We address the out-of-equilibrium thermodynamics of an isolated quantum system consisting of a cavity optomechanical device. We explore the dynamical response of the system when driven out of equilibrium by a sudden quench of the coupling parameter and compute analytically the full distribution of the work generated by the process. We consider linear and quadratic optomechanical coupling, where the cavity field is parametrically coupled to either the position or the square of the position of a mechanical oscillator, respectively. In the former case we find that the average work generated by the quench is zero, whilst the latter leads to a non-zero average value. Through fluctuations theorems we access the most relevant thermodynamical figures of merit, such as the free energy difference and the amount of irreversible work generated. We thus provide a full characterization of the out-of-equilibrium thermodynamics in the quantum regime for nonlinearly coupled bosonic modes. Our study is the first due step towards the construction and full quantum analysis of an optomechanical machine working fully out of equilibrium.

1. introduction

As a result of several decades of efforts stemming from different communities, the classical scientific body of thermodynamics has been experiencing a true renaissance. The reasons of this revival can mainly be traced back to the release of two constraints: on the one hand the departure from the thermodynamic limit, motivated by investigation of increasingly smaller systems, enabled fluctuations to be incorporated; on the other hand the tight requirement of quasistatic processes has been relaxed, in favor of generic finite-time transformations connecting non-equilibrium states. The overall picture is an exact, non-perturbative extension of thermodynamics to mesoscopic systems lying arbitrarily far from equilibrium; stochastic thermodynamics [1] is now a mature field which addresses thermodynamical quantities such as work, free energy and entropy at the level of single trajectories and fluctuation theorems relate the value that these quantities assume at equilibrium to out-of-equilibrium finite-time dynamics [2, 3].

Furthermore, given the ever-increasing control achievable over microscopic systems and the technological quest for devices miniaturization, one would eventually reach a point where quantum fluctuations, besides thermal ones, start playing a non-negligible role [4, 5]. The former scenario must then be amended with a full quantum treatment. Performances of thermal machines working in the quantum regime have recently been investigated in a plethora of different physical systems [6], and the statistics of relevant figures of merit such as work and entropy generated during time-dependent protocols inquired for different models [7].

Another motivation to achieve a better understanding of thermodynamics in the quantum regime, somehow complementary with respect to the perspective of scaling thermal machines down to the nanoscale, comes from the exploration of macroscopic quantum systems. The extension of quantum-limited control over objects in the mesoscopic—and possibly macroscopic—domain, is of primary interest both for fundamental

problems, e.g. the comprehension of the mechanism of decoherence, and for quantum technology. In particular, optomechanical systems provide an ideal platform where to investigate macroscopic quantum phenomena: mechanical oscillators made of 10^{15} particles are now approaching the quantum regime, offering unprecedented levels of tunability and control [8]. For that reason they are among the most promising candidates to shed light on the interplay between quantum theory and thermodynamics.

In this work we try to merge these scenarios: we explore and characterize the thermodynamical behavior of an optomechanical system driven out of equilibrium by a time-dependent transformation. We address an isolated quantum system, consisting of an optical mode confined in a cavity and parametrically coupled to a mechanical oscillator, evolving according to a time-dependent Hamiltonian and undergoing a two-step measurement protocol. Specifically, we will be concerned with a sudden quench of the interaction, realized by suddenly switching on the coupling between the two—initially uncoupled—modes. We derive analytic expressions for the characteristic function of the work distribution and analyze the full statistics of the work generated. Two different interaction Hamiltonians, both of relevance for present quantum technology, will be considered. We shall first discuss the more common case where radiation–pressure interaction couples the cavity field to the position of the oscillator, followed by the case of a quadratic optomechanical interaction, where the optical field couples to the square of the position of the mechanical resonator. The starting point for most analyses of optomechanical devices is a *linearization* of the interaction, where the Hamiltonian is cast into a quadratic form that is more amenable to analysis. Here, we eschew this simplification, which is formally valid when the cavity field is strongly driven [9], and address the full nonlinear optomechanical Hamiltonian. We note at this point that the thermodynamical properties of the equivalent linearized model were recently explored by some of us in [10]. By retaining the full optomechanical coupling, our work therefore aims to address the out-of-equilibrium thermodynamical behavior of nonlinearly coupled bosonic modes in the quantum regime, and thus go beyond the results reported in literature so far.

