15

16 **Abstract**

17 Despite being a fundamental component of biodiversity, several highly diverse taxa of aquatic
18 invertebrates are still poorly known and poorly considered in protection programs. This is the case
19 especially of several invertebrate species that inhabit groundwater. In this environment, invertebrates
20 play significant roles in ecosystem services closely connected to the usefulness of these systems for
21 human welfare and survival. The groundwater biodiversity of continental Italy is largely unknown
22 and its importance is neglected in national and regional legislation. One of the most poorly studied
23 groups of Italian groundwater fauna are planarians (Platyhelminthes, Tricladida). Most known
24 species are endemic to small, single karst areas or a single cave, their geographic range never having
25 been investigated in detail after the original description. The aims of this study are *i*) to provide the
26 first conservation assessment of cave-dwelling planarians in the Italian Alps and Apennines, whose
27 status is at present Not Evaluated in IUCN categories and *ii*) to evaluate which environmental
28 constraints, including potential threats, possibly affect the occurrence of the species within different
29 cave systems. Our results suggest that most of the cave-dwelling planarian species of continental Italy
30 are threatened by water pollution and habitat destruction/alteration; moreover, datasets underline that
31 there is a considerable conservation issue concerning stenoendemic planarians that may involve other
32 cave-dwelling invertebrates with narrow geographic ranges. Generally, the underground habitat of
33 most surveyed species appears to be deeply compromised and changed since the first species
34 description.

39 **Introduction**

40 Biodiversity loss has been one of the major conservation issues in the last decades (Naggs, 2017).
41 Biodiversity represents a priceless resource for the planet, as it is the engine that allows proper
42 ecosystem functioning (Rumeu et al., 2017). Despite multiple calls and efforts of conservationists,
43 we are still far from a proper understanding of the real magnitude of the Earth's biodiversity, and thus
44 many species are disappearing without us even knowing about their existence (Hochkirch, 2016;
45 Regnier et al., 2015). This is mostly linked to a biased consideration of neglected species, which in
46 turn leads to an inadequate method of assessing threats (Hayward, 2009). Indeed, the target of
47 conservation actions are usually charismatic animals, such as mammals, birds, and butterflies
48 (Lydeard et al., 2004; Naggs, 2017). In contrast, most invertebrate species, even if they represent the
49 majority of known biodiversity, are neglected and often considered as a potential threat to public
50 health (Hochkirch, 2016). Therefore, a very small portion of invertebrate species is considered in
51 conservation actions, generally only those that have a well-known economic value (Cardoso et al.,
52 2011; Koperski, 2011; Paillex et al., 2013).

53 Invertebrates occur worldwide in all environments and represent the keystone of many ecological
54 mechanisms, such as pollination, organic matter decomposition, nutrient cycling and biological pest
55 control (Bush et al., 2012; Thomson & Hoffmann, 2009). The high diversity of invertebrates likely
56 depends on their relatively small size and limited capability for dispersal , which confine them to
57 small areas where they can become extremely specialized, and thus undergo speciation events (Kunin
58 & Gaston, 1997). This fact leads to an evident high frequency of endemism and higher vulnerability
59 to risk of extinction, a feature that should promote conservation prioritisation (Davies et al., 2004;
60 Leroux & Schmiegelow, 2007; Swenson et al., 2012).

61 Among geographic areas/biotopes with high endemism and a wealth of species, karst systems
62 represent a key hotspot for groundwater biodiversity. The occurrence of a highly diversified karst
63 area gives rise to a wide range of underground aquatic systems, which host highly specialized

