has now: $G_i + \mu_j (B_i - B_j) K_i = G_i + b_i \delta_i K_i$, and one can apply the Theorem (3.1). □

Remark: Uncertain matrices δ_i do not depend anymore on the control gains but only on input matrices and membership functions which are known a priori. Their determination is thus quite easy and the membership functions are indeed embedded in the control synthesis. Note also that the corresponding *i* Riccati equations in (6) are decoupled, i.e. the *i*th equation only depends on the *i*th control gain, the influence of the other subsystems being lumped into the matrix $b_i \delta_i$. However, one can realize that equation (7) is a BMI in P and K_i, and thus less tractable for control gain synthesis, which motivates the following Corollary.

Corollary 3.3. *Let us suppose that:*

$$\forall\, i = 1 \cdots r,\ \exists\, Q_i \succ 0,\ K_i^T K_i - Q_i \prec 0.$$

Then, condition (7) can be expressed as:

$$\exists\, P \prec 0, \forall\, i = 1 \cdots r, P G_i + G_i^T P + Q_i' \prec 0, \quad (8)$$

ISBN: 978-989-95079-6-8

where $Q'_i = Pb_ib_i^TP + Q_i$, *with* $K_i^TK_i - Q_i \prec 0$,
which can be turned into:

$$\forall\, i = 1 \cdots r, \begin{cases} \begin{pmatrix} PG_i + G_i^TP + Q_i & Pb_i \\ b_i^TP & -I \end{pmatrix} \prec 0, \\ K_i^TK_i - Q_i \prec 0. \end{cases}$$

The Corollary simply reduces the search for a common Lyapunov matrix to a series of r Lyapunov equations and thus r LMIs. This is really a drastic improvement to other methods because, now, control gains can nearly be selected independently without the need to taking care of coupling terms, at the expense of a priori gain limitation.

4 Example

Let us take the 3 following systems:

$$A_1 = \begin{pmatrix} -1 & 2 \\ 0 & -2 \end{pmatrix}, B_1 = \begin{pmatrix} 2 \\ 1 \end{pmatrix};$$
$$A_2 = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}, B_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix};$$
$$A_3 = \begin{pmatrix} -2 & 1 \\ 1 & -2 \end{pmatrix}, B_3 = \begin{pmatrix} 1 \\ 0 \end{pmatrix};$$

along with local gains:

$K_1 = (\ 2 \quad 1\ ), K_2 = (\ -2 \quad 1\ ), K_3 = (\ 2 \quad 0\ ).$

The premisses corresponding to systems 1, 2 and 3 are:
$\mu_1 = z$, $\mu_2 = 1 - z$ and $\mu_3 = z$ where $z \in [-1 \cdots 1]$.

For every subsystem i, it is quite easy to compute the matrices b_i such that $\sum_{B_i \neq B_j} \mu_i(B_j - B_i) = b_i\delta_i$, since the upper bound depends on the fuzzy variable z.
One finds:
${b_1}^T = (\ 1 \quad 0.25\ )$, ${b_2}^T = (\ 0.75 \quad 0.25\ )$,
${b_3}^T = (\ 1 \quad 1\ )$.

The application of Theorem (3.2) allows to find a common positive definite matrix $P = \begin{pmatrix} 1.28 & -0.37 \\ -0.37 & 0.87 \end{pmatrix}$ whereas it is impossible to find one by the classical method; it is easy to check that the gain K_2 is unable to stabilize matrix A_1 and the converse for K_1 and A_2. It is quite interesting to note that the result is quite tied to the value of the matrices b_i.
When all other variables keep the same values, but $b_2^T = (\ 1 \quad 1\ )$, then the Theorem (3.2) is no more applicable because a positive definite CQLF cannot be found. Thus, Theorem (3.2) is able to relax stability conditions, depending strongly on the membership functions and input matrices values.

5 Conclusion

In this paper, the stability of a Takagi Sugeno fuzzy system under the Parallel Distributed Compensation controller has been studied. This control strategy allocates the same weight to a local controller that the one in the fuzzy combination of the local submodels.
The influence of the coupling between any local subsystem and any local controller (different from the corresponding local controller designed from the local subsystem considered) in the closed-loop response has been highlighted, and it has been shown to be effective when the input matrices of the subsystems are different. It has been subsequently shown that a controller synthesis based on an analysis of each local subsystem controlled by any local compensator, would lead to conservative results.

A new approach has been proposed which, for every local subsystem, takes the coupling term coming from other subsystems into account, and proposes to choose the gain in order to cope with the effect of the coupling terms. This strategy allows to minimize the number of Linear Matrix Inequalities to be solved for controller synthesis and to take into account the shape of the membership functions.

Abstract— *Lattice-valued up-sets and down-sets of a poset are investigated under the cutworthy approach. It is proved that the collections of all lattice valued up-sets and down-sets of a given poset are complete lattices under fuzzy inclusion. Properties of these are investigated. For a given collection of crisp up-sets of a poset, necessary and sufficient conditions are given under which the family represents a collection of cuts of a lattice valued up-set. The corresponding conditions are also obtained for the analogous case of down-sets.*

Keywords— L-valued sets (L-fuzzy sets), L-valued up-sets, L-valued down-sets.

1 Introduction

Lattice valued sets and structures have been widely studied from Goguen's first paper [1] on this topic, and since Negoita and Ralescu published their book [2] back in 1975. They appear when the membership grades can be represented by elements of an arbitrary partially ordered set L, instead of just by numbers in the unit interval $[0, 1]$. Although a lot of studies have been done for fuzzy order structures (see, e.g., [3, 4, 5, 6] among many others), the relaxation of the requirements allow us to use lattice-valued sets in a wider context, since they can be more appropriate to model natural problems. It turns out that recently this approach to fuzziness attracts more and more interest, in particular when a structure has a residuated or similar lattice as a co-domain. Thus, in the last decade, lattice-valued mathematics have undergone a significant development. This have created bridges between them and algebraic theories, quantales and order-theoretic structures, various subdisciplines of topology and theoretical computer science (see, e.g., [7, 8, 9, 10, 11, 12, 13, 14]).

Due to the importance of up-sets (semi-filters) and down-sets (semi-ideals) in the classical representation theory, the main purpose of this paper is to study the generalization of these concepts for L-valued sets. Fuzzy semi-ideals (down-sets) and semi-filters (up-sets) were investigated in [15], refereing to a particular T-norm, therefore not in the framework of our cutworthy approach. Let us remember that a property generalized to a fuzzy structure is said to be cutworthy if the corresponding crisp property is preserved by the cut-structures. It is known that many properties of relations or algebraic structures are cutworthy if the co-domain of the investigated fuzzy structure is a complete lattice (e.g., properties of equivalence or ordering relations, then subalgebras of algebraic structures etc.). On the other hand, if this co-domain is a lattice with some additional operations like residuation, product etc., then this cutwortheness is not fulfilled. Since our aim is to connect a lattice valued structure with its cut-structures, the co-domain of all fuzzy structures here is a complete lattice, without additional operations.

In the present investigation, we start with a finite poset X and a complete lattice L. Then we introduce L-valued up-sets (semi-filters) and L-valued down-sets (semi-ideals) as isotone and anti-isotone mappings from X to L, respectively. It turns out that the cut-sets of these are precisely crisp up-sets and down-sets on X. Next we investigate collections of all L-valued up-sets and all L-valued down-sets on X. We prove that under the order induced by the one in L, these collections are complete lattices, fulfilling all identities satisfied by the lattice L. Moreover, we analyze the problem of existence of a representation of collections of crisp up-set on X by collections of cut-set of an L-valued up-set on X. We give necessary and sufficient conditions (fulfilled by the lattice L) under which such representation exists.

Our main motivation in this work was to present a mathematical characterization of these algebraic objets, namely semi-filters and semi-ideals, in the fuzzy environment. The justification to consider lattice valued fuzzy sets has been widely explained in the literature, since lattices are more richer structure and we can obtain non-comparable values of fuzzy sets. They can be applied, for instance, in image processing.

The work is structured in 4 sections. In Section 2 we recall the most relevant concepts concerning classical order sets, up-sets and down-sets, as well as lattice-valued sets. In Section 3 we introduce L-valued up-sets and down-sets and we relate these concepts. The first part of this section is devoted to a wide study of the properties and characterizations for L-valued up-sets. In the second part of the section, analogue problems are investigated for L-valued down-sets. In Section 4 we briefly address some conclusions and future work.

2 Preliminaries

In this section, some well-known definitions and preliminary results are recalled. They will be necessary in order to understand the new concepts introduced in this paper and their associated studies.

2.1 Order, up-sets and down-sets

Some necessary notions from the classical order theory are listed in the sequel, together with relevant properties. For more comprehensive presentation, see e.g., books [16, 17].

A **poset** is a nonempty set X equipped with an ordering relation $\leq$. A poset is usually denoted as an ordered pair $(X, \leq)$, or simply by the underlying set X. A sub-poset of $(X, \leq)$ is a poset on a subset Y of X in which the order is the one restricted from X, and usually denoted in the same way ($\leq$). An **up-set** (**semi-filter**) on a poset X is any subposet U, satisfying the following: for $x \in U, y \in X$, $x \leq y$

ISBN: 978-989-95079-6-8

implies $y \in U$. Dually, an **down-set** (**semi-ideal**) on X is any sub-poset D, satisfying: for $x \in D, y \in X$, $y \leq x$ implies $y \in D$. A **lattice** is a poset L in which for each pair of elements x, y there is a greatest lower bound (glb, infimum, meet) and a least upper bound (lub, supremum, join), denoted respectively by $x \wedge y$ and $x \vee y$. These are binary operations on L. A non-empty poset L is said to be a **complete** lattice if infimum and supremum exist for each subset of L. Complete lattice possesses the **top** (1) and the **bottom** element (0). On the other hand, a lattice L is **distributive**, if each operation is distributive with respect to the other. An example of distributive lattices is presented in the following lemma.

Lemma 1 *The collection of all up-sets (down-sets) of a poset X is a distributive lattice under inclusion.*

Given a lattice L, an element a in L is **completely meet-irreducible** if $a \neq 1$ and for every family $\{x_i \mid i \in I\}$ of elements from L, from $a = \bigwedge_{i \in I} x_i$ it follows that $a = x_i$ for some $i \in I$. When L is a lattice of finite length, a is just said to be **meet-irreducible**.

A **closure operator** on a lattice L is a function $C : L \to L$ such that, for all $p, q \in L$, it fulfills the three following requirements:

- $p \leq C(p)$,
- $p \leq q \to C(p) \leq C(q)$,
- $C(C(p)) = C(p)$.

If $p = C(p)$, then p is a **closed element** under the corresponding closure operator.

Lemma 2 *Let C be a closure operator on a lattice L. Then,*

1. *The subset of all closed elements of L is closed under meets in L.*
2. *The top element of L is a closed element under C.*

Lemma 3 *Let L be a complete lattice. Then,*

1. *For any closure operator C on L, the subset of all closed elements of L is a complete lattice under the order inherited from L.*
2. *If F is a subset of L closed under arbitrary meets, then the map such that to any element p in L associates the value $\bigwedge\{q \in F \mid p \leq q\}$ is a closure operator on L.*

By the definition of the supremum and the infimum in a complete lattice, we also have that $\bigwedge \emptyset = 1$ and $\bigvee \emptyset = 0$.

Lemma 4 *Let C be a closure operator on a complete lattice L. If we consider the relation $\sim$ on L defined by $x \sim y$ iff $C(x) = C(y)$, then*

1. *$\sim$ is an equivalence relation on L.*
2. *Each such equivalence class has the top element and this element is closed.*
3. *The set $L/\sim$ (denoted also by L/C) can be ordered: $[x]_\sim \leq [y]_\sim$ iff $C(x) \leq C(y)$ in L.*
4. *The poset $(L/\sim, \leq)$ is a lattice isomorphic with the poset of closed elements of L, under C.*

2.2 Lattice-valued sets

We present some notions from the theory of lattice-valued structures. More details about the relevant properties can be found in [18, 19].

Lattice-valued, **L-valued sets** or **L-fuzzy sets** are here considered to be mappings from a non-empty set X (domain) into a complete lattice L (co-domain) with the top and bottom elements 1 and 0, respectively. This concept can be seen as a generalization of the concept of fuzzy or valued set and it was introduced by Goguen (see [1]).

If $\alpha : X \to L$ is an L-fuzzy set on X then, for $p \in L$, the set

$$\alpha_p := \{x \in X \mid \alpha(x) \geq p\}$$

is called the **p-cut**, a **cut set** or simply a **cut** of α.

Example 1 *Let us consider the poset $(X, \leq)$ and the complete lattice $(L, \leq)$ represented in Figure 1.*

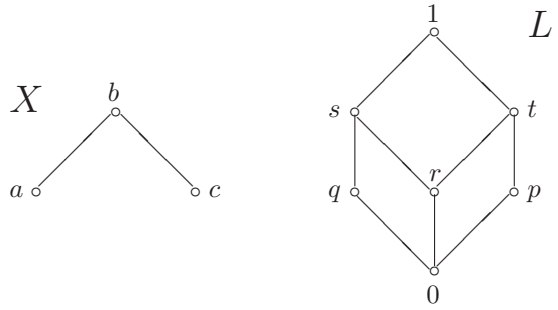

Figure 1: Hasse diagrams of X and L.

Some examples of L-valued sets are

X	a	b	c
α	r	t	p

X	a	b	c
ν	q	s	r

X	a	b	c
μ	r	0	p

X	a	b	c
λ	q	s	t

where we consider a tabular representation for the L-valued sets on X.

In the case of α, for instance, its p-cut is $\alpha_p = \{b, c\}$ and its t-cut is $\alpha_t = \{b\}$.

We can notice that the ordering in X does not have a role in this example. This ordering is used later in the paper.

Some characterizations of the collection of cuts of a lattice-valued set are presented in the next three results.

Proposition 1 *[18] Let $\mathcal{F}$ be a family of subsets of a nonempty set X which is closed under intersections and contains X. Let $\alpha : X \to \mathcal{F}$ be defined by*

$$\alpha(x) = \bigcap(p \in \mathcal{F} \mid x \in p).$$

Then, α is a $\mathcal{F}$-valued set on X with the codomain lattice $(\mathcal{F}, \supseteq)$ such that its family of p-cuts is $\mathcal{F}$ and for every $p \in \mathcal{F}$ it holds that $p = \alpha_p$.

Theorem 1 *[20] Let L be a fixed complete lattice. Necessary and sufficient conditions under which $\mathcal{F} \subseteq \mathcal{P}(X)$ is the collection of cut sets of an L-valued set with domain X are:*

ISBN: 978-989-95079-6-8

1. *$\mathcal{F}$ is closed under arbitrary intersections and contains X,*
2. *The dual poset of $\mathcal{F}$ under inclusion can be embedded into L, such that all infima and the top element are preserved under the embedding.*

Proposition 2 *[21] Let L be a lattice of finite length and let $\alpha : X \to L$ be an L-valued set. Then, all p-cuts of α are distinct if and only if all meet-irreducible elements of L belong to $\alpha(X)$.*

3 L-valued up-sets and down-sets

In classical order theory, the families of up-sets and down-sets, associated to any ordered set, play a central role in the representation theory. Once the L-valued sets are considered, a step forward would be to define and characterize up-sets and down-sets in the L-valued logic. That study is made in this section.

Classical up-sets and down-sets can be seen as sets which are "closed under going up" and "closed under going down", respectively. In fact, a subset is an up-set if and only if its characteristic function is order-preserving. Moreover, a subset is a down-set if and only if its characteristic functions is order-preserving, when the dual of the usual order is considered in $\{0, 1\}$. Thus, a natural generalization of these concepts for L-valued sets is presented in Definition 1.

Definition 1 *Let $(X, \leq)$ be a poset and let $(L, \leq)$[1] be a complete lattice in which 0 and 1 are the bottom and the top element, respectively.*

A function $\alpha : X \to L$ such that for all $x, y \in X$

$$x \leq y \implies \alpha(x) \leq \alpha(y)$$

*is an **L-valued up-set** or an **L-valued semi-filter** on X.*

Dually, a function $\mu : X \to L$ such that for all $x, y \in X$

$$x \leq y \implies \mu(y) \leq \mu(x)$$

*is an **L-valued down-set** or an **L-valued semi-ideal** on X.*

Example 2 *If we consider the L-valued sets introduced in Example 1, α and ν are L-valued up-sets, μ is an L-valued down-set and λ is neither L-valued up-set nor L-valued down-set.*

If $L = \{0, 1\}$, that is, if we are in a two-valued logic, it is immediate that any L-valued up-set is a classical up-set and the same happens for down-sets. Thus, these concepts generalize the classical ones.

The duality between these two concepts is showed in the following proposition, by means of complement operators [22].

Proposition 3 *Let $(X, \leq)$ be a poset and let $(L, \leq)$ be a complete lattice in which 0 and 1 are the bottom and the top element, respectively. If there exists a complement operator c on L, that is, a map $c : L \to L$ fulfilling*

1. *Boundary values: $c(0) = 1$ and $c(1) = 0$;*
2. *Non-increasing: $p \leq q \Rightarrow c(q) \leq c(p), \forall p, q \in L$;*
3. *Involution: $c(c(p)) = p, \forall p \in L$;*

then an L-valued set $\alpha : X \to L$ is an L-valued up-set if and only if, its c-complement α^c is an L-valued down-set, where α^c denotes the L-valued set on X defined by $\alpha^c(x) = c(\alpha(x))$.

3.1 Characterization of the family of L-valued up-sets

In this section we present a wide study of the concept of L-valued up-sets. This study is repeated later, in next section, for L-valued down-sets, due to the duality between these two classes of L-valued sets. Let us start with a characterization of the concept of L-valued up-set by means of α-cuts.

Theorem 2 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice and let α an L-valued set on X. The following two statements are equivalent:*

- *α is an L-valued up-set on X.*
- *The p-cut α_p of α is crisp up-set (semi-filter) on X, for any $p \in L$.*

The proof of this theorem is a immediate consequence of the definitions of p-cut and L-valued up-set.

Example 3 *Let us consider again the L-valued up-set α introduced in Examples 1 and 2. The family of its cuts is formed by the elements*

$$\alpha_0 = X, \alpha_p = \{b, c\}, \alpha_r = \{a, b\}, \alpha_t = \{b\}$$

$$\text{and } \alpha_q = \alpha_s = \alpha_1 = \emptyset.$$

As a consequence of the previous theorem, we know that all these crisp sets are up-sets. Conversely, since all the cuts are crisp up sets on X the previous theorem says that α is an L-valued up-set which is easy to check.

From now on, we denote by $\mathcal{U}_L(X)$ the subset of the L-valued power set of X formed by all L-valued up-sets on the poset X, that is,

$$\mathcal{U}_L(X) = \{\alpha : X \to L \mid \alpha \text{ is an } L\text{-valued up-set}\}.$$

This poset can be ordered naturally using the order induced by the one from the lattice L. Thus, for any $\alpha, \beta \in \mathcal{U}_L(X)$, we say that $\alpha \leq \beta$ if and only if for each $x \in X$ $\alpha(x) \leq \beta(x)$.

Moreover, meet and join exist for any subset of $\mathcal{U}_L(X)$, as it is stated in the following theorem.

Theorem 3 *The poset $(\mathcal{U}_L(X), \leq)$ is a complete lattice.*

In fact, the poset $(\mathcal{U}_L(X), \leq)$ is a complete sublattice of the lattice $(L^X, \leq)$. More specifically, it is a $\{0, 1\}$-complete sublattice with $0(x) = 0$ and $1(x) = 1$, for all $x \in X$.

Due to the definition of the order in $\mathcal{U}_L(X)$, we have the following obvious consequence.

Proposition 4 *If a lattice identity holds in L, then the same identity is satisfied in the lattice $(\mathcal{U}_L(X), \leq)$.*

[1] For simplicity, we consider the same notation for the order in X and in L. Of course these orders do not have to coincide. However, possible ambiguity is removed by the context, so that in any moment we are able to identify order represented by $\leq$.

ISBN: 978-989-95079-6-8

From Proposition 4, if L is e.g., a distributive lattice, then we also have that the lattice $(\mathcal{U}_L(X), \leq)$ is distributive.

Now, we prove a result which allows us to know when, starting from a given collection of crisp up-sets, it is possible to built an L-valued up-set.

Theorem 4 *Let $(X, \leq)$ be a poset, let $\mathcal{F} \subseteq \mathcal{P}(X)$ be a family of some up-sets of a poset X, and let $(L, \leq)$ be a complete lattice. Then, there is an L-valued up-set $\alpha : X \to L$ such that its family of cuts is equal to $\mathcal{F}$ if and only if the following two conditions hold:*

1. *$\mathcal{F}$ is closed under intersections and contains X;*
2. *there is a closure operator C on L, such that the poset $(L/C, \leq)$ is order isomorphic to $(\mathcal{F}, \supseteq)$.*

In the proof of this theorem we have to prove the equivalence among these conditions and the conditions imposed in Theorem 1.

Example 4 *Let us consider again the poset X, the complete lattice L and the L-valued sets α, ν introduced in Example 1. Let $\mathcal{F}$ be the family of up-sets of X defined by*

$$\mathcal{F} = \{X, \{a, b\}, \{b, c\}, \{b\}, \emptyset\}.$$

This family fulfills Conditions 1 and 2 in Theorem 4 and therefore, there exists an L-valued up-set whose family of cuts is equal to $\mathcal{F}$. This L-valued up-set is precisely the L-valued set α. Of course, it does not need to be unique. For instance, also ν is an L-valued up-set with $\mathcal{F}$ as its family of cuts.

In the previous theorem, we have characterized families of up-sets which are the cut-sets of an L-valued up-set. Now, we are going to characterize the L-valued up-set such that this family is formed by all the (crisp) up-sets.

Proposition 5 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice and let $\alpha : X \to L$ be an L-valued up-set. The following two statements are equivalent:*

- *The family of cut sets of α is formed by all the crisp up-sets of poset $(X, \leq)$.*
- *For every family $\{x_i \mid i \in I\}$ of elements from X and every $x \in X$, it holds that*

$$\alpha(x) \geq \bigwedge_{i \in I} \alpha(x_i) \Rightarrow \exists i \in I \mid x \geq x_i.$$

A main step in the proof of the previous proposition is to consider that the $\bigcup_{i \in I} {\uparrow} x_i$ is a crisp up-set of α, where $\{x_i \mid i \in I\}$ is the family of elements from X such that $\alpha(x) \geq \bigwedge_{i \in I} \alpha(x_i)$ for $x \in X$ and $x \not\geq x_i$ for all $i \in I$.

As a consequence of the previous proposition, we obtain two necessary conditions for a representation by means of all the crisp up-sets. They are presented in the two following corollaries.

Corollary 1 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice and let $\alpha : X \to L$ be an L-valued up-set. If the family of cut sets of α is formed by all the crisp up-sets of poset $(X, \leq)$, then α is an order-embedding.*

In the following result it is necessary to consider the subposet L^α of L associated to any L-valued set α on X and generated by taking all infima of all the subsets of $\alpha(X)$ (including infimum of the empty set - the top element of L). Thus, given an L-valued set α on X,

$$L^\alpha = \{p \in L \mid p = \wedge B \text{ with } B \subseteq \alpha(X)\}.$$

Let us note that it is immediate that L^α is a complete lattice.

Corollary 2 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice and let $\alpha : X \to L$ be an L-valued up-set. If the family of cut sets of α is formed by all the crisp up-sets of poset $(X, \leq)$, then $\alpha(x)$ is a completely meet-irreducible element in the lattice L^α for every $x \in X$ with $\alpha(x) \neq 1$.*

In order to illustrate Proposition 5 and Corollaries 1 and 2, we show an example of an L-valued set such that its family of cuts is formed by all the crisp up-sets of its domain.

Example 5 *Let us consider again the L-valued up-set α introduced in Example 1. In Example 4 we have obtained its family of cut sets. It is immediate that this is the family of all up-sets of X. Thus, by Corollaries 1 and 2, we know that α is an order-embedding and $\alpha(x)$ is a completely meet-irreducible element in the lattice $L^\alpha = \{0, p, r, t, 1\}$ for every $x \in X$.*

Now, we suppose that L is a lattice of finite length. Then, combining Proposition 2 and Proposition 5, we obtain the following result.

Theorem 5 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice of finite length and let $\alpha : X \to L$ be an L-valued up-set such that*

1. *α is an bijection to set $M(L)$ of all meet-irreducible elements of lattice L.*
2. *For every family $\{x_i \mid i \in I\}$ of elements from X, if $\alpha(x) \geq \bigwedge_{i \in I} \alpha(x_i)$ for $x \in X$, then $x \geq x_i$, for some $i \in I$.*

Then, the lattice L is isomorphic with the family of all up-sets of the poset X and therefore L is distributive.

Example 6 *Let us consider again the L-valued up-set α introduced in Example 1. Since $\alpha_s = \alpha_q = \emptyset$, it is not true that all its p-cuts are distinct (see Proposition 2) and therefore Condition (1) in the previous theorem does not hold. We can also notice that s is a meet irreducible element in lattice L and it is not a value of the function α. Therefore, we cannot use this example in order to illustrate Theorem 5.*

Let us consider a different poset $(X, \leq)$, a different complete lattice $(L, \leq)$ and a different L-valued up-set α, which are represented in Figure 2.

Given the L-valued set $\alpha : X \to L$, the p-cuts of α are all the up-sets of X:

$$\alpha_0 = \{0, a, b, c, 1\},\ \alpha_n = \{a, b, c, 1\},\ \alpha_p = \{a, b, 1\},$$

$$\alpha_q = \{a, c, 1\},\ \alpha_r = \{b, c, 1\},\ \alpha_s = \{a, 1\}\ \alpha_t = \{b, 1\},$$

$$\alpha_u = \{c, 1\},\ \alpha_v = \{1\},\ \alpha_1 = \emptyset,$$

which are all distinct.

Observe that using the mapping $E(l) = \alpha_l$ for all $l \in L$, that is, if we change l by α_l, the result is the set of all the upsets ordered by $\supseteq$.

ISBN: 978-989-95079-6-8

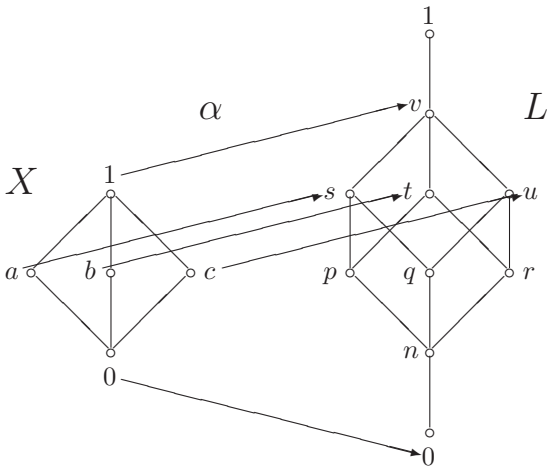

Figure 2: Hasse diagrams of X and L and L-valued set α.

Let us conclude this section with a version of the well-known Birkhoff Representation Theorem: on the one hand, by this theorem, we know that any finite distributive lattice L can be represented by the set of all up-sets on the set of all meet-irreducible elements of L. Now by Theorem 5, we can define an L-valued up-set whose cut sets are order isomorphic to L. Therefore, we can obtain a representation of any distributive lattice as a family of cut-sets of an L-valued up-set. This L-valued up-set is the embedding of $M(L)$ in L, that is, $\alpha : M(L) \to L$ with $\alpha(p) = p, \forall p \in M(L)$.

3.2 Characterization of the family of L-valued down-sets

All the previous studies made for L-valued up-sets could be repeated for L-valued down-sets. By the duality between these two concepts (see, for instance, Proposition 3), the obtained results are totally analogous.

Theorem 6 *Let $(X, \leq)$ be a poset and let $(L, \leq)$ be a complete lattice. A function $\mu : X \to L$ is an L-valued down-set on X if and only if any p-cut μ_p of μ is a crisp down-set (semi-ideal) on X, for every $p \in L$.*

Theorem 7 *Let $(X, \leq)$ be a poset and let $(L, \leq)$ be a complete lattice. If we consider the set $\mathcal{D}_L(X)$ formed by the collection of all L-valued down-sets on X and the induced order on $\mathcal{D}_L(X)$ is defined for any $\mu, \nu \in \mathcal{D}_L(X)$ as follows*

$$\mu \leq \nu \text{ if and only if } \mu(x) \leq \nu(x), \forall x \in X,$$

then the poset $(\mathcal{D}_L(X), \leq)$ is a complete lattice.

Proposition 6 *Let $(X, \leq)$ be a poset and let $(L, \leq)$ be a complete lattice. If a lattice identity holds in L, then the same identity is satisfied in the lattice $(\mathcal{D}_L(X), \leq)$. Thus, for a distributive lattice L, the lattice $(\mathcal{D}_L(X), \leq)$ is also distributive.*

Theorem 8 *Let $(X, \leq)$ be a poset, let $\mathcal{F} \subseteq \mathcal{P}(X)$ be a family of some down-sets of a poset X, and let $(L, \leq)$ be a complete lattice. Then, there is an L-valued down-set $\mu : X \to L$ such that its family of cuts is equal to $\mathcal{F}$ if and only if the following two conditions hold:*

1. *$\mathcal{F}$ is closed under intersections and contains X;*
2. *there is a closure operator C on L, such that the poset $(L/C, \leq)$ is order isomorphic to $(\mathcal{F}, \supseteq)$.*

Proposition 7 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice and let $\mu : X \to L$ be an L-valued down-set. The family of cut sets of μ is formed by all the crisp down-sets of poset $(X, \leq)$ if and only if for every family $\{x_i \mid i \in I\}$ of elements from X the condition $\mu(x) \geq \bigwedge_{i \in I} \mu(x_i)$ for $x \in X$ implies that $x \leq x_i$ for some $i \in I$.*

Corollary 3 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice and let $\mu : X \to L$ be an L-valued down-set. If the family of cut sets of μ is formed by all the crisp down-sets of poset $(X, \leq)$, then the two following statements hold:*

- *μ is an order-embedding.*
- *For any $x \in X$, $\mu(x)$ is a completely meet-irreducible element in the lattice L^{μ}.*

Theorem 9 *Let $(X, \leq)$ be a poset, let $(L, \leq)$ be a complete lattice of finite length and let $\mu : X \to L$ be an L-valued down-set such that*

1. *μ is an bijection to set $M(L)$ of all meet-irreducible elements of lattice L.*
2. *For every family $\{x_i \mid i \in I\}$ of elements from X, if $\mu(x) \geq \bigwedge_{i \in I} \mu(x_i)$ for $x \in X$, then $x \leq x_i$, for some $i \in I$.*

Then, the lattice L is distributive and L is isomorphic with the family of all down-sets of the poset X.

4 Conclusion

In this work, we have carried out an in-depth study of some particular classes of L-valued sets: up-sets and down-sets. We have started with the L-valued up-sets and we have proven that this is a cutworthy property. Moreover, we have established necessary and sufficient conditions under which for a given family of crisp up-sets, there exists an L-valued set such that its collection of cuts coincides with the family of crisp up-sets. In particular, we have done a deeper study for the L-valued up-sets such that its family of cuts is formed by all the crisp up-sets. In the case of lattices of finite length, we have arrived to the Birkhoff Representation Theorem. All these studies have been repeated for the case of L-valued down-sets and analogous results have been obtained.

In future works we would like to obtain some necessary and sufficient conditions not only for the existence of an L-valued up-set (resp. down-set) for a given family of up-sets (resp. down-sets), but for the uniqueness of such L-valued up-set (resp. down-set). The properties under which uniqueness is guaranteed were already studied for general fuzzy sets in [23]. Now, we try to adapt these results in two senses: L-valued sets instead of fuzzy sets (valued in the interval $[0, 1]$) and up-sets (resp. down-sets) instead of any sets.

Abstract—*Topological relations have played important roles in spatial query, analysis and reasoning in Geographic Information Systems (GIS) and spatial databases. The topological relations between crisp and fuzzy spatial objects based upon the 9-intersections topological model have been identified. However the formalization of the topological relations between fuzzy regions needs more investigation. The paper provides a theoretical framework for modelling topological relations between fuzzy regions based upon a new fuzzy topological model called the Fuzzy Intersection and Difference (FID) Model. A novel topological model is formalized based on Fuzzy Topological Space (FTS). In order to derive all fuzzy topological relations between two fuzzy spatial objects, the fuzzy spatial object (A) is decomposed in four components: the Interior, the Interior's Boundary, the Object's Boundary, and the Exterior's Boundary of A. By use of this definition of fuzzy spatial object, new 4*4-Intersection and Fuzzy Intersection and Difference (FID) models are proposed as a qualitative model for the identification of all topological relations between two simple fuzzy regions. These two new models are compared with other fuzzy models studied in the literature. Examples are provided to illustrate the use of these two models presented in this paper with results which can be applied for modeling GIS and geospatial databases.*

Keywords— Fuzzy Intersection and Difference Model, 4*4-Intersection Matrix, Fuzzy Objects, Topological Relations, GIS

1 Introduction

Topological relations have an important significance in GIS modelling since they are the basis for spatial modelling, spatial query, analysis and reasoning. How to identify the topological relations between spatial objects is a critical point in GIS modelling.

During recent years, topological relations have been much investigated in the crisp and fuzzy topological space. The well-known *4-intersection* approach described in [1, 2], as well as the *9-intersection* approach as discussed in [3], and the *Intersection and Difference* (*ID*) model studied in [4, 5, 6], were proposed to formalize topological relations between two simple regions in the *Crisp Topological Space* (*CTS*).

The *4-intersection* model is extended in [7] to deal with the topological relations between spatial objects with holes.

Geographical phenomena in GIS with uncertain boundaries can be modelled by *Regions with Broad Boundaries* (*BBRs*) as in [8]. A region with broad boundary is an extension of a region with a crisp boundary (refer to simple regions with holes as in [7]). Objects with broad boundaries as defined in [8] are spatial objects, whose crisp boundaries are replaced by an area expressing the boundary's uncertainty. The *9-intersection model* is extended in [9] to describe topological relations between *BBRs* by replacing the crisp boundary in the *9-intersection* with the *broad boundary*. Another method called *4-tuple representation* of topological relations between *BBRs* is used in [10] to infer new topological information. The *4-tuple representation* can distinguish the same topological relations as identified by the *extended 9-intersection*. The *4-tuple*, however, can be applied to the reasoning of topological relations between *BBRs* [10], because it uses the composition of topological relations between crisp regions to determine those between uncertain and vague regions.

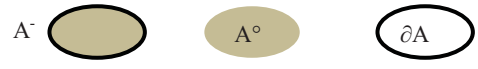
More recently fuzzy spatial objects have been emphasized since there are spatial features which are not always crisp. Fuzzy spatial objects are those with indeterminate boundaries. For fuzzy boundaries, that is, boundaries that are by nature not crisp, the broad boundary represents their minimum and maximum extent.

In order to derive the topological relations between fuzzy spatial objects, the *9-intersection approach* was updated into the *3*3-intersection approach* in the fuzzy topological space [11, 12]. Furthermore, in these two works, a *4*4-intersection matrix* was built up by using the topological properties of fuzzy sets, and then a *5*5-intersection matrix* can be built up based on certain conditions.

In the next section, we compare these models.

2 Related Work about Topological Relation Models and Spatial Objects

Crisp spatial objects have been formally defined in GIS. Point, line and polygon are three primitives in GIS. Fig. 1 represents the closure, interior and boundary of a closed disk as crisp spatial objects [2]. The *4-intersection* and *9-intersection matrix* are well-known approaches to identifying topological relation models between these two crisp spatial objects using the concept of the interior, boundary and exterior.