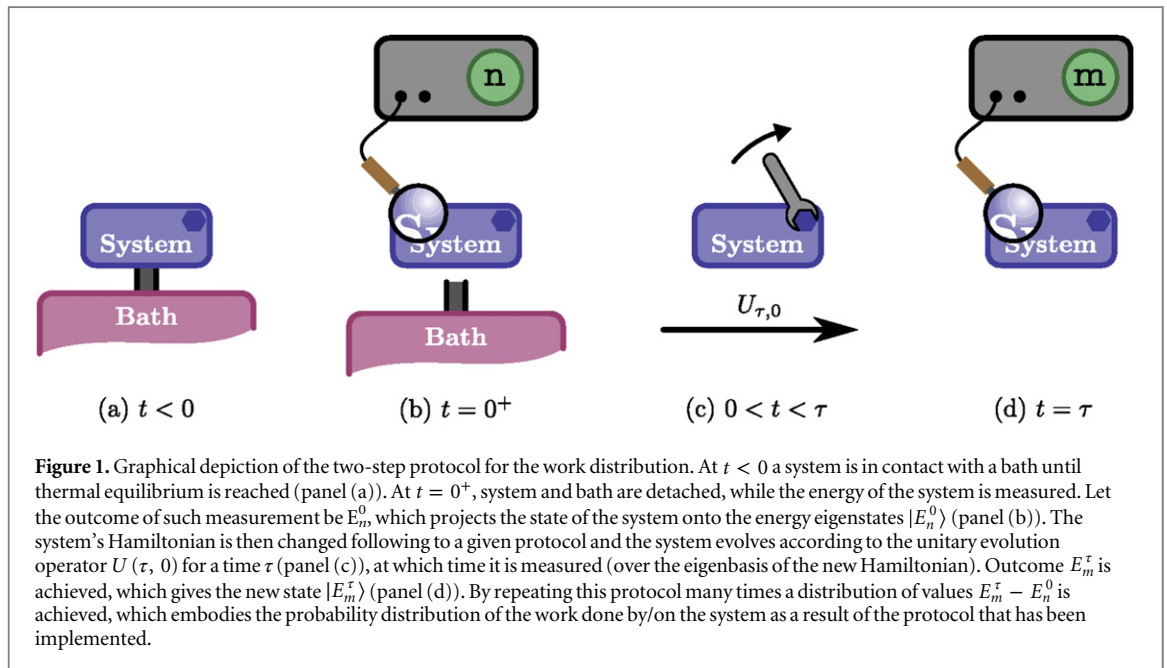

The remainder of this work is organized as follows: in section 2 we introduce the two-measurement protocol necessary to extract the work distribution, and review the quantum fluctuation relations. Section 3 contains a detailed analysis of the dynamical features of an optomechanical system subject to a sudden quench of the coupling parameter and assesses its thermodynamical behavior, first in the case of linear optomechanical coupling and then in the quadratically-coupled case. Finally, in section 4 we summarize our findings and discuss new perspectives opened up by this work.

2. Work distribution and quantum fluctuation theorems

Let us consider a system described by a time-dependent Hamiltonian $\hat{H}(G_t)$, whose dependence on time is realized via the externally tunable parameter G_t , which we refer to as the *driving parameter*. Moreover, let us assume that at $t = 0$ the system is in thermal equilibrium with a bath at inverse temperature β , and is hence described by the Gibbs state

$$\hat{\rho}_\beta(G_0) = \frac{e^{-\beta\hat{H}(G_0)}}{\mathcal{Z}(G_0)}, \quad (1)$$

where $\mathcal{Z}(G_0) = \text{Tr} \left\{ e^{-\beta\hat{H}(G_0)} \right\}$ is the canonical partition function of the system. This system is brought out of equilibrium by applying a chosen transformation that modifies G_t in time. Here we are concerned with the statistics of the work done on or by the system when applying such a protocol. We thus proceed as follows (cf figure 1 for a graphical depiction of the process): at time $t = 0^+$ the system is detached from the reservoir and a projective energy measurement is performed on the system in the energy eigenbasis of $\hat{H}(G_0)$, yielding an eigenstate which we label $|E_n^0\rangle$. The driving parameter is changed according to the aforementioned transformation until a final time τ . During this period, the state of the system evolves as dictated by the action of the unitary evolution operator $\hat{U}_{\tau,0}$ on the post-measurement state. Finally, a second projective energy measurement is made on the system, this time in the eigenbasis of $\hat{H}(G_\tau)$ and yielding eigenstate $|E_m^\tau\rangle$. Given the spectral decompositions of the initial and final Hamiltonians, $\hat{H}(G_0) = \sum_n E_n^0 |E_n^0\rangle\langle E_n^0|$ and $\hat{H}(G_\tau) = \sum_m E_m^\tau |E_m^\tau\rangle\langle E_m^\tau|$, respectively, the energy difference between the two outcomes $E_m^\tau - E_n^0$ may be interpreted as the work performed by the external driving in a single realization of the protocol. This particular value of the work occurs with probability $p_n^0 p_{m|n}^\tau$, where $p_n^0 = e^{-\beta E_n^0} / \mathcal{Z}(G_0)$ keeps track of the initial thermal statistics, while $p_{m|n}^\tau = |\langle E_m^\tau | \hat{U}_{\tau,0} | E_n^0 \rangle|^2$ embodies the transition probability arising from the change of basis. The work performed due to the protocol described above can be characterized by a stochastic variable W following the probability distribution

$$P(W, \tau) = \sum_n \sum_m p_n^0 p_m^\tau \delta[W - (E_m^\tau - E_n^0)]. \quad (2)$$

Instead of dealing directly with equation (2), it is often useful to work with its Fourier transform

$\chi(u, \tau) = \int dW e^{\frac{i}{\hbar} u W} P(W, \tau)$, which is referred to as the characteristic function of the work distribution and can be cast in the form

$$\chi(u, \tau) = \text{Tr} \left\{ \hat{U}_{\tau,0}^\dagger e^{\frac{i}{\hbar} u \hat{H}(G_\tau)} \hat{U}_{\tau,0} e^{-\frac{i}{\hbar} u \hat{H}(G_0)} \hat{\rho}_\beta(G_0) \right\}. \quad (3)$$