64 invertebrate fauna with unique, unusual, and sometimes even inexplicable morphological,
65 behavioural and ecological adaptations (Culver & Pipan, 2009; Romero, 2009). In several cases, both
66 stygobionts (aquatic specialised cave-dwelling organisms) and troglobionts (terrestrial specialized
67 cave-dwelling organisms) (Sket, 2008; Trajano & De Carvalho, 2017) are micro-endemic
68 invertebrate species which have been found in one or only a few caves (Culver & Pipan, 2014;
69 Mammola & Isaia, 2016; Wei et al., 2017). Moreover, most specialized cave species are often
70 considered to be numerically rare. This rarity may be linked to the low levels of trophic resources
71 occurring underground, although this should not be the case in species inhabiting shallow
72 subterranean habitats (SSHs) (Culver & Pipan, 2014) where food income is higher (Gers, 1998). The
73 rarity of cave-dwelling organisms may also be strongly overstated. According to different recent
74 overviews, the main habitat of most subterranean species is the network of fissures and interstices
75 occurring underground, which in karst areas is interconnected with caves (Culver & Pipan, 2014;
76 Mammola et al., 2016; Romero, 2012). This habitat is difficult to be investigated by humans, for
77 which caves are just windows to the more complex and mostly inaccessible subterranean domain
78 (Mammola et al., 2016; Romero, 2012). As a consequence, most often populations of cave-dwelling
79 species are just estimated to be small without true evidence. The conservation of cave ecosystems is
80 affected both by processes acting on the surface and by local factors linked to human activity. At a
81 global scale climate change (Mammola et al., 2018), deforestation (Trajano, 2000) and epigean
82 invasive species (Wynne et al., 2014) may threaten the environmental features and the biodiversity
83 of caves. Locally, also touristic exploitation, pollution and quarrying may be highly detrimental for
84 cave conservation (Doran et al., 1999; Romero, 2009).

85 Therefore, cave-dwelling organisms need to be targeted by specific conservation actions (Williams
86 et al., 2009). Besides their well-known importance as biodiversity hotspots, underground
87 environments (and associated cave-specialized fauna) are still underrepresented (or even neglected)

88 in conservation actions, with the exception of marine caves (Manconi et al., 2009; Gerovasileiou &
89 Voultsiadou, 2012).
90 Among groundwater fauna, the taxon Tricladida is one of the most poorly studied (Collier et al., 2016;
91 Stocchino et al., 2013). Planarians are small, free-living flatworms, generally predators, feeding on
92 small living invertebrates and decaying organisms (Reynoldson & Young, 2000). Most of the species
93 are particularly sensitive to organic matter pollution, water quality and environmental features
94 (Reynoldson & Young, 2000), therefore representing an optimal bioindicator for the world's largest
95 underground freshwater supply (Culver & Pipan, 2014). Most stygobiont planarians show extremely
96 narrow ranges, often being confined to a single cave (De Beauchamp, 1932; Gourbault, 1972;
97 Benazzi, 1982; Stocchino et al., 2013, 2017a) and show adaptations (e.g. anophthalmia,
98 depigmentation) to the subterranean environments. Besides their original description, no further
99 information is usually available for these species (Gourbault, 1972). As an example, for the Italian
100 peninsula ten species of stygobiont triclads have been described (Benazzi, 1982; Stocchino et al.,
101 2017a) for which only old and mainly morphological information is available, except for recently
102 described species (Stocchino et al., 2017a) (Tables 1, 2). No conservation status assessments exist for
103 these micro-endemic species, which might be potentially good bioindicators of subterranean aquifers
104 and karst areas.

105 The aims of this study are *i*) to provide the first conservation assessment of cave-dwelling planarians
106 in the Italian Alps and Apennines, whose status is at present Not Evaluated based on IUCN categories,
107 and *ii*) to evaluate which environmental constraints, including potential threats, possibly affect the
108 occurrence of the species within different cave systems.

109 **Materials and Methods**

110 *Target species*

111 We focused on eight cave-dwelling planarian species of the Italian Alps and Apennines:
112 *Dendrocoelum italicum* Vialli, 1937; *D. benazzii* De Beauchamp, 1995; *D. beauchampi* Del Papa,

113 1952; *D. cf. beauchampi* Sluys & Benazzi, 1992; *D. collini* (De Beauchamp, 1919); *Polycelis benazzii*
114 De Beauchamp, 1955; *Atrioplanaria morisii* Benazzi & Gourbault, 1977; and, *Dugesia brigantii* De
115 Vries & Benazzi, 1983. Also considered here is the population of *Dendrocoelum* sp. reported for a
116 Ligurian cave (Benazzi, 1982). We did not collect data on *Dendrocoelum leporii* Stocchino & Sluys,
117 2017, which was described after the beginning of our study, and on *D. spelaeum* (Kenk, 1924),
118 occurring in the Dinaric Massif between Italy and Slovenia. Most of the planarian species surveyed
119 were reported exclusively for single caves and represent excellent models of micro-endemic ranges
120 (Fig. 1, Table 1).