Closure Interior Boundary

Figure 1: Closure, Interior and Boundary of a Crisp Object

By using some topological invariants of the intersection such as the empty/non empty contents, the topological

ISBN: 978-989-95079-6-8

relations between two crisp spatial objects can be identified. This approach implies the following facts in *CTS*: (1) the interior, boundary and the exterior of a subset are topological invariants; (2) these topological invariants are mutually disjoint in *CTS*; and (3) the empty/non-empty contents of the intersections between these three topological parts of two subsets are topological invariants. Then the *4-intersection* and *9-intersection models* are defined as:

$$I_4(A,B)=\begin{bmatrix} A^\circ \cap B^\circ & A^\circ \cap \partial B \\ \partial A \cap B^\circ & \partial A \cap \partial B \end{bmatrix}$$

$$I_9(A,B)=\begin{bmatrix} A^\circ \cap B^\circ & A^\circ \cap \partial B & A^\circ \cap B^- \\ \partial A \cap B^\circ & \partial A \cap \partial B & \partial A \cap B^- \\ A^- \cap B^\circ & A^- \cap \partial B & A^- \cap B^- \end{bmatrix}$$

Eight topological relations of the spatial reasoning system (Region Connection Calculus) *RCC8* (*DC*, *EC*, *EQ*, *PO*, *TPP*, *TPPi*, *NTPP* and *NTPPi*) have been identified between two simple regions by using these two models in [2, 3].

In *ID model* [4, 5, 6], a crisp spatial object is defined by its interior and boundary; two intersection sets are $A^\circ \cap B^\circ$ and $\partial A \cap \partial B$; two difference sets are A - B and B - A. This model can also distinguish the eight topological relations. This crisp topological model is represented by:

$$ID(A,B)=\begin{bmatrix} A^\circ \cap B^\circ & A-B \\ B-A & \partial A \cap \partial B \end{bmatrix}$$

The main difference between the *4-intersection model* and *ID model* is that both intersection sets $A^\circ \cap \partial B$ and $\partial A \cap B^\circ$ of 4-intersection model are replaced by two differences A - B and B - A.

However, the fact (2) in CTS cannot hold in Fuzzy Topological Space (FTS). That means the interior; the boundary and the exterior of a fuzzy set may not be disjoint with each other. Therefore the *4-intersection, 9-intersection* and *ID models* cannot be directly applied for the identification of relations between two fuzzy sets.

The *9-intersection model* is extended in [8, 9] to spatial objects with broad boundary as simple fuzzy regions. It's expressed by the following matrix:

$$M = I_9(A,B)=\begin{bmatrix} A^\circ \cap B^\circ & A^\circ \cap \Delta B & A^\circ \cap B^- \\ \Delta A \cap B^\circ & \Delta A \cap \Delta B & \Delta A \cap B^- \\ A^- \cap B^\circ & A^- \cap \Delta B & A^- \cap B^- \end{bmatrix}$$

Using this model, *44 relations* between two simple fuzzy regions by using the *3*3-intersection matrix* are possible. For composite regions with broad boundaries, there are *14 additional* topological relations [8]. Fig. 2 represents a region with broad boundary as simple fuzzy spatial object.

Figure 2: Region with a Broad Boundary

In [14], they investigated a special space and formalized the 9-intersection in *Crisp FTS*. They proved that the *Crisp FTS* whose open sets are crisp is able to meet the above conditions.

The *9-intersection matrix* can be formalized as:

$$I_9(A,B)=\begin{bmatrix} A^\circ \cap B^\circ & A^\circ \cap \partial B & A^\circ \cap B^e \\ \partial A \cap B^\circ & \partial A \cap \partial B & \partial A \cap B^e \\ A^e \cap B^\circ & A^e \cap \partial B & A^e \cap B^e \end{bmatrix}$$

The above *3*3-intersection matrix* is derived based on the interior, boundary, and exterior of a simple fuzzy spatial object. By use of *9-intersection matrix*, *44 topological relations* are identified between two simple fuzzy regions (See Appendix 1. in [14]). Fig. 3 represents a region with indeterminate boundary as simple fuzzy spatial object.

Figure 3: Two Fuzzy Spatial Objects

In [14], it was shown that fuzzy spatial objects can be decomposed into four parts: the interior, the boundary of the boundary $\partial(\partial A)$, the interior of the boundary $(\partial A)^\circ$ and the exterior, which are mutually disjoint as in Fig. 4.

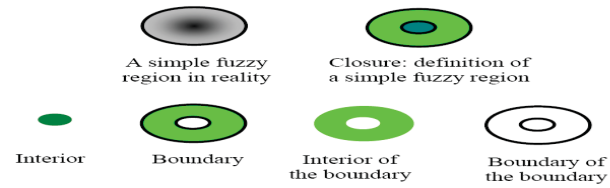


Figure 4: Interior, Boundary, Interior of the Boundary and Boundary of the Boundary of a Simple Fuzzy Region (After X. Tang and W. Kainz in [14])

Therefore, they introduced a *4*4-Intersection matrix* between two simple fuzzy spatial objects as follows:

$$I_{4*4}=\begin{bmatrix} A^\circ \cap B^\circ & A^\circ \cap \partial B & A^\circ \cap (\partial B)^\circ & A^\circ \cap B^e \\ \partial(\partial A) \cap B^\circ & \partial(\partial A) \cap \partial B & \partial(\partial A) \cap (\partial B)^\circ & \partial(\partial A) \cap B^e \\ (\partial A)^\circ \cap B^\circ & (\partial A)^\circ \cap \partial B & (\partial A)^\circ \cap (\partial B)^\circ & (\partial A)^\circ \cap B^e \\ A^e \cap B^\circ & A^e \cap \partial B & A^e \cap (\partial B)^\circ & A^e \cap B^e \end{bmatrix}$$

Under certain conditions, *152 relations* are identified by using the *4*4-intersection* approach (See Appendix 2. in [14] for more details).

After investigation about the topological relations between two simple fuzzy regions compared with these models studied in the literature, we can see that some topological relations can't be identified by these models. Here are some relations presented in Fig. 5.

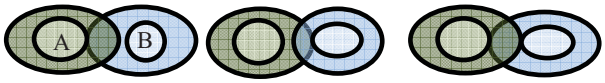

Figure 5: Some of Topological Relations to Identify

The question is how many topological relations there are exactly between two simple fuzzy objects? To answer this question, we will extend the *4-intersection* and the *ID models* with a new definition of the fuzzy boundary for fuzzy regions.

The disadvantage of the *3*3-intersection* and *4*4-intersection* models is that the *intersection operator* ($\cap$) is the most expensive one in terms of computation. In order to reduce the computational cost of the *3*3-intersection* and *4*4-intersection* models; and to reduce the computational complexity by avoiding spatial operations between

ISBN: 978-989-95079-6-8

topological components with different dimensions (1-D and 2-D), we will try to reduce the number of intersections by introducing the *difference operator* (-).

Finally, the motivation of the paper is trying to build a topological model for identification of all fuzzy topological relations between two fuzzy regions.

The structure of the paper is as follows. The fuzzy topological space is defined in section 3. Section 4 is our contribution which consists of a new definition of simple fuzzy regions, fuzzy boundaries and their properties. The novel major contribution of our study, proposed in section 5, is a new form of *4*4- intersection model* and *the Fuzzy Intersection and Difference (FID) model*. Section 6 shows the identification of fuzzy topological relations between two simple fuzzy regions by using two models (*4*4- intersection and FID*) based on empty/non-empty contents. We end with a discussion about results and a conclusion.

3 Fuzzy Topological Space (FTS)

Fuzzy topology is constructed based on fuzzy sets. It is an extension of general (crisp) topology.

Let A be a fuzzy subset of an ordinary (crisp) set X, and $\wp(X)=[0,1]^X$ be the fuzzy power set of X. $[0,1]^X$ can be viewed as a lattice in which a supremum (or *join*) is denoted by $\vee$ and an infimum (or *meet*) by $\wedge$, conventionally. They correspond to the *union* and the *intersection*, respectively. $\forall\delta\in\wp(X)$ if $(1)\,\Phi, X\subseteq\delta$, $(2)\,\forall A_i\in\delta,\ \vee A_i\in\delta,(3)$ $\forall U,V\in\delta,\ U\wedge V\in\delta$, then δ is called a *fuzzy topology* on *X* (*i*∈*I* is an index set). (*X, δ*) is called a *Fuzzy Topological Space (FTS)* as defined in [15, 16]. Every element of δ is called an open (fuzzy) set in (X, δ). A set A is a closed (fuzzy) set if its complement A^c is open. The union of all open sets contained in A is the interior of A, denoted by A°. The intersection of all closed sets containing A is called the closure of A, denoted by A^-. The exterior of A is the complement of A^- and is denoted by A^e. Obviously, it is an open set. The boundary ∂A of a subset A is the intersection of the closure of A with the closure of the complement of A.

The boundary of a subset may also have its interior and its boundary of the boundary. On the other hand, the interior and the closure of a subset also have their boundaries. For example, the boundary of the boundary of a fuzzy set A is the union of the boundary of the closure and the boundary of the interior of a fuzzy set [14].

Based on this information, one can define a maximum of four other different areas from that defined in [14] for each object: Interior, Boundary of the Object, Interior of the Boundary, and Exterior of the Boundary in the next section.

4 Definition of Simple Fuzzy Regions and a Fuzzy Boundary

In this section, we will develop a definition of simple fuzzy region, fuzzy boundary and their properties.

4.1 Definition of Simple Fuzzy Region

A crisp region is defined in *CTS*. Correspondingly, a fuzzy region should be defined in *FTS*. We now define a simple fuzzy region in *FTS*.

A simple fuzzy region is made up of two regions A_1 and A_2 with $A_1\subset A_2$ (see Fig. 6), where: (1) the interior of A is the interior of A_1 $A^\circ=(A_1)^\circ$ and A° is an open subset and connected; (2) the interior's boundary of A is the boundary of A_1 as $A^i=\partial(A^\circ)=\partial A_1$, and A^i is a closed subset and connected; (3) the boundary of A is ∂A defined as the interior of the difference between A_1 and A_2 as $\partial A=(A_2-A_1)^\circ$, and ∂A is an open subset and connected; (4) the exterior's boundary of A is the boundary of ∂A_2 as $A^e=\partial^e(\partial A)=\partial A_2$, and A^e is a closed subset and connected; and (5) the intersection of all closed sets containing A is called the closure of A, denoted by A^-. Fig. 6 shows the four components of simple fuzzy regions.

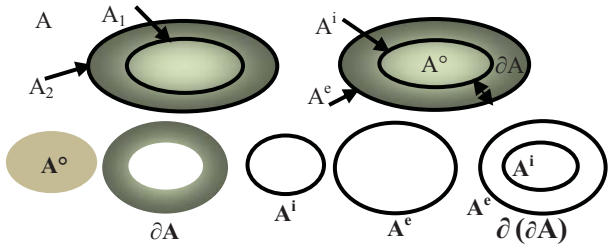

Figure 6: Interior, Boundary, Interior's Boundary, and Exterior's Boundary of a Simple Fuzzy Region

This definition is considered as the de decomposition of the boundary in [14, 15, 16] into disjoint subsets such as the interior boundary of the boundary, the exterior boundary of the boundary and the interior of the boundary with condition that is the interior of the boundary couldn't be a non-empty set.

We called the boundary (∂A) of A by the fuzzy boundary. This definition of fuzzy regions is very interesting to identify all topological relations between two simple fuzzy regions that other models [8, 9, 14] can't identify. We will prove that in the next section by developing a *4*4-intersection* matrix. In the next part, we will define the properties of the fuzzy boundary.

4.2 Properties of Fuzzy Boundary

Let A be a fuzzy set in *FTS* (X, δ). Based on the definition of simple fuzzy regions, we find the properties of the fuzzy boundary (∂A) as follows: (1) ∂A is an open subset of A; (2) ∂A = ¬ Ø is a non-empty subset; (3) the boundary of A (∂A) is the interior of the difference $\partial A=(A^e-A^i)^\circ$ between the exterior's boundary (A^e) and the interior's boundary (A^i) of A; (4) the union $A^i\cup\partial A\cup A^e$ of the interior's boundary (A^i), the boundary (∂A) and the exterior's boundary (A^e) of A is a closed subset of A; (5) the interior boundary of the boundary (∂A) of A $\partial^i(\partial A)=A^i=\partial(A^\circ)$ is the interior's boundary (A^i); and (6) the exterior boundary of the boundary (∂A) of A $\partial^e(\partial A)=A^e=\partial^e(A)$ is the exterior's boundary (A^e).

We also find that the intersections between A^o, A^i, ∂A, A^e are, respectively, always empty, and the union of these parts

ISBN: 978-989-95079-6-8

is equal to A as follows: $A^{\circ} \cap A^{i} = \emptyset$; $A^{i} \cap \partial A = \emptyset$; $\partial A \cap A^{e} = \emptyset$; $A^{\circ} \cap A^{i} \cap \partial A \cap A^{e} = \emptyset$; and $A^{\circ} \cup A^{i} \cup \partial A \cup A^{e} = A$.

It also can be easily proven by the above intersections that the interior (A^{o}), the interior's boundary (A^{i}), the boundary ∂A and the exterior's boundary (A^{e}) of a simple fuzzy region (A) are mutually disjoint.

In order to identify all possible topological relations, the condition of the mutual disjointness of these four parts of simple fuzzy regions is important to propose and construct a new method to form the intersection matrix. In the next section, a new *4*4-intersection matrix* and *fuzzy intersection and difference model* are proposed based upon this definition of simple fuzzy region.

5 Contributions: 4*4 - Intersection and Fuzzy Intersection and Difference (FID) Models

In this section, we will develop two models to identify the topological relations between two simple fuzzy regions.

Supposing there are two simple fuzzy objects A and B in the *FTS*, we adopt the interior, boundary, interior's boundary, and exterior's boundary to formalize two new topological models as in the next.

*5.1 Contribution 1: 4*4 - Intersection Model*

In the first contribution, the first model is a new *4*4 - intersection matrix* which uses the operator (∩) of intersection. Between these two simple fuzzy spatial regions A and B, the *4*4-intersection matrix* will be as presented in Table 1:

Table 1: 4*4 - Intersection Matrix

∩	B°	B^{i}	∂B	B^{e}
A°	A°∩ B°	A°∩ B^{i}	A°∩ ∂B	A°∩ B^{e}
A^{i}	A^{i} ∩B°	A^{i} ∩ B^{i}	A^{i} ∩∂B	A^{i} ∩ B^{e}
∂A	∂A ∩B°	∂A ∩ B^{i}	∂A ∩∂B	∂A ∩ B^{e}
A^{e}	A^{e} ∩B°	A^{e} ∩ B^{i}	A^{e} ∩ ∂B	A^{e} ∩ B^{e}

And the *4*4-inetrsection model* applied to simple fuzzy objects is expressed by the following expression:

$$I_{4*4}(A,B) = \begin{bmatrix} A^{\circ} \cap B^{\circ} & A^{\circ} \cap B^{i} & A^{\circ} \cap \partial B & A^{\circ} \cap B^{e} \\ A^{i} \cap B^{\circ} & A^{i} \cap B^{i} & A^{i} \cap \partial B & A^{i} \cap B^{e} \\ \partial A \cap B^{\circ} & \partial A \cap B^{i} & \partial A \cap \partial B & \partial A \cap B^{e} \\ A^{e} \cap B^{\circ} & A^{e} \cap B^{i} & A^{e} \cap \partial B & A^{e} \cap B^{e} \end{bmatrix}$$

This new *4*4- intersection matrix* (I_{4*4}) is considered as an extension of the *4-intersection* model [1, 2] for simple fuzzy spatial regions.

The *intersection operator* (∩) is perhaps the most expensive one in terms of computation. In order to reduce the computational cost of this *4*4-intersection* model, we will extend this model to the fuzzy intersection and difference model in the next part.

5.2 Contribution 2: Fuzzy Intersection and Difference (FID) Model

In this model, we will introduce the *difference operator* (-). In order to avoid spatial operations between topological components with different dimensions (A°, B°, ∂A, ∂B as 2-D; and A^{i}, B^{i}, A^{e}, B^{e} as 1-D), we will replace the intersection between the terms A°∩ B^{i}, A°∩ B^{e}, A^{i} ∩B°, A^{i} ∩∂B, ∂A ∩ B^{i}, ∂A ∩ B^{e}, A^{e} ∩B° and A^{e} ∩ ∂B in the *4*4-intersection* model by the differences as in the matrix (see Table 2).

The four intersections (A°∩B°, A°∩∂B, ∂A∩B°, ∂A∩∂B) with topological components with dimension 2-D and the four intersections (A^{i}∩B^{i}, A^{i}∩B^{e}, A^{e}∩B^{i}, A^{e}∩B^{e}) with topological components with dimension 1-D remain unchanged as similar as in [4, 5, 6] for the ID model.

Table 2: 4*4 - Intersection and Difference Matrix

∩	B°	B^{i}	∂B	B^{e}	-
A°	A°∩ B°	A^{i} - B^{i}	A°∩ ∂B	A^{i} - B^{e}	A°
A^{i}	B^{i} - A^{i}	A^{i} ∩ B^{i}	B^{i} - A^{i}	A^{i} ∩ B^{e}	A^{i}
∂A	∂A ∩B°	A^{e} - B^{i}	B^{e} – A^{i} ∂A ∩∂B	A^{e} - B^{e}	∂A
A^{e}	B^{i} - A^{e}	A^{i} - B^{i} A^{e} ∩ B^{i}	B^{i} – A^{e} B^{e} - A^{e}	A^{i} - B^{e} A^{e} ∩ B^{e}	A^{e}

By simplification and arrangement of this *4*4 - Intersection and Difference matrix*, we obtain two intersection matrices and two difference matrices (Table 3):

Table 3: Intersection and Difference Matrices

∩	B°	∂B
A°	A°∩ B°	A°∩ ∂B
∂A	∂A ∩B°	∂A ∩∂B

∩	B^{i}	B^{e}
A^{i}	A^{i}∩ B^{i}	A^{i}∩ B^{e}
A^{e}	A^{e} ∩ B^{i}	A^{e} ∩ B^{e}

-	B^{i}	B^{e}
A^{i}	A^{i} - B^{i}	A^{i} - B^{e}
A^{e}	A^{e} - B^{i}	A^{e} - B^{e}

-	A^{i}	A^{e}
B^{i}	B^{i} - A^{i}	B^{i} - A^{e}
B^{e}	B^{e} - A^{i}	B^{e} - A^{e}

At the end, the *Fuzzy Intersection and Difference (FID) model* is written as follows:

$$FID_{4*4}(A,B) = \begin{bmatrix} A^{\circ} \cap B^{\circ} & A^{\circ} \cap \partial B & A^{i} - B^{i} & A^{i} - B^{e} \\ \partial A \cap B^{\circ} & \partial A \cap \partial B & A^{e} - B^{i} & A^{e} - B^{e} \\ A^{i} \cap B^{i} & A^{i} \cap B^{e} & B^{i} - A^{i} & B^{i} - A^{e} \\ A^{e} \cap B^{i} & A^{e} \cap B^{e} & B^{e} - A^{i} & B^{e} - A^{e} \end{bmatrix}$$

The *FID* model combines two different operators (intersection and difference). The *FID* has two advantages: first, it reduces the computational complexity by avoiding spatial operations between topological components with different dimensions, e.g., A°∩ B^{i}, A°∩ B^{e}, A^{i} ∩B°, A^{i} ∩∂B, ∂A ∩ B^{i}, ∂A ∩ B^{e}, A^{e} ∩B° and A^{e} ∩ ∂B, with A°, B°, ∂A, ∂B as 2-D, and A^{i}, B^{i}, A^{e}, B^{e} as 1-D; and second, it reduces the computational cost due to only eight intersections in the matrix of *FID* model.

This *FID* model is considered as an extension of the *ID* model [4, 5, 6] for simple fuzzy spatial regions.

In general, there are 2^{16}= 65536 relations between two fuzzy regions by using the *4*4-intersection* matrix and *FID* model. For GIS applications, some conditions will limit the number of these relations as in [7, 8, 14]. However, how to find all possible topological relations between two simple fuzzy regions needs more investigation. It's done in the next section for the *4*4-intersection* matrix and *FID* model.

ISBN: 978-989-95079-6-8

6 Identification of Topological Relations based upon 4*4 - Intersection and FID Models

In this section, we focus on the identification of all fuzzy topological relations between two simple fuzzy regions by *4*4-intersection* and *FID* models.

Let A and B be two simple fuzzy regions. For relation identification, each intersection or difference in *4*4-intersection* and *FID matrices* takes value of either empty ($\emptyset$) or non-empty ($\neg\emptyset$). Every different set of *4*4-intersection* and *FID* matrices describes a different topological relation. Some values of these two matrices have no sense on the topological relation.

*6.1 Identification by 4*4 - Intersection Model*

For identification by *4*4-intersection model*, by respecting the definition in section 3, we scan all possible configurations for A and B in two different steps as following: (1) If the exterior's boundary of A intersects with the exterior's boundary of B ($A^e \cap B^e = \neg\emptyset$), then, we search all possible topological relations between A and B, we find *105 relations*; (2) If the exterior's boundary of A doesn't intersect with the exterior's boundary of B ($A^e \cap B^e = \emptyset$), then, we search all topological relations between A and B, we find *47 relations*. The total number of topological relations identified between A and B is *152 relations*. Some of these topological relations are not identified and determined in [8, 9, 14]. Here are some examples in Fig .7 and Fig .8.

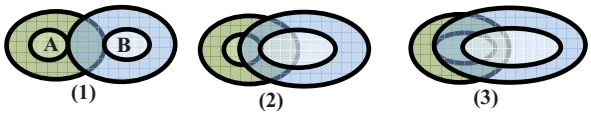

Figure 7: Examples for $A^e \cap B^e = \neg\emptyset$

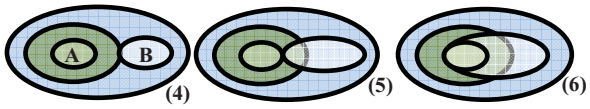

Figure 8: Examples for $A^e \cap B^e = \emptyset$

The *4*4-intersection matrices* correspondent for (1), (2) and (3) in Fig .7, and for (4), (5) and (6) in Fig .8 are given, respectively, by:

$$(1)\begin{bmatrix}\phi & \phi & \phi & \phi\\ \phi & \phi & \phi & \neg\phi\\ \phi & \phi & \neg\phi & \neg\phi\\ \phi & \neg\phi & \neg\phi & \neg\phi\end{bmatrix}\ (2)\begin{bmatrix}\phi & \phi & \neg\phi & \neg\phi\\ \phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\end{bmatrix}\ (3)\begin{bmatrix}\neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\end{bmatrix}$$

$$(4)\begin{bmatrix}\phi & \phi & \neg\phi & \phi\\ \phi & \phi & \neg\phi & \phi\\ \phi & \phi & \neg\phi & \phi\\ \phi & \neg\phi & \neg\phi & \phi\end{bmatrix}\ (5)\begin{bmatrix}\phi & \phi & \neg\phi & \phi\\ \phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\end{bmatrix}\ (6)\begin{bmatrix}\neg\phi & \phi & \phi & \phi\\ \neg\phi & \neg\phi & \phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\end{bmatrix}$$

We note that the separateness between these relations can't be realized by other models studied in [8, 14]. In the next part, we will identify all relations by the *FID model*.

6.2 Identification by FID Model

For identification by *FID model*, by respecting the definition in section 3, we apply the same two steps in previous part (6.1) for $A^e \cap B^e = \neg\emptyset$ and $A^e \cap B^e = \emptyset$. 152 topological relations can be identified by using the *FID model*. These relations identified by *FID model* is the same relations by *4*4-intersection model*. We give some examples in Fig .9 and Fig .10.

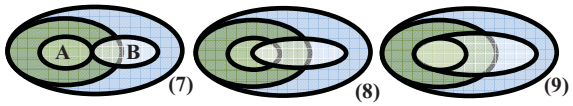

Figure 9: Examples for $A^e \cap B^e = \neg\emptyset$

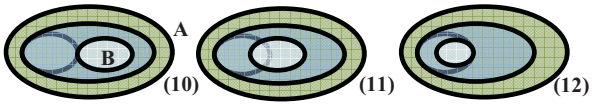

Figure 10: Examples for $A^e \cap B^e = \emptyset$

The *FID* matrices correspondent to (7), (8) and (9) in Fig .9, and to (10), (11) and (12) in Fig .10 are given, respectively, by:

$$(7)\begin{bmatrix}\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\end{bmatrix}\ (8)\begin{bmatrix}\neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\end{bmatrix}\ (9)\begin{bmatrix}\neg\phi & \phi & \phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\end{bmatrix}$$

$$(10)\begin{bmatrix}\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \phi & \phi & \neg\phi & \phi\end{bmatrix}\ (11)\begin{bmatrix}\neg\phi & \neg\phi & \neg\phi & \phi\\ \neg\phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \neg\phi & \phi\\ \phi & \phi & \neg\phi & \phi\end{bmatrix}\ (12)\begin{bmatrix}\neg\phi & \neg\phi & \neg\phi & \phi\\ \phi & \neg\phi & \neg\phi & \neg\phi\\ \neg\phi & \neg\phi & \phi & \phi\\ \phi & \phi & \neg\phi & \phi\end{bmatrix}$$

To find and extract these relations by the *4*4-intersection* and *FID models*, we have developed and implemented these two steps on MATLAB.

7 Applications and Discussion

For GIS applications, satellite images and spatial databases, these two models (*4*4-intersection* and *FID*) can determine the topological relations between simple fuzzy regions. For that, we need to know how to generate fuzzy spatial objects from satellite images and to find the four components of our definition (interior, interior's boundary, boundary and exterior's boundary) for satellite images and GIS objects. We can adopt processed data such as classification or segmentation results of satellite images. For example, Land Use and Land Cover (LULC), most of which is obtained from the classification results of satellite images, may be a good example of a fuzzy spatial object as in [17]. In principle, a fuzzy spatial object can also be generated by other methods as in [14, 18].

These two models can be used in order to evaluate the change detection process (for Land Cover changes)of geographical objects (Beach, Forest, Residential Area…) represented in GIS and satellite imagery (TM and SPOT images) databases as in [14, 17, 19, 20].

Comparing between the relations identified in [8, 9, 14] and our models (*4*4-intersection and FID*), we find that there are *100 new relations* which can't be discriminated and identified by other models. Some of these *100 new topological relations* identified by *4*4-intersection and FID* models are presented in the appendix of this paper.

8 Conclusion

In this paper, we have proposed a new definition of simple fuzzy spatial region by decomposing the spatial region into

ISBN: 978-989-95079-6-8

four components: interior, interior's boundary, boundary and exterior's boundary. Based upon these four components, a *4*4-intersection matrix* is introduced to identify all topological relations between two simple fuzzy regions. Then, in order to reduce the computational complexity of the *4*4-intersection model,* the *Fuzzy Intersection and Difference (FID) model* is developed based on the *4*4-intersection matrix*. The main contribution of this work is these two models *4*4-intersection and FID. 152* fuzzy topological relations can be identified by using the *4*4-intersection and FID models*. Among these *152 relations*, *100 new relations* can't be discriminated or identified as different relations by other models [8, 9, 14].

In our future work, we will try to find more topological relations which can be identified if we adopt in the definition $A^e \cap A^i = \neg\emptyset$, $\partial A = \neg\emptyset$ and A^i don't intersect with the exterior of A. Then, we will try to classify these fuzzy topological relations identified by I4*4 and FID models to be grouped into the eight relations DC, EC, PO, TPP and TPPi, NTPP and NTPPi, and EQ of the spatial reasoning system *RCC8*.

T-norm-based fuzzy logics and logics for reasoning under vagueness

Thomas Vetterlein, Klaus-Peter Adlassnig

Vienna, Austria
Email: {Thomas.Vetterlein,Klaus-Peter.Adlassnig}@meduniwien.ac.at

Abstract— *We contrast the concept underlying t-norm-based propositional fuzzy logics with the problem to whose solution fuzzy logics are frequently suggested as helpful – namely, to find a model of reasoning with vague information. We argue that fuzzy logics are useful as long as truth values can be identified with the meaning of the considered propositions. This, however, is rarely the case in practice; hence we see the need to broaden the concept underlying this important class of logics and try fresh approaches. In particular, we should flexibilise the formalism to allow that propositions do not arise in the same context, but are just known to be related in some way.*

We tackle the problem tentatively. We define a set of rules which, as we assume, are minimally required to enable us to argue about vague propositions whose content is not taken into account. Our choice of rules reflects the practical requirements of a certain expert system on which we work.

Although we deal here with fuzzy logic in a very direct sense, we arrive at calculi completely different from the t-norm-based ones. Without incorporating truth degrees explicitly, we are led to Belnap's logic, which can, but need not, be endowed with a semantics based on graded truth degrees. When formalising also truth degrees, we get a logic which can be based on what we call metric De-Morgan lattices.

Keywords— t-norm-based fuzzy logics, reasoning under vagueness, medical expert system, De-Morgan lattices, metric De-Morgan lattices

1 T-norm-based fuzzy logic for reasoning about vague information – a trap

Fuzzy logics are distinguished from classical logic by the incorporation of an extended set of truth values. In the standard case, the value 0 is used to express falsity, the value 1 is used to express trueness, and all remaining real values in between these two limit points are added in order to cope with the fact that objects may fulfil a property to an intermediate degree. We arrive naturally at the idea to evaluate propositions in the real unit interval, whose most basic feature is its linear order.

The connectives used in fuzzy logics consequently need to be interpreted by operations on $[0, 1]$. Typically, a conjunction is present, which is typically interpreted by a left-continuous t-norm. Sometimes, an involutive negation is present as well, conveniently interpreted by the standard negation $1 - \cdot$. A further connective, which logicians, in contrast to engineers, generally consider as the most basic one, is the implication, which is typically interpreted by the residuum belonging to the t-norm. Finally, the logic may or may not offer the possibility to express explicitly to which degree a proposition holds.

Based on this approach, more than just a few logics have been defined and intensively studied. Monographs of basic importance include [14, 13] as well as, as regards the explicitation of truth degrees, [18]. We remark that we certainly do not address all logics which have been called "fuzzy" in the literature; this would be impossible as it seems that nowadays any logic has a "fuzzy" counterpart. Here, we just speak about logics of the indicated type.

We wish to address in this note the peculiar relationship between t-norm-based fuzzy logics and a problem which is regularly mentioned in discussions on the fundamentals of fuzzy logics: how to formalise reasoning when the referred information is possibly vague. The discussion on the very nature of fuzzy logics is old. An aim has been to develop fuzzy logics, as they are, from clear, meaningful principles; see, among many papers, e.g. [9, 10, 21, 22]. Here, we want to approach once the subject from the other side, namely, from the point of view of a specific application: an appropriate formalisation of justifiable reasoning can simply be a practical need.

Let us first try to formulate our concern in an abstract way. We assume to be given a set of propositions whose content does not matter. This means that for the derivation of consequences, the meaning is not taken into account and can be assumed to be unknown. We just know that the propositions refer to the observable or unobservable properties of somebody or something, describable in, possibly scientific, natural language. Important for us, the propositions express the presence of some property which can be vague, where, as usual, vagueness is characterised by the possibility of borderline cases. Moreover, we assume to have some knowledge about the mutual relationships. These relationships may express that some property is more general than another one, or a causal implication based on experience; again, we do not require the relationships to hold necessarily strict. What we are finally interested in, is to find a formal framework which tells us how to derive new information from the one we have to our disposal. Since the outlined situation is very general, the framework must be very general as well; we wonder, so to say, about a minimal logic for reasoning under vagueness.

The described problem is not purely academic and in particular not part of any "ivory-tower" philosophical theory, but has a practical background. We work towards an appropriate formalisation of a medical expert system [7]. The system which we are to analyse is called Cadiag-2, the second generation of the expert systems Cadiag – "*C*omputer-*A*ssisted *Dia*gnosis", and aims at the differential diagnostic decision support in patient care [1, 2]. Cadiag-2 processes both vague and uncertain data; we restrict here to the first case only. The procession of uncertain data calls for a probabilistic logic and causes completely different problems than those discussed here; for probability theory, well-founded calculi exist, whose unpleas-

ISBN: 978-989-95079-6-8

ant feature, however, can be a too high complexity as well as incomprehensible inference rules.

As we intend to formalise propositions disregarding their content, our problem is clearly a case for a propositional logic. As mentioned, many propositional fuzzy logics have been proposed in the past, based on different ways how to endow the real unit interval with a structure. Moreover, a wide range of logics has been introduced related to the problem which we address here, in particular different versions of "logics of argumentation". For a comprehensive overview and a large collection of references, we recommend the handbook [12]. Here, we just mimic the first steps towards the generally much more sophisticated and often more specialised systems found in the literature. What we have in mind is to concentrate exclusively on the aspect of vagueness, to proceed in a way which can hardly be further generalised, and to see how the result relates to t-norm-based fuzzy logics.

The set of eligible propositional logics is much restricted by one basic requirement, dictated by the intended application: all constituents of the formal logic need to have a counterpart on the informal level. Specifically, there must exist a plausible way how to think about each connective which appears in the logic's language, most easily obtained by a clear correlation with a natural-language expression. Moreover, if a proposition is provable from others, there must exist a proof in a proof system such that each step is comprehensible as a plausible argument, rather than a pure manipulation of strings; in the best case, each step can easily be translated to an explanation in natural language, exhibiting the causal or logical relationship on which the argument is based.

A fuzzy logic of the above-indicated kind does not meet any of these requirements. To see the problem, let us assume that we actually can find a logic fitting to our needs. We actually feel that it is natural to assume so; after all, we wish to formalise possibly vague statements, and these are appropriately evaluated on a linear continuous scale. So let us see how the logic could look like. We need a conjunction $\wedge$ and a negation $\sim$; the interpretation by the infimum and the standard negation, respectively, will do in our case. We note that the interpretation of truth values is not our subject here, and our particular choices for the connectives provide just an example. Moreover, we need to express truth degrees explicitly; to this end, we add constants $\bar{r}$ for each rational $r \in [0,1]$. So far, we do not encounter problems.

The first serious problem comes with the implication. Let us tentatively add the connective $\rightarrow$ interpreted by the residuum belonging to $\wedge$. Note that we then arrive at the logic $\mathsf{RGL}_\sim$, the Gödel logic enriched with the standard negation and truth constants [8]. Now, there is a natural way how to think about a statement "$\alpha \rightarrow \beta$": we interpret it as "α implies β". However, this clarity disappears as soon as we nest implications on the left side, like in "$(\alpha \rightarrow \beta) \rightarrow \gamma$". If our reference, a set of propositions, has a priori the structure of a residuated lattice, we can say that $\alpha \rightarrow \beta$ denotes the weakest element which, together with α, implies β. But in our case, there is no such structure available; we recall that we do not wish to assume any a priori structure as we would have to analyse the propositions by content then.

We note that this critics is related to the discussion out of which relevance logics arose [3]. Furthermore, a discussion in which the role of the implication connective in fuzzy logics is opposed to the needs of certain applications, can be found in [4].

For us, there is a reasonable way how to proceed: to drop the implication as a generally applicable connective. To this end, we consider in [7] a logic in which the implication always appears at the only place at which it can be appropriately called an implication: on the outermost level. Namely, we consider pairs of implication-free formulas, with the intended meaning that the left one denotes a proposition which is stronger then the right one. Thus we leave the area of t-norm-based logics and enter the field of lattice word problems. Namely, our model is the following algebra K, a Kleene algebra with added constants: $([0,1]; \wedge, \vee, \sim, (\bar{r})_{r \in \mathbb{Q}[0,1]})$.