The utility of the characteristic function becomes apparent when calculating the moments of the work probability distribution explicitly. Indeed, the k th moment of $P(W)$ can be obtained from the characteristic function as

$$\langle W^k \rangle = (-i \hbar)^k \partial_u^k \chi(u) \Big|_{u=0}. \quad (4)$$

For the special cases of $k = 1, 2$ it can be shown that this relation acquires the simple form

$$\langle W^k \rangle = \text{Tr} \left\{ \left[\hat{H}(G_\tau) - \hat{H}(G_0) \right]^k \hat{\rho}_\beta(G_0) \right\}. \quad (5)$$

In what follows we will be concerned with a specific driving protocol, known as sudden quench, where G_t is abruptly changed from its initial value to the final one. In this case, $\hat{U}_{\tau,0} = \mathbf{1}$ and any dependence on τ disappears. We will thus refer to the work distribution and the characteristic function simply as $P(W)$ and $\chi(u)$, respectively.

Work fluctuation theorems relate the probability distribution of a given process (cf equation (2)) with its time-reversed counterpart, and account for the emergence of irreversibility in isolated systems. In the time-reversed (or backward) process the system is initially in a Gibbs state of the final Hamiltonian $\hat{H}(G_\tau)$, and the transformation acting on the driving parameter is reversed in time as $G_t \rightarrow G_{\tau-t}$. Expressed in terms of the characteristic functions for the forward [$\chi(u)$] and backward [$\tilde{\chi}(u)$] processes, the Tasaki–Crooks fluctuation relation [11] reads

$$\Delta F = -\frac{1}{\beta} \ln \left[\frac{\chi(u)}{\tilde{\chi}(i\beta\hbar - u)} \right], \quad (6)$$

where $\Delta F = -\beta^{-1} \log [\mathcal{Z}(G_\tau)/\mathcal{Z}(G_0)]$ is the free energy difference between the initial states for the forward and backward processes. The main implication of this relation is that the probability to extract an amount of work W from the system during the backward process is exponentially suppressed with respect to the probability that the same amount of work is done on the system during the forward process.

Linked to such relation is the celebrated Jarzynski equality [12]

$$\chi(i\beta\hbar) = \langle e^{-\beta W} \rangle = e^{-\beta\Delta F}, \quad (7)$$

which links the average of a quantity arbitrarily far from equilibrium with the state function ΔF . From equation (7) $\Delta F \leq \langle W \rangle$ follows immediately, which embodies a statement of the second principle of thermodynamics. The difference between the two quantities, which we denote by $W_{\text{irr}} \equiv \langle W \rangle - \Delta F$, is referred to as the irreversible work generated during the transformation.

3. Work distribution of quenched optomechanical systems

Let us consider the optomechanical interaction between a field mode within a single-mode electromagnetic cavity of resonance frequency ω_c and a mechanical resonator characterized by its mass M and oscillation frequency ω_m . These two subsystems will be associated to bosonic annihilation operators, denoted by \hat{a} ($[\hat{a}, \hat{a}^\dagger] = \mathbb{1}$) and \hat{b} ($[\hat{b}, \hat{b}^\dagger] = \mathbb{1}$), respectively. The cavity frequency is modulated by, and couples parametrically to, the mechanical displacement x , so that it can be expanded as

$$\omega_c(x) = \omega_c(0) + x\partial_x\omega_c(x)\Big|_{x=0} + \frac{1}{2}x^2\partial_x^2\omega_c(x)\Big|_{x=0} + \mathcal{O}(x^3). \quad (8)$$

If the leading term in the expansion is the linear one, the two oscillators interact via radiation–pressure and the much-studied linear optomechanical regime is recovered. On the contrary, if this term vanishes only the position-squared term contributes so that the so-called quadratic optomechanical regime is accessed; examples of physical systems where the latter coupling is achievable are ‘membrane-in-the-middle’ setup [13], levitating nano-beads [14, 15], trapped ions or atoms [16]. Note that the adjectives ‘linear’ and ‘quadratic’ here refer to the power of the mechanical displacement coupled to the field; we stress, however, that the interaction is inherently nonlinear in the field modes, involving three- or four-wave mixing processes. In order to proceed, we assume to be able to control the optomechanical coupling strength, and suddenly turn it on at $t = 0^+$. As a function of the mechanical position and momentum variables $\hat{x} = x_{\text{zpf}}(\hat{b} + \hat{b}^\dagger)$ and $\hat{p} = i(\hbar/2x_{\text{zpf}})(\hat{b}^\dagger - \hat{b})$, with $x_{\text{zpf}} = \sqrt{\hbar/2M\omega_m}$ the extent of oscillator ground state, the time-dependent Hamiltonian $\hat{H}_t = \hat{H}(G_t)$ reads ($t > 0$)

$$\hat{H}_t = \hbar\omega_c\hat{a}^\dagger\hat{a} + \frac{\hat{p}^2}{2M} + \frac{1}{2}M\omega_m^2\hat{x}^2 + \hbar G_t^{(k)}\hat{a}^\dagger\hat{a}\hat{x}^k, \quad (9)$$