121 *Surveys*

122 Multiple surveys were performed from October 2016 to September 2017 in 33 caves (minimum
123 surveys per species = 3; average (\pm SD) = 7.69 ± 2.7). Eight caves correspond to the already known
124 localities of the previously known eight stygobiont planarian species. We also included a Ligurian
125 cave for which *Dendrocoelum* sp. was reported; 24 caves hosting accessible freshwater sites were
126 selected in the surroundings of the known locality of each species/taxon (generally at a maximum
127 distance of 6 km, except for *Dendrocoelum benazzii* for which we extended the research over a larger
128 karst area at 20 km from the known locality). All caves were fully explored, focusing on all freshwater
129 habitats (streams, creeks, drip pools, dripping layers on the walls). Planarians were first searched by
130 visual census, i.e. observing each habitat for 30 minutes, and subsequently by disturbing the substrate
131 and removing possible shelters under which the worms may hide. For each cave we recorded the
132 minimum distance from the cave entrance to the first freshwater biotope in which we found
133 planarians. In caves in which planarians were not found we recorded the minimum distance from the
134 cave entrance to the first freshwater habitat that we encountered. For caves that were dry during our
135 surveys, we recorded the minimum distance from the cave entrance to the first collection site that was
136 indicated in the planimetric map. We also recorded as water quality indicators the abundance of
137 periphyton in the main freshwater bodies, the level of habitat alterations in the cave, and the

138 occurrence of aquatic crustaceans that could be potential prey items for the planarians. The abundance
139 of periphyton over the substrate was visually assessed using a rank scale (1 = periphyton absent or
140 substrate cover < 5%; 2 = 5% ≤ periphyton cover < 40%; 3 = 40% ≤ periphyton cover < 60%; 4 =
141 60% ≤ periphyton cover < 80% and 5 = periphyton cover ≥ 80% of the substrate). The habitat
142 alteration level of the caves was assessed considering the occurrence/absence of three main indicators:
143 touristic pathways; artificial lighting; water catching or other man-made structures altering the
144 subterranean freshwater bodies. The level of habitat alteration was scored using a rank scale from 0
145 to 3, where 0 means no signs of any anthropogenic habitat alteration, while we assigned a point to
146 each habitat alteration recorded.

147 We used a binomial Generalized Linear Mixed Model (GLMM) to assess the relationship between
148 the occurrence of planarians and the recorded environmental variables. Planarians were considered
149 present in the caves if we found them in at least one survey per cave. In particular, the occurrence of
150 planarians was considered as a dependent variable. As independent variables we included periphyton
151 cover, level of habitat alteration, water depth, and the occurrence of crustaceans. To compare different
152 sites of different species ranges, species identity was used as a random factor. We built models
153 representing all possible combinations of independent variables and we selected only the best model
154 using the Akaike Information Criterion for small samples (AICc) values (Rolls, 2011). Variance
155 inflation factor (VIF) was calculated within each model and only models with a VIF value < 5 were
156 considered. The best model contained only a variable and the random factor. To test the performance
157 of this model we applied a Hosmer Lemeshow goodness-of-fit (GoF) test which was not significant
158 ($\chi^2 = 13.6$; $P = 0.09$). The significance of the variable in the best model was assessed with a Wald
159 test (Bolker et al., 2008). The analysis was performed in R 3.3-2 environment (R Development Core
160 Team, 2016) using the packages MuMIn 1.15-6 (Barton, 2016), multcomp 1.4-6 (Hothorn et al.,
161 2008), lmerTest 2.0-33 (Kuznetsova et al., 2016), car 2.1-4 (Fox & Weisberg, 2011) and
162 ResourceSelection 0.3-2 (Subhash et al., 2017).