We arrive at a logic, which we call GZL, whose formal expressions possess straightforward interpretations. However, we encounter the second and even more serious problem when considering a proof system for GZL. Following the lines of [5], we have in [7] presented a proof system based on sequents-of-relations. Unfortunately, our requirement that proof steps should be comprehensible in an informal way, is far from being fulfilled. Consider the K-tautology

$$\alpha \wedge \sim\alpha \;\rightarrow\; \beta \vee \sim\beta. \tag{1}$$

In its proof, we have to make necessarily use of the possibility to use multisets of relations, namely,

$$\alpha \Rightarrow \beta \;\mid\; \beta \Rightarrow \alpha \tag{2}$$

will appear in the proof. However, α and β refer to arbitrary facts, and the tentative translation "α implies β, or β implies α" is nonsense. Note that the problem concerns the proved result as well; (1) cannot be interpreted as a statement which anybody would ever tell.

The deeper reason for this difficulty is the semantics. An element of $[0,1]$ is intended to be the truth degree of a proposition; but it is treated like its meaning. What we might think as being associated to a property, telling that the property does not fully apply, is already the property itself. As a consequence, when using $[0,1]$ as a model, we may be led to the situation that we compare something by strength what by content would never be comparable. A valid statement of the form "$\alpha \rightarrow \beta$" is not really translatable to "from α we can conclude β", but only that α is under all circumstances assigned a smaller truth value than β, and based on this interpretation, (2) becomes indeed meaningful and just expresses the linear order of the truth degrees. However, this interpretation is not what we want.

The interpretation in the linearly ordered set of reals may certainly be useful at other places. A requirement comes into play which we have frequently argued for: to put fuzzy logics on firm grounds, we need first to be aware of the nature of what we reason about. In case of t-norm-based fuzzy logic, we reason about a set of propositions which has the internal structure of a residuated lattice, as it is the case for universes of fuzzy sets. The same, by the way, applies to classical propositional logic, which exactly reasons about a collection of propositions endowed a priori with the structure of a Boolean algebra; the popular claims about a "general validity" of this logic are meaningless.

ISBN: 978-989-95079-6-8

For us, the only way out is to restrict the calculus for GZL to those inferences which are not in conflict with our intended interpretation: the sequent $\alpha \Rightarrow \beta$ should mean that α is a statement stronger than β. We can achieve this is by not allowing multisets of relations, but only single relations. The interesting observation in [7] is that by means of this restriction, we get – not exactly but, say – very close to the logic which is actually used for the expert system which we examine.

The observation that the logic which we need arises by a certain restriction of a t-norm-based fuzzy logic, might be considered interesting, but not really satisfying. It rather suggests that the conceptual differences between the logic underlying systems like Cadiag-2 or similar expert systems on the one hand, and fuzzy logics on the other hand, cannot be bridged.

2 A minimal logic for reasoning under vagueness, without explicit degrees

The problem how to formalise ways to argue about vague propositions of unspecified content and their mutual interrelations, calls for alternative solutions. Let us opt for the syntactical approach; we will assemble some inference rules which translate to argumentation steps in a straightforward way. We will then check if some semantics with a reasonable interpretation can be found ex post, taking all imaginable possibilities into account and in particular not restricting ourselves to structures known from fuzzy logics or fuzzy set theory.

We note that this procedure seems to be in sharp contrast to the guiding principles of mathematical modelling which we have defended earlier, namely the principle that prior to any formalisation, the structure of reference needs to be specified first, in a way that the meaning of all its constituents is clear. However, in the present case, we do not do metamathematics, we do not examine ways how structures of a certain type are generally examined in a sound way; we do mathematics. Namely, it is the way of reasoning itself which is our object of investigation, and we do not share the opinion that rules for proper argumentation are fixed and thus can be derived from some higher-level truth. Intuitively acceptable inference rules will rather constitute a structure over a set of atomic propositions, and we do not assume a canonical answer how it may look like. In any case, we examine a logic as a mathematical object, the notion "logic" just being a name for it.

As indicated, there is not really a canonical way to select rules. One may argue against certain rules shown below, or feel that there is something missing. A discussion would not be fruitful if no guidelines were provided. We keep with the application in medicine; the rules shown below are extracted from those essential for the medical expert system with whose formalisation we are concerned.

In this section, we consider the case that we do not deal with truth values explicitly. We define the propositional logic DML as follows.

Definition 2.1 The *propositions* of DML are built up from a set of symbols $\varphi_1, \varphi_2, \ldots$ and the two constants $\bar{0}, \bar{1}$ by means of the binary connectives $\wedge, \vee$ and the unary connective $\sim$; the set of propositions is denoted by $\mathcal{F}_L$. The *implications* of DML are ordered pairs of propositions, denoted by $\alpha \to \beta$, where $\alpha, \beta \in \mathcal{F}_L$; the set of implications is denoted by $\mathcal{F}_I$.

Moreover, a *sequent* is an ordered pair of a non-empty finite set of propositions and a single proposition, notated by $\gamma_1, \ldots, \gamma_k \Rightarrow \delta$. The axioms and rules of DML are the following, for any propositions α, β, γ and sequent Γ:

$$\bar{0} \Rightarrow \alpha \quad \alpha \Rightarrow \alpha \quad \alpha \Rightarrow \bar{1}$$

$$\frac{\Gamma \Rightarrow \alpha \quad \alpha \Rightarrow \beta}{\Gamma \Rightarrow \beta} \qquad \frac{\Gamma \Rightarrow \alpha}{\Gamma, \beta \Rightarrow \alpha}$$

$$\frac{\Gamma \Rightarrow \alpha \quad \Gamma \Rightarrow \beta}{\Gamma \Rightarrow \alpha \wedge \beta} \qquad \frac{\Gamma, \alpha, \beta \Rightarrow \gamma}{\Gamma, \alpha \wedge \beta \Rightarrow \gamma}$$

$$\frac{\Gamma, \alpha \Rightarrow \gamma \quad \Gamma, \beta \Rightarrow \gamma}{\Gamma, \alpha \vee \beta \Rightarrow \gamma} \qquad \frac{\Gamma \Rightarrow \alpha}{\Gamma \Rightarrow \alpha \vee \beta} \qquad \frac{\Gamma \Rightarrow \beta}{\Gamma \Rightarrow \alpha \vee \beta}$$

$$\frac{\alpha \Rightarrow \beta}{\sim\beta \Rightarrow \sim\alpha} \qquad \frac{\sim\alpha \Rightarrow \beta}{\sim\beta \Rightarrow \alpha} \qquad \frac{\alpha \Rightarrow \sim\beta}{\beta \Rightarrow \sim\alpha}$$

The notion of a proof of a sequent from a finite set of sequents is defined in the expected way. A *theory* of DML is a finite set of implications. An implication $\alpha \to \beta$ is called provable from $\mathcal{T} = \{\alpha_1 \to \beta_1, \ldots, \alpha_n \to \beta_n\}$ if there is a proof of $\alpha \Rightarrow \beta$ from $\{\alpha_1 \Rightarrow \beta_1, \ldots, \alpha_n \Rightarrow \beta_n\}$, in signs $\mathcal{T} \vdash \alpha \to \beta$.

As to be expected, a sequent $\gamma_1, \ldots, \gamma_k \Rightarrow \delta$ is meant to express that "γ_1 and ... and γ_k imply δ".

Note that this logic again does not contain the implication as a connective, and it does contain a negation. Moreover, the calculus is sound, but not complete, with respect to classical two-valued interpretations; again (1) is not derivable. For the lack of the implication connective, also the comparison with intuitionistic logic is (probably) not well possible.

But a semantics is easily found, since DML is Belnap's logic of De-Morgan lattices; DML differs only slightly from the calculus presented in [11]. A structure $(M; \wedge, \vee, \sim, 0, 1)$ is a De-Morgan lattice if (i) $(M; \wedge, \vee, 0, 1)$ is a distributive lattice and (ii) $\sim$ is an order-reversing and involutive unary operation. De-Morgan lattices are subalgebras of direct products of the algebra $(\mathcal{M}_4; \wedge, \vee, \sim, 0, 1)$, where $(\mathcal{M}_4; \wedge, \vee, 0, 1)$ is the four-element Boolean lattice and $\sim$ maps each of the two atoms to itself [16]. It follows that we can provide a semantics based on $\mathcal{M}_4$; we note that assigning one of the four truth values to a proposition φ is usually interpreted as that φ is known to be true, false, neither true nor false, both true and false, respectively.

Most remarkably, fuzziness does not appear. However, the algebra $\mathcal{M}_4$ possesses a natural "fuzzified" extension, and we may alternatively base DML on a kind of fuzzy semantics. To make the comparison possible, we consider the pair V_c and V_f; note that the algebra V_c is isomorphic to $\mathcal{M}_4$.

Definition 2.2 Let $V_c = \{(s,t) : s,t \in \{0,1\}\}$, endowed with the componentwise natural order and the operation $\sim$ defined by

$$\sim(s,t) = (1-t, 1-s) \tag{3}$$

for $s,t \in \{0,1\}$. A *crisp evaluation* of DML is a mapping $v\colon \mathcal{F}_L \to V_c$ preserving $\wedge, \vee, \sim$ and mapping $\bar{0}$ to $(0,0)$ and $\bar{1}$ to $(1,1)$. An implication $\alpha \to \beta$ is then said to be *satisfied* by v if $v(\alpha) \leq v(\beta)$. A theory $\mathcal{T}$ is said to *crisply entail* an implication $\alpha \to \beta$ if the latter is satisfied by all crisp evaluations satisfying every element of $\mathcal{T}$; we write $\mathcal{T} \models_c \alpha \to \beta$ in this case.

ISBN: 978-989-95079-6-8

Furthermore, let $V_f = \{(s,t)\colon\ s,t \in [0,1]\}$, endowed with the componentwise natural order and the operation $\sim$, which is again defined by (3), where however this time $s,t \in [0,1]$. We define *fuzzy evaluations*, *satisfaction*, and *fuzzy entailment* similarly as above.

Theorem 2.3 *Let $\mathcal{T}$ be a theory and $\alpha \to \beta$ an implication of* DML. *Then $\mathcal{T} \vdash \alpha \to \beta$ if and only if $\mathcal{T} \models_c \alpha \to \beta$ if and only if $\mathcal{T} \models_f \alpha \to \beta$.*

Proof. Completeness in the indicated sense, but with respect to arbitrary De-Morgan lattices, holds due to [11, Theorem 4.11, (A1)]. But any De-Morgan lattice is a subalgebra of a direct product of copies of V_c, or alternatively, of a direct product of copies of V_f. □

As regards the interpretation of the semantics which we have proposed for DML, the situation is surprising with respect to the fuzzy variant. There is a close connection of DML to a logic which has been proposed in the context of decision making, based on the observation that we often consider separately the arguments in favour and the arguments against a possible decision [19].

On the other hand, the fact that we can work, without the need to change the inference rules, with crisp truth values as well, is somewhat disillusioning. The reasoning is the same if we assume our propositions to refer to vague or crisp properties. The situation certainly changes when we include truth degrees, as to be done next.

3 A minimal logic for reasoning under vagueness, with explicit degrees

The logic DML discussed in the last section is intended to be useful for reasoning about relationships between statements involving vagueness. The vagueness, however, cannot be addressed directly; and the logic can actually equally well considered as a logic not concerning vagueness. Moreover, a possible non-strictness of the relationships themselves is not expressible.

In applications, it can be desirable to have the possibility to denote a vague property by one single symbol, to which the degree of presence is explicitly attached. In this chapter, we attempt to formulate a calculus similarly to DML, but with explicit reference to truth degrees.

This problem is much more involved. We believe that there are many possibilities, and that the decision which is the best is even more difficult than in the above case.

According to a common procedure, we could enrich the language by truth constants. We will not follow this way; apart from the fact that we have not succeeded to produce a reasonable result concerning a logic DML enriched with truth constants, the idea is actually not well in accordance with the guidelines formulated above: truth constants should not be mixed with the meaning of a proposition. So we will use the two sharp truth constants only, representing falsity and trueness.

Truth constants should appear on a separate level. We propose to make a graded implication the basic syntactical constituent:

$$\alpha \xrightarrow{t} \beta,$$

with the intended meaning that α implies β to a degree $\geq t \in [0,1]$, where α and β are propositions of DML. As an example, let α denote a crisp proposition like "having a body temperature of $37.8°C$", and let β denote "having fever"; then the statement would hold with, say, $t = 0.8$.

In general, α and β are meant to refer to any vague property. Then either t refers to the compatibility of α with β. Alternatively, we can mean that α and β are causally related; then the smaller t is, the less strict is this relationship. Finally, we may also deal with single properties. Namely, the expressions

$$\bar{1} \xrightarrow{t} \delta \quad \text{and} \quad \delta \xrightarrow{t} \bar{0} \tag{4}$$

may serve to express that δ holds to the degree t, or δ is refused with the degree t, respectively.

To formulate inference rules is not straightforward; in the present context, our aim can only be plausibility. The basic question is which truth degree is, by tendency, assumed after two successive inference steps which are both based on a non-strict relationship. To examine this problem is even more difficult than to make a reasonable choice with regard to the truth values themselves, a problem which has been studied numerous times, see e.g. [15, 17]. It would clearly be desirable to have methods at hand to examine also the present situation empirically, in analogy to the procedure followed in [15].

Only the case of implications of the form $\alpha \xrightarrow{1} \beta$ is clear; they are supposed to express strict relationships, and for them, the rules of DML should be applicable. Furthermore, the degrees are assumed to be lower bounds, hence an implication is the less expressive the smaller the indicated truth degree is. Statements of the form $\alpha \xrightarrow{0} \beta$ do not express anything.

So let us see how the set of rules for our refined logic could look like. For implications $\alpha \xrightarrow{1} \beta$, we will use the rules of DML. For implications of the form $\alpha \xrightarrow{t} \beta$, where $t < 1$, the rules of DML introducing $\wedge$ or $\vee$ are not generalisable though; the degree of the conclusion cannot be assumed to be calculable from the degrees of the assumptions. However, what we should be able to say is, if we replace α by a stronger proposition, or β by a weaker proposition, then the relationship between α and β should be characterised by a higher truth value, so that t will still be a lower bound. Next, assume that we have proved $\alpha \xrightarrow{s} \beta$ and $\beta \xrightarrow{t} \gamma$; then $\alpha \xrightarrow{u} \gamma$ will be derivable as well, and we have to offer a way to calculate the degree u from s and t. As mentioned above, a well-founded decision is impossible, hence just like in case of the design of a fuzzy logic, a pragmatic solution is needed here. We opt for the operation dual to the truncated addition: we take here the Łukasiewicz t-norm $\odot\colon\ [0,1]^2 \to [0,1],\ \ (a,b) \mapsto (a+b-1) \vee 0$.

We specify the propositional logic ArgL as follows.

Definition 3.1 The set $\mathcal{F}_L$ of *propositions* is defined like for DML. An *implication* of ArgL consists of ordered triples of two propositions and a rational value $t \in [0,1]$; we write $\alpha \xrightarrow{t} \beta$, where $\alpha, \beta \in \mathcal{F}_L$; the set of implications is denoted by $\mathcal{F}_I$.

Moreover, a *sequent* is an ordered triple consisting of a non-empty finite set of propositions, a single proposition, and a rational value $t \in [0,1]$; we write

$$\gamma_1, \ldots, \gamma_k \overset{t}{\Rightarrow} \delta.$$

ISBN: 978-989-95079-6-8

The *crisp* rules of ArgL are those of DML, the symbol $\Rightarrow$ being replaced at all places by $\stackrel{1}{\Rightarrow}$.

The *fuzzy* rules of ArgL are the following:

$$\frac{\Gamma \stackrel{s}{\Rightarrow} \alpha \quad \alpha \stackrel{t}{\Rightarrow} \beta}{\Gamma \stackrel{s \odot t}{\Rightarrow} \beta} \qquad \frac{\Gamma \stackrel{t}{\Rightarrow} \alpha}{\Gamma \stackrel{s}{\Rightarrow} \alpha}, \text{ where } s \leq t$$

$$\frac{\Gamma, \alpha \stackrel{t}{\Rightarrow} \delta}{\Gamma, \alpha \wedge \beta \stackrel{t}{\Rightarrow} \delta} \qquad \frac{\Gamma \stackrel{t}{\Rightarrow} \alpha}{\Gamma \stackrel{t}{\Rightarrow} \alpha \vee \beta}$$

The notion of a *proof*, a *theory*, the *provability* of an implication from a theory, is defined similarly like for DML.

To associate to this calculus a reasonable semantics, is the next challenge. Only one point seems to be certain – we are not led to fuzzy sets. The only remarkable fact is that a t-norm is involved; for connections between t-norms and a somewhat similar setting, see [6, 20].

Let us consider the following structures, so-to-say the algebraic counterpart of ArgL. Here, $\oplus : [0,1]^2 \to [0,1]$, $(a,b) \mapsto (a+b) \wedge 1$ is the t-conorm associated to $\odot$.

Definition 3.2 A structure $(A; \wedge, \vee, \sim, 0, 1, d)$ is called a *metric De-Morgan lattice* if $(A; \wedge, \vee, \sim, 0, 1)$ is a De-Morgan lattice and $d\colon A \times A \to [0,1]$ is such that (i) $d(a,b) = 0$ if and only if $a \leq b$ and (ii) $d(a,c) \leq d(a,b) \oplus d(b,c)$.

An *evaluation* of ArgL in a metric De-Morgan lattice A is a mapping $v : \mathcal{F}_L \to A$ preserving $\wedge, \vee, \sim$ and the constants. An implication $\alpha \stackrel{t}{\to} \beta$ is *satisfied* by an evaluation v if $d(v(\alpha), v(\beta)) \leq 1 - t$. Semantic entailment is defined as usual.

Let us consider the following instructive example. Let $(A; \wedge, \vee, \sim, 0, 1)$ be a Boolean algebra, and let $\mu\colon A \to [0,1]$ be a strictly positive submeasure on A, meaning that, for $a, b \in A$, (i) $\mu(0) = 0$, (ii) $\mu(a) > 0$ if $a > 0$, (iii) $a \leq b$ implies $\mu(a) \leq \mu(b)$, (iv) $\mu(1) = 1$, and (v) $\mu(a \vee b) \leq \mu(a) \oplus \mu(b)$. Furthermore, put $d(a,b) = \mu(a \wedge \sim b)$. Then we may check that $(A; \wedge, \vee, \sim, 0, 1, d)$ is a metric De-Morgan lattice.

Theorem 3.3 *Let $\mathcal{T}$ be a theory and $\alpha \stackrel{t}{\to} \beta$ an implication of* ArgL*, where $t \in (0,1]$. Then $\mathcal{T} \vdash \alpha \stackrel{t}{\to} \beta$ if and only if $\mathcal{T} \models \alpha \stackrel{t}{\to} \beta$.*

Proof. The "only if" part is easy; just define the satisfaction of sequents by identifying the set on the left side with its conjunction.

For the "if" part, assume that $\mathcal{T}$ does not prove the implication $\gamma \stackrel{s}{\to} \delta$.

Let A be the quotient of $\mathcal{F}_L$ w.r.t. the equivalence relation $\Leftrightarrow$, where $\alpha \Leftrightarrow \beta$ if $\alpha \stackrel{1}{\to} \beta$ and $\beta \stackrel{1}{\to} \alpha$ are provable from $\mathcal{T}$. Then A is naturally endowed with the structure of a De-Morgan lattice.

For $\alpha, \beta \in \mathcal{F}_L$, let $d([\alpha],[\beta]) = 1 - t$, where $t \in [0,1]$ is maximal such that $\mathcal{T} \vdash \alpha \stackrel{t}{\to} \beta$. Endowed with d, A is a metric De-Morgan lattice. By construction, the elements of $\mathcal{T}$ are satisfied by the natural embedding of $\mathcal{F}_L$ into A, but not $\gamma \stackrel{s}{\to} \delta$. □

Needless to comment, our formalism comes closer to measure theory than to fuzzy set theory.

From the interpretational point of view, the semantics based on metric De-Morgan lattices is to be clarified though. Note that only the special case of a Boolean algebra with a submeasure offers an intuitively well comprehensible picture.

4 Conclusion

T-norm-based propositional fuzzy logics are frequently discussed as a suitable tool to model reasoning under vagueness. We have stressed that this is the case as long as the propositions which are formalised share the same reference; namely, they must be modellable by a system of fuzzy sets over a common universe.

If propositions are arbitrary, we run into difficulties when trying to apply techniques of fuzzy logics. This is, for example, the case for the medical expert system Cadiag-2, whose knowledge base contains information on logical and causal relationships between entities which are processed regardless of their meaning. We have risen the question how to define, in this general setting, a minimal frame for what we could call formalised argumentations. As a proposal, we have designed two minimal, but for our needs fully sufficient, systems; we have done so purely syntactically, allowing only rules with a clear interpretation.

The first version concerns reasoning without explicit reference to truth degrees; what comes out is the De-Morgan logic, which allows for interpretations without any connection to fuzziness. The second version incorporates truth values, but the calculus which comes out, still is by no means related to t-norm-based fuzzy logic. The semantics which can be defined ex post are De-Morgan lattices endowed with a non-symmetric distance function.

Our calculi are qualified in that they allow to reproduce the inference mechanism of Cadiag-2. The further elaboration on details of the calculus is work to be done, as well as the analysis of the newly introduced notion of a metric De-Morgan lattice.

Abstract— *Formal concept analysis has become an important and appealing research topic. There exist a number of different fuzzy extensions of formal concept analysis and of its representation theorem, which gives conditions for a complete lattice in order to be isomorphic to a concept lattice. In this paper we concentrate on the study of operational properties of the mappings α and β required in the representation theorem.*

Keywords— Formal concept analysis, multi-adjoint framework.

1 Introduction

Formal concept analysis [12] has become an important and appealing research topic both from a theoretical perspective [18, 29, 32] and from the applicative one. Regarding applications, we can find papers ranging from ontology merging [10, 27], to applications to the Semantic Web by using the notion of concept similarity [11], and from processing of medical records in the clinical domain [14] to the development of recommender systems [8].

Soon after the introduction of "classical" formal concept analysis, a number of different approaches for its generalization were introduced and, nowadays, there are works which extend the theory with ideas from fuzzy set theory [3, 21, 22] or fuzzy logic reasoning [2, 4, 9] or from rough set theory [20, 30, 33] or some integrated approaches such as fuzzy and rough [31], or rough and domain theory [19].

In this paper we concentrate on the fuzzy extensions of formal concept analysis, for which a number of different approaches have been presented. To the best of our knowledge, the first one was given in [6], although they did not advance much beyond the basic definitions, probably due to the fact that they did not use residuated implications. Later, in [3, 28] the authors independently used complete residuated lattices as structures for the truth degrees; for this approach, a representation theorem was proved directly in a fuzzy framework in [5], setting the basis of most of the subsequent direct proofs.

In [23, 24] as a new general approach to formal concept analysis multi-adjoint concept lattices were introduced, in which the philosophy of the multi-adjoint paradigm [15, 26] to formal concept analysis is applied. With the idea of providing a general framework in which the different approaches stated above could be conveniently accommodated, the authors worked in a general non-commutative environment; and this naturally led to the consideration of adjoint triples, also called implication triples [1] or bi-residuated structures [25] as the main building blocks of a multi-adjoint concept lattice.

The representation (or fundamental) theorem gives conditions for a complete lattice in order to be isomorphic to a concept lattice. This theorem is proved in the classical case [12] and in the fuzzy paradigms [5, 13, 16, 23, 28]. As a consequence, to obtain the isomorphism it is necessary to search two mappings α and β that satisfy some properties, one of these relate the mappings with the relation. In this paper, we present a characterization of this last property, which is more efficient than the actual from the computationally point of view. Moreover, some other interesting properties of mappings α and β are introduced.

The structure of the paper is as follows: in Section 2 we recall the definition of the multi-adjoint concept lattices and, in particular, the mappings α and β required in the definition of lattice representing a multi-adjoint concept lattice. Then, in Section 3, we prove some new results concerning α and β. Finally, some concluding remarks are added.

2 Multi-adjoint concept lattices

In this section we will recall the more important definitions and results from [23]. The first definition introduces the basic building blocks of the multi-adjoint concept lattices, the *adjoint triples*, which are generalisations of the notion of adjoint pair under the hypothesis of having a non-commutative conjunctor.

The lack of commutativity of the conjunctor, directly provides two different ways of generalising the well-known adjoint property between a t-norm and its residuated implication, depending on which argument is fixed in the conjunction.

Definition 1 *Let $(P_1, \leq_1)$, $(P_2, \leq_2)$, $(P_3, \leq_3)$ be posets and $\&\colon P_1 \times P_2 \to P_3$, $\swarrow\colon P_3 \times P_2 \to P_1$, $\nwarrow\colon P_3 \times P_1 \to P_2$ be mappings, then $(\&, \swarrow, \nwarrow)$ is an* adjoint triple *with respect to P_1, P_2, P_3 if:*

1. *$\&$ is order-preserving in both arguments.*
2. *$\swarrow$ and $\nwarrow$ are order-preserving in the consequent and order-reversing in the antecedent.*
3. *$x \leq_1 z \swarrow y$ iff $x \,\&\, y \leq_3 z$ iff $y \leq_2 z \nwarrow x$, where $x \in P_1$, $y \in P_2$ and $z \in P_3$.*

Note that in the domain and codomain of the considered conjunctor we have three (in principle) different sorts, thus providing a more flexible language to a potential user. Furthermore, notice that no boundary condition is required, in difference to the usual definition of multi-adjoint lattice [26] or implication triple [1]. Nevertheless, some boundary conditions follow from the definition, specifically, from the adjoint property (condition (3) above) [23].

ISBN: 978-989-95079-6-8

Lemma 1 *If $(P_1, \leq_1)$, $(P_2, \leq_2)$, $(P_3, \leq_3)$ have bottom element and $(\&, \swarrow, \nwarrow)$ is an adjoint triple, then $(P_1, \leq_1)$ and $(P_2, \leq_2)$ have top element and for all $x \in P_1, y \in P_2$ and $z \in P_3$ the following properties hold:*

1. $\bot_1 \,\&\, y = \bot_3, \qquad x \,\&\, \bot_2 = \bot_3.$
2. $z \nwarrow \bot_1 = \top_2, \qquad z \swarrow \bot_2 = \top_1.$

In order to provide more flexibility into our language, we will allow the existence of several adjoint triples for a given triplet of posets. Notice, however, that since these frames will be used as the underlying structures of our generalization of concept lattice, it is reasonable to require the lattice structure on some of the posets in the definition of adjoint triple.

Definition 2 *A* multi-adjoint frame *$\mathcal{L}$ is a tuple*

$$(L_1, L_2, P, \preceq_1, \preceq_2, \leq, \&_1, \swarrow^1, \nwarrow_1, \ldots, \&_n, \swarrow^n, \nwarrow_n)$$

where $(L_1, \preceq_1)$ and $(L_2, \preceq_2)$ are complete lattices, $(P, \leq)$ is a poset and, for all $i = 1, \ldots, n$, $(\&_i, \swarrow^i, \nwarrow_i)$ is an adjoint triple with respect to L_1, L_2, P.

For short, a multi-adjoint frame will be denoted as $(L_1, L_2, P, \&_1, \ldots, \&_n)$.

Following the usual approach to formal concept analysis, given a frame, a *multi-adjoint context* is a tuple consisting of sets of objects and attributes and a fuzzy relation among them; in addition, the multi-adjoint approach also includes a function which assigns an adjoint triple to each object (or attribute). This feature is important in that it allows for defining subgroups of objects or attributes in terms of different degrees of preference, see [23]. Formally, the definition is the following:

Definition 3 *Let $(L_1, L_2, P, \&_1, \ldots, \&_n)$ be a multi-adjoint frame, a* context *is a tuple (A, B, R, σ) such that A and B are non-empty sets (usually interpreted as attributes and objects, respectively), R is a P-fuzzy relation $R\colon A \times B \to P$ and $\sigma\colon B \to \{1, \ldots, n\}$ is a mapping which associates any element in B with some particular adjoint triple in the frame.*[1]

Once we have fixed a multi-adjoint frame and a context for that frame, we can define the following mappings $^{\uparrow_\sigma}\colon L_2^B \longrightarrow L_1^A$ and $^{\downarrow^\sigma}\colon L_1^A \longrightarrow L_2^B$ which can be seen as generalisations of those given in [4, 17]:

$$g^{\uparrow_\sigma}(a) = \inf\{R(a,b) \swarrow^{\sigma(b)} g(b) \mid b \in B\} \quad (1)$$

$$f^{\downarrow^\sigma}(b) = \inf\{R(a,b) \nwarrow_{\sigma(b)} f(a) \mid a \in A\} \quad (2)$$

These two arrows, $(^{\uparrow_\sigma}, ^{\downarrow^\sigma})$, generate a Galois connection [23]. For the sake of self-containment, this concept is defined below:

Definition 4 *Let $(P_1, \leq_1)$ and $(P_2, \leq_2)$ be posets, and $^{\downarrow}\colon P_1 \to P_2$, $^{\uparrow}\colon P_2 \to P_1$ mappings, the pair $(^{\uparrow}, ^{\downarrow})$ forms a* Galois connection *between P_1 and P_2 whenever the following conditions hold:*

1. *$^{\uparrow}$ and $^{\downarrow}$ are order-reversing.*
2. *$x \leq_1 x^{\downarrow\uparrow}$ for all $x \in P_1$.*
3. *$y \leq_2 y^{\uparrow\downarrow}$ for all $y \in P_2$.*

Proposition 1 ([23]) *Let $(L_1, L_2, P, \&_1, \ldots, \&_n)$ be a multi-adjoint frame and (A, B, R, σ) be a context, then the pair $(^{\uparrow_\sigma}, ^{\downarrow^\sigma})$ is a Galois connection between L_1^A and L_2^B.*

As usual in the different frameworks of formal concept analysis, a *multi-adjoint concept* is a pair $\langle g, f\rangle$ satisfying that $g \in L_2^B$, $f \in L_1^A$ and that $g^{\uparrow_\sigma} = f$ and $f^{\downarrow^\sigma} = g$; with $(^{\uparrow_\sigma}, ^{\downarrow^\sigma})$ being the Galois connection defined above.

Definition 5 *The* multi-adjoint concept lattice *associated to a multi-adjoint frame $(L_1, L_2, P, \&_1, \ldots, \&_n)$ and a context (A, B, R, σ) is the set*

$$\mathcal{M} = \{\langle g, f\rangle \mid g \in L_2^B, f \in L_1^A \text{ and } g^{\uparrow_\sigma} = f, f^{\downarrow^\sigma} = g\}$$

where the ordering is defined by $\langle g_1, f_1\rangle \preceq \langle g_2, f_2\rangle$ if and only if $g_1 \preceq_2 g_2$ (equivalently $f_2 \preceq_1 f_1$).

The ordering just defined above actually provides $\mathcal{M}$ with the structure of a complete lattice [23]. This follows from proposition 1 (the arrows $(^{\uparrow_\sigma}, ^{\downarrow^\sigma})$ forms a Galois connection) and the theorem below.

Theorem 1 ([7]) *Let $(L_1, \preceq_1)$, $(L_2, \preceq_2)$ be complete lattices, let $(^{\uparrow}, ^{\downarrow})$ be a Galois connection between L_1, L_2 and consider $\mathcal{C} = \{\langle x, y\rangle \mid x^{\uparrow} = y, x = y^{\downarrow}; x \in L_1, y \in L_2\}$; then $(\mathcal{C}, \preceq)$ is a complete lattice, where*

$$\bigwedge_{i\in I}\langle x_i, y_i\rangle = \langle \bigwedge_{i\in I} x_i, (\bigvee_{i\in I} y_i)^{\downarrow\uparrow}\rangle;$$

$$\bigvee_{i\in I}\langle x_i, y_i\rangle = \langle (\bigvee_{i\in I} x_i)^{\uparrow\downarrow}, \bigwedge_{i\in I} y_i\rangle$$

and $\langle x_1, y_1\rangle \preceq \langle x_2, y_2\rangle$ if and only if $x_1 \preceq_1 x_2$.

From now on, we will fix a multi-adjoint frame $(L_1, L_2, P, \&_1, \ldots, \&_n)$ and context (A, B, R, σ). Moreover, to improve readability, we will write $(^{\uparrow}, ^{\downarrow})$ instead of $(^{\uparrow_\sigma}, ^{\downarrow^\sigma})$ and $\swarrow^b$, $\nwarrow_b$ instead of $\swarrow^{\sigma(b)}$, $\nwarrow_{\sigma(b)}$.

In the next section, we will present some new properties about the functions α and β involved in the representation (or fundamental) theorem for the multi-adjoint framework presented in [23]. In order to do this, we will recall some necessary definitions.

Definition 6 *Given a complete lattice L, a subset $K \subseteq L$ is* infimum-dense *(resp.* supremum-dense*) if and only if for all $x \in L$ there exists $K' \subseteq K$ such that $x = \inf(K')$ (resp. $x = \sup(K')$).*

A multi-adjoint concept lattice is said to be represented by a complete lattice provided there is a pair of functions, α and β, satisfying the conditions stated in the definition below:

Definition 7 *A multi-adjoint concept lattice*[2] *$(\mathcal{M}, \preceq)$ is* represented *by a complete lattice $(V, \sqsubseteq)$ if there exists a pair of mappings $\alpha\colon A \times L_1 \to V$ and $\beta\colon B \times L_2 \to V$ such that:*

[1] A similar theory could be developed by considering a mapping $\tau\colon A \to \{1, \ldots, n\}$ which associates any element in A with some particular adjoint triple in the frame.

[2] Recall that we are considering a multi-adjoint concept lattice on a fixed frame $(L_1, L_2, P, \&_1, \ldots, \&_n)$ and context (A, B, R, σ).

ISBN: 978-989-95079-6-8

1a) $\alpha[A \times L_1]$ *is infimum-dense;*

1b) $\beta[B \times L_2]$ *is supremum-dense; and*

2) For all $a \in A$, $b \in B$, $x \in L_1$, $y \in L_2$*:*

$$\beta(b, y) \sqsubseteq \alpha(a, x) \quad \textit{if and only if} \quad x \,\&_b\, y \leq R(a, b)$$

From the definition of representability above the following properties follow:

Proposition 2 *Given a complete lattice* $(V, \sqsubseteq)$ *which represents a multi-adjoint concept lattice* $(\mathcal{M}, \preceq)$*, and mappings* $f \in L_1^A$ *and* $g \in L_2^B$*, we have:*

1. β *is order-preserving in the second argument.*
2. α *is order-reversing in the second argument.*
3. $g^{\uparrow}(a) = \sup\{x \in L_1 \mid v_g \sqsubseteq \alpha(a, x)\}$*, where* $v_g = \sup\{\beta(b, g(b)) \mid b \in B\}$.
4. $f^{\downarrow}(b) = \sup\{y \in L_2 \mid \beta(b, y) \sqsubseteq v_f\}$*, where* $v_f = \inf\{\alpha(a, f(a)) \mid a \in A\}$.
5. *If* $g_v(b) = \sup\{y \in L_2 \mid \beta(b, y) \sqsubseteq v\}$*, then* $\sup\{\beta(b, g_v(b)) \mid b \in B\} = v$.
6. *If* $f_v(a) = \sup\{x \in L_1 \mid v \sqsubseteq \alpha(a, x)\}$*, then* $\sup\{\alpha(a, f_v(a)) \mid a \in A\} = v$.