where $k = 1$ leads to the linear regime and $k = 2$ to the quadratic one, $G_t^{(k)} = \Theta(t)k^{-1}\partial_x^k\omega_c(x)|_{x=0}$ is the coupling parameter, and $\Theta(t)$ is the Heaviside step function. Since we set $G_0 = 0$, both systems are initially uncorrelated and prepared in a global thermal state at inverse temperature β , i.e., $\hat{Q}_\beta(G_0) = \hat{Q}_\beta^{(c)} \otimes \hat{Q}_\beta^{(m)}$, where $\hat{Q}_\beta^{(\alpha)} = \sum_n p_n^{(\alpha)} |n\rangle_{\alpha\alpha}\langle n|$, with $p_n^{(\alpha)} = N_\alpha^n / (1 + N_\alpha^{n+1})$, and $N_\alpha = (e^{\beta\hbar\omega_\alpha} - 1)^{-1}$ being the average number of thermal excitations in mode $\alpha = c, m$. Our main goal is to evaluate the characteristic function of the work distribution equation (3), which encompasses all the thermodynamically relevant information. Using the above notation, we have

$$\chi(u) = \text{Tr} \left\{ e^{\frac{i}{\hbar}\hat{H}_t u} e^{-\frac{i}{\hbar}\hat{H}_0 u} \hat{Q}_\beta^{(c)} \otimes \hat{Q}_\beta^{(m)} \right\}. \quad (10)$$

Before moving to the calculation of $\chi(u)$, $P(W)$, and ΔF for both linear and quadratic coupling cases, let us make a remark about the implementation of the quench. The somehow contrasting requirements of having an initial equilibrium state of the cavity–mirror system and turning on the optomechanical interaction at a desired time can be reconciled in the following way (here illustrated for the linear coupling case). Let us consider a perfectly reflecting mirror coupled on each side to the field mode \hat{a}_j of cavity c_j , $j = 1, 2$, with equal strength, so that $G_{c_1} = -G_{c_2} = G$ and the interaction Hamiltonian will be given by $\hat{H}_{\text{int}} = \hbar G(\hat{a}_1^\dagger\hat{a}_1 - \hat{a}_2^\dagger\hat{a}_2)\hat{x}$. If we assume the tripartite system to equilibrate and consider the reduced state of one cavity mode and the mirror we have $\hat{Q}_\beta^{(c_1 m)} = \mathcal{Z}_{c_1}\mathcal{Z}_{c_2}\mathcal{Z}_m\mathcal{Z}_{c_1 c_2 m}^{-1} \sum_{n,m} p_n^{(c_1)} p_m^{(c_2)} e^{\beta\hbar\omega_m n} \hat{D}^\dagger(\mu_{n,m}) \hat{Q}_\beta^{(m)} \hat{D}(\mu_{n,m}) \otimes |n\rangle\langle n|_{c_1}$, where $\mu_{n,m} = G(x_{\text{zpf}}\omega_m)^{-1}(n - m)$. We can see that, unless the thermal states of the two cavities are perfectly correlated (in a classical way), this state does not reduce to $\hat{Q}_\beta^{(c_1)} \otimes \hat{Q}_\beta^{(m)}$, namely the initial state required by the protocol. However, we computed the Kullback–Leibler divergence of the diagonal part $\hat{Q}_\beta^{(c_1 m)}$ (the only entering the protocol) with respect to thermal statistics $p_n^{(c_1)} p_k^{(m)}$, and we found that in the range of parameters explored in this work it never exceeds values of the order of 10^{-4} . Therefore, this configuration may provide a viable method for approximating the initial state of the protocol. The quench would then consist in the sudden shut-off

of the auxiliary mode \hat{a}_2 . A detailed feasibility analysis of the whole protocol is however beyond the scope of this work and it is left for future investigations.

3.1. Quenched linear optomechanical interaction

For the case of a Fabry–Pérot cavity of length L and oscillating mirror of mass M the coupling can be shown to be equal to $G_{r>0}^{(1)} = \omega_c/L \equiv g/x_{zpf}$, where g is referred as the single-photon coupling strength and quantifies the shift in the equilibrium position of the mechanical resonator induced by a single photon. In order to keep the notation as simple as possible, we will explicitly denote by \hat{H}_I the (initial) uncoupled Hamiltonian

$$\hat{H}_{t=0} = \hbar\omega_c \hat{a}^\dagger \hat{a} + \hbar\omega_m \left(\hat{b}^\dagger \hat{b} + \frac{1}{2} \right) \equiv \hat{H}_I, \quad (11)$$

and by \hat{H}_F the (final) interacting one

$$\hat{H}_{t>0} = \hat{H}_I + \hbar g \hat{a}^\dagger \hat{a} \left(\hat{b} + \hat{b}^\dagger \right) \equiv \hat{H}_F. \quad (12)$$

It is straightforward to prove that

$$e^{-\frac{i}{\hbar}\hat{H}_F u} = e^{-i\omega_c u \hat{a}^\dagger \hat{a} + i\frac{g^2}{\omega_m^2} (\omega_m u - \sin \omega_m u) (\hat{a}^\dagger \hat{a})^2} e^{-\frac{g}{\omega_m} \hat{a}^\dagger \hat{a} (\eta \hat{b}^\dagger - \eta^* \hat{b})} e^{-i\omega_m u \hat{b}^\dagger \hat{b}}, \quad (13)$$

where $\eta = (1 - e^{-i\omega_m u})$ [17]. Expression (13) provides us with physical insight into the dynamical evolution induced by radiation–pressure interaction: apart from two free-rotating terms (the first and last in the above product), the propagator reduces to a displacement of the mechanical mode conditioned on the number of cavity photons, followed by an evolution generated by a Kerr-like term.