163 **Results**

164 *General conservation status of cave-dwelling planarians*

165 The presence of three out of the eight Italian cave-dwelling planarians species was reconfirmed at
166 their type/known locality (Table 2). The presence of *Dendrocoelum* sp. in the “Grotta Grande di
167 Pignone” cave was also reconfirmed. Only two caves showed no signs of threat for the planarians,
168 while in all other caves we recorded habitat alterations linked to pollution, touristic activity, artificial
169 lighting, and quarrying activities (Fig. 2, Table 2). The type localities of *A. morisii*, *P. benazzii*, *D.*
170 *beauchampi* and *D. cf. beauchampi*, were completely dry during at least one survey although they are
171 listed in the speleological registers as perennial emitting caves or hosting perennial freshwater
172 habitats. The species that we still detected at their type locality were *D. italicum* and *A. morisii*. We
173 also detected *D. collini* and *Dendrocoelum* sp. in their known caves. No planarians were found in the
174 type localities of *D. beauchampi*, *D. cf. beauchampi*, *D. benazzii*, *Dugesia brigantii* and *Polycelis*
175 *benazzii*. (Table 2).

176 *Dendrocoelum italicum*

177 The species *D. italicum* was the first endemic cave-dwelling flatworm described for the fauna of Italy.
178 Maffo Vialli discovered this species in the “Bus del Budrio” cave (speleological land registry
179 number: LO BS 71) in the Italian Prealps and described it on the basis of 20 specimens collected on
180 13 October 1936 (Vialli, 1937). The original description also reports some second-hand data on the
181 collection site and habitat of *D. italicum* which was found exclusively in a large pool below a small
182 waterfall (Vialli, 1937). No other data is presently available for this species.

183 During our surveys we detected on average (\pm SD) 30 ± 1.6 planarians, all localised in small dripping
184 pools, while the large pools described in Vialli’s paper no longer existed because of a water catching
185 structure that was installed in the cave (Table 2).

186 *Dendrocoelum collini*

187 This species was reported for the first time in France in wells and springs in some localities of Côte-
188 d'Or in Bourgogne. Del Papa (1959) ascribed some planarians from the “Grotta Nuova di Villanova”
189 cave (northeast Italy, slrn: FR 656) to *D. collini*. Since then no other studies or surveys have been
190 performed on this species in its Italian range.

191 The “Grotta Nuova di Villanova” cave is nowadays open to tourists. On average (\pm SD), we detected
192 48 ± 8.4 planarians at each survey in the natural part of the cave, while none occurred in the part with
193 artificial lighting (Table 2). Numerous still unidentified stygobiont dendrocoelids were found in a
194 cave nearby.

195 *Atrioplanaria morisii*

196 The planarian *Atrioplanaria morisii* was found in 1974 in the “Tana di San Luigi” (slrn: 112 pi/cn)
197 cave in Piedmont (northwestern Italy; Fig. 1) (Benazzi & Gourbault, 1977). No further studies have
198 been performed on this cave. This species was also reported in the “Grotta di Bossea” cave (Morisi,
199 1991), a touristic cave situated 8 km from the type locality of *A. morisii*.

200 During our surveys the occurrence of this species was confirmed at the type locality, where on average
201 (\pm SE) 27 ± 4.2 planarians were recorded.

202 The record of *A. morisii* for the “Grotta di Bossea” cave is to be considered a misinterpretation of the
203 first data reporting the occurrence of specimens presumably belonging to the genus *Dendrocoelum*
204 (see Morisi, 1972). A recent histological study performed by one of us (G.A. Stocchino pers. obs.)
205 on specimens collected in 2011 by E. Lana confirmed the presence of only *Dendrocoelum* sp. from
206 the “Grotta di Bossea” cave. Unfortunately, absence of fully sexually developed individuals
207 prevented a detailed assessment of their taxonomic status. No planarians were found during our
208 surveys in the “Grotta di Bossea” cave (Table 2).