Finally, the fundamental theorem for multi-adjoint concept lattices presented in [23] is the following.

Theorem 2 *A complete lattice* $(V, \sqsubseteq)$ *represents a multi-adjoint concept lattice* $(\mathcal{M}, \preceq)$ *if and only if* $(V, \sqsubseteq)$ *is isomorphic to* $(\mathcal{M}, \preceq)$.

3 New results about the mappings α and β

In this section, we introduce some new interesting properties about the mappings α and β. So, let us assume a complete lattice $(V, \sqsubseteq)$ which represents a multi-adjoint concept lattice $(\mathcal{M}, \preceq)$ and the mappings $\alpha\colon A \times L_1 \to V$, $\beta\colon B \times L_2 \to V$.

We will restate below the isomorphism constructed in fundamental theorem, based on both the α and β functions, since these expressions will be used later.

Proposition 3 ([23]) *If a complete lattice* $(V, \sqsubseteq)$ *represents a multi-adjoint concept lattice* $(\mathcal{M}, \preceq)$*, then there exists an isomorphism* $\varphi\colon \mathcal{M} \to V$ *and two mappings* $\beta\colon B \times L_2 \to V$, $\alpha\colon A \times L_1 \to V$*, such that:*

$$\begin{aligned} \varphi(\langle g, f\rangle) &= \sup\{\beta(b, g(b)) \mid b \in B\} \\ &= \inf\{\alpha(a, f(a)) \mid a \in A\} \end{aligned}$$

for all concept $\langle g, f\rangle \in \mathcal{M}$.

The following result shows continuity-related properties of α and β in their second argument.

Proposition 4 *The mappings* $\beta\colon B \times L_2 \to V$ *and* $\alpha\colon A \times L_1 \to V$ *satisfy that:*

1. *For all indexed set* $Y = \{y_i\}_{i \in I} \subseteq L_2$ *and* $b \in B$*:*

$$\beta(b, \sup\{y_i \mid i \in I\}) = \sup\{\beta(b, y_i) \mid i \in I\}$$

2. *For all indexed set* $X = \{x_i\}_{i \in I} \subseteq L_1$ *and* $a \in A$*:*

$$\alpha(a, \sup\{x_i \mid i \in I\}) = \inf\{\alpha(a, x_i) \mid i \in I\}$$

Proof: 1. Consider $b \in B$ and $Y = \{y_i\}_{i \in I} \subseteq L_2$, as $\alpha[A \times L_1]$ is infimum-dense and $\beta(b, \sup Y) \in V$, there exists an indexing set Λ such that $\beta(b, \sup Y) = \inf\{\alpha(a_j, x_j) \mid j \in \Lambda\}$; as a result $\beta(b, \sup Y) \sqsubseteq \alpha(a_j, x_j)$ for every $j \in \Lambda$. From proposition 2(1), we obtain that $\beta(b, y_i) \sqsubseteq \alpha(a_j, x_j)$, for every $i \in I$ and $j \in \Lambda$, and hence $\sup\{\beta(b, y_i) \mid i \in I\} \sqsubseteq \alpha(a_j, x_j)$ for every $j \in \Lambda$, then

$$\begin{aligned} \sup\{\beta(b, y_i) \mid i \in I\} &\sqsubseteq \inf\{\alpha(a_j, x_j) \mid j \in \Lambda\} \\ &= \beta(b, \sup Y) \end{aligned}$$

For the other inequality, let us consider $\sup\{\beta(b, y_i) \mid i \in I\}$ and, as $\alpha[A \times L_1]$ is infimum-dense, there exists an indexing set Λ' such that $\sup\{\beta(b, y_i) \mid i \in I\} = \inf\{\alpha(a_j, x_j) \mid j \in \Lambda'\}$. Now, for all $i \in I$ and $j \in \Lambda'$ we obtain that $\beta(b, y_i) \sqsubseteq \alpha(a_j, x_j)$, therefore, from Definition 7(2), $x_j \,\&_b\, y_i \leq R(a_j, b)$. Now, as $(\&_b, \swarrow^b, \nwarrow_b)$ is an adjoint triple, we have the following chain of equivalent statements:

$$\begin{aligned} x_j \,\&_b\, y_i &\leq R(a_j, b) && \text{for all } i \in I \\ y_i &\preceq_2 R(a_j, b) \nwarrow_b x_j && \text{for all } i \in I \\ \sup Y &\preceq_2 R(a_j, b) \nwarrow_b x_j \\ x_j \,\&_b \sup Y &\leq R(a_j, b) \end{aligned}$$

so, $\beta(b, \sup Y) \sqsubseteq \alpha(a_j, x_j)$ for every $j \in \Lambda'$, and thus

$$\begin{aligned} \beta(b, \sup Y) &\sqsubseteq \inf\{\alpha(a_j, x_j) \mid j \in \Lambda'\} \\ &= \sup\{\beta(b, y_i) \mid i \in I\} \end{aligned}$$

2. This proof is analogous using that $\beta[B \times L_2]$ is supremum-dense. □

We continue below by proving some boundary conditions fulfilled by α and β.

Proposition 5 *The two mappings* $\alpha\colon A \times L_1 \to V$ *and* $\beta\colon B \times L_2 \to V$ *are such that* $\alpha(a, \bot_1) = \top_V$ *and* $\beta(b, \bot_2) = \bot_V$ *for all* $b \in B$ *and* $a \in A$.

Proof: Given $a \in A$, let us prove that $\alpha(a, \bot_1) = \top_V$. Firstly, recall that lemma 1 implies that $\bot_1 \,\&_b\, y \leq R(a, b)$ for all $b \in B$ and $y \in L_2$; now, from Definition 7(2) we obtain that $\beta(b, y) \sqsubseteq \alpha(a, \bot_1)$ for all $b \in B$ and $y \in L_2$, that is, $\alpha(a, \bot_1)$ is an upper bound of the set of elements $\beta(b, y)$ for all $b \in B$ and $y \in L_2$. Now, as β is supremum-dense, there is an indexing set Λ such that $\top_V = \sup\{\beta(b_i, y_i) \mid i \in \Lambda\}$, therefore, we have that: $\top_V \sqsubseteq \alpha(a, \bot_1)$. Hence, $\top_V = \alpha(a, \bot_1)$.

The other equality follows similarly. □

From the propositions above, we obtain the following corollary which states the behaviour of α and β regarding suprema of any set (either empty or non-empty).

Corollary 1 *The mappings* $\beta\colon B \times L_2 \to V$, $\alpha\colon A \times L_1 \to V$ *satisfy that:*

ISBN: 978-989-95079-6-8

1. $\beta(b, \sup Y) = \sup\{\beta(b, y) \mid y \in Y\}$, *for all* $Y \subseteq L_2$ *and* $b \in B$.

2. $\alpha(a, \sup X) = \inf\{\alpha(a, x) \mid x \in X\}$, *for all* $X \subseteq L_1$ *and* $a \in A$.

As a consequence of the property above we have the following result, which gives us a more efficient form to write Property (2) in Definition 7 to check if a lattice is isomorphic to a concept lattice, that is, in order to apply Theorem 2.

Proposition 6 *Given* $a \in A$, $b \in B$, *the applications* $\beta_b: L_2 \to V$, $\alpha_a: L_1 \to V$ *have residuated mappings, that is, there exist* $\beta'_b: L_2 \to V$, $\alpha'_a: L_1 \to V$ *such that:*

$$\begin{array}{lll} \beta_b(y) \sqsubseteq v & \textit{if and only if} & y \preceq_2 \beta'_b(v) \\ v \sqsubseteq \alpha_a(x) & \textit{if and only if} & x \preceq_1 \alpha'_a(v) \end{array}$$

for all $x \in L_1$, $y \in L_2$ *and* $v \in V$.

Proof: If we define $\beta'_b(v) = \sup\{y \in L_2 \mid \beta_b(y) \sqsubseteq v\}$ and, similarly, $\alpha'_a(v) = \sup\{x \in L_1 \mid v \sqsubseteq \alpha_a(x)\}$, we obtain the result straightforward from Corollary 1. □

The following proposition states a necessary and sufficient condition for the mappings α and β to fulfill the second condition in the definition of representable lattice.

Proposition 7 *The mappings* α *and* β *satisfy Property (2) in Definition 7 if and only if, for all* $a \in A$, $b \in B$, $x \in L_1$, $y \in L_2$, *any of the following equalities holds:*

$$\begin{array}{lcl} \beta'_b(\alpha_a(x)) & = & R(a,b) \nwarrow x \\ \alpha_a(\beta'_b(y)) & = & R(a,b) \swarrow y \end{array}$$

Proof: Firstly, we assume that the mappings α and β satisfy Property (2) in Definition 7. The first equality is given from the following chain of equivalences, given $a \in A$, $b \in B$, $x \in L_1$, $y \in L_2$:

$$\begin{array}{lcl} y \preceq_2 \beta'_b(\alpha_a(x)) & \iff & \beta(b,y) \sqsubseteq \alpha(a,x) \\ & \iff & x \,\&_b\, y \leq R(a,b) \\ & \iff & y \preceq_2 R(a,b) \nwarrow x \end{array}$$

if we substitute y by $R(a,b) \nwarrow x$ in the first sentence and y by $\beta'_b(\alpha_a(x))$ in the last one. The second equality follows similarly.

Now, we assume that $\beta'_b(\alpha_a(x)) = R(a,b) \nwarrow x$, hence

$$\begin{array}{lcl} \beta(b,y) \sqsubseteq \alpha(a,x) & \iff & y \preceq_2 \beta'_b(\alpha_a(x)) \\ & \overset{(*)}{\iff} & y \preceq_2 R(a,b) \nwarrow x \\ & \iff & x \,\&_b\, y \leq R(a,b) \end{array}$$

where $(*)$ is given from the hypothesis. □

As a result of the previous proposition, we obtain a straightforward mechanism to obtain the mappings α and β in order to check whether a lattice is isomorphic to a concept lattice.

Finally, the following property shows that any subset of $A \times L_1$ or of $B \times L_2$ is related to a concept via α and φ, or β and φ, respectively.

Proposition 8 *Consider a multi-adjoint concept lattice* $(\mathcal{M}, \preceq)$ *represented by a complete lattice* $(V, \sqsubseteq)$ *and the mappings* $\alpha: A \times L_1 \to V$, $\beta: B \times L_2 \to V$, *then for each* $K \subseteq A \times L_1$, *there exists a unique concept* $\langle g, f\rangle \in \mathcal{M}$ *such that*

$$\inf\{\alpha(a,x) \mid (a,x) \in K\} \quad = \quad \varphi(\langle g, f\rangle)$$

Analogously, for each $K' \subseteq B \times L_2$, *there exists a unique concept* $\langle g, f\rangle \in \mathcal{M}$ *such that*

$$\sup\{\beta(b,y) \mid (b,y) \in K'\} \quad = \quad \varphi(\langle g, f\rangle)$$

Proof: Given $K \subseteq A \times L_1$, let us consider the sets $K_a = \{x \mid (a,x) \in K\}$, and the function $h: A \to L_1$ defined as $h(a) = \sup K_a$.

By Corollary 1, we have that, for all $a' \in A$, the following equality holds

$$\alpha(a', h(a')) = \inf\{\alpha(a', x) \mid x \in K_a\}$$

Therefore:

$$\begin{array}{l} \inf\{\alpha(a', h(a')) \mid a' \in A\} = \\ \qquad = \quad \inf\{\inf\{\alpha(a', x) \mid x \in K_{a'}\} \mid a' \in A\} \\ \qquad = \quad \inf\{\alpha(a', x) \mid (a', x) \in K\} \end{array}$$

Finally, we obtain the following chain of equalities:

$$\begin{array}{lcl} \inf\{\alpha(a,x) \mid (a,x) \in K\} & = & \inf\{\alpha(a', h(a')) \mid a' \in A\} \\ & \overset{(1)}{=} & \sup\{\beta(b', h^{\downarrow}(b')) \mid b' \in B\} \\ & \overset{(2)}{=} & \varphi(\langle h^{\downarrow}, h^{\downarrow\uparrow}\rangle) \end{array}$$

where (1) follows by Proposition 2, (2) by Proposition 3. This means that the concept whose existence is postulated in the statement is $\langle h^{\downarrow}, h^{\downarrow\uparrow}\rangle$.

Now, the uniqueness follows from the isomorphism φ:
If there would exist another concept $\langle g, f\rangle$ such that $\sup\{\beta(b, g(b)) \mid b \in B\} = \inf\{\alpha(a,x) \mid (a,x) \in K\}$, we would have:

$$\begin{array}{lcl} \varphi(\langle h^{\downarrow}, h^{\downarrow\uparrow}\rangle) & = & \sup\{\beta(b, h^{\downarrow}(b)) \mid b \in B\} \\ & = & \inf\{\alpha(a,x) \mid (a,x) \in K\} \\ & = & \sup\{\beta(b, g(b)) \mid b \in B\} \\ & = & \varphi(\langle g, f\rangle) \end{array}$$

Thus, $\langle h^{\downarrow}, h^{\downarrow\uparrow}\rangle = \langle g, f\rangle$.

The second statement follows similarly. □

4 Conclusions

The representation theorem is one of the most important results in the theory of formal concept analysis, since it provides conditions in order to determine whether a given lattice is isomorphic to some concept lattice. In this paper, an analytic expression for the mappings α and β involved in the representation theorem of t-concept lattices is provided, together with some interesting properties.

A Neuro-fuzzy System for Fraud Detection in Electricity Distribution

C. Muniz, M. Vellasco, R. Tanscheit, K. Figueiredo

Computational Intelligence Lab., Department of Electrical Engineering,
Pontifical Catholic University of Rio de Janeiro
Rio de Janeiro, Brazil
Email: cyroassis@gmail.com, {marley, ricardo, karla}@ele.puc-rio.br

Abstract *— The volume of energy loss that Brazilian electrical utilities have to deal with has been ever increasing. Electricity distribution companies have suffered significant and increasing losses in the last years, due to theft, measurement errors and other irregularities. Therefore there is a great concern to identify the profile of irregular customers, in order to reduce the volume of such losses. This paper presents a combined approach of a neural networks committee and a neuro-fuzzy hierarchical system intended to increase the level of accuracy in the identification of irregularities among low voltage consumers. The data used to test the proposed system are from Light S.A., the distribution company of Rio de Janeiro. The results obtained presented a significant increase in the identification of irregular customers when compared to the current methodology employed by the company.*

Keywords— neural nets, hierarchical neuro-fuzzy systems, binary space partition, electricity distribution, fraud detection.

1 Introduction

Commercial electricity loss due to irregularities (energy theft and measurement errors) reach about R$ 5 billion a year in Brazil, which is around 5% of the total amount spent in energy consumption. A great part of that loss occurs in the area operated by Light S.A.: 3.8 million customers in 28 cities in the state of Rio de Janeiro. Electricity bills are, in some cases, up to 17% more expensive than they should be, so as to compensate for energy thefts and other fraudulent practices [1].

The company makes use of heuristics to indicate a set of low voltage customers who may practice some kind of irregularity. This set of customers, initially classified as suspects, is then analyzed by an expert, who selects a certain number to be directly inspected. The inspection is performed by an employee that visits each residence to confirm (or not) the irregularity. Based on this simple approach, Light S.A. has reached a low identification rate. It is evident that the adopted procedure is not effective and that a more accurate system must be developed.

Some researches have already tackled this problem, confirming the difficulty of correctly identifying irregular consumption. In [2], Rough Sets have been used to fraud detection among electrical energy consumers. The results obtained are promising but accuracy is still low (around 20%) due to the presence of noisy information in the company's database. In [3] and [4] a similar approach is presented, where only past consumption information is considered in the analysis. Due to the temporal nature of the data, time series analysis methods [5] are applied in order to get new invariant characteristics. However, other relevant variables, such as information about the measurement device and the average temperature are not considered.

This paper describes a new intelligent methodology, based on neural networks and fuzzy systems, that takes into consideration historical consumption as well as other important variables. The main objective is to increase the accuracy level when identifying irregular low voltage consumers, selected from a group of suspicious clients.

The proposed methodology is composed of two basic modules: Filtering and Classification, the former comprising an ensemble of five artificial neural networks, while the latter consists of a Neuro-fuzzy Hierarchical System [6]. In the Filtering module, each neural network indicates whether customers are suspected of irregularities or not. As in any ensemble-based methodology, the use of a committee of neural networks aims at improving accuracy by producing a consensus decision that is potentially more accurate than individual neural networks [7]. The Filtering Module was developed to better extract actual normal and irregular customers for training the Classification Module. This module is introduced in the expectation of improving even further the detection of irregularities. It should be noted that the database contains untrustworthy data, due to incorrect information filled in by some visiting employees.

The paper is organized in four additional sections: Section 2 describes the current methodology used by Light S.A. for detecting irregularities, Section 3 describes the proposed methodology, Section 4 presents the case studies considered, and, finally, Section 5 concludes the work.

2 Current Methodology for Fraud Detection

Currently, Light S.A. makes use of diverse methodologies for selecting low voltage customers that present irregularity indications. The *Quarterly Indicator* methodology consists of comparing the past three months' consumption. The *Annual Indicator* consists of evaluating clients' consumption during the last 24 months. The *Adjustment Factor* methodology compares last month consumption to that in the corresponding month of the preceding year. Finally, the *Tendency Factor* methodology consists of comparing clients' previous month's consumption with that expected in the present month. In all cases, if the reduction in consumption is higher than expected, the client is considered a suspect.

All customers identified by those methodologies form

ISBN: 978-989-95079-6-8

the set of suspects, which is analyzed by an expert; some are then recommended for direct inspection. Through this methodology, Light has attained an average *Positive Predictive Value* (PPV) of 25%, which is the proportion of proven irregular customers among all those who have been classified as suspects of some irregularity and have been inspected. Table 1 shows a typical confusion matrix [8] for a two-class problem (*normal* and *irregular* consumers).

Table 1: Suspected x Inspected Customers

System Output	Inspection Result	
	Irregular	Normal
Irregular	A	B
Normal	C	D

The PPV is computed by:

$$PPV = A / (A + B)$$

3 Proposed Methodology

The methodology proposed in this work consists of three basic modules: Pre-Processing and Normalization, Filtering and Classification.

The whole methodology is shown in Fig. 1. Fig. 1a shows the system's configuration used during the learning phase, which contains all three modules; Fig. 1b, on the other hand, presents a simpler configuration, used for the recall phase, which does not include the Filtering Module.

The first module, present in both training and recall phases and called Pre-processing and Normalization, is where all attributes are selected, normalized and coded.

It should be pointed out, however, that the available inspection database is, unfortunately, very noisy, containing unreliable information due to (intentional or not) incorrect indication of an irregular consumer as a normal one during inspection. Therefore, to create a more reliable database for training the Classification Module, a Filtering Module was conceived.

The Filtering Module makes use of a committee of five neural networks, which select *irregular* and *normal* consumers that better characterize the two different classes. The resulting filtered database is then employed for training the Classification Module, which eventually identifies a customer as *normal* or *irregular*. Therefore, future classifications of customers (recall phase) will employ only the Pre-processing and Classification modules. The Filtering Module is only necessary if the system needs to be retrained.

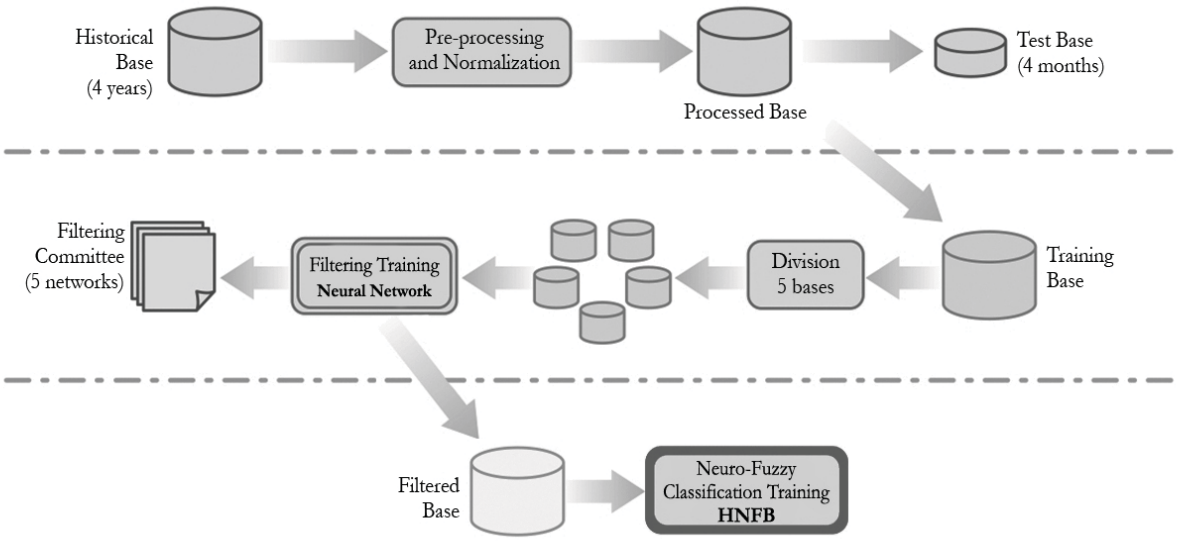

Figure 1(a): Complete methodology of the Learning Phase – Pre-processing, Filtering and Classification

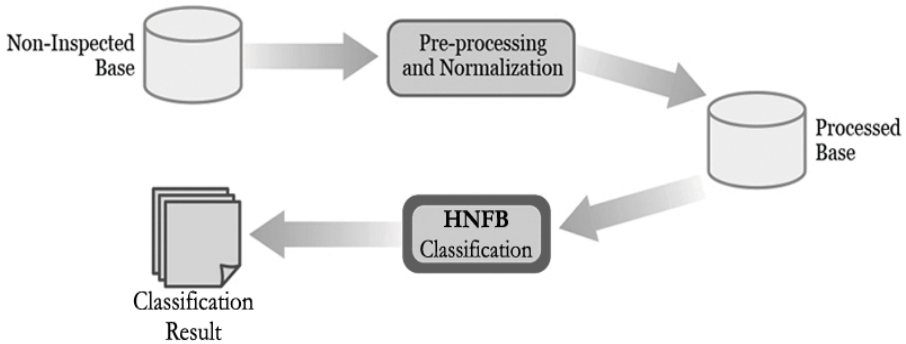

Figure 1(b): Methodology for the Recall Phase - Pre-processing and Classification modules.

ISBN: 978-989-95079-6-8

The following sub-sections present in more detail each of the modules.

3.1 Pre-Processing and Normalization Module

The data pre-processing module is composed of the following phases: selection of attributes, data cleaning and normalization. The database contains general information on both commercial/industrial and residential consumers in the so-called East Regional of Rio de Janeiro. It is well known that the behaviours of residential and non-residential clients are very distinct. Therefore, the database was divided into residential and non-residential clients, resulting in a specific Module for each class of clients.

After the evaluation of the entire available attributes, those which refer to customers' consumption for the last 4 years were selected, as well as some attributes that characterize the installation made at the consumer unit. Table 2 presents the attributes selected in this phase.

Table 2: Attributes selected from the database

Attribute	Description
Local	Consumer Unity Identification code
Inspection date	Date when the inspection was made
Related Month	Month used as a reference. Previous month to the inspection.
Origin	Main reason for the inspection
Measurer	Measuring device identifier
MonoBiTri	Indicates if the installation is mono, bi or triphasic
Consumption irregularity code	Last detected consumption irregularity
Reading irregularity code	Last confirmed reading irregularity
Month consumption	Consumer unity consumption during the related month
Previous year consumption	Registered consumption one year before the related month
Quarterly Indicator	Variation in the past three months' consumption, one by one
Adjustment Factor	Variation from the current month consumption to the same month from the previous year
Annual Indicator	Clients' consumption during the last 24 months
Tendency Factor	Clients' previous month's consumption with the consumption expected in the present month
Fraud indicator	Indicates whether the inspector found an irregularity or not

The first three attributes in the database identify, respectively, the installation where the inspection was made, the date of inspection and the month used as a reference for data acquisition. Those three attributes are presented only to identify consumer registers and are not used as inputs to the system. The five following attributes describe in detail the technical aspects of the installation and the customer's behavior. These are nominal attributes, coded as follows:

Origin – 60 different origins, divided into 4 classes (encoded in 2 binary inputs):

1. Intelligence: information extracted from the database
2. System: automatically identified information by the system of Light S.A
3. Report: complaints made by other customers or readers
4. Grouping: inspection without fraud suspicion

Measuring device – 90 models of measuring devices, grouped in 6 classes (encoded in 3 binary inputs):

1. MMD – direct mechanical measurer
2. OMMD – direct mechanical measurer (obsolete)
3. MMI – indirect mechanical measurer
4. OMMI – indirect mechanical measurer (obsolete)
5. MED – direct electronic measurer
6. OMED – direct electronic measurer (obsolete)

MonoBiTri – three different classes: monophasic, biphasic and triphasic (encoded by 2 binary inputs).

Reading Irregularity Code and *Consumption Irregularity Code* – coded in such a way that if one customer presents any kind of irregularity, his attribute will be 1; otherwise, it is zero.

The next six attributes – *consumption in a given month*, *previous year consumption* and the indicators explained below – define the consumption profile of the customer. Since these are numerical attributes, they have been normalized through:

$$value_{NORM} = \frac{v_{MAX} - value}{v_{MAX} - v_{MIN}}$$

where *value* is the attribute to be normalized, $value_{NORM}$ is the normalized attribute, v_{MAX} is the maximum attribute value registered in the last two years and v_{MIN} is the minimum attribute value registered in the last 2 years.

Four additional indicators have been computed from the monthly consumption information of each customer: *three-months moving average*, *six-months moving average*, *last 12 months average* and the *previous year average* (from the 24th previous month to the 12th previous month).

The *Fraud Indicator* attribute provides the result of the inspection, and indicates if any irregularity was found. This attribute was used as output (target) in training.

Finally, the following variables were also added to the set of attributes: *minimum* and *maximum monthly temperatures*, according to the customer's geographic area, and the *amount of consumption of all customers in the month* under analysis.

All data have been filtered (spurious data, redundant and incomplete were eliminated) and normalized [9]. Through normalization all attributes present the same interval of variation, which is important for training.

ISBN: 978-989-95079-6-8

3.2 Filtering Module

As already mentioned, the available database is rather noisy, due to some unreliable information in the Fraud Indicator attribute. In order to extract patterns from the database that are more reliable examples of actual *normal* and *irregular* customers, the Filtering Module was proposed. This consists of a committee of five neural network, all of them Multi-Layer Perceptrons (MLP) [10][11], with 21 inputs, one hidden layer and one neuron in the output layer, with sigmoidal threshold function (Fig. 2). The output neuron represents two classes: *irregular* customers (measurement or technical irregularities) and *normal* customers (those who do not show any irregularity).

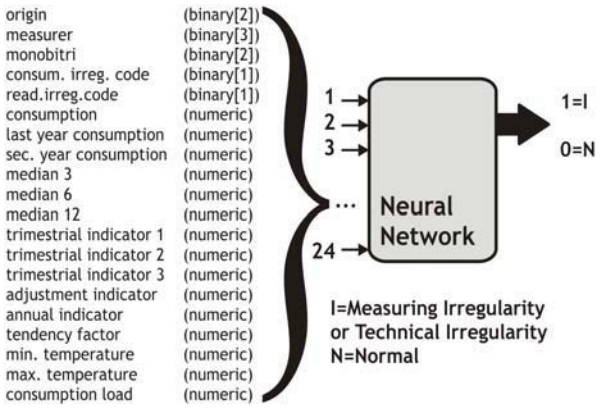

Figure 2: MLP Neural Network topology with one output

As the network output is a continuous value between zero and one, a threshold level of 0.5 was defined so as to distinguish *irregular* (output value ≥ 0.5) from *normal* customers (output value < 0.5). It should be mentioned that different threshold limits, between [0.3, 0.8] with steps of 0.05 were also evaluated, but the best performance has been achieved for 0.5.

The complete database is divided into five disjoint sets in order to train each of the networks that form the committee. After training, the complete database is processed by the neural networks. The selection of more reliable training patterns (filtering process) is carried out as follows: a pattern that is labeled as *irregular* in the dataset and is indicated by three or more votes in the committee evaluation as also *irregular* is taken as a positive true pattern, that is, a customer that actually characterizes an *irregular* pattern. On the other hand, patterns specified as *normal* in the database and indicated by at least three votes from the committee as being *normal* are called negative true patterns. These patterns are then considered as reliable examples of normal customers (see Fig. 3).

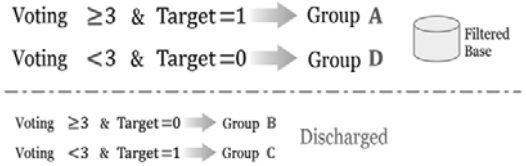

Figure 3: Limits for the Filtering Committee

A new filtered database is then formed, containing all positive and negative true patterns, which will then be used for training the Classification Module. The positively false registers (those normal patterns that receive three or more votes as being irregular from the committee) and the negatively false registers (irregular patterns that receive at least three votes as being normal) are discarded as noisy patterns and are not used to train the Classification Module.

3.3 Classification Module

As mentioned above, the main difference between this and the filtering module is the database used for training. Now only the filtered database, obtained from the filtering module, is used to adjust the classifier parameters. Once training is completed, the Classification Module is ready for use with new input patterns. In this phase, the Filtering Module is no longer necessary (see Fig. 1b), and will only be used again if retraining becomes necessary.

The structure used in this stage is a Hierarchical Neuro-fuzzy with Binary Space Partition (BSP) system [6] [12], briefly described below.

Hierarchical Neuro-Fuzzy Systems have been devised to overcome limitations of traditional neuro-fuzzy systems, which in general have a limited capacity for creating their own structure and rules. Additionally, most of the models employ grid partition of the input space, which, due to the rule explosion problem, are more adequate for applications with a smaller number of inputs. When a greater number of input variables are necessary, the system's performance deteriorates.

The Neuro-fuzzy Hierarchical BSP (HNFB) system used here makes use of basic cells. An HNFB cell is a neuro-fuzzy mini-system that performs fuzzy binary partitioning of the input space. The HNFB cell generates a crisp output after a defuzzification process. Fig. 4 illustrates the cell's functionality, where x represents the input variable, $\rho(x)$ and $\mu(x)$ are the membership functions *low* and *high*, respectively, which generate the antecedents of the two fuzzy rules, and y is the output. The linguistic interpretation of the mapping implemented by the HNFB cell is given by the following rules:

- If $x \in \rho$ then $y = d_1$
- If $x \in \mu$ then $y = d_2$

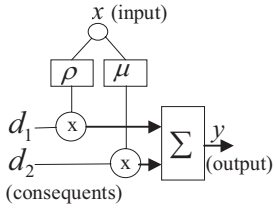

Figure 4: Neuro-Fuzzy BSP cell

Each rule corresponds to one of the two partitions generated by BSP. Each partition can in turn be subdivided into two parts by means of another HNFB

ISBN: 978-989-95079-6-8

cell. The profiles of membership functions $\rho(x)$ and $\mu(x)$ are complementary logistic functions.

The output y of an HNFB cell (defuzzification process) is given by the weighted average. Due to the fact that the membership function $\rho(x)$ is the complement to 1 of $\mu(x)$, the following equation applies:

$$y = \rho(x) * d_1 + \mu(x) * d_2 \quad \text{or} \quad y = \sum_{i=1}^{2} \alpha_i d_i$$

where α_i symbolizes the firing level of the rule in partition i and are given by $\alpha_1=\rho(x)$ and $\alpha_2=\mu(x)$. Each d_i corresponds to one of the possible consequents below:

- A singleton: d_i = constant.
- A linear combination of inputs: $d_i = \sum_{k=1}^{n} w_k x_k + w_0$

  where: x_k is the k-th input, w_k represent the weight associated with input x_k, n is the total number of inputs and w_0 is a constant value.
- The output of a generic cell j: $d_i = y_j$

The HNFB model may be described as a system that is made up of interconnections of HNFB cells, as illustrated in Fig. 5, along with the respective partitioning of the input space. In the system presented in Fig. 5, the initial partitions 1 and 2 ('BSP0' cell) have been subdivided; hence, the consequents of its rules are the outputs of BSP1 and BSP2, respectively. In turn, these subsystems have, as consequents, values d_{11}, y_{12}, d_{21} and d_{22}, respectively. Consequent y_{12} is the output of the 'BSP12' cell. The output of the system in Fig. 3(b) is:

$$y = \alpha_1(\alpha_{11}d_{11} + \alpha_{12}(\alpha_{121}d_{121} + \alpha_{122}d_{122})) + \alpha_2(\alpha_{21}d_{21} + \alpha_{22}d_{22})$$

Although each BSP cell divides the input space only into two fuzzy sets (*low* and *high*), the complete HNFB architecture divides the universe of each variable into as many partitions as necessary. The number of partitions is determined during the learning process. In Fig. 5, for instance, the upper left part of the input space (partition 12) has been further subdivided by the horizontal variable x_1, resulting in three fuzzy sets for the complete universe of discourse for this specific variable.

The training algorithm makes use of the gradient descent method for learning the structure of the model and, consequently, linguistic rules. The parameters that define the the membership functions of the antecedents and consequents are regarded as fuzzy weights of the neuro-fuzzy system.

A tuning parameter δ, called decomposition rate prevents the structure from growing indefinitely.

4 Experimental Results

This section presents the results obtained for Filtering, the Neural Networks Committee, and Classification, performed by the HNFB system.

4.1 Filtering

After processing the selected data three databases were obtained. These were composed of 4159 customers with non technical irregularity, 3754 customers with technical irregularity and 14405 normal customers.

Data were divided into Training, Validation and Testing databases. Training and Validation sets refer to the period between September 2002 and June 2006, with the exception of February and March 2006. The data for these two months, together with those for July and August 2006 were used to form the test set. These months were selected to evaluate the system's performance in different seasons (summer and winter in the southern hemisphere). Due to the unbalanced characteristic of the database, with many more examples of *normal* customers than the available number of *irregular* patterns (technical and non-technical irregularities), the training and validation sets were equalized to avoid a biased behaviour of the neural networks. The datasets actually used in the experiments consisted of 3754 customers with technical irregularities, 3754 randomly selected customers with non-technical irregularities and 7508 normal ones, also randomly chosen. For training, 75% of the balanced samples have been considered; the rest was left for validation.

Five different databases were created, each to train one of the five neural networks that form the filtering committee. For each neural network, 10 training processes were realized and the best performing network from the validation set has been selected to form the committee. The early stopping methodology was used during each training process, which specifies the optimal number of epochs to avoid over fitting and attain best generalization performance.

As the main objective of the proposed system was to increase the PPV of irregularity detection, two experiments were carried out: one considering the PPV as the error metric for the neural networks training, and another considering the general classification error as the metric used to select the best neural network. It was observed that the latter provided better results, since when the classification error for both classes is minimized, the PPV is indirectly maximized. Thus, in the following experimental results, the general classification error metric was used.

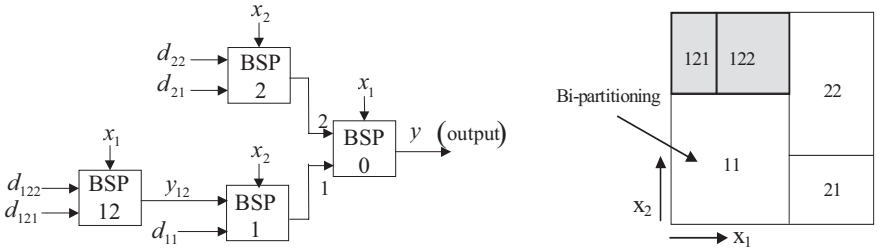

Figure 5: Example of an HNFB system and respective input space Partitioning

ISBN: 978-989-95079-6-8

After all neural networks had been trained and the committee members had been selected, a test was carried out with the data of customers investigated during the months of February, March, July and August 2006. That test base has 4663 registers of inspected customers.
Table 3 illustrates filtering results for one specific ZEI (Elementary Intervention Zones) of East Regional, in the same fashion of Table 1.