The characteristic function in equation (10) can then be explicitly worked out. The form of the interaction suggests taking the trace over the number states $\{|n\rangle_c\}$ for mode \hat{a} and over the coherent states $\{|\alpha\rangle_m\}$ for \hat{b} (we reserve Latin letters for Fock-state labels and Greek letters for coherent-state labels throughout), i.e.,

$$\chi(u) = \sum_{n=0}^{\infty} \int_{\mathcal{C}} d^2\alpha p_n^{(c)} \mathcal{P}^{(m)}(\alpha) \langle n, \alpha | e^{\frac{i}{\hbar}\hat{H}_F u} e^{-\frac{i}{\hbar}\hat{H}_I u} | n, \alpha \rangle, \quad (14)$$

where $\mathcal{P}^{(m)}(\alpha) = \exp(-|\alpha|^2/N_m)/(\pi N_m)$ is the Glauber–Sudarshan P -representation of an equilibrium thermal state in the coherent-state basis and the compound kets are defined as $|n, \alpha\rangle \equiv |n\rangle_c \otimes |\alpha\rangle_m$. It is possible to gather the following analytical expression for the characteristic function

$$\chi(u) = \sum_{n=0}^{\infty} N_c^n e^{-\frac{g^2 n^2}{\omega_m^2} [i(\omega_m u - \sin \omega_m u) + (1 + 2N_m)(1 - \cos \omega_m u)]} \frac{1}{(1 + N_c)^{n+1}}, \quad (15)$$

which cannot be summed analytically. We can however appreciate a few significant features of such expression: first, we recognize the thermal statistics of the cavity field modulated by an exponential whose argument keeps track of the average number of phonons N_m . Second, the characteristic function is periodic in u .

To proceed further, since the Fourier transform of equation (15) cannot be explicitly worked out, we evaluate the probability distribution of the work by calculating equation (2) directly. To do this, energy eigenvalues and eigenstates of \hat{H}_I and \hat{H}_F are required. As \hat{H}_I is the free Hamiltonian of the uncoupled system, it satisfies the eigenvalue equation $\hat{H}_I |n, k\rangle = E_{n,k} |n, k\rangle$, where $|n, k\rangle = |n\rangle_c \otimes |k\rangle_m$, and

$E_{n,k} = \hbar\omega_c n + \hbar\omega_m (k + \frac{1}{2})$. Owing to the fact that $[\hat{a}^\dagger \hat{a}, \hat{H}_F] = 0$, the post-quench Hamiltonian can be written

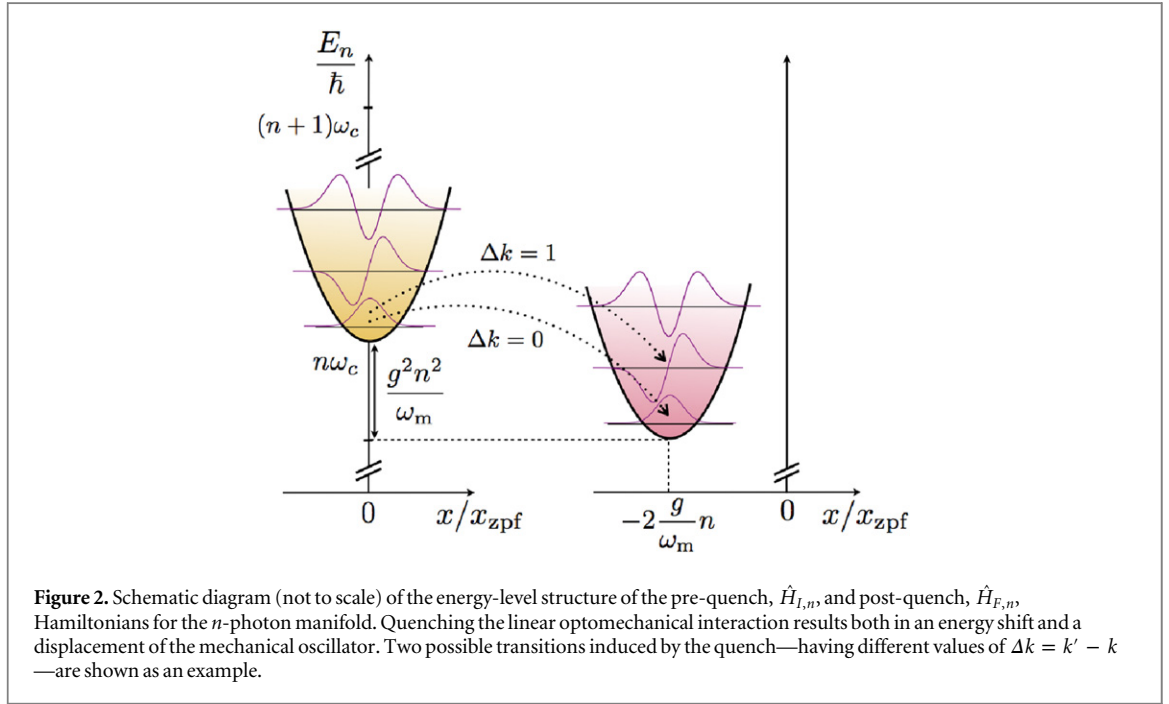

as $\hat{H}_F = \bigoplus_{n=0}^{\infty} \hat{H}_{F,n}$, where $\hat{H}_{F,n} = |n\rangle\langle n|_c \left[\hbar\omega_c n + \hbar\omega_m (\hat{b}^\dagger \hat{b} + \frac{1}{2}) + \hbar g n (\hat{b} + \hat{b}^\dagger) \right]$ refers to the