209

210 *Dendrocoelum* sp. from “Grotta Grande di Pignone” cave

211 Individuals of *Dendrocoelum* sp. were found in the “Grotta Grande di Pignone” cave (slrn: LI SP 36)
212 in the district of La Spezia (Liguria, northwestern Italy; Fig. 1) (Benazzi, 1982). The asexual condition
213 of the specimens prevented a detailed assessment to species level. No further surveys or studies were
214 ever performed on this cave-dwelling planarian.

215 During our surveys we recorded animals in a very shallow perennial stream 80 m from the cave
216 entrance. In this habitat we counted on average 12 planarians during each survey (Table 2). Moreover,
217 during a study on the diet of the salamander *Hydromantes ambrosii* Lanza, 1954 (Lunghi et al., 2018),
218 the stomach flushing performed on several individuals revealed that planarians may represent a
219 potential prey item for these salamanders; in this specific case, a planarian specimen was found
220 among the stomach contents of one adult male. The salamander was found 21 m from the cave
221 entrance, much closer to the surface than the small creek in which planarians were regularly observed;
222 this may mean that planarian topographic distribution inside this cave is wider than previously
223 thought.

224 *Dendrocoelum beauchampi*

225 This species was described on the basis of some individuals collected in 1950 by the speleologist
226 Nino Sanfilippo (Del Papa, 1952). The species is endemic to the “Grotta di Cavassola” cave (slrn: LI
227 GE 125), near Genoa (Liguria, northwestern Italy; Fig. 1). Some information on the habitat was
228 reported by Sanfilippo (1950) who stated that the access to this cave was obtained through two
229 artificial openings made during the Second World War. The author found the planarians in a small
230 subterranean spring in the 10 m natural part of the cave. At present, it is reported in the speleological
231 register of the Region Liguria that the natural configuration of the cave has collapsed due to digging
232 activities.

233 During our surveys we recorded no planarians in the “Grotta di Cavassola” cave, which was
234 completely dry during summer (Table 2). However, we found a population of *Dendrocoelum* sp. in

235 the deepest sectors of a cave nearby. We detected on average (\pm SD) 10.3 ± 8.1 planarians during 12
236 surveys. Some individuals were collected and are currently being taxonomically identified.

237 *Dendrocoelum cf. beauchampi*

238 *Dendrocoelum cf. beauchampi* was reported by Sluys & Benazzi (1992) from the “Tann-a da Suja”
239 cave (Genoa district, Liguria, northwestern Italy; Fig. 1, slrn: LI GE 5). This cave is relatively close
240 (4.5 km) to the *D. beauchampi* type locality (“Grotta di Cavassola” cave).

241 The “Tann-a da Suja” cave was completely dry during summer and autumn of 2017 (Table 2), except
242 for some small pools in which the leech *Erpobdella octoculata* Linnaeus, 1758 (Arhynchobdellida,
243 Erpobdellidae) occurred.

244

245 *Dendrocoelum benazzii*

246 The species *Dendrocoelum benazzii* was described on the basis of several individuals collected by
247 Valerio Sbordoni in 1971 from the “Grotta di Stiffe” cave (Apennines, central Italy; Fig. 1, slrn: 7
248 ab/aq) (Del Papa, 1973).

249 The “Grotta di Stiffe” cave is quite developed and now open to tourists in its accessible parts, with
250 artificial lighting and extensive alteration of the stream that crosses the cave through dam construction
251 and stream bed modifications (Table 2). During our surveys we also detected evidence of water
252 pollution with extensive periphyton cover on the substrate of the stream (Table 2). We detected no
253 planarians, but we did observe an abundant population of the leech *Erpobdella octoculata*.

254

255 *Dugesia brigantii*

256 *Dugesia brigantii* is known only from the “Grotta di Bocca Lupara” cave in the city of La Spezia
257 (Liguria, northwestern Italy; Fig. 1, slrn: LI SP 74). It was described by De Vries & Benazzi (1983)

258 and a subsequent paper provided second-hand information on the location (Puccinelli & Benazzi,
259 1985). Planarians were found only inside the cave at 16 m from the entrance. Also for this species no
260 other studies have been performed. Although endemic to the cave, *D. brigantii* shows no
261 troglomorphic features, exhibiting both eyes and pigmentation.