Table 3: Results with the filtering committee

	Committee	
	Irregular	Normal
Irregular	960	1164
Normal	572	1970
	PPV_{NN}:	45.2%
	Class. Error:	37.2%
	PPV_{Light}:	32.8%

As can be observed, by using only the Filtering Module the PPV has already increased from 32.8% to 45.2%.

4.2 Classification

The same inputs considered for filtering were initially considered for classification, performed by the HNFB system. After variable selection by the least-square estimator (LSE) [13], nine were effectively used as inputs to the system. The test database was identical to that used for testing in the filtering stage.

It can be seen from the classification results shown in Table 4 that the VPP has improved even further, reaching 51.2%. This attests the advantage of the proposed methodology.

Table 4: Results for classification

	Committee	
	Irregular	Normal
Irregular	991	943
Normal	541	2191
	PPV_{HNFB}:	51.2%
	Class. Error:	31.8%
	PPV_{Light}:	32.8%

In addition to performing classification, the HNFB also produces fuzzy rules as a result. In this experiment 45 rules have been generated, of which an example is:
If *Origin* is *low* and *minimum temperature* is *low* then class is *normal*.

5 Conclusions

This paper presented an intelligent system, based on a neural networks committee and on a Hierarchical Neuro-fuzzy BSP system, to identify consumers' frauds in an electrical distribution company of Rio de Janeiro, Brazil.

The system is formed by two modules, one for filtering the database and another for actual classification of a consumer. The use of this methodology greatly improved the current fraud detection rate.

Besides increasing the performance regarding the correct identification of fraudulent consumers, the system has the additional advantage of ranking irregular costumers as a result of the number of votes the neural networks committee provides to identify a customer as irregular.

The proposed methodology is being applied to other areas covered by the company. Additionally, a clustering algorithm will be applied to non-residential consumers in order to group them in classes with similar consumption behaviour.

Abstract *— This work presents a methodology for the characterization of human reliability based on fuzzy sets concepts, which has been implemented in an innovative decision support system, providing managers with an intelligent computational tool for reducing the possibility of human errors in industrial activities. Considering that such activities can be described as operational, maintenance or inspection processes, which are composed of a set of procedures, the methodology is carried out in two levels: the process level and the procedure level. The proposed system provides a human reliability index, which allows the identification of problems that may constitute causes of human errors, as well as the indication of possible strategies for the control of potentially adverse impacts of interactions that add uncertainty and complexity to processes.*

Keywords— fuzzy sets, human reliability, industrial process safety.

1 Introduction

Human reliability has received much attention in areas such as nuclear, aviation and petrochemical industries. Although resources have been historically applied mostly in equipment reliability and process optimization, it has been realized that priority should be given to the study of human reliability, focusing on the adaptation of the equipment and the working environment to the capabilities, limitations and needs of the human being. Human error usually arises from inadequacies of the system design, such as task complexity and error-likely situations. Errors are likely to occur when the task requirements exceed human limitations regarding perception, attention, remembering, etc. Some situational characteristics may predispose operators to errors, such as inadequate workspace and training procedures, as well as poor supervision. Errors may also reflect individual differences, related to human attributes such as abilities and attitudes. Important individual factors are susceptibility to stress and inexperience, for example, which may increase tenfold the possibility of occurrence of a human error.

Studies in human reliability are generally divided into two generations [1]. First-generation methods are characterized by comparing human performance to that of a machine, associating probabilities of success or of a fault to the operators' actions. Second-generation methods extend the analysis of human reliability to cognitive systems, by considering decision levels, diagnosis processes, dexterity, knowledge and organizational factors. These are probability-based methods, which makes it difficult to establish a precise model for human fault prediction, since a large quantity of data is needed for mapping all the uncertainties inherent to human behavior.

Probabilistic analysis is used for analyzing system reliability objectively and assumes that an equipment or human failure occurs at random. A failure of a single component may occur at random; a human error, however, does not necessarily occur in that way, since a human factor is composed of a large number of attributes (or performance shaping factors) and its functional structure is very complex. By using the probabilistic approach, where the equipment and procedure are qualified, it is assumed that the operator correctly implements all the procedure's provisions and thus isolates the human factor elements.

Other works [2] have contributed to human reliability research employing Fuzzy Set Theory and the concept of possibility of failure instead of probability of failure. Lian and Wang [3] used fuzzy relations to estimate the *fuzzy probability*. Nowakowski [4][5] observed that, when applying the fuzzy approach, probabilistic interpretations of human reliability are abandoned; instead, human reliability is defined in terms of possibility measures. Wang [6] used the concept of fuzziness to evaluate human performance in an inspection task. Onisawa [7] analyzed human reliability in the events that preceded the nuclear accident in Chernobyl and showed the importance of considering the possibility approach in human reliability analysis. More recently, Onisawa [8] created a model that integrates the subjectivity in specialists' opinions to reliability analysis.

This work presents a fuzzy-based decision support system for the analysis of human reliability in operation, maintenance and inspection activities in industrial and production processes, where the human error may have a great impact on safety and on the environment. As operational, maintenance and inspection processes consist of a set of procedures, the human reliability characterization method is carried out at both process and procedure levels.
This paper comprises four additional sections. Section 2 presents the methodology, describing in detail the human reliability characterization at both process and procedure levels. Section 3 presents a decision support system developed to provide managers with computational tools for the application of the human reliability characterization method, helping them to choose the most adequate strategic actions to be taken. Section 4 discusses a case study in the oil industry and Section 5 concludes the work.

2 Proposed Methodology

This work deals with a two-level analysis of human reliability in industrial activities. On a first level, each of the operation, maintenance and inspection processes are

ISBN: 978-989-95079-6-8

analyzed as a whole; then, on a second level, human reliability is considered for every procedure that composes each of the processes.

The following sub-sections describe in details the two-level analysis contemplated by the proposed methodology.

2.1 Process Level Characterization

This module is an improved version of the process level characterization first introduced in [9].

The characterization of human reliability in a process has the objective of establishing the degree of attendance of Performance Shaping Factors (PSFs), which can be of human, technical or environmental types. Such characterization may be carried out in any category: operation, maintenance or inspection.

The method for determining the degree of attendance of a set of attributes (see Fig. 1) begins with the selection of PSFs that affect the human being. After that, experts specify, through a questionnaire, the influence of each of these factors on human reliability. By aggregating the experts' opinions about the PSFs' influences, weighed by the degree of importance of each expert, a standard degree of influence is established for each PSF. By considering the degrees for all PSFs, a Quality Standard is obtained. In a second stage, workers' opinions on the attendance of each of the PSFs are collected, also through a questionnaire, producing the degree of attendance of each PSF [9].

For human PSFs that are related to cognitive characteristics, namely intelligence, communication ability, sociability, attention, stress and anticipation, the attendance degree is determined by psychometric tests applied to each operator. It is considered that, for such type of factors, the operators opinion would correspond to a self judgment, which could result in biased information about the attendance degree. Psychometric tests are likely to provide more reliable results, since they are constructed to determine individual psychosomatic characteristics in an unbiased manner. The enhanced process level characterization method is depicted in the diagram of Fig. 1, which highlights the Psychometrics tests module, one of the significant contributions of this work.

2.2 Procedure Level Characterization

The human reliability characterization at procedure level focuses on two main objectives: establish a failure possibility index for each procedure in an operation, maintenance or inspection process, and for each of the human actions that are performed to accomplish it; and secondly, establish the degree of attendance for each worker with respect to the cognitive demands of each action within the procedure.

The characterization method requires that experts specify the failure expectation for each action, the degree of dependency of each action on the preceding one, the influence that a failure in one action may have on subsequent ones and the cognitive demands of each action. All this information is acquired through the application of questionnaires, where experts give linguistic answers such as *low*, *medium*, or *high*. The experts' opinions are aggregated and weighed by the degree of importance of each expert so as to produce, for each action, a failure possibility index and standard demand degrees with respect to the cognitive factors considered. The overall failure index for the procedure can be obtained by combining the actions indexes. By submitting the workers to psychometric tests, the degree of attendance of each cognitive factor for all operators can be determined. The method is depicted in the diagram of Fig. 2.

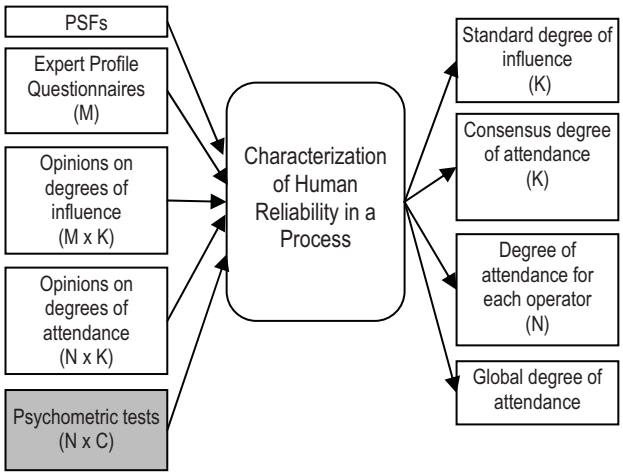

Figure 1: Characterization of Human Reliability in a Process, with K PSFs, C cognitive factors, M experts and N operators.

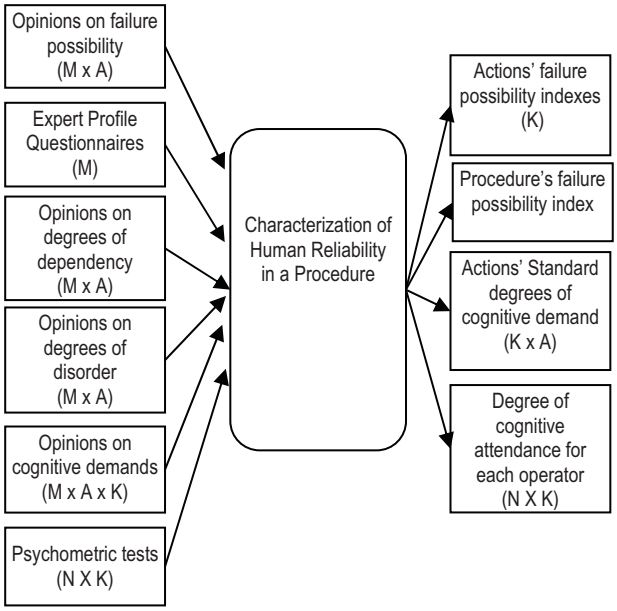

Figure 2: Characterization of Human Reliability in a Procedure, with A actions, K cognitive factors, M experts and N operators.

The procedure level characterization methodology consists of the following stages.

Establishment of a committee of decision-makers

This is one of the most important steps in the methodology, since the quality of information will depend on the experts' proficiency.

Establishment of the relative importance of each expert

This step is accomplished through an Expert Profile Identification Questionnaire (EPIQ), which consists of a set

ISBN: 978-989-95079-6-8

of questions for the evaluation of each expert's relative importance and thus assigning him a weight [10]. This weight will establish the influence of the expert's opinions on the final standard degrees and failure possibility indexes.

Choice of linguistic values for the evaluation of actions

This stage consists of choosing linguistic terms, or values, for the evaluation (by experts) of the expectation of failure of an action, its degree of dependency on the preceding one, its influence on subsequent ones and its cognitive demands. For instance, the terms used for the evaluation of the expectation of failure usually are: *very high, high, medium, low,* and *very low***.** All terms are associated to triangular fuzzy sets, defined by three parameters.

Acquirement of experts' opinions

This step consists of obtaining from the selected experts, through questionnaires, their opinions on the expectation of failure of each action, its degree of dependency on the preceding action, its influence on succeeding ones and its cognitive demands.

Application of psychometric tests to operators

Psychometric tests are applied to operators in order to obtain the degree of attendance of cognitive demands for each worker.

Fuzzy treatment of the data provided by experts and of psychometric tests results

Here, the individual prognoses from each expert for failure expectation, dependency, influence on future actions and cognitive demands are aggregated, generating a consensus for each evaluated attribute. The Hsu and Chen's model [11] is used to pool the expert's opinions: the similarity aggregation method (SAM) is used for combining the opinions of each expert. The opinion of an expert i is expressed by a fuzzy set denoted by $\tilde{A}_i$. The agreement degree (or similarity measure) $S(\tilde{A}_i, \tilde{A}_j)$ between two experts i and j can be determined by the proportion of the consistent area to the total area:

$$S(\tilde{A}i,\ \tilde{A}j) = \frac{\int_x \min(\mu_{\tilde{A}_i}(x), \mu_{\tilde{A}_j}(x))dx}{\int_x \max(\mu_{\tilde{A}_i}(x), \mu_{\tilde{A}_j}(x))dx} \quad (1)$$

Once all agreement degrees between experts are measured, an agreement matrix (AM) can be built, giving an insight into the agreement between the experts.

$$AM = \begin{bmatrix} 1 & S_{12} & S_{13} & ..... & S_{1n} \\ S_{21} & 1 & S_{23} & ..... & S_{2n} \\ . & . & . & . & . \\ . & . & . & . & . \\ S_{n1} & S_{n2} & S_{n3} & ..... & 1 \end{bmatrix} \quad (2)$$

The average agreement degree AAD_i of expert E_i (i = 1 to n) is given by:

$$AAD_i = \frac{1}{n-1}\sum_{\substack{j=1 \\ j\neq i}}^{n} S_{ij} \quad (3)$$

The relative agreement degree RAD_i of expert E_i (i = 1 to n) is given by:

$$RAD_i = \frac{AAD_i}{\sum_{i=1}^{n} AAD_i} \quad (4)$$

Finally, by weighing the relative agreement degree of each expert k by the degree of importance Gi_k (obtained through a questionnaire), the consensus coefficient for that expert can be calculated by equation (5).

$$CC_k = \frac{RAD_k * Gi_k}{\sum_{i=1}^{n}(RAD_i * Gi_i)} \quad (5)$$

The aggregated opinions are given by:

$$\tilde{N} = \sum_{i=1}^{n} CC_i \times \tilde{A}_i \quad (6)$$

In order to obtain a single value for each of the evaluated attributes – representing the failure expectation index, the dependency and adverse influence degrees, and the cognitive demands for each action, the *max* defuzzification method is applied [12].

For the case of cognitive demand, after normalization, and considering all cognitive demands for all actions, a Cognitive Demand Standard is built.

The overall failure possibility index for an action i (P_i) is obtained from its failure expectation index (F_i), its dependency degree on the previous action ($D_{i,(i-1)}$) and the adverse influence degree caused by failure of preceding actions ($T_{j,i}$; where $j< i$):

$$P_i = (1-(1-F_i)*(1-D_{i-(i-1)})*\prod_{j<i}(1-T_{j,i})) \quad (7)$$

The overall failure possibility for a procedure is obtained from the actions indexes:

$$P_{procedure} = (1-\prod_{i}(1-P_i)) \quad (8)$$

Finally, a degree of attendance of the operators to the Cognitive Demand Standard of each action is obtained. For that matter, the degree of attendance (OP_k) to each cognitive demand is multiplied by its demand standard (DS_k) and a weighted average R is then calculated:

$$R = \frac{\sum_{k=1}^{n} DS_k * OP_k}{\sum_{k=1}^{n} DS_k} \quad (9)$$

3 Decision Support System

The decision support system for human reliability analysis was developed as an Intranet application, maintaining all information in a centralized database and being accessible to all professionals involved in a characterization project: managers, experts, operators and psychologists.

The system is totally configurable to any company or business area and can de used for characterization and analysis at process and procedure levels, allowing for:

- human reliability characterization trials or *projects*, as they are called in the system, for different units of the company and different periods of time;
- the complete configuration of the PSFs to be considered, as well as the corresponding questionnaires to be applied to experts and workers, so

ISBN: 978-989-95079-6-8

that questions can be set up in accordance with the personnel's profile and company's characteristics;
- the complete configuration of the sequence of actions that make up the procedures to be analyzed;
- the on-line answering of EPIQ, PSF and procedure evaluation questionnaires by experts;
- the on-line answering of PSF questionnaires by operators;
- the on-line input of the psychometric test results for all workers by an authorized psychologist;
- the association of reference files to each project, such as manuals or norms that must be followed on the given human reliability characterization trial.

The system provides two sets of reports that give managers effective support on strategic decisions regarding the improvement of human reliability, and, consequently, the minimization of process failure.

The first set of reports, called *Process Reports*, comprises results from the process level characterization, including:

- Degree of importance of *PSFs*:
  The opinions of all experts with respect to the degree of importance of all PSFs are presented in a comparative chart.
- Average degree of attendance of PSFs:
  The average degrees of attendance of all PSFs, as seen by each operator, are presented in a comparative chart. A degree close to 1 indicates that, in the environment being evaluated, the operator considers that, in average, the quality standard is being met. On the other hand, a degree closer to 0 indicates that the operator evaluates that, in average, the quality standard is not being attended to. In this case, the possibility of failure for this worker is high.
- Distance to quality standard for all PSFs, as seen by a given operator:
  The quality standard for PSFs, established by the experts, represents the PSF *demand*, while the attendance degrees specified by a worker represent the PSF *offer*. This report shows graphically and in tabular form the distances between offer and demand. The greater the distance between the attendance degree and the quality standard, the more efforts and investments should the company dedicate to the given PSF to increase its attendance level. Factors with distances larger than 0.5 should merit special attention (Fig. 3).
- Inclusion coefficients for all PSFs, as seen by a given operator:
  This report shows the inclusion degree of the fuzzy set *quality standard* in the fuzzy set *attendance*, given by each operator. An inclusion coefficient close to 1 indicates that, in the environment being evaluated, the particular operator assimilation is greater than the quality standard.

The second set of reports, called *Procedure Reports*, present results from the procedure level characterization, including:

- Failure expectation for actions:
  The experts' aggregated expectations with regard to the failure of each action are presented. Failure expectations are presented together with the corresponding aggregated certainty degrees, which indicate the overall degree of sureness of the experts with respect to their opinions.

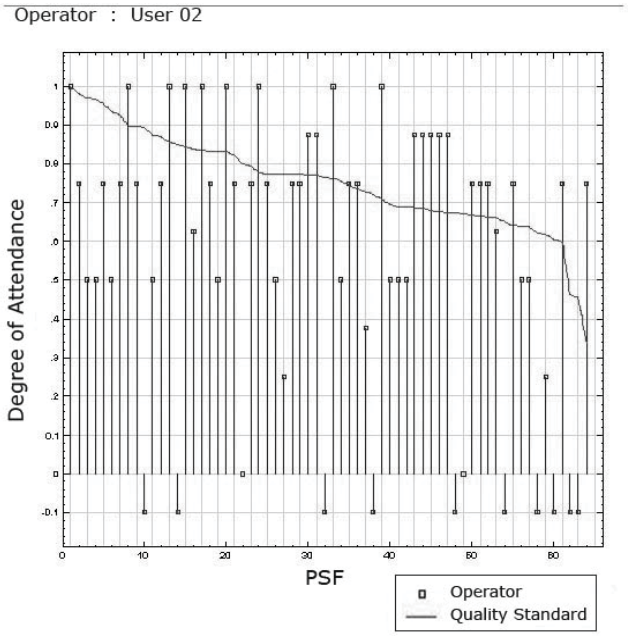

Figure 3: Distance to quality standard for all PSFs, as seen by a given operator.

- Dependency degree of actions:
  The experts' aggregated opinions on the dependency of each action on the previous one are presented. A degree close to 1 indicates that a failure on the previous action will most probably cause a failure on the current action. Actions with degrees higher than 0.6 deserve special attention. The dependency degrees are also presented together with the related aggregated certainty degrees.
- Influence of actions:
  In a matrix form, this report presents the experts' aggregated opinions about the possibility of a failure in each action having an influence on succeeding actions (Fig. 4). Degrees higher than 0.6 should be analyzed.

Action	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18

18																		**1.00**

Figure 4: Influence of actions on subsequent ones

- Cognitive demands of actions:
  This report presents the degree with which a cognitive aspect is demanded for a worker to correctly execute an action (in the consensual opinion of all experts). The

ISBN: 978-989-95079-6-8

degree of attendance of each cognitive factor for each operator is also shown. It indicates on which cognitive aspects the worker should receive training. Cognitive demands higher than 0.6 deserve special attention.

- Procedure overall failure possibility:
  The overall failure possibility indexes for the procedure and its actions are shown.

4 Case Study

An oil refinery was chosen as the unit for the case study, namely REDUC (Refinery of Duque de Caxias). This is located at Campos Elísios district, Rio de Janeiro, Brazil, and produces petrol, lubricants and other oil derivatives. The object of this case study is Procedure 1 (part of the Refinery Operation Process [9]), composed of the actions listed in Fig. 5.

The influence on each action by each cognitive factor was evaluated by 17 experts, who answered the questionnaire. The cognitive factors studied were: Anticipation, Attention, Calculation, Emotional State, Group Identification, Intelligence, Memory, Perception, Personality and Stress.

Taking as a basis the API 770 norm, two PSFs questionnaires, one for operators and another for experts, were configured for the considered unit. Both questionnaires correlate one question to each PSF. By using this specific questionnaire, an expert can evaluate which are the most critical PSFs. The system generates the PSFs quality standard by putting together the answers of all experts and weighing them based on EPIQ. By answering his questionnaire, an operator evaluates each PSF attendance. To evaluate the attendance of PSFs associated to cognitive factors, a questionnaire is used by a specialized psychologist, who analyses, based on standard psychology tests, how each interviewed operator is responding to each cognitive factor.

In total, 51 workers of the Operation Process answered the PSFs questionnaire, giving opinions about their working conditions. The 17 available experts answered the questionnaire in order to determine which PSFs had higher need to be attended. They also answered the EPIQ and the questionnaires about actions of Procedure 1, that is, expectation of failure, degree of dependency, influence on subsequent actions and cognitive demands. After all operators and experts of REDUC answered their respective questionnaires, the final reports could be consulted in the system by *project* administrators and managers.

The reports obtained in this case study are described below.

Report of Failure Expectation of Actions

From the report presented in Fig. 6, it is possible to conclude that the actions which had the higher failure expectation were: Return of Line to The Operation, Release of Line to The Maintenance, Return of Tank to The Operation, Aliments Change, and Area Survey.

Action Dependency Ratio Report

This report, depicted in Fig. 6, demonstrates that the actions which had higher dependency ratio on the preceding action were: Return of Pot Flare (18), Return of Line to The Operation (16), and Product Shipments to CIAS, BR/GEI, PETROFLEX (8).

Action Influence Report (see Fig. 4)

Based on this report, it is possible to conclude that actions Demands (1) and Aliments Change (7) have more influence on subsequent actions than any other. Additionally, Product Shipments to CIAS, BR/GEI, PETROFLEX (8) and Loading of Trucks (12) are most affected than other actions.

	Action	Failure Expectation	Certainty Degree

Cognitive Demand Attendance Degree of Actions

ISBN: 978-989-95079-6-8

This report, shown in Fig. 7, is used for comparison between the cognitive demand of actions of Procedure 1 and the attendance of each worker. Therefore, a manager can infer whether an operator is capable of executing the actions he/she is assigned to. For instance, it can be seen in Fig. 7 that the given operator does not attend the Anticipation requirement of actions 9, 13 and 16.

Global Index of Failure Possibility of Actions

This report, shown in Fig. 8, indicates the possibility of failure of each action, considering every influence it experiences (such as influences and dependencies from other actions, failure expectation). The system allows the manager to choose the cut level of the influence to be considered. A higher cut level means that the preceding actions which have low influence will not be considered. As a result, in this case study, a 0.6 cut level returns the mid and final actions as the ones with the highest failure possibilities. In opposition, a 0.9 cut level returns a more disperse failure profile, since it only considers the preceding actions that have large influence on the action itself.

5 Conclusions

An innovative system for the evaluation of human reliability in industry has been presented. The approach taken makes use of fuzzy sets, so that experts and operators' opinions can be translated into mathematical terms. As a consequence, a Quality Standard (QS) can be established and the attendance to performance shaping factors can be evaluated.

This system can be used at both process and procedure (consisting of series of actions) levels and produces several reports that help managers to make decisions aimed at reducing the possibility of human errors. A case study considered a unit of a Petrobras (Brazilian Oil Company) refinery, where the system has been actually applied to.

Acknowledgment

The authors would like to thank Petrobras S.A. for the financial support to develop the decision support system.

Multivariate Segmentation of Time Series with Differential Evolution

Daniel Graves[1] Witold Pedrycz[2]

Abstract—*A new method of time series segmentation is developed using differential evolution. Traditional methods of time series segmentation focus on single variable segmentation and as such often determine sections of the time series with constant slope (i.e. linear). The problem of segmenting multivariate time series is significantly more involved since several time series have to be jointly segmented. Thus the concept of boundary becomes ill-defined since each time series may not be exactly synchronized and change identically in time. The problem is rectified by minimizing the mean of the variance of the slopes determined in each segment. Performance of the method is measured in terms of the classification rate and the accuracy of determination of boundaries. Experimental evidence shows the effectiveness of the method when applied to synthetic and real-world data compared with multivariate time series clustering approaches.*

Keywords—Multivariate segmentation, differential evolution, time series, fuzzy clustering.

1 Introduction

Many data come in the form of time series that need to be partitioned into contiguous blocks in time. Tools of Computational Intelligence have been applied to solve the time series partitioning problem are commonly referred to as time series segmentation including fuzzy clustering, hierarchical clustering, and genetic algorithms. Time series segmentation of a single variable has been studied extensively in the literature, c.f. [1,2,3,4,5]. However, there is a lack of research in the area of multivariate time series segmentation or the joint segmentation of several time series.

Only a few multivariate segmentation algorithms found in the literature cluster the time series by taking into account temporal information, e.g., [5,6,7,8]. Unfortunately clustering a time series to perform segmentation poses a few problems. An important issue with segmentation of a time series which has to be addressed is that segments must be contiguous in time. Several approaches have been considered to solve this problem. One method uses constrained clustering to find contiguous segments in time, i.e. constrained hierarchical clustering. Another approach uses time information as an auxiliary component exploited directly in the clustering process. A significant problem is to effectively use this auxiliary information in the clustering procedure leading to boundary identification. However, augmenting clustering with time information is not an appropriate vehicle for segmenting a time series since identification of boundaries requires use of time information as auxiliary information in clustering. A common problem produced by augmented clustering algorithms that account for time information is that the resulting partition does not necessarily consist of contiguous segments. Currently, the literature lacks an effective method of using the auxiliary information in clustering.

The focus of this research is in multivariate time series segmentation by a more direct segmentation method that avoids the problems produced by using clustering as a vehicle for segmentation by employing differential evolutionary optimization of an objective function. As well, evolutionary methods such as differential evolution are well suited for structural optimization. The reason for using differential evolution (DE) to segmentation a time series is that the segmented boundaries to be optimized cannot be *explicitly* expressed in the underlying objective function. This makes gradient-based optimization methods not feasible in this problem. The optimization calls for methods of structural optimization and various techniques of Evolutionary Computing are of interest. In this category of methods, DE has shown to be effective as far as quick convergence is concerned.

We focus on detecting slope changes in the time series in order to determine segments. The motivation behind approaching the problem of segmentation by detecting monotonicity is that often a time series can be represented quite effectively using only a handful of monotonic models for each segment. An example is with a set of ECG time series which are often characterized by sharp spikes in the middle. A potential application of segmentation that detects changes in slope is in signal compression, c.f. [2].

There are a number of other applications of multivariate time series segmentation. An example is presented in [9] for process monitoring, diagnosis and control of a medium and high-density polyethylene plant. Another application of multivariate time series segmentation is with music structural segmentation where the objective is to automatically determine a partition of structural elements in music, i.e. verse, chorus, bridge, by detecting significant transition points in the music.

The material is organized in five sections. A literature review is covered in Section 2. Section 3 includes a description of the segmentation algorithm and presents the essentials of differential evolution. Section 4 concentrates on the experimental evaluation of the multivariate segmentation algorithm. The proposed method is evaluated on synthetic data sets and on several real-world time series data sets coming from Time Series Data Library [10]. Section 5 presents the conclusions.

2 Literature Review

Time series segmentation is a very important topic with temporal information processing as long time series need to be broken down into relevant segments. The problem of segmentation has not been solved with high boundary detection accuracy in the literature hence most of research conducted in the literature focuses on the segmentation aspect and leaves the labelling of segments to be done later.

Most time series segmentation approaches look at the problem of segmenting a time series of a single variable. There are three main categories of classical segmentation algorithms available in the literature:

- Bottom-up
- Top-down
- Sliding-window

Unfortunately high segmentation accuracy is not always achieved and there is no one method preferred than the others. The three algorithms are described in [1]. All three have an error threshold where they stop segmenting once the error is exceeded. The first bottom-up starts with each sample in its own segment much like agglomerative hierarchical clustering. Likewise top-down is similar to divisive hierarchical clustering in that the entire time series is broken down into smaller segments until the error for each segment is less than the error threshold. Sliding-window is a real-time segmentation algorithm that starts with the first sample and extends the segment with each new sample until an error threshold is exceeded.

Determining segments via linear approximation and evolutionary methods is common in the literature such as methods using genetic algorithms to approximate an ECG time series trough a set of its linear segments, cf. [2]. In [2], the fitness function minimizes the variability between the maximum and minimum slopes for each consecutive sample within the proposed segment. The number of segments is determined beforehand. The experiments are conducted on ECG signals which show fairly good match on the data, i.e. little information appears to be lost during segmentation (which also leads to dimensionality reduction).

Multivariate time series are common in practical problems. Many of the approaches discussed in the literature are not directly applicable to them. An inherent problem with multivariate time series segmentation is that it difficult to determine boundary points where each feature time series in the multivariate time series unanimously agree. For example, a question arises whether a significant change in one feature's value where all other features do not change significantly constitutes a boundary change point for a time series. Also not all features may change at exactly the same point in time; hence, multivariate segmentation approaches require greater boundary point flexibility to account for the latent changes among the feature values. As a result, some limited work has been done in the literature directly applicable to multivariate time series segmentation, c.f. [5,6,7,9].

The multivariate time series segmentation method developed in [9] approaches the problem as a constrained clustering problem with the constraint that a cluster (i.e. segment) must contain patterns at successive time points. The approach also constructs fuzzy sets for specifying the segments detected with fuzzy boundaries. Local Principal Component Analysis (PCA) models are used in clustering of the time series into segments based on Gath-Geva clustering. They apply the segmentation algorithm to process monitoring, diagnosis and control in particular monitoring a medium and high-density polyethylene plant, i.e. production of a versatile plastic. The data is multivariate and is successfully segmented via the proposed clustering algorithm.

A Gath-Geva-based clustering algorithm similar to the approach in [7,9] is introduced for application to multivariate time series segmentation. The approach described in [9] and [7] utilize a modified Gath-Geva clustering based on the probabilistic PCA (PPCA) [11] for each cluster. The method in [9] and [7] constrain the segment (cluster) fuzzy sets (membership matrix) to Gaussian membership functions. The method in [7] uses modified Gath-Geva clustering (a.k.a. fuzzy maximum likelihood clustering) to cluster a multivariate time series. The time information is included as an attribute in the time series. The segments are projected onto principal components based on a localized PPCA models for the rationale that the correlation between variables often changes with multivariate time series. The distance measure in the clustering is chosen to include two parts: Gaussian fuzzy sets determining distance in the time domain and a second term that measures the distance of the data from the PCA hyperplane model. The number of principal components to keep in the PPCA model and the number of segments (clusters) are two important parameters that need to be selected via some other method. The authors include some case studies in the literature for the application of the approach to multivariate time series segmentation although the experimental evidence is limited.

Speaker segmentation is discussed in [5]. The method exploits the BIC (Bayesian Information Criterion) procedure, known also as the minimum description length (MDL). The objective is to determine segments of different speakers. Some improvements are found in their approach over traditional BIC approaches. Multivariate segmentation in [6] is accomplished via constrained clustering for the purpose to determine the important structural components of a musical recording, i.e. intro, verse, chorus, solo, bridge, outro. They report some improvements in the classification rate and boundary f-value with their method over traditional approaches. A multivariate time series segmentation algorithm based on hierarchical Bayesian clustering was developed in [12] specifically designed for astronomical data that can be modelled as a Poisson counting process. Some experiments on synthetic data and real astronomical data are provided however they are limited. Authors in [8] describe multivariate segmentation approach for motion data using singular value decomposition (SVD) in the distance measure between multivariate motion time series. The experimental results are very limited.

3 Multivariate Segmentation

3.1 *Problem Formulation*

The problem of multivariate segmentation involves finding the boundaries in a time series that denote changing behaviour in the time series. For instance a time series might be increase steadily and then at a time t_o the time series changes behaviour and starts decreasing steadily. Extending this to the multivariate case, each variable which is a time series in itself, exhibits changes in behaviour after the boundary at t_o. With single-variable time series segmentation, segments are contiguous homogenous partition series that are specified by a set of boundaries that divides segments from their adjacent ones. Multivariate segmentation is the problem of finding a set of boundaries that jointly divides each time series into a set of contiguous partitions of multivariate time series. With multivariate time series, segmentation is more complicated since each feature can be considered a separate time series and hence what might be considered a boundary in one may not be considered a boundary in the other. i.e., the transitions in each feature signal may start and end at different points in time providing conflicting clues as to where the segment starts and ends.

Given a multivariate time series $x_{t,k}$ for t=1…T with M features k=1…M, the time series can be segmented through slope analysis of each feature. The idea is to find segments with similar slopes, i.e. finding segments that are monotonic with relatively constant slopes. Assuming the number of segments c is known a priori, the boundaries for the segments are the free-parameters given by $[b_1, b_2, \dots, b_{c-1}]$ where $b_0 = 1$ and $b_c = T$. An example of a multivariate segmentation is given in figure 1.

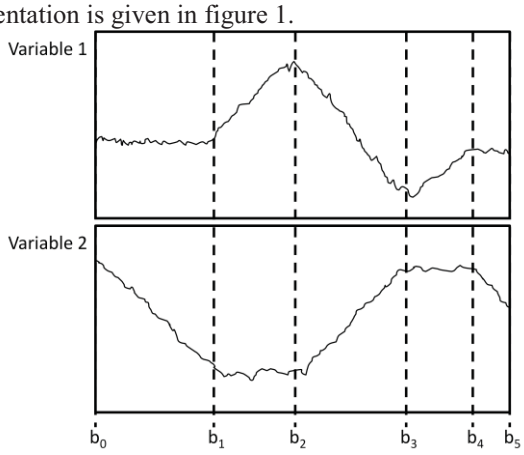

Figure 1: Multivariate segmentation illustration

3.2 *Differential Evolution*

Differential evolution is simple population-based evolutionary optimization technique that minimizes (or maximizes) an objective function much like genetic algorithms, c.f. [13]. Differential evolution uses mutation and crossover operations just as genetic algorithms; however, the mutation operation is based on population vector differences. The population of vectors are given by the set $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_P\}$ where each vector $\mathbf{x}_i$ is real-valued and has dimensionality M. The objective function to be minimized is denoted by f(**x**). The vectors in the population assume values in the unit interval and P is the size of the population. The range of values for the population vectors is on the interval [0,1].