Hamiltonian of the n -photon manifold. Each $\hat{H}_{F,n}$ can then be diagonalized using a displacement operator

$\hat{D}(z) = \exp(z\hat{b}^\dagger - z^*\hat{b})$ on the mechanical mode, whose amplitude we take conditioned to the photon number n [18]. Denoting the quantities referring to $\hat{H}_{F,n}$ with a prime we find the energy eigenstates, written in the energy eigenbasis of the initial Hamiltonian \hat{H}_I , $|n'\rangle_c \otimes \hat{D}^\dagger \left(\frac{g n'}{\omega_m} \right) |k'\rangle_m$, with eigenvalues

$E_{n',k'} = \hbar\omega_c n' + \hbar\omega_m (k' + \frac{1}{2}) - \hbar \frac{g^2}{\omega_m} n'^2$. A pictorial view of pre- and post-quench eigenstates in the subspace at fixed number n of photons is sketched in figure 2. As stated by equation (2), the transitions from a set of eigenstates to another are responsible—at the microscopic level—for the work performed on or by the system.

The probability distribution of the work is thus given by

$$\begin{aligned}
 P(W) &= \sum_{n,n',k,k'} p_n^{(c)} p_k^{(m)} |m\rangle\langle k'| \hat{D}\left[\left(\frac{g}{\omega_m}\right)n'\right] |k\rangle\langle m|^2 \delta\left[W - \left(E_{n',k'} - E_{n,k}\right)\right] \delta_{n,n'} \\
 &= \sum_{n,k,k'} p_n^{(c)} p_k^{(m)} \frac{k!}{k'} e^{-(g/\omega_m)^2 n^2} \left[\left(\frac{g}{\omega_m}\right)n\right]^{2(k'-k)} \left\{ \mathcal{L}_k^{(k'-k)} \left[\left(\frac{g}{\omega_m}\right)^2 n^2\right] \right\}^2 \delta\left\{W - \hbar\omega_m \left[k' - k - \left(\frac{g}{\omega_m}\right)^2 n^2\right]\right\}, \quad (16)
 \end{aligned}$$