262 During our surveys we detected no planarians, but we found evidence of strong organic water
263 pollution, with extensive periphyton cover of the substrate (Table 2) and a dense population of the
264 leech *Erpobdella testacea* (Savigny, 1820).

265 *Polycelis benazzii*

266 *Polycelis benazzii* was described by De Beauchamp (1955) on the basis of individuals collected by
267 Franciscolo during 1952 (Franciscolo, 1955). The species is endemic to the “Tana di Spettari” cave
268 (Liguria, northwestern Italy; Fig. 1, slrn: LI SA 183) and was found at its entrance only in a small
269 dripping pool (Franciscolo, 1955).

270 We found no planarians in the “Tana di Spettari” cave. The dripping pool described by Franciscolo
271 (1955) no longer existed and the entire cave showed extensive signs of vandalism (Table 2).
272 Moreover, it is likely that the subterranean aquifer has been modified by quarrying activity in an
273 adjacent watershed.

274 *Determinants of planarian occurrence*

275 Of the eight already known caves, two showed a high degree of periphyton cover (Table 2). They
276 correspond to the type localities of *Dendrocoelum benazzii* and *Dugesia brigantii*, which were no
277 longer detected (Table 2). Only habitat alteration was included in the best model. Planarians
278 occurrence was negatively related to caves with a high level of alteration ($F_{1,28} = 6.9$, $p = 0.01$).

279 **Discussion**

280 Our research underlines that since their description, no or very little information on the status of
281 continental Italian cave-dwelling planarians has been collected; in 75% of the cases the environmental
282 conditions of the type locality of a species has been altered and 50 % of the species is no longer
283 present at its type locality. Our results show that habitat destruction through watercourse alteration,
284 water catching and artificial lighting are important threats to cave-dwelling planarians (Table 2).

285 Generally, pools and streams occurring in caves are considered only one of the habitats that can be
286 inhabited by planarians adapted to subterranean environments (Ginet & Puglisi, 1964; Gourbault,
287 1972). In many cases, planarians also exploit interstices under the perennial groundwater table and
288 the hyporheic biotopes (Culver & Pipan, 2014; Ginet & Puglisi, 1964; Gourbault, 1972). These are
289 environments in which cave-dwelling planarians have occasionally been found but which are very
290 difficult to sample (Gourbault, 1972). For this reason, the fact that we did not find some of the
291 planarian populations does not necessarily mean that they are extinct. However, in the case of water
292 pollution it is likely that the conditions of the whole aquifer are unsuitable for planarian survival and
293 persistence. Freshwater planarians are an important component of the community of unpolluted lakes,
294 springs and streams (Knakiewicz, 2014). Planarians are generally sensitive to organic pollution and
295 water quality, as in the case in the genera *Polycelis* and *Crenobia* (Manenti, 2010; Alonso & Camargo,
296 2011; Wu et al., 2012), indeed cave-dwelling species generally require oligotrophic waters
297 (Gourbault, 1972). With respect to the species that we no longer found to be present in caves, further
298 research in other portions of the aquifer will be necessary to assess whether they have really become
299 locally extinct.

300 It is relevant that in most of the investigated caves, the freshwater habitat has been greatly modified
301 without any evaluation by authorities, environmental managers or zoologists on the impact that these
302 changes may have on both planarians and all other underground freshwater invertebrate fauna. Most
303 cave invertebrates belong to species with very narrow distributional ranges which have attracted the
304 interest of taxonomists but, at the same time, are scarcely considered in general zoological and
305 ecological studies. This situation, as exemplified by cave-dwelling planarians, reveals a great lack of