The essence of the differential evolution is expressed via the following pseudo code

1. Initialize Population of size P
2. Loop until stopping criterion met
    1. For each element $\mathbf{x}_i$ in the population
        1. Randomly select three parameter vectors: $\mathbf{x}_{r1}$, $\mathbf{x}_{r2}$, $\mathbf{x}_{r3}$ (not the same)
        2. Generate a mutant vector $\mathbf{v}_i=\mathbf{x}_{r1}+G[\mathbf{x}_{r2}-\mathbf{x}_{r3}]$ *[Mutation]*
        3. Generate trial vector $\mathbf{u}_i=\text{crossover}(\mathbf{v}_i,\mathbf{x}_i)$ by mixing vectors $\mathbf{v}_i$ and $\mathbf{x}_i$ *[Crossover]*
        4. If $f(\mathbf{u}_i) < f(\mathbf{x}_i)$ then replace $\mathbf{x}_i$ with $\mathbf{u}_i$ in population
3. Termination

The difference factor G controls the intensity of mutation (i.e. vector differences). The difference factor G can take on positive real numbers as well as zero, c.f. [4]. There is also a crossover operation. Many different kinds of crossover operations are possible. Here we use the one presented in [4]. This crossover operation combines two vectors $\mathbf{x}_i$ and $\mathbf{y}_i$ according to the pre-specified probability p_{cr}. The resulting crossover vector produced by crossover is give by the expression

$$u_{i,k} = \begin{cases} v_{i,k} & if\ r_k < p_{cr} \\ x_{i,k} & otherwise \end{cases} \quad (1)$$

where r_k is a uniform random sequence of numbers on the interval [0,1] for k=1 … M.

3.3 *Fitness Function*

The boundaries of the segments are determined via differential evolution. Here we elaborate on the pertinent algorithmic details.

A difference (describing slope) sequence is calculated for each variable k=1…M in the multivariate time series

$$D_{tk} = x_{t+1,k} - x_{t,k} \quad (2)$$

for t=1…T-1.

Given a set of boundaries $[b_1, b_2, \dots, b_{c-1}]$ where $b_0 = 1$ and $b_c = T$, the length of each segment is given as

$$L_i = b_i - b_{i-1} \quad (3)$$

The variance of the slopes of each variable are calculated via the expression

$$S_{ik}^2 = \sum_{t=b_{i-1}}^{b_i} \frac{(D_{tk} - \overline{D}_{ik})^2}{L_i - 1} \quad (4)$$

where $\overline{D}_{ik} = 1/L_i \sum_{t=b_{i-1}}^{b_i} D_{tk}$ is the mean slope of each variable k=1…M for each segment i=1...c. The mean of the standard deviations across the variables is calculated for each segment, i.e.

$$S_i = \frac{1}{M} \sum_{k=1}^{M} \sqrt{S_{ik}^2} \quad (5)$$

for i=1…c.

ISBN: 978-989-95079-6-8

Finally multivariate segmentation is accomplished by minimizing the following fitness function

$$F = \sum_{i=1}^{c} S_i L_i \tag{6}$$

where S_i is the standard deviation defined in (4) and L_i is the segment length defined in (2). The resulting segmentation favors segments with slopes that do not vary greatly; hence, the resulting segments are approximately linear.

3.4 *Population Encoding*

Each population vector is encoded in differential evolution as a vector of real-valued numbers denoted by $\mathbf{y} = [y_1, y_2, \ldots y_{c+1}]$. The set of boundaries $\mathbf{b} = [1, b_1, b_2, \ldots, b_{c-1}, T]$ is calculated from the vector $\mathbf{y}$ where the first and last elements ($b_0 = 1$ and $b_c = T$) can be discarded. The boundaries are calculated in the form:

1. $\mathbf{z} = sort - least - to - greatest(\mathbf{y})$
2. $\mathbf{a} = \frac{\mathbf{z} - z_1}{z_{c+1}}$
3. $\mathbf{b} = round(1 + (T-1)\mathbf{a})$

The elements of vector $\mathbf{y}$ is sorted from least to greatest and its sorted version is denoted as a new vector $\mathbf{z}$ so that the boundaries are given in order. The vector $\mathbf{z}$ is normalized to a vector of numbers on the range [0,1] called $\mathbf{a}$ by subtracting the smallest element in $\mathbf{z}$ given by z_1 since the vector is sorted and divided by the largest element z_{c+1}. The vector $\mathbf{a}$ maps directly to boundaries in the time series where 0 is the start of the time series and 1 is the end of the time series. The vector $\mathbf{b}$ is calculated by expanding the range of $\mathbf{a}$ to the set of integer time coordinates $\{1, T\}$. The reason for sorting the vector is that taking vector differences (the mutation operation in differential evolution) can result in negative values. Simply normalizing the vector by its sum as done in [2] would produce erroneous results since vector elements are not necessarily positive. Elements of $\mathbf{y}$ needed to be mapped to the interval [0,1] where the smallest value of $\mathbf{y}$ is mapped to the start of the time series.

4 Experiments

The objective function described in section 3.2 minimizes slope variance for each segment. The optimization procedure is unsupervised, i.e. does not use pre-labelled data during optimization. The following synthetic experiments are evaluated against an *a priori* segmentation provided by a human expert. The classification rate and boundary f-value criteria are used to evaluate the synthetic experiments. The classification rate is the percentage of correctly classified samples according to a pre-segmented time series (human labelled) and is indicative of the precision. The boundary f-value is a measure of the number of correct boundaries in the resulting segmentation. The boundaries discovered by the algorithm are denoted by vector $\mathbf{b}$ and the human labelled boundaries are given by the vector $\mathbf{h}$ where $\mathbf{b}$ and $\mathbf{h}$ have length denoted by $L_{\mathbf{b}}$ and $L_{\mathbf{h}}$ respectively. The boundary f-value is determined according to the following expression

$$f = \frac{2pr}{p + r} \tag{7}$$

where p is the boundary precision and r is the boundary recall calculated as follows

$$n = \sum_{i=1}^{L_{\mathbf{h}}} \begin{cases} 1 & if\ \theta > \left| \mathbf{h} - \min_{\forall j = 1 \ldots L_{\mathbf{b}}} \{|h_i - b_j|\} \right| \\ 0 & otherwise \end{cases} \tag{8}$$

$$p = \frac{n}{L_{\mathbf{b}}} \tag{9}$$

$$r = \frac{n}{L_{\mathbf{h}}} \tag{10}$$

where n is the number of correctly classified boundaries with respect to the provided human labelled boundaries and θ is a threshold value which determines the tolerance or region of acceptable difference between the human labelled boundary and machine labelled boundary. The following figure demonstrates the calculation of the f-value.

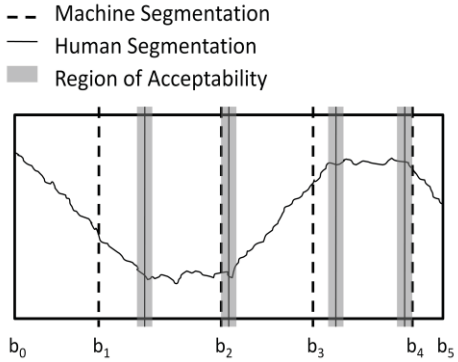

Figure 2: Multivariate segmentation illustration

The reconstruction error is the performance index for the real-world data sets since no human labels are present, i.e.

$$E = \frac{1}{MT} \sum_{k=1}^{M} \sum_{t=1}^{T} \left(\hat{x}_{t,k} - x_{t,k} \right)^2 \tag{11}$$

where $\hat{x}_{t,k}$ is the reconstructed time series. The time series $\hat{x}_{t,k}$ is reconstructed by approximating each segment via a linear line of the form $\hat{x}_{t,k} = m_k t + b_k$ from the first point in the segment to the last point in the segment for each variable k=1...M. The values m_k and b_k are the slope and intercept, respectively, of the line for each variable k.

Four synthetic time series were segmented using the described multivariate time series segmentation algorithm. Each variable for time series DATA1, DATA2, DATA3, and DATA4 are given in the figure below where DATA1 and DATA3 have four feature time series and DATA2 and DATA4 have three. The length of each time series is 325, 300, 775, and 700 samples respectively. These time series were generated by creating a collection of linear segments and then adding white noise.

The experimental results on the synthetic data are shown in table 1. They are compared with FCM-DFS (Fuzzy C-Means clustering with Distinct Feature Sets) time series clustering described in [14] for segmentation. The value of theta was chosen to be relatively small, i.e. 3, since the synthetic data sets are relatively simple often with an underlying linear component mixed with white noise. Also, it was noted that generally the segmented boundaries were either very close to the human defined boundary (within 3 samples) or the boundary was not properly discovered by the segmentation algorithm.

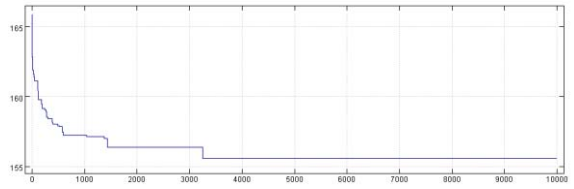
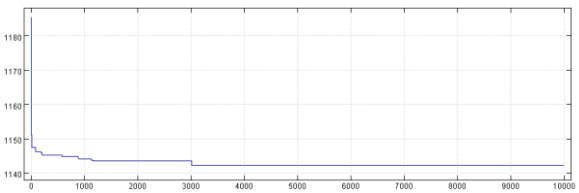
(b) DATA2



(c) DATA3



(d) DATA4

Figure 4: Fitness function in successive generations of differential evolution

Table 1: Synthetic experimental results

	P	G	p_{cr}	Num Iter.	F-value ($\theta = 3$)	Classification Rate
DATA1	100	1	0.25	500	100%	99.7%
DATA2	100	0.1	0.35	10000	50%	67.3%
DATA3	100	0.1	0.3	10000	100%	99.6%
DATA4	100	0.1	0.35	10000	66.7%	57.3%

The differential evolution parameters were fairly robust meaning that changes in the crossover rate and differential gain did not change performance dramatically. However, as the time series became more complex, i.e. DATA3, the differential evolution parameters had to be tuned to prevent the method from being trapped in local minima. From the practical point of view, the essential differential evolution parameters are differential gain, and crossover probably. It was found that increasing population size beyond 100 did not greatly improve the final boundaries. Initially the crossover probably was set to 0.5 and differential gain was set to 1. It was found through parameter adjustments that performance improved with slightly smaller crossover probability. A differential gain of 1 was sufficient on simple data sets; however, more complicated data sets such as DATA2, DATA3, and DATA4 required a smaller value for differential gain (i.e. less mutation) in order to obtain better classification rates and boundary f-value.

Table 2: Synthetic experimental results with FCM-DFS

	m	α	F-Value ($\theta = 3$)	Classification Rate
DATA1	2	0.5	66.7%	99.7%
DATA2	2	0.1	25.0%	80.3%
DATA3	2	0.4	71.4%	99.7%
DATA4	1.3	0.5	16.1%	81.2%

The accuracy of the boundaries discovered by FCM-DFS is not as high when compared with differential evolutionary multivariate segmentation on these synthetic data sets. The classification rate is higher for FCM-DFS but since the boundary f-value is much higher for the proposed method, the segmentation with DE is much more accurate with the determined boundary locations. The reason for the smaller classification rate with DE is that in some of the data sets, only one boundary is be determined correctly and its location is way-off the expected value. With FCM_DFS, several boundaries are not determined very well (accuracy is very low) but the locations are a bit closer to their expected values when a boundary is missed. The experiments on FCM-DFS were run for several different values of m {1.3, 1.5, 1.7, 2, 2.3, 2.5, 3} and several values of α {0.05, 0.1, 0.2, 0.4, 0.5, 0.6, 0.8, 0.9, 0.95}.

The segmentation approach was applied to several real valued time series [10]. The performance of the segmentation is evaluated against reconstruction error (11) as shown in Table 3.

The number of clusters was based on a visual estimate of the number of segments from the plot and then running several different values of c in close proximity to the estimated number of clusters. The results show that the segmentation algorithm does fairly well on some of the data sets with small reconstruction errors especially on power station and hog data sets.

ISBN: 978-989-95079-6-8

Table 3: Real-world time series experimental results

	P	G	p_{cr}	Num Iter.	c	Reconstruction Error
Lynx Pelts	100	0.1	0.9	4000	13	0.1253
Power Station	100	0.5	0.3	4000	12	0.0917
Hog	100	0.1	0.9	4000	16	0.0940
Housing	100	0.5	0.3	4000	17	0.1386
Housing Starts	100	2	0.3	4000	23	0.2185

5 Conclusions

The results on synthetic data show that multivariate time series segmentation show promise as a multivariate time series segmentation tool. The results are quite good on noisy synthetic data with boundary f-values reaching upto 100% and classification rates around 99%. Parameter tuning was important especially as the time series become more complicated and required smaller differential gain values, smaller crossover probability values and more iterations to achieve best results.

Future directions in research involve applying the multivariate segmentation algorithm to the problem of musical segmentation – a particularly difficult problem that automatically finds a partition in music that corresponds to the structural labels of a song, i.e. intro, verse, chorus, bridge, outro. Replacing the linear segment models with more flexible autoregressive models will be developed in future segmentation algorithms.

Abstract— *In this paper we study a genetic fuzzy system approach to assess suitable bidding strategies for agents in online auction environments. Assessing efficient bidding strategies allows evaluation of auction models and verification whether the mechanism design achieves its goals. Day-ahead electricity auctions are particularly explored to give an experimental instance of the approach developed in this paper. Previous works have reported successful fuzzy bidding strategies developed by genetic fuzzy systems and coevolutionary algorithms. Here we review the coevolutionary algorithm and present recent results of the bidding strategies behavior. We analyze how the evolutionary strategies perform against each other in dynamic environments. Coevolutionary approaches in which coevolutionary agents interact through their fuzzy bidding strategies permit realistic and transparent representations of the behavior of the agents in auction-based markets. They also improve market representation and evaluation mechanisms. Experimental results show that coevolutionary agents can enhance their profits at the cost of increasing system hourly price paid by demand, an undesirable outcome from the perspective of the buyers.*

Keywords— Genetic fuzzy systems, electricity markets, auctions, multiagent systems, computational economics.

1 Introduction

The restructuring process of electricity markets has raised new challenges and opportunities, because currently there is no consensual market architecture. The progress of the power industry has mirrored the lack of insight about the mechanism design issues to be addressed. An electricity market is inherently a complex system populated by self interested, interacting economic agents. Tools rooted in the neoclassical economic theory have shown to be of limited value to study the behavior of economic agents in electricity markets. The approach considered in this paper is derived from agent-based computational economics (ACE) [15] and computational intelligence tools. The purpose is to find bidding strategies for a set of agents playing in a market using genetic fuzzy systems principles. The approach can be extended to other negotiation environments and contexts.

Evolutionary bidding strategies support decisions of market players and may uncover unknown and unexpected agents behaviors that help designers to simulate and analyze negotiation mechanisms. When coevolutionary agents extract benefits of strategic behavior, the mechanism designer can review the decision making process to correct eventual unfavorable decisions and fix mechanism flaws.

Recently a coevolutionary approach was suggested to assess bidding strategies for multiagent systems. The focus was on strategies encoded in fuzzy rule-based systems [18]. The aim was to learn models represented by coevolving knowledge bases and improve the performance of the agents when acting in competitive environments. In competitive environments data for learning and tuning of knowledge bases are rare and rule bases must evolve jointly with databases. An evolutionary algorithm whose operators use a variable length chromosome, a hierarchical relationship among individuals through fitness, and a scheme that successively explores and exploits the search space along generations has also been developed [17]. In this paper we first review the coevolutionary algorithm of [18], summarize recent results of coevolutionary bidding strategies, and analyze how evolutionary agent strategies react against each other in dynamic environments.

Electricity auctions are the main application example addressed in this paper due to its practical relevance and the experimental instance they provide. The example illustrates the design of bidding strategies to exploit the negotiation space and to take advantage of market power aiming at improved negotiation mechanisms.

This paper is organized as follows. After this introduction, a brief overview of strategic bidding and survey of related work are presented in section 2. Next, section 3 summarizes the approach addressed in this paper. Section 4 presents and discusses the experimental results. Section 5 concludes the paper and suggests issues for further research.

2 Evolutionary Techniques for Electricity Market Bidding Strategies

Currently, many power industries worldwide use auctions as a mechanism of resource allocation and system coordination. The design of auction mechanisms can give agents the ability to explore market imperfections for gaming.

A energy supplier (generator) competing in an electricity market has to decide upon how much energy to offer and at which price. In a perfectly competitive market, risk averse agents have an incentive to offer energy at a price equivalent to their marginal costs [7]. Electricity markets are, however, much more an oligopoly than a laissez-faire, with low or no demand elasticity in the short term, barriers to entry, and physical constraints. Thus, a energy supplier may have an incentive to offer energy at a price other than its marginal costs and to extract some surplus from such an imperfect market.

ISBN: 978-989-95079-6-8

The behavior of a generator bidding other than marginal costs in an effort to exploit market imperfections is defined as strategic bidding [6]. The most common strategy is to maximize the expected profit but other strategies may interest a supplier exercising its market power such as competing for being a base-load generator, increasing market share, increasing profit margin, etc.

2.1 Related Work

Evolutionary approaches for strategic bidding in electricity markets have been addressed in the literature in the realm of genetic algorithms, evolutionary strategies, and classifier systems. Multiagent system approaches have been proposed to model the electricity market as well, among them [8, 14].

The evolutionary strategy approach suggested in [19] evolves a single bid value, assumed to be valid for all hours of a day ahead market. In this sense, it does not give a bidding strategy, but a bid value that is narrowly valid for a specific situation.

The approach proposed in [1] is a classifier system capable of dealing with the grid constraints of the UK market and electrical restrictions that constraint generators to be *on* or *off* by the dispatch.

In [3] a coevolutionary approach based on a coevolutionary cooperative genetic algorithm (CCGA) is devised to analyze electricity market equilibrium. Results for a 3-firms market is presented. They show that the approach finds Cournot-Nash equilibrium and Pareto solutions. In a related work [4] the same coevolutionary CCGA scheme is used together with a Cournot model and a supply function equilibrium (SFE) model of a 5-firms experiment. In this case, the coevolutionary scheme converges to a Nash equilibria.

The coevolutionary approach to model the electricity market can be based on different coevolutionary methods such as the one addressed in [2] for duopolies. In this method, discretization of the state space imposes limitations.

The coevolutionary process proposed in [11] is more complex[1]. The intent is to coevolve agents strategies and market mechanisms. The authors use a genetic programming (GP) method to evolve a function the auctioneer uses to set the price between the ask and the bid price in a double auction framework. GP is used to represent the auctioneer and traders (buyers and sellers). Simulation results based on the Nicolaisen's experiment report a function with several terms after 10,000 generations. The authors claim that the function evolved was approximately equivalent to a discriminatory price k-double auction with $k = 0.5$.

3 Coevolutionary Fuzzy Bidding Strategies

The approach employed in this paper is to coevolve fuzzy bidding strategies. Previous work [17] has devised evolutionary fuzzy bidding strategies. In [18] a coevolutionary algorithm was introduced to study how the evolving strategies react against each other in dynamic bidding environment[2]. Contrary to alternative evolutionary approaches, the aim was to model bidding information and strategies within the framework of fuzzy set theory. By enabling a fuzzy system to learn trough an evolutionary algorithm, one expects to find effective and transparent bidding strategies. We assume that bidding strategies are encoded by fuzzy rule-based systems (FRBS). As opposed to trial and error methods, genetic algorithms are especially attractive to develop bidding strategies because they can optimize the knowledge base (dimension, membership functions and rules) for a given market configuration. Genetic algorithms are also more appropriate than conventional optimization techniques because rule base tuning may involve operators and high dimensionality search spaces.

Here a GFRBS (Genetic Fuzzy Rule-Based System[3]) scheme is adopted to simultaneously evolve the data base (granularity and membership functions) and the rule base of a FRBS with the aim to find the most profitable bidding strategy. Each population of the GFRBS is a coevolving specie that represents a market agent. The result is a set of fuzzy rule-based systems able to handle imprecise data typically found in auction environments.

The evolutionary approach detailed in [17] is used to evolve the data base employing a variable length chromosome to represent the rule base. In the rule base, both, the number of rules and size of each rule may change during the evolutionary process. A particularly suitable crossover operation detailed in [17] was developed to enhance system performance.

Many coevolutionary approaches emphasize explicit competition such as the host-parasite scheme to minimize sorting networks in [10]. The coevolutionary approach focused in this paper is based on the CCGA of Potter and De Jong [13]. As detailed below in Algorithm 1, our approach selects a representative agent for each coevolutionary specie. The species model bidding agents. The representatives are the ones who compete in the auctions. When representatives bid, their strategy may improve the profit of the remaining bidders. Thus, the remaining coevolutionary species may act in a tacit cooperation in this competitive game. Therefore, although CCGA was originally developed to coevolve subcomponents of a problem in an explicit cooperative framework, we use its main idea in a competitive environment: auction in electricity markets[4].

3.1 Genetic Algorithm

The genetic algorithm employed in this paper uses a variable length chromosome representation for both: data base and rule bases. The encoding schemes are similar to the ones adopted in [17]. Crossover operations in data base and rule base are synchronous, that is, crossover points of database and rule base induce exchange of chromosome portions to keep the rule structure and fuzzy terms meaningful in their offspring.

The first step to design a GFRBS must decide which part of the FRBS will be optimized by the genetic algorithm [5]. This decision usually means a trade off between granularity and search efficiency. In the approach adopted here, the following FRBS components are evolved: database (granularity and membership functions parameters) and rule base (number of "active" rules[5] and rule structure).

[1] A more complete report of this work can be found in [12].

[2] This and all previous papers are a result of the PhD thesis of the first author and has no links with the Regulatory Agency.

[3] For a taxonomy, a comprehensive survey of past and recent developments, as well as future trends of genetic fuzzy systems see [9].

[4] A similar approach was adopted in [3].

[5] An "active" rule is a rule that is processed during fuzzy inference while an "inactive" rule remains in the rule base genotype but it is not used during fuzzy inference.

ISBN: 978-989-95079-6-8

The GA also assumes the simultaneous evolution of the FRBS in the sense that each individual represents a complete fuzzy rule-based system as in the Pittsburgh approach. The FRBS is encoded in a chromosome Cr composed by three major components (Cr_1, Cr_2, and Cr_3) to represent the data and rule base.

More specifically, the chromosome component Cr_1 encodes granularity in a variable length chain of integers, and Cr_2 encodes membership functions parameters in a variable length chain of real numbers. The number of rules, rules size and the rules themselves define chromosome component Cr_3. Component Cr_3 has, in addition to two integers (number of rules and rules size), several variable chains of alleles of '0' or '1', where a '1' means that a linguistic term is used in the rule, otherwise it is '0'.

Algorithm 1 Coevolutionary GFRBS Algorithm

```
t ← 0
for each specie s do
   create random initial population Ω_0^s
end for
repeat
   for each specie s do
      for each specie r such that r ≠ s do
         choose a representative in Ω_t^r
      end for
      evaluate each individual in Ω_t^s through fitness function
      with the chosen representatives
      select parents in Ω_t^s based on relative fitness in Ω_t^s
      apply crossover and mutation on parents to produce
      offspring Ω_{t+1}^s
      t ← t + 1
   end for
until (stop criteria is satisfied)
```

As stated before, the coevolutionary algorithm detailed in Algorithm 1 is based on CCGA [13]. The specifics of the genetic operators are described next.

3.2 Genetic Operators

Due to the particular chromosome encoding structure used to represent the knowledge base, the nature of the genetic operators becomes an important issue to effectively evolve the FRBS. Since there are strong relationships among chromosome components, we need operators that work cooperatively on the chromosome.

Selection is performed using *roulette wheel*. We adopt an elitist model, but the best individual is not guaranteed to be selected for crossover, albeit kept intact in the offspring.

Crossover of the database follows the approach detailed in [17]. Summing up, two different crossover operators are used depending on whether the selected individuals have the same granularity or not. When the granularity is the same, a promising zone in the search space is found and must be appropriately exploited. In this case, the granularity of the offspring database (Cr_1) is kept the same and the membership functions parameters (Cr_2) combined following the max-min-arithmetic algorithm of [17]. When the selected pair has different granularity, a random crossover position p is chosen. Both, granularity (Cr_1) and the corresponding parameters of the membership functions (Cr_2) are recombined. Crossover operations of database and rule base are synchronous: crossover points of database and rule base induce exchange of chromosome portions that keep the rule structure and terms meaningful in their offspring.

Different operators can be used to mutate chromosomes, similarly as reported in [17]: a local variation is introduced to the granularity by adding or subtracting one with equal probability, mutation of membership function parameters uses the Michalewicz non-uniform mutation operator, and rule bases are mutated via the standard, bitwise reversing operation.

3.3 Electricity Market

The application example focused in this paper is electricity markets. The approach can, however, be extended to distinct negotiation applications. The coevolutionary GFRBS agents are thermal power suppliers that have to decide how to bid in auctions. The coevolutionary GFRBS species were evolved using a day-ahead electricity auction. We assume that the remaining agents are non evolutionary and conservative competitors. Conservative agents offer energy bidding all their capacity at their marginal costs [7]. The negotiation protocol is an uniform price sealed bid auction: the price paid for the energy is the same for all accepted bids and is equal to the last bid accepted. The auctioneer decides the hourly dispatch choosing the electricity generator agents outputs and the corresponding price to minimize overall energy cost. Cost minimization results in a merit order dispatch procedure, i.e., bids at lower prices come first. The performance of the best FRBS obtained were verified using test demand data for two weeks day-ahead auctions against conservative and evolutionary competitors. The results are presented and discussed in section 4.

The experiments use actual public data made available from the Brazilian Independent System Operator (ISO)[6]. Demand is supposed to be known to all the participant agents. The data used to evolve the GFRBS is the load of the week beginning on May 19th, 2002, for a portion of the national grid: the South sub-market. The fitness of the coevolutionary agents are the profit on the electricity auction of the decoded GFRBS for the training week. The best individual found by training is tested using the next two remaining weeks period that begins on May 26th 2002 [7].

3.4 Cost Function

A pool of power generator agents was setup based on actual, ISO's publicly available data. Electrical constraints and geoelectrical location are neglected in this work: all the plants are supposed to be in the same sub-market. There is some excess of supply and the running costs of producing electricity in coal, gas and oil plants have been modeled as quadratic functions of the power P_s supplied by the agent, expression (1). Nuclear plants are assumed to have linear cost functions.

$$F(P_s) = a + bP_s + cP_s^2 \quad \text{[GJ/h]} \tag{1}$$

The supplier cost function $C^j(.)$ is given by $F(P_s)$ multiplied by the fuel cost in \$/GJ. Hence costs are quadratic func-

[6] ONS: Operador Nacional do Sistema.

[7] These same data set was used in [17, 18]. Data set contains 504 samples; 168 used for training and 336 for testing.

ISBN: 978-989-95079-6-8

Table 1: Thermal power generator agents characteristics and cost functions.

Plant	Type	Capacity (MW)	Marginal cost ($/MWh)	$C^j(.)$
Ibirité	Gas	766.5	39.065	$3,632.08 + 31.966g + 0.00463g^2$
TermoRio	Gas	824.7	39.109	$3,904.05 + 31.912g + 0.00436g^2$
Argentina I	Gas	1,018	41.045	$4,459.61 + 32.775g + 0.00406g^2$
Argentina II	Gas	1,000	41.046	$4,379.82 + 32.774g + 0.00414g^2$

tions given by (2), where g_h^j is the amount supplied by agent j at hour h.

$$C^j(g_h^j) = \alpha + \beta g_h^j + \gamma {g_h^j}^2 \quad [\$/h] \tag{2}$$

3.5 Competitive Environment

We assume power demand D_h inelastic with price. Therefore, the auctioneer must assure, as commonly found in a single buyer auction, that for each hour h: $\sum_{j=1}^{T_h} g_h^j = D_h$, where g_h^j is the power supplied by agent j and T_h is the number of suppliers. Thus, allocation would cost the market $D_h \pi_h(D_h)$. The supplier agents profit is given by(3):

$$P_h^j = \pi_h g_h^j - C^j(g_h^j) \quad [\$/h] \tag{3}$$

Supplier agents (generators) must internalize all costs to a simple bid, a pair (q_h^j, p_h^j) of the amount offered (in MW) and its price ($/MWh), where the amount q_h^j is less than or equal to the agent capacity, G^j. Conservative agents bid a pair $(G^j, MC^j(G^j))$ where $MC^j(G^j)$ is the marginal cost at capacity G^j.

Table 1 shows the thermal generator agents characteristics for the agents we have chosen to coevolve. The complete data set of the thermal generation park can be found in [17]. The fourth column, the marginal cost ($/MWh), is the marginal cost at full capacity corresponding to conservative bids. The last column gives the cost functions of the thermal suppliers[8].

3.6 Fitness

Algorithm 2 Evaluation of Population Individuals

for each individual i such as $i \in \Omega_t^s$ **do**
  decode database and rule base of i as agent A_i
  add the agent A_i to the market
  simulate market (run auction) for the training period
  keep fitness F_{A_i} as the profit for the period
  remove A_i from the market
end for

The fitness of a GFRBS individual is defined as the profit of the corresponding agent during the training week. Algorithm 2 summarizes the evaluation of the fitness of each individual of the population.

4 Results

The experiments reported in this paper use a population of 40 individuals. Each individual encodes a single input-single output (SISO) FRBS: the input is the hourly load and the output the corresponding the bid price. The genetic operators described in section 3.2 were employed in all the experiments[9] with probability of crossover 0.5 and probability of mutation 0.01. We let the evolutionary process run for 500 or 1,000 generations[10]. While several experiments were performed with 2 to 5 species, some of them did not achieve stable behavior. For instance, for 5 coevolutionary species stability was not attained after 1,000 generations. Section 4.2 discusses briefly why stable behavior may not be necessarily expected, as the 5 coevolutionary species case shows.

Table 2: Comparison between coevolutionary and conservative strategies.

conservative strategy			
agent	hours	energy (MWh)	profit ($)
Ibirité	332	232,954	849,960
TermoRio	277	199,390	959,133
Argentina I	202	179,595	1,065,262
Argentina II	149	116,381	1,049,804
coevolutionary strategy: testing			
agent	hours	energy (MWh)	profit ($)
Ibirité	334	255,856	2,082,681
TermoRio	336	248,367	2,237,294
Argentina I	150	89,969	1,825,135
Argentina II	335	301,710	2,304,976
variation: coevolutionary / conservative			
agent	hours	energy (MWh)	profit ($)
Ibirité	+0.60%	+9.83%	+145.03%
TermoRio	+21.30%	+24.56%	+133.26%
Argentina I	-25.74%	-49.90%	+71.33%
Argentina II	+124.83%	+159.24%	+119.56%

4.1 Experiment: Four Coevolutionary Strategies

In [18] two thermal plants coevolved. They are the same used as evolutionary agents in [17]: Argentina I and Argentina II, respectively.

Here we report an experiment in which Argentina I and Argentina II are coevolved together with other two natural gas plants: TermoRio and Ibirité. The fitness of the best individual of each specie during 1,000 generations of the evolutionary process (training period) is depicted in Fig. 1. Notice that, after a short unstable period lasting about 100 genera-

[8] g_h^j is denoted by g for short.

[9] The choice of the evolutionary parameters is not subject to any optimization process.

[10] The training process can take about 2 hours of processing time for 2 species, corresponding to 500 generations, and above 6 hours for 4 species and 1,000 generations. Experiments were done using a Pentium 4,2 GHz 256 Mb RAM PC running GNU/Linux Fedora.

ISBN: 978-989-95079-6-8

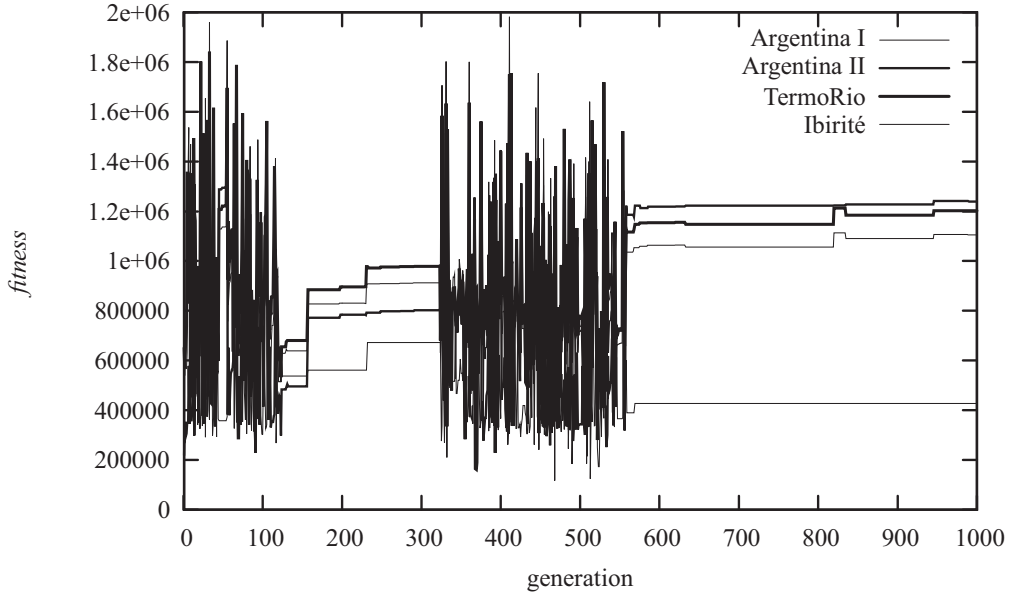

Figure 1: Fitness for coevolutionary species (4 thermal plants: Argentina I, Argentina II, TermoRio and Ibirité).

tions, the fitness of the best individual of each specie increases and stabilizes after about 200 generations and suddenly fitness behavior becomes unstable again. After approximately another 250 generations, the fitness becomes stable again, beginning at 550^{th} generation, and remains stable until the end of the evolutionary process window (1,000 generations). Notice also that the resulting outcome for the specie representing Argentina I becomes worse than in the one achieved during the first stable interval. This behavior suggests that the other three thermal plants may have learned how to exploit Argentina I agent weakness. All the remaining agents increase their profits. A close look at the fitness values shows that the species interact with each other during the whole evolutionary process.

After the end of the evolutionary process, the best individual of each specie is decoded into the corresponding bidding strategies to be played by the four agents. Table 2 summarizes the energy produced and profits obtained when the agents compete in the electricity market using the coevolutionary strategies. Table 2 shows how evolutionary agents outperform the corresponding conservative strategy of bidding their marginal costs at full capacity. The last four rows show the variation when using conservative and evolutionary strategies. We notice in Table 2 that Argentina I decreases energy production by half and still, with the hourly prices that result from the coevolutionary strategic bidding, increases its profit. This is a typical example of an undesirable behavior (from the perspective of the buyers) that mechanism designers wants to avoid before putting any market to work.

Clearly, the coevolutionary strategies affected the electric energy prices. The maximum hourly price of energy reached in the testing period was the same for both, purely conservative strategies or coevolutionary strategies, but coevolution made the average price 10.6% higher. The average price increase for the experiment reported in [18] was smaller, about 7.1%. Similarly as in [18], the individual hourly prices can be up to 53.2% higher for the coevolutionary strategies than purely conservative ones.

4.2 Multiagent Learning Equilibrium

It is important clarify that, while the results presented here and in [18] converge to a stable outcome, some of the experiments performed did not achieve stable outcome at all, remaining unstable for 500 or even 1,000 generations. Unstable outcomes typically occurred when there are many evolutionary agents (5 thermal generators in our experiments). While the dynamics of unstable behavior still is to be investigated, it does not seem to be a novelty, as it has been pointed out by Vidal in [16], who asserts that most multiagent learning systems do not necessarily converge to an equilibrium or stable behavior.