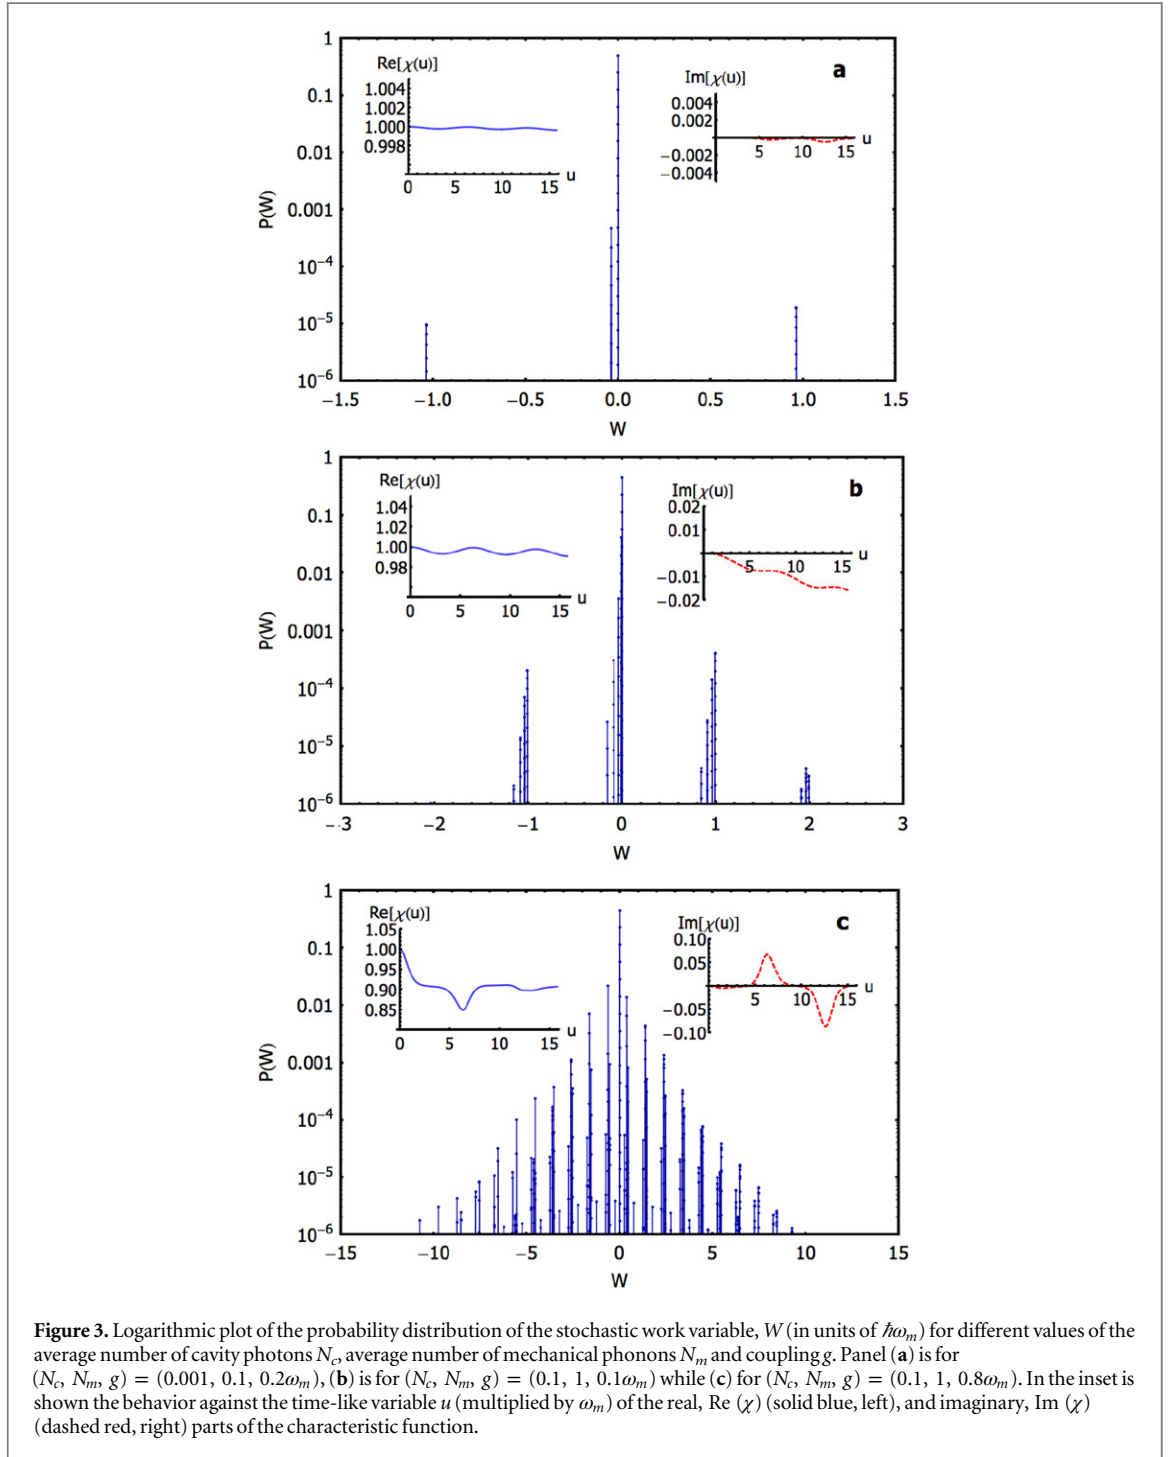

where $\mathcal{L}_a^b(x)$ are the generalized Laguerre polynomials coming from the evaluation of the overlap between pre- and post-quench mechanical oscillator eigenstates [19]. A comparison with equation (2) enables to unambiguously discriminate the contribution of the first projective measurement (which consist of a sampling from the joint thermal distribution of the cavity and the mirror) from the quantum transition probability, and explicitly provides an analytical expression for the latter.

The probability distribution of the work, together with real and imaginary parts of the characteristic function, is shown in figure 3, for different values of N_c , N_m , and coupling strength. By differentiating the expression of characteristic function equation (15) and evaluating it in the origin, according to the prescription in equation (4), one can see that each term of the series identically vanishes, so that the average work generated by quenching the optomechanical coupling is in fact zero. This is in agreement with the behavior of the imaginary part of $\chi(u)$, shown in the inset of figure 3, which approaches $u = 0$ with zero derivative. Having access to the characteristic function also gives us information about the statistical moments of $P(W)$; for instance, the variance of the distribution is given by

$$\langle W^2 \rangle - \langle W \rangle^2 = \hbar^2 g^2 N_c (1 + 2N_c) (1 + 2N_m). \quad (17)$$

As expected, this quantity increases both with respect to the intensity of the quench, as quantified by g/ω_m , and the average number of thermal excitations. This feature is apparent by comparing the topmost distribution, relative to $N_c = 0.001$, $N_m = 1$ and $g/\omega_m = 0.2$, to the other two, both obtained for $N_c = 0.1$ and $N_m = 1$ —thus varying the ratio ω_c/ω_m —but corresponding to $g/\omega_m = 0.1$ and $g/\omega_m = 0.8$ respectively, i.e., increasing both the temperature and the coupling strength.