306 knowledge, especially for the early described species. Planarians are bioindicators with a key role in
307 the trophic web of both epigeal and underground freshwater habitats (Reynoldson & Young, 2000).
308 Nearly 200 species of Platyhelminthes, mostly planarians, have been recorded in underground
309 environments (Romero, 2009). Most of these species are blind and unpigmented, thus showing a
310 strong adaptation to subterranean life (Harrath et al., 2012, 2016; Stocchino et al., 2013, 2017a,b). In
311 subterranean biotopes, planarians hold an intermediate position in the food web: they represent
312 occasional prey for cave fishes, crayfishes and salamanders (Gillespie, 2013; Manenti, 2014; present
313 paper), while in turn they feed on living or dead cave-dwelling animals such as amphipods, isopods
314 and drowned arthropods such as crickets and dipterans (Romero, 2009). From a conservation point
315 of view, planarians are generally neglected, being neither charismatic nor noticed by humans (Sluys,
316 1999). Our study is the first extensive assessment of the conservation status of multiple freshwater
317 planarian species. Among freshwater triclads, only one species has a high conservation profile, viz.
318 the pink planarian *Kenkia glandulosa* (Hyman, 1956), inhabiting a cave in Missouri, USA. This latter
319 species is the only cave-dwelling planarian regularly monitored for conservation purposes and for
320 which recent research has been done at the level of micro-habitat preferences (Wicks et al., 2010).
321 The situation revealed by our study for continental Italy may arouse interest in cave-dwelling
322 planarians worldwide. Planarian conservation and ecological studies after the first taxonomic
323 description of the species remain rare and a general lack of conservation information affects most
324 cave-dwelling planarians worldwide. The description/record of a species is only a first step, after
325 which there is the necessity, especially for not particularly attractive species such as flatworms, to
326 promote awareness of their important role and their inclusion in ecological and conservation studies
327 when surveys of their habitat are performed. Our research on the conservation status of planarians
328 could be extended to other karst areas to understand the actions needed to preserve these key
329 organisms for the subterranean environment. The fact that three cave type localities that were
330 previously defined and officially listed as perennial emitting caves or as having perennial freshwater
331 habitats were found completely dry during at least one of our surveys is noticeable. Planarians are

332 highly sensitive to dryness, even though some species may show some resistance (Ginet & Puglisi,
333 1964; Gourbault, 1972); therefore, the impact of prolonged periods of drought may be detrimental to
334 population survival and fitness.

335 The overall results of our assessment underline the necessity to establish proper conservation actions
336 for neglected invertebrate species; in particular, our results show the need for stronger protection in
337 terms of laws (Hochkirch, 2016). Cardoso et al. (2011) discussed several different causes currently
338 obstructing a larger inclusion of invertebrates in contemporary conservation actions, which included
339 low public interest in inconspicuous invertebrate species as compared with large vertebrates, together
340 with an incomplete knowledge of the ecology, population dynamics and even distribution and
341 taxonomy of invertebrates. This is particularly evident when we consider freshwater invertebrates: of
342 the 8,000 species currently listed in the IUCN Red List, some 35% are considered as threatened
343 (Collen et al., 2012). Given broadly differing levels of accessible knowledge on the geographic
344 distribution of invertebrate groups, combined with the large number of species, it has so far been
345 possible to assess only the conservation status for a relatively small number of taxonomic groups.
346 Our study indicates that despite their narrow distributional range, micro-endemic species may
347 represent important conservation issues. Indeed, species having a narrow distributional range are
348 more vulnerable to extinction than widespread ones, as any environmental change may be detrimental
349 for the whole species' populations (Davies et al., 2004; Williams et al., 2009; Swenson et al., 2012).
350 Conservation actions focusing on freshwater cave-dwelling micro-endemic species should take into
351 account the whole aquifer and its relationship with the surrounding environment (Culver & Papan,
352 2014). As most cities and regions rely on groundwater for their water supply, the conservation of
353 these biotopes is fundamental not only for biodiversity but also for humans themselves (Culver &
354 Papan, 2014). Our results indicate that different actions are needed to conserve cave-dwelling
355 planarians and other freshwater cave-dwelling invertebrates: protection of water quality in the whole
356 aquifer/watershed; restoration of at least some microhabitats in caves visited by tourists; management

357 of surface habitats; and development of a proper outreach plan to increase interest in neglected
358 invertebrates such as flatworms.

359 Finally, the fact that we recorded planarians at new sites underlines the necessity to perform further
360 research, which could also include training for caving groups and speleologists to stimulate the
361 recording of flatworms which are generally difficult to observe.