One reason for designers to use learning agents is because they do not know, at design time, the specific circumstances that the agents will face at run time. We will often see a multiagent system with learning agents when the designer can neither predict that an equilibrium solution will be found, nor which equilibria might emerge. The result is a form of closed loop feedback evolving system in which evolution and learning play a complementary role.

As stated in [16], the main reasons behind the difficulty to predict equilibrium solutions of a system include the existence of unpredictable environmental changes that affect the payoffs of the agents, and the fact that, in many systems, an agent only has access to its own set of payoffs. These reasons partially justify the difficulty a designer finds to predict equilibria, if any, a system could reach. However, the agents in a system may still play a game for which an equilibrium exists, even though the designer cannot predict it at design-time. Since in general the payoffs change, it is often the case that the agents are constantly modifying their strategies as an attempt to get better payoffs. This may result in unstable outcomes.

5 Conclusion

A coevolutionary genetic fuzzy systems approach to develop fuzzy bidding strategies was suggested in this paper. Coevo-

ISBN: 978-989-95079-6-8

lutionary approaches provide more realistic representation of agents in auction-based environments because they allow the bidding strategies to interact during the evolutionary process.

The results reported here for an electricity market example show that coevolution can improve agents profits at the expense of increasing the average electricity hourly price paid by demand, an outcome that is undesirable from the perspective of the buyers, and for auction based markets in general. Further research is needed to obtain design methods for bidding strategies in multiagent systems framework populated by intelligent agents. In particular, stability and equilibrium analysis of evolutionary learning in multiagent systems environments still remains a challenge.

Abstract—*This paper considers a portfolio selection problem with type-2 fuzzy future returns involving ambiguous and subjectivity. Since this proposed problem is not well-defined due to fuzziness, introducing the fuzzy goal for the total future return and the degree of possibility, the main problem is transformed into the standard fuzzy programming problem including the secondary fuzzy numbers. Furthermore, using the hybrid solution approaches based on the linearity of the deterministic equivalent problem and the crisp possibilistic mean value, the efficient solution is constructed.*

Keywords— Portfolio selection, Type-2 fuzzy, Possibility measure, Crisp possibilistic mean value, Efficient solution method

1 Introduction

Portfolio selection problems are standard and most important problems in investment and financial research fields, and various studies have been so far performed. Furthermore, in recent investment fields, not only big companies and institutional investors but also individual investors called Day-Traders invest in stock, currency, land and property. Therefore, the role of investment theory called portfolio theory becomes more and more important. As for the research history on mathematical approach, Markowitz (Markowitz [18]) has proposed the mean-variance analysis model. It has been central to research activity in the real financial field and numerous researchers have contributed to the development of modern portfolio theory (cf. Elton and Gruber [4], Luenberger [17]). On the other hand, many researchers have proposed models of portfolio selection problems which extended Markowitz model; mean-absolute deviation model (Konno [13], Konno, et al. [14]), safety-first model [4], Value at Risk and conditional Value at Risk model (Rockafellar and Uryasev [19]), etc.. As a result, nowadays it is common practice to extend these classical economic models of financial investment to various types of portfolio models. In practice, after Markowitz's work, many researchers have been trying different mathematical approaches to develop the theory of portfolio selection.

Particularly, the prediction of future returns is one of the most important factors in theoretical and practical investment, and they have been treated as only random variables in many previous studies. Then, the expected returns and variances also have been assumed to be fixed values. However, investors receive effective or ineffective information from the real world and ambiguous factors usually exist in it. Furthermore, investors often have the subjective prediction for future returns which are not derived from the statistical analysis of historical data. Then, even if investors hold a lot of information from the investment field, it is difficult that the present or future random distribution of each asset is strictly set. Consequently, we need to consider not only random conditions but also ambiguous and subjective conditions for portfolio selection problems.

Recently, in the sense of mathematical programming, some researchers have proposed various types of portfolio models under randomness and fuzziness. These problems with probabilities and possibilities are generally called stochastic programming problems and fuzzy programming problems, respectively, and there are some basic studies using a stochastic programming approach, goal programming approach, etc.., and fuzzy programming approach to treat ambiguous factors as fuzzy sets (Inuiguchi and Ramik [8], Leon, et al. [15], Tanaka and Guo [20], Tanaka, et al. [21], Watada [23]). Furthermore, some researchers have proposed the mathematical programming problems with both randomness and fuzziness as fuzzy random variables (for instance, Katagiri et al. [11, 12]). In the studies [11, 12], fuzzy random variables were related with the ambiguity of the realization of a random variable and dealt with a fuzzy number that the center value occurs according to a random variable. Then, Yazenin considered some models for portfolio selection problems in the probabilistic-possibilistic environment, that profitabilities of financial assets are fuzzy random variables (Yazenin [25, 26]). On the other hand, future returns may be dealt with random variables derived form the statistical analysis, whose parameters are assumed to be fuzzy numbers due to the decision maker's subjectivity, i.e., random fuzzy variables which Liu (Liu [16]) defined. There are a few studies of random fuzzy programming problem (Katagiri et al. [9, 10], Huang [7]). Most recently, Hasuike et al. [6] proposed several portfolio selection models including random fuzzy variables and developed the analytical solution method.

However, in [6], the random distribution of each asset is assumed to be a normal distribution. From some practical studies with respect to the present practical market, it is not clear that price movements of assets occur according to normal distributions. In fact, considering the existence of various types of investors in the practical market and the subjectivity of investors, it is important that we need to develop a new portfolio selection problem to deal with a lot of subjectivity. In this paper, we assume future returns to be Type-2 fuzzy numbers which can be dealt with various types of membership functions, and propose a new Type-2 portfolio selection problem.

ISBN: 978-989-95079-6-8

In the sense of mathematical programming, since the proposed model is not formulated as a well-defined problem due to fuzziness, we need to set some certain optimization criterion so as to transform into well-defined problems. In this paper, introducing a fuzzy goal and the degree of possibility, we transform the main problem into the possibility maximization problem. However, this problem includes the fuzzy number and it is also not a well-defined. Therefore, in order to solve possibility maximization problem analytically, we introduce the crisp possibilistic mean value proposed by Carlsson and R. Fullér [1] and develop an efficient solution method to find a global optimal solution of deterministic equivalent problem.

This paper is organized in the following way. In Section 2, we introduce mathematical concepts of type-2 fuzzy set and crisp possibilistic mean value. In Section 3, we propose a type-2 fuzzy portfolio selection problem maximizing the total future return. Then, introducing the degree of possibility and the crisp possibilistic mean value, we transform the proposed model into the deterministic equivalent problem. In Section 4, in order to compare our proposed models with other models for portfolio selection problems, we provide a numerical example derived from current practical market data. Finally, in Section 5, we conclude this paper.

2 Mathematical concept

2.1 Type-2 fuzzy set

A type-2 fuzzy set is a set in which we also have uncertainty about the membership function, i.e., a type-2 fuzzy set is characterized by a fuzzy membership function whose grade for each element is a fuzzy set [0,1] (Castillo and Melin [3]). In the real world, there are many problems where the decision maker cannot determine the exact form of the membership function such as in time series prediction because of noise in the data. Therefore, it is important that the type-2 fuzzy set is introduced into real world problems.

Example 1 (Castillo and Melin [3])
Consider the case of a fuzzy set characterized by a Gaussian membership function with mean m and a standard deviation that can take values in $[\sigma_1, \sigma_2]$, i.e.,

$$\mu(x) = \exp\left\{-\frac{1}{2}\left(\frac{x-m}{\sigma}\right)^2\right\},\ \sigma \in [\sigma_1, \sigma_2]$$

In this paper, with respect to future returns we treat the following *L*-shape fuzzy numbers as fuzzy numbers based on the type-2 fuzzy set:

$$\mu_{\tilde{r}_j}(\omega) = \max\left\{0, L\left(\frac{\omega - \bar{r}_j}{\alpha_j}\right)\right\},\ \alpha_j \in [\alpha_j^L, \alpha_j^U] \tag{1}$$

where $L(\omega)$ is a shape function from $\mathbb{R}$ to $\mathbb{R}$ satisfying the following conditions:

1. $L(-\omega) = L(\omega)$ for $\forall \omega \in \mathbb{R}$
2. $L(0) = 1$
3. $L(\cdot)$ is nonincreasing on $[0, \infty)$
4. Let $t_0 = \inf\{t > 0 | L(t) = 0\}$. Then $0 < t_0 < \infty$

The *L*-shape fuzzy number includes the more general membership function than the Gaussian in Example 1. Therefore, by using the *L*-shape fuzzy number, it is possible that we represent more versatile social problems.

2.2 Crisp possibilistic mean value

Carlsson and Fullér [1] introduced the notation of crisp possibilistic mean value of continuous possibility distribution, which are consistent with the extension principle. Let A a fuzzy number. Then, $[A]^\gamma$ denote the γ -level set of A as the following form:

$$[A]^\gamma = [a_L(\gamma),\ a_U(\gamma)]$$

Using this γ -level set of A, the crisp possibilistic mean value of A is introduced as follows:

$$E(A) = \int_0^1 \gamma\left(a_L(\gamma) + a_U(\gamma)\right) d\gamma$$

Example 2
In the case that a fuzzy number A is a trapezoidal fuzzy number with tolerance interval $[a, b]$, left spread α and right spread β. Then, the crisp possibilistic mean value of A is

$$\begin{aligned} E(A) &= \int_0^1 \gamma\left(a - (1-\gamma)\alpha + b + (1-\gamma)\beta\right) d\gamma \\ &= \frac{a+b}{2} + \frac{\beta - \alpha}{6} \end{aligned}$$

This crisp possibilistic mean value has been applied to various types of portfolio selection problems with fuzzy numbers (in detail, see [5]), and it becomes one of the most useful tool in the sense of fuzzy programming problem.

3 Type-2 fuzzy portfolio selection problem

In this paper, we deal with the following portfolio selection problem with future returns based on the type-2 fuzzy set maximizing total future returns.

$$\begin{aligned} &\text{Maximize} && \sum_{j=1}^n \tilde{r}_j x_j \\ &\text{subject to} && \sum_{j=1}^n x_j = 1, \quad 0 \le x_j \le p_j, \quad j = 1, 2, \cdots, n \end{aligned} \tag{2}$$

where $\boldsymbol{x} = (x_1, \cdots, x_n)$ is a composition of the portfolio and p_j is a limited upper rate of *j*th asset. In this problem, the objective function $\tilde{Z} = \sum_{j=1}^n \tilde{r}_j x_j$ is also a fuzzy number characterized by the following membership function:

ISBN: 978-989-95079-6-8

$$\mu_{\tilde{Z}}(\omega)=\max\left\{0,L\left(\frac{\omega-\sum_{j=1}^{n}\overline{r}_j x_j}{\sum_{j=1}^{n}\alpha_j x_j}\right)\right\},\ \alpha_j\in\left[\alpha_j^L,\alpha_j^U\right] \tag{3}$$

Due to the fuzziness of objective function, problem (2) is not a well-defined problem, and so we need to set some certain optimization criterion. Until now, researchers have proposed some solution approaches to solve fuzzy programming problem based on not only strict solution methods such as linear and nonlinear programming but also approximate solution methods such as GA and NN. In this paper, we focus on the strict solution method in the sense of mathematical programming, and so we introduce the possibility measure as follows:

$$\mathrm{Pos}\left\{\sum_{j=1}^{n}\tilde{r}_j x_j\geq f\right\}=\sup_{\omega}\left\{\mu_{\tilde{Z}}(\omega)\middle|\omega\geq f\right\}$$

where f is the target value to total future return. The possibility measure means that the total future return is more than f as much as possible in the aspiration level of each investor.

3.1 Possibility maximization model for the proposed type-2 fuzzy portfolio selection problem

On the other hand, in practical situations, the investor considers increasing the goal of total future return and that of possibility, simultaneously. Furthermore, considering many real decision cases and taking account of the vagueness of human judgment and flexibility for the execution of a plan, the investor often has subjective and ambiguous goals with respect to the target return f such as "Total future return $\sum_{j=1}^{n}\tilde{r}_j x_j$ is approximately larger than f_1 .". In this subsection, we propose the more flexible model considering the aspiration level to the goal for the total future return. We represent the subjective and ambiguous goals with respect to f as a fuzzy goal characterized by the following membership function:

$$\mu_{\tilde{G}}(f)=\begin{cases}1 & f_1\leq f\\ g(f) & f_0\leq p<f_1\\ 0 & f<f_0\end{cases} \tag{4}$$

where $g(f)$ is the strict increasing function. Furthermore, using a concept of possibility measure, we introduce the degree of possibility as follows:

$$\prod_{\tilde{Z}}(\tilde{G})=\sup_{f}\min\left\{\mu_{\tilde{Z}}(f),\mu_{\tilde{G}}(f)\right\} \tag{5}$$

Using this degree of possibility, we formulate a possibility maximization model for the proposed portfolio selection problem as the following form:

$$\begin{aligned}&\text{Maximize}\quad \prod_{\tilde{Z}}(\tilde{G})\\ &\text{subject to}\quad \sum_{j=1}^{n}x_j=1,\quad 0\leq x_j\leq p_j,\quad j=1,2,\cdots,n\end{aligned} \tag{6}$$

Then, this problem is equivalently transformed into the following problem introducing a parameter h:

$$\begin{aligned}&\text{Maximize}\quad h\\ &\text{subject to}\quad \prod_{\tilde{Z}}(\tilde{G})\geq h,\\ &\qquad\sum_{j=1}^{n}x_j=1,\quad 0\leq x_j\leq p_j,\quad j=1,2,\cdots,n\end{aligned} \tag{7}$$

In this problem, the possibility constraint $\prod_{\tilde{Z}}(\tilde{G})\geq h$ is transformed into the following form:

$$\begin{aligned}&\prod_{\tilde{Z}}(\tilde{G})\geq h\\ \Leftrightarrow\ &\sup_{f}\min\left\{\mu_{\tilde{Z}}(f),\mu_{\tilde{G}}(f)\right\}\geq h\\ \Leftrightarrow\ &\mu_{\tilde{Z}}(f)\geq h,\ \mu_{\tilde{G}}(f)\geq h\\ \Leftrightarrow\ &L\left(\frac{f-\sum_{j=1}^{n}\overline{r}_j x_j}{\sum_{j=1}^{n}\alpha_j x_j}\right)\geq h,\ f\geq g^{-1}(h)\\ \Leftrightarrow\ &f\leq\sum_{j=1}^{n}\overline{r}_j x_j+L^*(h)\sum_{j=1}^{n}\alpha_j x_j,\ f\geq g^{-1}(h)\\ \Leftrightarrow\ &\sum_{j=1}^{n}\overline{r}_j x_j+L^*(h)\sum_{j=1}^{n}\alpha_j x_j\geq g^{-1}(h)\end{aligned} \tag{8}$$

Using these inequalities, the main problem (6) is equivalently transformed into the following problem:

$$\begin{aligned}&\text{Maximize}\quad h\\ &\text{subject to}\quad \sum_{j=1}^{n}\overline{r}_j x_j+L^*(h)\sum_{j=1}^{n}\alpha_j x_j\geq g^{-1}(h),\\ &\qquad\sum_{j=1}^{n}x_j=1,\quad 0\leq x_j\leq p_j,\quad j=1,2,\cdots,n\end{aligned} \tag{9}$$

In this problem, if each spread of fuzzy number α_j is fixed, this problem is analytically solved by using the hybrid solution method of bisection algorithm on parameter h and the linear programming problem. However, in the case that α_j is not fixed but a fuzzy number, it is difficult that this problem is analytically solved by standard linear programming approaches due to including secondary fuzzy numbers.

3.2 Solution method based on the crisp possibilistic mean value

In order to solve problem (9) in the sense of mathematical programming, we introduce the crisp possibilistic mean value. Subsequently, we assume that each spread $\tilde{\alpha}_j$ is the following trapezoidal fuzzy number:

ISBN: 978-989-95079-6-8

$$\mu_{\tilde{\alpha}_j}(\omega)=\begin{cases}\dfrac{\omega-\alpha_j^L}{\underline{\alpha}_j-\alpha_j^L} & \left(\alpha_j^L\le\omega<\underline{\alpha}_j\right)\\ 1 & \left(\underline{\alpha}_j\le\omega\le\overline{\alpha}_j\right)\\ \dfrac{\alpha_j^U-\omega}{\alpha_j^U-\overline{\alpha}_j} & \left(\overline{\alpha}_j<\omega\le\alpha_j^U\right)\\ 0 & \text{otherwise}\end{cases},\ j=1,2,...,n \qquad (10)$$

Using these trapezoidal fuzzy numbers and the fuzzy extension principle, the membership function of fuzzy number $\tilde{\alpha}(\boldsymbol{x})=\sum_{j=1}^{n}\tilde{\alpha}_j x_j$ is also the following trapezoidal fuzzy number:

$$\mu_{\tilde{\alpha}(\boldsymbol{x})}(\omega)=\begin{cases}\dfrac{\omega-\sum_{j=1}^{n}\alpha_j^L x_j}{\sum_{j=1}^{n}\underline{\alpha}_j x_j-\sum_{j=1}^{n}\alpha_j^L x_j} & \left(\sum_{j=1}^{n}\alpha_j^L x_j\le\omega<\sum_{j=1}^{n}\underline{\alpha}_j x_j\right)\\ 1 & \left(\sum_{j=1}^{n}\underline{\alpha}_j x_j\le\omega\le\sum_{j=1}^{n}\overline{\alpha}_j x_j\right)\\ \dfrac{\sum_{j=1}^{n}\alpha_j^U x_j-\omega}{\sum_{j=1}^{n}\alpha_j^U x_j-\sum_{j=1}^{n}\overline{\alpha}_j x_j} & \left(\sum_{j=1}^{n}\overline{\alpha}_j x_j<\omega\le\sum_{j=1}^{n}\alpha_j^U x_j\right)\\ 0 & \text{otherwise}\end{cases},\ j=1,2,...,n \qquad (11)$$

Then, the γ -level set of $\tilde{\alpha}(\boldsymbol{x})$ is as follows:

$$\left[\tilde{\alpha}(\boldsymbol{x})\right]^{\gamma}=\left[\gamma\sum_{j=1}^{n}\underline{\alpha}_j x_j+(1-\gamma)\sum_{j=1}^{n}\alpha_j^L x_j,\ \gamma\sum_{j=1}^{n}\overline{\alpha}_j x_j+(1-\gamma)\sum_{j=1}^{n}\alpha_j^U x_j\right] \qquad (12)$$

Therefore, from the mathematical concept in Subsection 2.2, the crisp possibilistic mean value of $\tilde{\alpha}(\boldsymbol{x})$ is as follows:

$$\begin{aligned}E\left(\tilde{\alpha}(\boldsymbol{x})\right)&=\int_0^1\gamma\left(\gamma\sum_{j=1}^{n}\left(\underline{\alpha}_j+\overline{\alpha}_j-\alpha_j^L-\alpha_j^U\right)x_j+\sum_{j=1}^{n}\left(\alpha_j^L+\alpha_j^U\right)x_j\right)d\gamma\\&=\frac{1}{3}\sum_{j=1}^{n}\left(\underline{\alpha}_j+\overline{\alpha}_j\right)x_j+\frac{1}{6}\sum_{j=1}^{n}\left(\alpha_j^L+\alpha_j^U\right)x_j\end{aligned} \qquad (13)$$

Consequently, problem ( ) is transformed into the following problem from the viewpoint of crisp possibilistic mean value:

$$\begin{aligned}&\text{Maximize}\quad h\\&\text{subject to}\quad\sum_{j=1}^{n}\overline{r}_j x_j+\frac{L^*(h)}{3}\sum_{j=1}^{n}\left(\underline{\alpha}_j+\overline{\alpha}_j+\frac{1}{2}\left(\alpha_j^L+\alpha_j^U\right)\right)x_j\ge g^{-1}(h),\\&\qquad\sum_{j=1}^{n}x_j=1,\quad 0\le x_j\le p_j,\quad j=1,2,\cdots,n\end{aligned} \qquad (14)$$

In this problem, coefficients $\underline{\alpha}_j+\overline{\alpha}_j+\frac{1}{2}\left(\alpha_j^L+\alpha_j^U\right)$ are initially set as fixed values, and so this problem is similar to problem (9), which is one of the standard possibility programming problem. Then, it should be noted here that problem (14) is a nonconvex programming problem and it is not directly solved by the linear programming techniques or convex programming techniques. However, a decision variable h is involved only in first constraint. Therefore, we introduce the following subproblem involving a parameter q :

$$\begin{aligned}&\text{Maximize}\quad\sum_{j=1}^{n}\overline{r}_j x_j+\frac{L^*(q)}{3}\sum_{j=1}^{n}\left(\underline{\alpha}_j+\overline{\alpha}_j+\frac{1}{2}\left(\alpha_j^L+\alpha_j^U\right)\right)x_j\\&\text{subject to}\quad\sum_{j=1}^{n}x_j=1,\quad 0\le x_j\le p_j,\quad j=1,2,\cdots,n\end{aligned} \qquad (15)$$

In the case that parameter q is fixed, problem (15) is degenerated to a linear programming problem. Therefore, in a way similar to the standard possibility maximization model, we construct the following efficient solution method using the hybrid approach of bisection algorithm and linear programming based on the study [6].

Solution algorithm

STEP1: Elicit the membership function of a fuzzy goal for the total future return with respect to the objective function value.

STEP2: Set $q\leftarrow 1$ and solve problem (14). If the optimal objective value $Z(q)$ of problem (14) satisfies $Z(q)>g^{-1}(q)$, then terminate. In this case, the obtained current solution is an optimal solution of main problem.

STEP 3: Set $q\leftarrow 0$ and solve problem (14). If the optimal objective value $Z(q)$ of problem (14) satisfies $Z(q)\le g^{-1}(q)$, then terminate. In this case, there is no feasible solution and it is necessary to reset a fuzzy goal for the probability or the aspiration level f.

STEP 4: Set $U_q\leftarrow 1$ and $L_q\leftarrow 0$.

STEP 5: Set $\gamma\leftarrow\left(U_q+L_q\right)/2$.

STEP 6: Solve problem (14) and calculate the optimal objective value $Z(q)$ of problem (14). If $Z(q)>g^{-1}(q)$, then set $L_q\leftarrow q$ and return to Step 5. If $Z(q)\le g^{-1}(q)$, then set $U_q\leftarrow q$ and return to Step 5. If $Z(q)=g^{-1}(q)$, then terminate the algorithm. In this case, $\boldsymbol{x}^*(q)$ is equal to a global optimal solution of main problem.

4 Numerical example

In order to compare our proposed models with other models for portfolio selection problems, let us consider a numerical example based on the data of securities on the Tokyo Stock Exchange. In this paper, we compare our proposed model (14) in Section 3 with Carlsson et al. model [2] and Vercher et al. model [22]. These models are type-1 fuzzy portfolio models and include the possibilistic mean value and variance. These problems are formulated as the following form:

(Carlsson et al. model)

$$\begin{aligned}&\text{Maximize}\quad\sum_{j=1}^{n}\frac{1}{2}\left[a_j+b_j+\frac{1}{3}\left(\beta_j-\alpha_j\right)\right]x_j\\&\qquad-\frac{0.0123}{4}\left(\sum_{j=1}^{n}\frac{1}{2}\left[b_j-a_j+\frac{1}{3}\left(\alpha_j+\beta_j\right)\right]x_j\right)^2-\frac{0.0123}{72}\left(\sum_{j=1}^{n}\left(\alpha_j+\beta_j\right)x_j\right)^2\\&\text{subject to}\quad\sum_{j=1}^{n}x_j=1,\quad 0\le x_j\le p_j,\quad j=1,2,\cdots,n\end{aligned}$$

ISBN: 978-989-95079-6-8

(Vercher et al. model)

$$\text{Minimize} \quad \sum_{j=1}^{n}\frac{1}{2}\left[b_j - a_j + \frac{1}{3}(\alpha_j + \beta_j)\right]x_j$$

$$\text{subject to} \quad \sum_{j=1}^{n}\frac{1}{2}\left[a_j + b_j + \frac{1}{3}(\beta_j - \alpha_j)\right]x_j \geq \rho,$$

$$\sum_{j=1}^{n} x_j = 1, \quad 0 \leq x_j \leq p_j, \quad j = 1,2,\cdots,n$$

Let us consider ten securities shown in Table 1, whose mean values and standard deviations are based on historical data in the decade between 1995 and 2004. Then, we introduce the asset allocation rate x_j, $(j = 1,2,...,10)$ to each security, and its upper value is assumed to be 0.2.

Table 1: Sample data from Tokyo Stock Exchange

Returns	Sample mean	SD
R1	0.055	0.445
R2	0.046	0.289
R3	0.015	0.306
R4	0.114	0.208
R5	0.043	0.253
R6	0.034	0.269
R7	0.018	0.230
R8	0.171	0.297
R9	0.087	0.388
R10	0.090	0.318

With respect to our proposed type-2 fuzzy portfolio model, parameter $\overline{r}_j$ of the primary *L*-fuzzy number is assumed to be sample mean in Table 1. Then, in two previous models parameters, parameters of trapezoidal fuzzy number a_j, b_j, α_j, β_j, $(j = 1,2,...,10)$ based on study [22] are shown in Table 2 using the historical data in Table 1.

Table 2. Each parameter value based on the historical data

Returns	a_j	b_j	α_j	β_j
R1	-0.123	0.005	0.239	0.868
R2	-0.069	0.069	0.301	0.467
R3	-0.129	0.025	0.200	0.713
R4	0.005	0.177	0.198	0.235
R5	-0.082	0.114	0.217	0.323
R6	-0.052	0.108	0.290	0.382
R7	-0.056	0.067	0.236	0.369
R8	0.060	0.193	0.310	0.456
R9	-0.093	0.130	0.312	0.626
R10	0.009	0.236	0.563	0.264

The secondary membership functions for $\tilde{\alpha}_j$ of type-2 fuzzy numbers are assumed to be triangle fuzzy numbers, whose $\underline{\alpha}_j = \overline{\alpha}_j$ are variances based on the SD in Table1 and the spreads $\underline{\alpha}_j - \alpha_j^L$ and $\alpha_j^U - \overline{\alpha}_j$ become α_j and β_j in Table 2, respectively. Therefore, using these data and introducing the following fuzzy goals for our proposed model;

$$\mu_G(f) = \begin{cases} 1 & (0.15 \leq f) \\ \dfrac{f - 0.12}{0.03} & (0.12 \leq f < 0.15) \\ 0 & (f < 0.12) \end{cases},$$

we set the parameter ρ in the Vercher et al. model as $\rho = 0.06$, and obtain optimal portfolios for three models shown in Table 3.

Subsequently, we consider the case where an investor purchases securities at the end of 2004 according to each portfolio shown in Table 3. Then, the total return of three models at term ends of 2005, 2006 and 2007 become the following values shown in Table 4, respectively.

Table 3. Each optimal solution with respect to three models

	Proposed model	Carlsson model	Vercher model
R1	0.200	0	0

Table 4. Total return to the portfolio of each model

Term end	Proposed	Carlsson	Vercher
2005	0.2524	0.2194	0.2852
2006	0.4050	0.3575	0.3257

From the result in Table 4, we find that our proposed model obtains the larger total return than the Carlsson et al. model dealt with the only crisp possibilistic mean value. Furthermore, from the total return at the term end of 2006, in the case that the investment period is longer, our proposed model obtains much larger total return.

5 Conclusion

In this paper, we have proposed a new portfolio selection problem based on the type-2 fuzzy set. Our proposed model has been initially not a well-defined problem due to primary and secondary fuzzy numbers. Therefore, in order to solve analytically in the sense of mathematical programming, we have introduced the possibility maximization model with fuzzy goal for the object and degree of possibility. Furthermore, by using the concept of crisp possibilistic mean value for the secondary fuzzy numbers, the main problem has been equivalently transformed into the parametric linear programming problem. Consequently, we have developed the efficient solution method to combine the bisection algorithm with the standard linear programming approach. Since this proposed model includes various types of investor's subjectivity in the form of type-2 fuzzy number, it is more versatile than previous models. Our proposed model is dealt with various practical situations in the investment such as the case putting the whole policy of investors including a lot of subjectivity by using the possibilistic mean value and the case

ISBN: 978-989-95079-6-8

indicating the sensible decision making to the investor with shaken investment policy due to uncertain but attractive information.

In this paper, as the criterion for the object, we introduced the possibility measure and the crisp possibilistic mean value. On the other hand, there are various types of criterions with respect to fuzzy object and constraints such as necessity and credibility measure, fuzzy interval approach, etc.. Therefore, as the future works, we need to consider more general and versatile type-2 fuzzy portfolio selection problems with such criterions.

Abstract—*In this study, Turkish automotive sector needs for flexibility will be determined, and the relationships between flexibility levers and flexibility performance criteria will be evaluated with respect to the sectoral needs. The choice of the appropriate lever combinations will be made for the sector by using the results of this evaluation. The flexibility strategies will be ranked by using a fuzzy extended AHP approach. At the second phase of this study, the QFD tool will be used to find the best flexibility lever portfolio related to automotive sector strategies.*

Keywords— Flexibility Management, Fuzzy AHP, QFD, Turkish Automotive Sector.

1 Introduction

The markets in which manufacturers and service firms compete are increasingly influenced by intense foreign competition, rapid technological change, shorter product life-cycles and customers increasingly unwilling to settle for mass-produced items or services with limited value. The "new breed of customer" [1], who demands greater responsiveness to a dynamic set of requirements, and a new competitive environment, which exposes local companies to competition with the companies around the globe, form a new scenario that has challenged firms in most industries ([2]; [3]; [4]). In this new scenario, flexibility may be one of the most important capabilities needed for firms to achieve competitive advantage ([5]; [6]; [7]).

We defined flexibility as the capacity of adaptation under the double constraint of uncertainty and the urgency. This uncertainty can come from the providers (rupture, problems of transport), from the customers (variation of the request) or from the company itself (breakdowns of the equipment, problems of provisioning). The possible behaviors of the company face to these problems are called levers of flexibilities. After the mass production era of Ford and lean management era of Toyota, these days are witnessing the era of flexibility. Modern organization should keep as much as possible flexibility capability to be used in case of an incident.

This paper will briefly summarize the flexibility concept and flexibility levers as well as the existing situation of Turkish automotive industry by the flexibility point of view. It will introduce a model, based on Analytic Hierarchy Process (AHP) and Quality Function Deployment (QFD) methodology, which determine the best flexibility levers' portfolio to deal with consumers needs for flexibility in term of delivering a 5R product (right place-RP, right time-RT, right quantity-RQ, right product-RPr, right price-RPc). The Turkish automotive industry including the parts and components producers is considered in this study as a case industry. Automotive industry is considered as a complete industry covering all entities of the value chain.

In the second section of the paper, the flexibility management literature will be reviewed and Turkish automotive sector needs for flexibility will be determined. In the third section, the fuzzy extended AHP model will be introduced and the flexibility strategies will be ranked by using this approach. At the fourth phase of this study, the QFD tool will be used to find the best flexibility lever portfolio related to automotive sector strategies. The relationships between flexibility levers and flexibility performance criteria will be evaluated with respect to the sectoral needs. The choice of the appropriate lever combinations will be made for the sector by using the results of this evaluation. The study will be concluded with the presentation of the selected portfolio.

2 Flexibility Management

2.1 Literature Review

Flexibility becomes a strategic resource from the late 70s due to the uncertainty in the environment faced by most of the enterprises. This uncertainty is due to several factors, such as diversification in product range, reduced product life cycle, fragmentation and globalization of markets, sophistication of customers etc. In a broad view flexibility is defined as the capability of adaptation to change. The flexibility is a total capacity, which will be activated as a function of events, which are not controlled by the company. It has a passive vision and defensive usage of the capability. But flexibility may create some offensive strategies as well. By offering more diverse products than the competitors, by renewing the products more frequently or by customizing associated services, flexible pioneers can set the rules of game of the industry by creating uncertainty for their competitors. Therefore flexibility is defined as a strategic asset for the companies not only for adapting to the changes in the environment but also to change the environment in favor of itself.

ISBN: 978-989-95079-6-8

Some authors distinguish between internal and external flexibilities. For instance, Swamidass [8] distinguishes machine-level flexibility from plant-level flexibility. The former being "predominantly technology based" and the latter being derived from a combination of technology, infrastructure, design and engineering capabilities, and the competitive goals and objectives of a firm. Upton [9] defines internal flexibility as the operations strategy and the set of capabilities a firm nurtures to respond to its environment, and external flexibility as capabilities possessed by the firm and used to accommodate sources of variability to which the firm must respond and which are seen as flexible by the market. This external dimension fits the two major strategies proposed by Hyun and Ahn [10] for using flexibility: reactive and proactive. In the same vein, Gerwin [11] also suggests two major strategies for using flexibility: adaptive and redefinition. The adaptive strategy refers to the defensive or reactive use of flexible competencies to accommodate unknown uncertainty, while the redefinition strategy refers to the proactive use of flexible competencies to raise customer expectations, increase uncertainty for rivals and gain competitive edge.

The reasons companies are motivated to be flexible include the need to make design changes quickly, when competitors introduce new models and customers start switching supply sources; to focus on volume flexibility, when large customers reduce inventories and their demand rates become volatile; more flexible product mixes, when importers or domestic competitors start offering multiple quality and price levels; to respond quickly and supply the new products/services, when the customer tastes change quickly.

Especially, four types of flexibilities are important in point of view of the consumer: the volume (VF), the product mix (PMF), the new product (NPF) and the design flexibilities (DF). Volume flexibility can be defined as the ability to operate profitably at different production volumes [9]. Product mix flexibility is adopted to deal with uncertainty about the products that will be demanded by customers at a particular period ([12]; [13]). It is characterized by the ability to produce several products at one manufacturing facility without incurring a major cost penalty. New product flexibility is the ability of a system to add or substitute new products to the product mix. Finally, the design flexibility is the ability to change the design of a product very economically and quickly

The need for flexibility can be expressed as a satisfaction of the demand with delivery on time (I), at the right place (II), in required quantity (III) with the right product (IV) and the right price (V).

It may be noted that each of the above external elements are the causes beyond the control of any company. Further, none of these needs can be satisfied by the mass production strategy. Consequently, the classical methods as the affair with large production runs and economies of scale are a thing of the past, and are being replaced by a new concept - flexibility management.

To satisfy the need for various types of flexibility, Aggorwal [14] define three groups of levers or mechanisms. The first group is referred to as levers for internal flexibility. Each of these levers remains under the control of management at all times. The salient levers in this group are Planning/Scheduling Flexibility (1), Sequencing Flexibility (2), Routing Flexibility (3), Labor Flexibility (4), Machine/Equipment Flexibility (5), Design/Development Flexibility (6), Process/Technology Flexibility (7), Raw Materials Flexibility (8), Transport/Shipping Flexibility (9), Layout Flexibility (10), Expansion Flexibility (11), Financial Resources Flexibility (12).

The second group consists of levers for soft flexibilities. Each of these levers can enhance internal flexibility. In contrast to hard levers, they are never completely under management's control as each requires heightened participation and support of specialists and other employee groups. The levers constituting this group and their respective code numbers are Organizational Structure Flexibility (13), Decision Making Flexibility (14), Job Design Flexibility (15), Employee's Willingness for Change Flexibility (16), Managerial Perception Change Flexibility (17). These flexibility levers cannot be measured on a hard (quantitative) scale, as was the case with the levers of the first group; therefore they are designated soft levers flexibilities.

The third group of levers involves managerial manipulation of intangibles. Each of these levers can enhance one or more of the flexibilities either externally or internally. Again, their effectiveness cannot be measured on a hard scale, so they are called intangible levers (flexibilities). These are Reputation Building Flexibility (18), Flexibility in Enhancing Knowledge and Experience Base (19), Flexibility in Identifying Undiscovered and Unused Talents of Workforce (20), Flexibility in Development of Standing Agreements with Suppliers and Customers (21).

2.2 Changing Landscape in Turkish Automotive Industry

The present-day automotive industry of Turkey was first developed within the broader context of import substitution in the 1960s. High tariffs, quantitative restrictions and local content regulations were used to create a local vehicle industry. Access to the local market could only be achieved through local production. In Turkey, the government succeeded in attracting a number of assemblers (most notably Ford, Fiat and Renault), and by the early 1970s cars with a high degree of local content were being produced. While the assemblers were joint ventures between foreign companies and local groups by the late 1970s, a thriving components industry was created, much of which was locally owned. The industry continues to grow in the 1970s and 1980s mainly by protectionist policies. The rapid expansion of the automotive industry arose from a coming together of two distinct interests. However, the developing impact of the automotive industry in the 1990s is likely to be very different from that seen in the 1960s and 1970s. This is because the industry has globalized and changed its governance structures

Protectionist policies continued throughout the early 1990s. In 1995, by signing the Customs Union agreement with European Union, Turkey abolished high taxes over European origin vehicles. With customs union Turkish automotive industry changed its nature and it results Turkish

ISBN: 978-989-95079-6-8

car manufacturers to produce competitive products both in price and in quality. Another impact of the customs union over the industry is the shift of focus from local market to global markets. As a direct result of globalization, local producers have begun to manufacture vehicles for global markets. Due to global strategies of multinational vehicle producers, manufacturing facilities in Turkey are dedicated to manufacture specific models. This shift in the assemblers had an immediate impact over the suppliers that are faced to the obligations of the globalized environment. It become important in this uncertain environment to be armed with performer flexibility levers in order to deal with the rapid changes in the sector.

3 Proposed Methodology

3.1 Ranking Flexibility Strategies with Fuzzy Extended AHP Approach

In this paper the fuzzy extension of one of the most widely used MCDM methods namely FAHP is used to find the relative importance of the problems alternatives and criteria. The choice of the method used in this stage is arbitrary but the wide range and the ease of use for FAHP was determinant for us to choose it. And with fuzzy logic, we wanted to handle as precisely as possible the unprecised qualitative data collected from the experts.

The FAHP approach is introduced, with the use of Triangular Fuzzy Numbers-TFNs for pairwise comparison scale of FAHP according to the method of Chang's [15] fuzzy extent analysis and the correct normalization formula given later by Wang et al. [16].

In the conventional AHP, the pairwise comparisons for each level with respect to the goal are conducted using a nine-point scale proposed by Saaty [17]. According to Zadeh [18], it is very difficult for conventional quantification to define the complex situations, so the notion of a linguistic variable, whose values are words or sentences, is necessary. To assess the relative importance of the criteria and to evaluate the alternatives with respect to the problems criteria an assumed weighting set has been developed. The decision makers can use this linguistic rating set. The triangular fuzzy conversion scale of the linguistic values in the weighting set is shown in Table 1.

Table1. The triangular fuzzy conversion scale

Linguistic Values	***Triangular Fuzzy Numbers***
Very Low (VL) Very Poor (VP)	$\left(\frac{1}{5},\frac{1}{5},\frac{1}{3}\right)$
Low (L) Poor (P)	$\left(\frac{1}{5},\frac{1}{3},1\right)$
Exactly Equal	$(1,1,1)$
Medium (M) Fair (F)	$\left(\frac{1}{2},\frac{3}{2},\frac{5}{2}\right)$
High (H) Good (G)	$(1,3,5)$
Very High (VH) Very Good (VG)	$(3,5,5)$

Assume that $X=\{x_1,x_2,...,x_n\}$ is an object set, and $U=\{u_1,u_2,...,u_m\}$ is a goal set. According to the method of Chang's [24] fuzzy extent analysis, each object is taken and extent analysis is performed for each goal respectively. Therefore, *m* extent analysis values for each object can be obtained, with the following representation:

$$M_{g_i}^1, M_{g_i}^2,..., M_{g_i}^m \text{ for } i=1,2,...,n \quad (1)$$

Note that all the $M_{g_i}^j$, $j=1,2,\ldots,m$, are TFNs representing the performance of the object x_i with regard to each goal u_j. The steps of Chang's [19] extent analysis can be given as in the following:

- First, by fuzzy arithmetic operations, take the sum of each row of the fuzzy comparison matrix.

$$RS_i=\sum_{j=1}^{n}\tilde{a}_{ij}=\left(\sum_{j=1}^{n}l_{ij},\ \sum_{j=1}^{n}m_{ij},\ \sum_{j=1}^{n}u_{ij}\right),\quad i=1,\ldots,n \quad (2)$$

- Using fuzzy synthetic extent analysis, the value of fuzzy synthetic extent with respect to the i^{th} object x_i, $i=1,2,\ldots,n$ that represents the overall performance of the object across all goals can be determined by the following normalization formula given by Wang et al. [25]:

$$\tilde{S}_i=\frac{RS_i}{\sum_{j=1}^{n}RS_j}=\left(\frac{\sum_{j=1}^{n}l_{ij}}{\sum_{j=1}^{n}l_{ij}+\sum_{k=1,k\neq i}^{n}\sum_{j=1}^{n}u_{kj}},\ \frac{\sum_{j=1}^{n}m_{ij}}{\sum_{k=1}^{n}\sum_{j=1}^{n}m_{ij}},\ \frac{\sum_{j=1}^{n}u_{ij}}{\sum_{j=1}^{n}u_{ij}+\sum_{k=1,k\neq i}^{n}\sum_{j=1}^{n}l_{kj}}\right),\quad i=1,\ldots,n \quad (3)$$

- The degree of possibility of $M_1\geq M_2$ is defined as :

$$V(M_1\geq M_2)=\sup_{x\geq y}\left[\min\left(\mu_{M_1}(x),\mu_{M_2}(y)\right)\right] \quad (4)$$

- Compute the degree of possibility of $\tilde{S}_i\geq\tilde{S}_j$ by the following equation where $\tilde{S}_i=(l_i,m_i,u_i)$ and $\tilde{S}_j=(l_j,m_j,u_j)$:

$$V(\tilde{S}_i\geq\tilde{S}_j)=\begin{cases}1, & \text{if } m_i\geq m_j,\\ \dfrac{u_i-l_j}{(u_i-m_i)+(m_j-l_j)}, & \text{if } l_j\leq u_i,\quad i,j=1,\ldots,n;i\neq j\\ 0, & \text{otherwise,}\end{cases} \quad (5)$$

- To compare $\tilde{S}_i=(l_i,m_i,u_i)$ and $\tilde{S}_j=(l_j,m_j,u_j)$, we need both the values of $V(\tilde{S}_i\geq\tilde{S}_j)$ and $V(\tilde{S}_j\geq\tilde{S}_i)$. The degree of possibility for a convex fuzzy number $\tilde{S}$ to be greater than *k* convex fuzzy numbers $\tilde{S}_i$, *i*=1,…,k can be defined by:

$$V(M\geq M_1,\ldots,M_k)=V[(M\geq M_1)\wedge\ldots\wedge(M\geq M_k)]=\min V(M\geq M_i)$$
$$\text{for } i=1,2,...,k$$

- Assume that for the alternative A_i,

$$d'(A_i)=\min V(S_i\geq S_j),\qquad \text{for } j=1,2,...,n;\ j\neq i \quad (6)$$

- Then the weight vector is given by,

$$W'=(d'(A_1),d'(A_2),...,d'(A_n))^T \quad (7)$$

- Via normalization, the normalized weight vectors are,

$$W=(d(A_1),d(A_2),...,d(A_n))^T \quad (8)$$

ISBN: 978-989-95079-6-8

To illustrate our model, a decision-making group is formed that consists of the 5 experts from the Turkish automotive industry. After a detailed discussion on every criterion, four main criteria of flexibility types have been identified for the hierarchical structure. The AHP hierarchy scheme is constructed and shown in Figure 1.

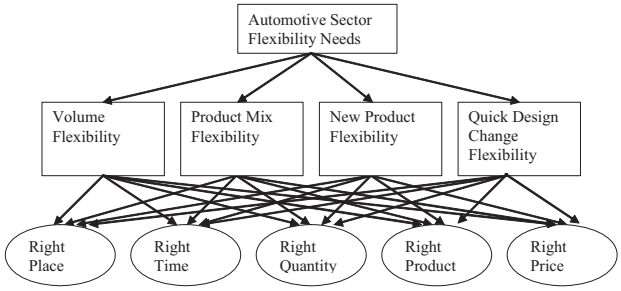

Figure 1. Hierarchical Structure of Flexibility Needs

The aim of the evaluation is to rank the importance of consumers needs for flexibility in the sector. The normalized weight vectors of alternatives with respect to criteria are calculated and shown in Table 2.

Table 2. The normalized weight vectors of the alternatives

	VOLUME	MİX	NEW PRODUCT	QUICK DESIGN CHANGE	
	0,752	0,1	0,045	0,103	
RP	0,108	0,129	0,131	0,083	0,109
RT	0,148	0,144	0,154	0,203	0,154
RQ	0,221	0,094	0,096	0,144	0,195
RPr	0,276	0,228	0,489	0,252	0,278
RPc	0,247	0,404	0,131	0,318	0,265

The need for volume flexibility is highly important in the automotive sector. The consumer demand in this sector is significantly sensible to the global economic indicators. On the other hand, the right price is very important when we are faced to a mix product flexibility problem. In the same way, placing the right product in the market is extremely important when we have to satisfy a new product flexibility need. Finally, the 5R strategies are ranked for their relative importance as follows: $RPr \succ RPc \succ RQ \succ RT \succ RP$.

3.2 Selection of the best flexibility lever portfolio using QFD

Quality function deployment (QFD) is ‘‘an overall concept that provides a means of translating customer requirements into the appropriate technical requirements for each stage of product development and production (i.e., marketing strategies, planning, product design and engineering, prototype evaluation, production process development, production, sales)’’ [19]. QFD belongs to the sphere of quality management methods, offering us a linear and structured guideline for converting the customer’s needs into specifications for, and characteristics of new products and services. The method involves developing four matrixes, or ‘houses’, that we enter by degrees as a project for a given product or production process is developed on increasingly specific levels [20]. In the present article, our attention focuses on the Planning Matrix, or (HOQ) [21] (Fig. 2).

The HOQ provides the specifications for product design (or engineering characteristics) in terms of their relative importance and of target values that have to be reached in design and production. In a sense, the HOQ is the hub of the whole QFD method: its construction enables us to proceed from the customer’s requirements to the design specifications ([22]; [23]). This paper describes the HOQ and its process following the approaches suggested by Brown [24], and Griffin and Hauser [25]. Step 1: Identify the WHATs. The expected benefits in a product or service in the customer’s own words are customer needs and are usually called customer attributes (CA) or ‘‘WHATs’’, area (A) in Fig. 2. In assigning priorities to WHATs, it is necessary to balance efforts in order to accomplish those needs that add value to the customer. The priorities are usually indicated in the area designated as (B) in Fig. 2. Step 2: Determination of HOWs. Engineering characteristics are specified as the ‘‘HOWs’’ of the HOQ and also called measurable requirements. HOWs are identified by a multidisciplinary team [26] and positioned on the area marked as (C) on the matrix diagram, Fig. 2. Step 3: Preparation of the relationship matrix (D). A team judges which WHATs impact which HOWs and to what degree. Step 4: Elaboration of the correlation matrix. The physical relationships among the technical requirements are specified on an array known as ‘‘the roof matrix’’ and identified as (E) in Fig. 2. Step 5: Action plan. The weights of the HOWs, identified as area (F), are placed at the base of the quality matrix. These weights are one of the main outputs of the HOQ, and are determined by

$$\text{Weight (HOW)}_i = V(\text{HOW})_{i1} * \text{imp}(\text{WHAT}_1) + \ldots + V(\text{HOW})_{in} * \text{imp}(\text{WHAT}_n)$$

where $V(\text{HOW})_{in}$ is the correlation value of HOW_i with WHAT_n, and imp (WHAT_n) represents the importance or priority of WHAT_n.

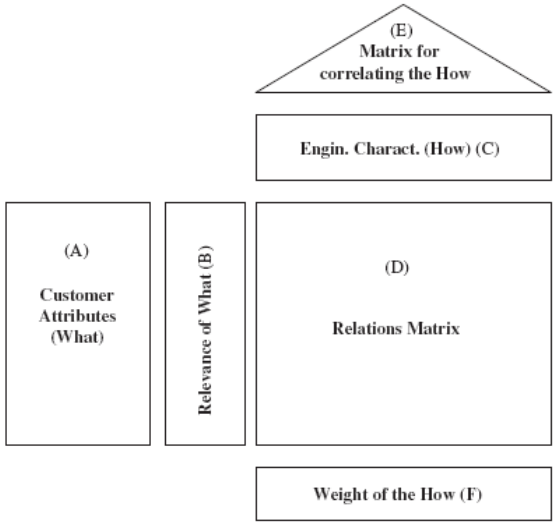

Figure 2. House of quality.

Various quantitative methods have been suggested to use in QFD to improve its reliability and objectiveness, noticeably the methods of management science/operational research (MS/OR), marketing research, and fuzzy logic.

Figure 3. The HOQ applied to the flexibility levers portfolio choice

Works applying MS/OR methods to QFD include analytic hierarchy process (AHP) to prioritize customer needs (whats) ([27]; [28]; [29]), AHP and benchmarking integrated to rate ‘‘whats’’ [30], AHP and QFD for combining customers’ requirements and preferences [31], AHP and two multi-attribute decision-making methods for rating ‘‘whats’’ [32], AHP, multiattribute utility theory, and linear programming methods for rating ‘‘whats’’ [33], value functions to capture ‘‘whats’’ [34], AHP to study the ranking sensitivity of ‘‘whats’’ in QFD [35].

In this paper, we are using the F-extended AHP method which is described in the previous section for ranking the WHAT column of the HOQ (fig. 3). These are the flexibility levers in the HOW column. The experts have judged which flexibility levers impact which flexibility needs and to what degree. The physical relationships among the technical requirements are also specified but not given here. Finally, the table 3 indicates the importance weights of the flexibility levers.

4 Conclusions

In this paper, a decision making model, based on Analytic Hierarchy Process (AHP) and Quality Function Deployment (QFD) methodology, which determine the best flexibility levers’ portfolio to deal with consumers needs for flexibility in term of delivering a 5R product is developed. Thus, the need for flexibility is calculated with the F-extended AHP method. The experts have judged which flexibility levers impact which flexibility needs and to what degree.

The need for volume flexibility is highly important in the automotive sector. On the other hand, the right price is very important when we are faced to a mix product flexibility problem. In the same way, placing the right product in the market is extremely important when we have to satisfy a new product flexibility need.

Facing continuous change in the automotive industry, using the flexible human resources factors and being able to develop the flexible agreements with suppliers and customers are very important. On the other hand, an automotive firm must have a flexible technology to adapt any change and be highly flexible in his transport and shipping design.

For the future works, the study will develop a Fuzzy-QFD for better represent the vagueness of the experts’ opinions on the flexibility levers. In a next time, the three phases of QFD will be included for a global design strategy.

Table 3. The importance weight of the flexibility levers

Row Number	Flexibility Levers	Relative Weight (Relative Importance)
4	Labor Flexibility	10,14%
21	Flexibility in Development of Standing Agreements with Suppliers and Customers	10,04%
7	Process/Technology Flexibility	8,35%
9	Transport/Shipping Flexibility	6,71%
12	Financial Resources Flexibility	6,38%
6	Design/Development Flexibility	5,95%
11	Expansion Flexibility	5,56%
19	Flexibility in Enhancing Knowledge and Experience Base	5,32%
1	Planning/Scheduling Flexibility	4,61%
13	Organizational Structure Flexibility	4,18%
14	Decision Making Flexibility	4,18%
5	Machine/Equipment Flexibility	3,95%
20	Flexibility in Identifying Undiscovered and Unused Talents of Workforce	3,50%
10	Layout Flexibility	3,38%
15	Job Design Flexibility	3,35%
18	Reputation Building Flexibility	3,35%
8	Raw Materials Flexibility	2,36%
17	Managerial Perception Change Flexibility	2,36%
16	Employee's Willingness for Change Flexibility	2,21%
3	Routing Flexibility	2,12%
2	Sequencing Flexibility	2,01%

Abstract*— *In this paper, we study the OWA operator on the real line, which corresponds to the Continuous OWA operator (COWA). After defining it, we introduce some properties and fundamental formulas for its computation. Among them, we give as an example, a differential equation for the COWA operator. **Keywords:** Fuzzy measures, Order weighted averaging operator, Choquet integral, Continuous OWA operator

1 Introduction

Aggregation operators [1, 3, 8] are used to combine information to obtain a datum of better quality. In recent years there is an increasing interest in these topics for their application in decision problems and artificial intelligence.

Among aggregation operators, one of the most well known and useful one is the Ordered Weighted Averaging operator (OWA) introduced by Yager [12, 13, 14]. The OWA is regarded as a Choquet integral with respect to a fuzzy measure[6, 9].

In classical statistics, when the amount of data is large, it is usual to approximate a discrete distribution, such as a binomial distribution, by a continuous distribution. A continuous distribution, such as the normal distribution, is a Lebesgue integral on the real line and is based on lots of results of classical integral theory. At present, there are a very few theoretical results about the Choquet integral on the real line. This paper is the first step for a theory of Choquet integral on the real line.

The structure of this paper is as follows. In Section 2 we review fuzzy measures and the OWA operator, and introduce a few results related to the OWA operator.

In Section 3, we define the OWA operator on the real line, called the Continuous OWA operator (COWA) operator and introduce some fundamental formulas and expressions for their computation.

In Section 4, we show an example of differential equation, which will be a hint to find a weighting function for the COWA operator. The paper finishes with some conclusions.

2 Preliminaries

In this section, we define fuzzy measures, the Choquet integral and the OWA operator, and show their basic properties.

To introduce both a discrete space and a non-discrete space in a unified way, we use the terms in general topology in this section. Let X be a locally compact Hausdorff space and $\mathcal{B}$ be a class of Borel sets, that is, the smallest $\sigma-$algebra which includes the class of all closed sets. We say that $(X, \mathcal{B})$ is a measurable space.

Example 1 *We consider two examples of Hausdorff spaces:*

(1) *The set of all real numbers R is a locally compact Hausdorff space. If $X = R$, $\mathcal{B}$ is the smallest $\sigma-$ algebra which includes the class of all closed intervals.*

(2) *Let $X := \{1, 2, \ldots, N\}$. X is a compact Hausdorff space with a discrete topology. Then we have $\mathcal{B} = 2^X$.*

Definition 1 [7] Let $(X, \mathcal{B})$ be a measurable space. A fuzzy measure (or a non-additive measure) μ is a real valued set function, $\mu : \mathcal{B} \longrightarrow [0, 1]$ with the following properties;

(1) $\mu(\emptyset) = 0$

(2) $\mu(A) \leq \mu(B)$ whenever $A \subset B$, $A, B \in \mathcal{B}$.

We say that the triplet $(X, \mathcal{B}, \mu)$ is a fuzzy measure space if μ is a fuzzy measure.

A fuzzy measure is said to be continuous if $A_n \uparrow A$ implies $\mu(A_n) \uparrow \mu(A)$ and $A_n \downarrow A$ implies $\mu(A_n) \downarrow \mu(A)$.

Definition 2 Let $(X, \mathcal{B})$ be a measurable space. A function $f : X \to R$ is said to be measurable if $\{x | f(x) \geq \alpha\} \in \mathcal{B}$ for all $\alpha \in R$.

Example 2 *Let f be a continuous function. Then, for all $\alpha \in R$, $\{f \geq \alpha\}$ is a closed set. Therefore, f is measurable.*

$\mathcal{F}(X)$ denotes the class of non-negative measurable functions, that is,

$$\mathcal{F}(X) = \{f | f : X \to R^+, f : \text{measurable}\}$$

Definition 3 [2, 5] Let $(X, \mathcal{B}, \mu)$ be a fuzzy measure space. The Choquet integral of $f \in \mathcal{F}(X)$ with respect to μ is defined by

$$(C) \int f d\mu = \int_0^\infty \mu_f(r) dr,$$

where $\mu_f(r) = \mu(\{x | f(x) \geq r\})$.

Let $A \subset X$. The Choquet integral restricted on A is defined by

$$(C) \int_A f d\mu := (C) \int f \cdot 1_A d\mu.$$

ISBN: 978-989-95079-6-8

Definition 4 *Let $D \subset R^N$. An aggregation operator Ag is a function $Ag : D \to R$ with the following properties;*

(1) *(Unanimity or idempotency)*

$Ag(a, \ldots, a) = a$ *if* $(a, \ldots, a) \in D$

(2) *(Monotonicity)*

If $a_i \leq b_i$ *for all* $i = 1, \ldots, n$, $\mathbf{a} = (a_1, \ldots, a_N), \mathbf{b} = (b_1, \ldots, b_N)$ $\mathbf{a}, \mathbf{b} \in D$, *then* $Ag(\mathbf{a}) \leq Ag(\mathbf{b})$.

Yager introduced the Ordered Weighted Averaging operator in [12].

Definition 5 *[12] Given a weighting vector* $\mathbf{w}$ *with weights* $(w_1, \ldots, w_N)$, *the Ordered Weighted Averaging operator is defined as follows:*

$$OWA_{\mathbf{w}}(\mathbf{a}) = \sum_{i=1}^{N} w_i a_{\sigma(i)}$$

where σ *defines a permutation of* $\{1, \ldots, N\}$ *such that* $a_{\sigma(i)} \geq a_{\sigma(i+1)}$, $\mathbf{a} = (a_1, \ldots, a_n)$.

A fuzzy measure μ on $\mathcal{B}$ is said to be symmetric [4] if $\mu(A) = \mu(B)$ for $|A| = |B|$, $A, B \in \mathcal{B}$. Symmetric fuzzy measures on $\{1, \ldots, N\}$ can be represented in terms of N weights w_i for $i = 1, \ldots, N$ so that $\mu(A) = \sum_{i=1}^{|A|} w_i$. Using a symmetric fuzzy measure, we can represent any OWA operator as a Choquet integral.

Proposition 6 *Let* $X := \{1, 2, \ldots, N\}$; *then, for every* $OWA_{\mathbf{w}}$, *there exists a symmetric fuzzy measure satisfying* $\mu(\{1\}) := w_1$ *and* $\mu(\{1, \ldots, i\}) := w_1 + \cdots + w_i$ *for* $i = 1, 2, \ldots, N$, *such that*

$$OWA_{\mathbf{w}}(\mathbf{a}) = (C) \int \mathbf{a} d\mu$$

for $\mathbf{a} \in R_+^N$.

3 Continuous OWA operator

In the following we consider aggregation operators on the real line. Let λ be a Lebesgue measure on $[0, 1]$, that is, $\lambda([a, b]) = b - a$ for $[a, b] \subset [0, 1]$.

Definition 7 *Let* $\mathcal{F}_b([0, 1])$ *be a class of bounded measurable function on* $[0, 1]$. *A continuous aggregation operator Ag on the real line is a functional* $Ag : \mathcal{F}_b([0, 1]) \to R$ *with the following properties;*

(1) *(Unanimity or idempotency)*

$Ag(a) = a$ *if* $a(x) = a$ *for all* $x \in [0, 1]$

(2) *(Monotonicity)*

If $a(x) \leq b(x)$ *for all* $x \in [0, 1]$, *then* $Ag(a) \leq Ag(b)$.

(3) *(Continuity) Let* a_n, $a \in \mathcal{F}_b([0, 1])$ *for* $n = 1, 2, 3, \ldots$ *and* $\lim_{n\to\infty} a_n = a$. *Then,* $\lim_{n\to\infty} Ag(a_n) = Ag(a)$.

Let $D \subset R^N$. For every $a := (a_1, \ldots, a_n) \in D$, we can define a function $f \in \mathcal{F}_b([0, 1])$ by $f(x) := a_k$ if $(k-1)/n \leq x < k/n$. Therefore the definition above is one of the generalization of aggregation operators on D.

Since the Choquet integral with respect to a continuous fuzzy measure satisfies all the conditions above, the Choquet integral with respect to a continuous fuzzy measure is a continuous aggregation operator.

Using the Choquet integral we can define the continuous OWA (COWA) operator.

Definition 8 *Let* μ *be a fuzzy measure on* $([0, 1], \mathcal{B})$. μ *is said to be symmetric, if* $\lambda(A) = \lambda(B)$ *implies* $\mu(A) = \mu(B)$.

Definition 9 *Let* $a \in \mathcal{F}_{\lfloor}([0, 1])$. *The continuous OWA operator is defined by*

$$COWA_{\mu}(\mathbf{a}) = (C) \int \mathbf{a} d\mu$$

where μ *is a symmetric fuzzy measure.*

Let μ be a symmetric fuzzy measure on $([0, 1], \mathcal{B})$. Suppose that $\lambda(A) < \lambda(B)$. Then there exists $B' \in \mathcal{B}$ such that $\lambda(B) = \lambda(B')$ and $A \subset B'$. Then we have

$$\mu(A) < \mu(B') = \mu(B).$$

Therefore we have the next proposition.

Proposition 10 *Let* μ *be a symmetric fuzzy measure on* $([0, 1], \mathcal{B})$. *Then there exists a monotone function* $\varphi : [0, 1] \to [0, 1]$ *such that* $\mu = \varphi \circ \lambda$.

It follows from the proposition above that we can consider the Choquet integral with respect to $\varphi \circ \lambda$ as the COWA operator. We will write $COWA_{\varphi}$ instead of $COWA_{\varphi\circ\lambda}$ and we will say that φ is the weight for the COWA operator.

Let $f : [0, 1] \to R$ be monotone increasing with $f(0) = 0$ and differentiable. We define the sequence of functions $\{f_k\}$ by $f_1 = f$, $f_{k+1} = \int_0^x f_k d\lambda$ for $x \in [0, 1]$, $k = 1, 2, \ldots$. Then we have

$$\begin{aligned}(C) \int_{[0,1]} f d\lambda^n &= \int_0^{\infty} \lambda^n (f \cdot 1_{[0,x] \geq \alpha}) d\alpha \\ &= \int_0^{f(x)} (x - f^{-1}(\alpha))^n d\alpha\end{aligned}$$

Let $t := x - f^{-1}(\alpha)$, Since we have $d\alpha = -f'(x - t)dt$, $t = x$ if $\alpha = 0$ and $t = 0$ if $\alpha = f(x)$, then

$$\begin{aligned}(C) \int_{[0,1]} f d\lambda^n &= \int_x^0 t^n \cdot (-f'(x - t)) dt \\ &= \int_0^x t^n f'(x - t) dt\end{aligned}$$

Next let $s := x - t$, we have

$$\begin{aligned}(C) \int_{[0,1]} f d\lambda^n &= \int_0^x (x - s)^n f'(s) ds \\ &= [(x - s)^n f(s)]_0^x + n \int_0^x (x - s)^{n-1} f_1(s) ds\end{aligned}$$

ISBN: 978-989-95079-6-8

Since $f(x) = 0$, we have

$$(C)\int_{[0,1]} f d\lambda^n = n\int_0^x (x-s)^{n-1} f_1(s) ds.$$

It follows from integration by part again that

$$\int_0^x (x-s)^{n-1} f_1(s) ds = (n-1)\int_0^x (x-s)^{n-2} f_2(s) ds.$$

Repeating above calculation, we have the next lemma.

Lemma 11 *Let $f : [0,1] \to R$ be monotone increasing with $f(0) = 0$ and differentiable. We define the sequence of functions $\{f_k\}$ by $f_1 = f$, $f_{k+1} = \int_0^x f_k d\lambda$ for $x \in [0,1]$, $k = 1, 2, \ldots$. Then we have*

$$(C)\int_{[0,x]} f d\lambda^n = n! f_n(x)$$

for $x \in [0,1]$.

Example 3 *Let $f(t) = t$, we have $f_1 = \frac{1}{2}x^2, \cdots, f_n = \frac{1}{(n+1)!}x^{n+1}$.*

$$(C)\int_{[0,x]} t d\lambda^n(t) = \frac{1}{n+1}x^{n+1}$$

for $x \in [0,1]$.

Let the weight w be ∞-order differentiable. Then we can express w by

$$w(x) := \sum_{k=1}^{\infty} a_k x^k.$$

Since the Choquet integral is linear with respect to the fuzzy measures. We have

$$(C)\int_{[0,x]} f dw \circ \lambda = \sum_{k=1}^{\infty} k! a_k f_k(x)$$

for $x \in [0,1]$. Therefore we have the next theorem.

Theorem 12 *Let $f : [0,1] \to R$ be monotone increasing with $f(0) = 0$ and differentiable. We define the sequence of functions $\{f_k\}$ by $f_1 = f$, $f_{k+1} = \int_0^x f_k d\lambda$ for $x \in [0,1]$, $k = 1, 2, \ldots$.*

$$COWA_{\mathbf{w}}(f) = \sum_{k=1}^{\infty} k! a_k f_k(1)$$

for $x \in [0,1]$.

4 Differential equation for COWA operator

In this section we consider the definition of a weight for the COWA. As we will see below, a differential equation helps in this definition.

Let us define a weight $w(x) := \dfrac{e^x - 1}{e - 1}$. Then we have

$$w(x) = \frac{1}{e-1}\sum_{k=1}^{\infty} \frac{1}{k!} x^k.$$

Since $a_k = \dfrac{1}{(e-1)k!}$, we have

$$(C)\int_{[0,x]} f dw \circ \lambda = \frac{1}{e-1}\sum_{k=1}^{\infty} k! f_k(x)$$

for $x \in [0,1]$.

Then we have the next differential equation for a weighting function.

$$\frac{d}{dx}(C)\int_{[0,x]} f dw \circ \lambda = f(x) + \frac{1}{e-1}\sum_{k=1}^{\infty} k! f_k(x)$$

for $x \in [0,1]$. Therefore we have the next differential equation.

$$\frac{d}{dx}(C)\int_{[0,x]} f dw \circ \lambda = f(x) + (C)\int_{[0,x]} f dw \circ \lambda$$

for $x \in [0,1]$.

Proposition 13 *Let f be a monotone increasing function with $f(0) = 0$ and let f be differentiable. If the weighting function satisfies the next equation:*

$$\frac{d}{dx}(C)\int_{[0,x]} f dw \circ \lambda = f(x) + (C)\int_{[0,x]} f dw \circ \lambda$$

for $x \in [0,1]$, then we have

$$w(x) = \frac{e^x - 1}{e - 1}$$

5 Conclusion

We defined the OWA operator on the real line (COWA operator), and show some fundamental formulas for its calculation. We give an example of differential equation to find a weighting function for COWA operator. This methods will be applicable to the Weighted OWA (WOWA) operator introduced by Torra [10, 11], which is one of the generalization of OWA operator. We expect to have some new results related to the WOWA operator in the near future.

***Abstract*— *Fuzzy systems address the imprecision of the input and output variables, which formally describe notions like "rather warm" or "pretty cold", while provide a behaviour that depends on fuzzy data. This class of systems are classically represented by means of Fuzzy Inference Systems (FIS), a computing framework based on the concepts of fuzzy if-then rules and fuzzy reasoning. Even if FIS are largely used, these lack in compositionality. Moreover, the analysis of modeled behaviuors needs complex analytic tools. In this paper we propose a process algebraic approach to specification and analysis of fuzzy behaviours. Indeed, we introduce a Fuzzy variant of CCS (*Calculus of Communicating Processes*), that permits compositionally describing fuzzy behaviours. Moreover, we also show how standard process algebra formal tools, like modal logics and behavioural equivalences, can be used for supporting fuzzy reasoning.*

***Keywords*—** Fuzzy Systems, Process Algebras, Compositional Fuzzy Reasoning

1 Introduction

Human perception of real world abounds with concepts without strictly defined constraints (examples are fat, very, more, slowly, old, etc). Such concepts can be described by means of Fuzzy Sets [1, 2]: classes of objects in which transit from membership to not membership gradually takes place.

Fuzzy Sets are widely used in control systems where the system behaviour can depend on data without precise values. In a *Fuzzy System* input values are described by means of variables that model data (temperature, speed) representing them as fuzzy sets, each of which identifies a different range of values (e.g. *cold*, *warm*, *hot*,...).

These systems are classically represented by means of Fuzzy Inference Systems (FIS) [3], a computing framework based on the concepts of fuzzy if-then rules, fuzzy set theory and fuzzy reasoning. A Fuzzy If-Then-Rule is a rule of the form *If* x *is* A *then* y *is* B where A and B are linguistic values defined by fuzzy sets on universes of discourse X and Y, respectively. Fuzzy reasoning is an inference procedure used to derive conclusions from a set of fuzzy If-Then-Rules and one or more conditions.

Defuzzification is the essential "process" to translate the fuzzy result in a crisp result. The most frequently used defuzzification strategy is the centroid of area defined as:

$$z_{coa} = \frac{\int_z \mu_{C'}(z)\, z\, dz}{\int_z \mu_{C'}(z)\, dz}$$

where $\mu_{C'}(z)$ is the aggregated output membership function. Other defuzzification strategies arise for specific applications: maximum membership, mean of maximum, largest of maximum, smallest of maximum, weighted average and so on. Generally speaking, these defuzzification methods are computation intensive Theoretical results are available [4, 5]. Even if Fuzzy Inference Systems are largely used, these lack in compositionality, in the sense that the rules interactions as well as how a rule interferes with the others is not completely clear. Moreover, it is difficult to compare different implementations of a system as well as verifying the properties satisfied by a given specification.

Process algebras are a set of mathematically rigorous languages with well defined semantics that permit modelling behaviour of concurrent and communicating systems. Verification of concurrent systems within the process algebraic approach can be performed by checking that processes enjoy properties described by some temporal logic's formulae.

In this paper we propose a process algebra approach to specification and analysis of fuzzy behaviours. Indeed, we introduce a Fuzzy variant of CCS (*Calculus of Communicating Processes*), that permits compositionally describing fuzzy behaviours. Operational semantics of Fuzzy CCS (FCCS) is described by means of *Fuzzy Labelled Transition Systems* [6] (FLTS). These are an extension of Labelled Transition Systems where fuzziness is used for modeling imprecision in concurrent systems.

Moreover, we also show how standard process algebra formal tools can be used for supporting fuzzy reasoning. Indeed, we define a fuzzy behavioural equivalence and a fuzzy modal logic that can be used for specifying and verifying properties of fuzzy systems.

The rest of the paper is organised as follows. In Section 2 we introduce Process Algebras conceptually. In Section 3 we recall the basic notions related to L-Fuzzy Sets while in Section 4 we present the Fuzzy CCS. In Section 5 we show how Fuzzy Hennessy-Milner Logic can be used for specifying and verifying properties of Fuzzy Systems. Finally, Section 6 concludes the paper.

2 Process Algebras

Process algebras are a set of mathematically rigorous languages with well defined semantics that permits describing and verifying properties of concurrent communicating systems. They can be seen as mathematical models of processes, regarded as agents that act and interact continuously with other similar agents and with their common environment. The agents may be real-word objects (even people), or they may be artefacts, embodied perhaps in computer hardware or software systems.

Process algebras provide a number of constructors for system description and are equipped with an operational semantics that describes systems evolution. Moreover, they often