362 Overall, our study reveals that the conservation status of the populations that we monitored is not
363 good. For many of them our surveys represented the first time that they were searched for after the
364 first record, which often dates back several decades. For four of the eight continental species, the type
365 locality has profoundly changed since their first description.

366 **Acknowledgments**

367 This research was funded by The Mohamed bin Zayed Species Conservation Fund, Project n.
368 162514520, sponsoring the Biospeleology Congress that took place in Cagliari, Italy, in 2017. Several
369 people helped us by providing permission to access the cave, information on cave location or
370 technical support during the surveys. In particular, we wish to thank: Paolo Moro, the Gruppo
371 Ricerche Ipogee Friuli, Gianbattista Tonni, Andrea Melotto, Roberto Santinelli, the Gruppo Grotte
372 Tassi of Milan, Valentina Balestra, Silvestro Papinuto, the Gruppo Grotte e Forre CAI Teramo, Lia
373 Sisino, Tiziana Angotzi, Franco Persello, the Municipality of Pignone, and the Mayor Mara
374 Bertolotto. We are grateful to the two anonymous reviewers for their very useful suggestions that
375 helped improve the manuscript.

Cave group 5						
Grotta Nuova di Villanova e; low entrance	46.253	13.280	300	<i>Dendrocoelum collini</i>	AI, Tp, Cw	6
Grotta Nuova di Villanova e; high entrance	46.257	13.282	640	<i>Dendrocoelum collini</i>	P	6
Tirfore	46.248	13.285	930	<i>Dendrocoelum</i> sp.		2
Abisso Vigant	46.244	13.289	30	-		2
Risorgiva Cimitero	46.247	13.284	10	-		2
Cave group 6						
Bus del Budrio	45.591	10.347	60	<i>Dendrocoelum italicum</i>	Cw, P	15
Artificial unnamed cave	45.592	10.363	6	-		3
Draining gallery	45.582	10.361	50	-		6
Cave group 7						
Grotta Grande di Pignone e	44.176	9.723	200	<i>Dendrocoelum</i> sp.	M	9
Griotta Seconda di Pignone	44.176	9.724	56	-	D	8
Faggiona 1 mine	44.196	9.704	80	-		2
Fornace	44.175	9.721	42	-	D	4

Faggiona 2 mine	44.196	9.703	65	-		2
Grotta di Sant'Antonio	44.183	9.724	12	-	D	3
Cave group 8						
Grotta di Bocca Lupara	44.121	9.796	42	-	P, Cw	9
Ninpharum Domus	44.122	9.797	44	-	P, Cw	2
Cave group 9						
Tana di Spettari	44.139	8.169	136	-	D, Q	5
Grotta di Rio Mezzane	44.136	8.165	8	-	Q, D	2
Risorgente Acquaranda	44.162	8.172	6	-	D	2

568 Table 2. Complete list of the Italian caves surveyed during our study, considering both the type/known
569 localities of cave-dwelling planarians and surrounding caves never surveyed for the occurrence of
570 planarians. Each cave group refers to caves, including the type/known locality of a species/population
571 and the surrounding caves surveyed. Cave group 1 = type locality area of *Atrioplanaria morisii*; Cave
572 group 2 = type locality area of *Dendrocoelum beauchampi*; Cave group 3 = type locality area of
573 *Dendrocoelum cf. beauchampi*; Cave group 4 = type locality area of *D. benazzii*; Cave group 5 =
574 area of the Italian known locality of *D. collini*; Cave group 6 = type locality area of *D. italicum*;
575 Cave group 7 = area including *Dendrocoelum* sp. from “Grotta Grande di Pignone” cave; Cave group
576 8 = type locality area of *Dugesia brigantii*; Cave group 9 = type locality area of *Polycelis benazzii*.
577 Assessed threats indicated as Al = artificial lighting; Cw = catchwater systems collecting the
578 subterranean streams or aquifers inside the cave; D = dryness (i.e. no water occurring in caves in
579 which pools, streams or other water bodies were officially inserted in the speleological land registry):
580 P = pollution; Q = quarrying activities; Tp = tourist pathways.