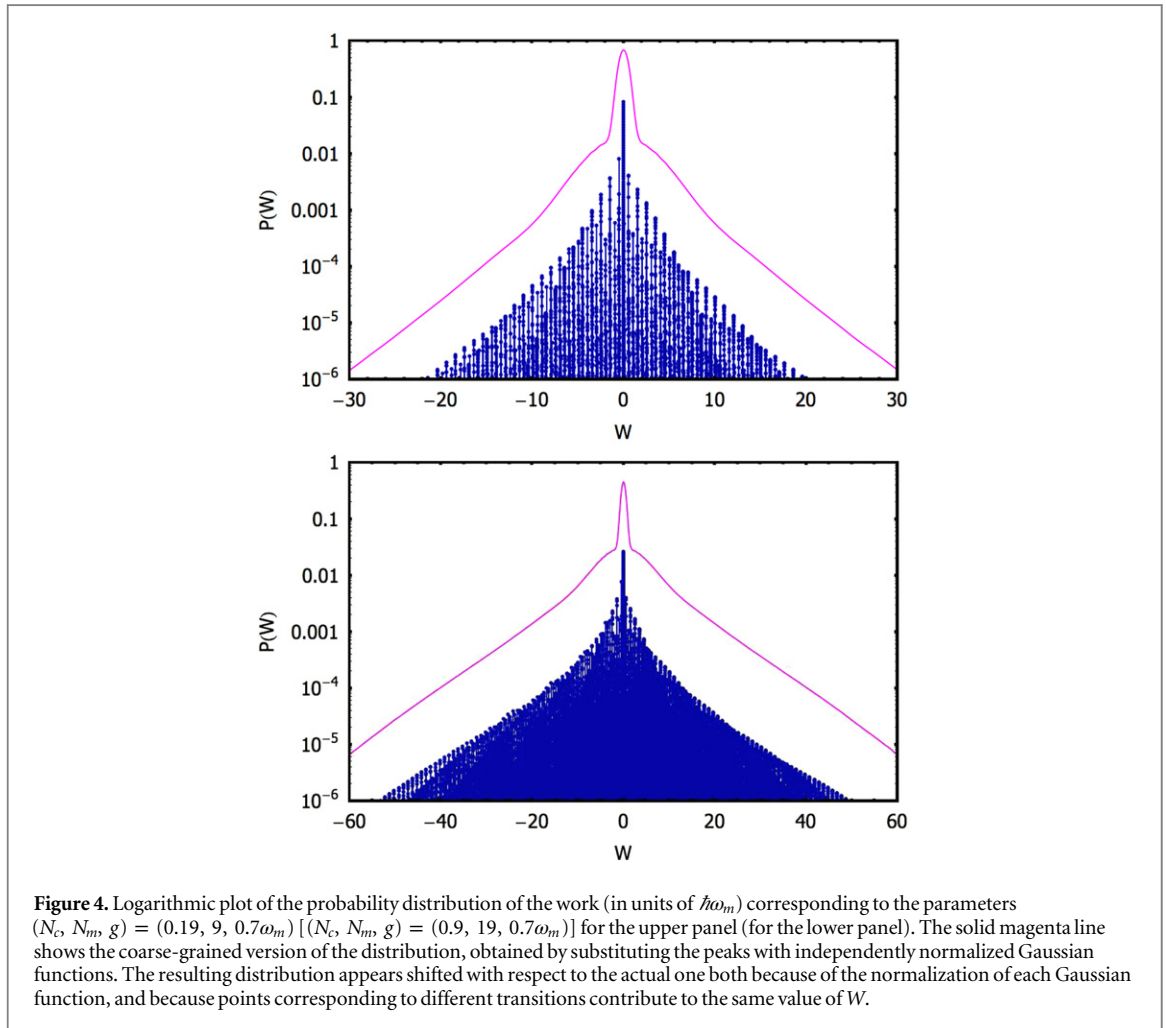

Let us first analyze $P(W)$ as illustrated for a few representative cases in figure 3, where we consider small values of $g/\omega_m \lesssim 1$. In such conditions and for relatively small values for N_c , the probability distribution appears to be dominated by peaks occurring close to multiple values of $\hbar\omega_m$. These peaks originate from different initially-populated Fock states of the mechanical subsystem. Indeed, the number of peaks with appreciable amplitude increases strongly with N_m . In figure 3(b) we notice that the sparse peak-distribution associated with very low values of N_c changes into a ‘clustered’ one, where groups of peaks develop close to multiples of $\hbar\omega_m$ and are biased towards less positive values of W . This is directly caused by the Kerr-like term in \hat{H}_F , whose contribution to the overall energy is always negative. A natural question to ask at this point is why the average work done is zero when each of these fine structures is biased in the same direction. The answer to this lies in the positive skewness of the distribution, which is given by

$$\gamma = \frac{\langle (W - \langle W \rangle)^3 \rangle}{\langle (W - \langle W \rangle)^2 \rangle^{3/2}} = \frac{\omega_m/g}{(1 + 2N_m)\sqrt{N_c(1 + 2N_c)}}, \quad (18)$$

and is more apparent in the low-temperature regime; indeed, by simply looking at the distribution shown in figure 3(b), it is possible to appreciate the positive skewness of the distribution.

Shifting our attention from figures 3 to 4, we can appreciate the effects of increasing the temperature significantly. The two effects we discussed above, namely the increasing number of peaks upon increasing N_m and the fine structure that appears more and more prominently when increasing N_c , work together to turn $P(W)$ from a distribution consisting of well-separated peaks to a dense forest of points. It is readily apparent from the latter figure that the tails of the distribution decay exponentially with increasing $|W|$. In order to investigate this effect more thoroughly, we show in figure 4(a) coarse-graining of the probability distributions. This coarse-graining was performed by convolving $P(W)$ with a Gaussian of appropriate width ($0.5 \hbar\omega_m$ in this case). The resulting distributions, drawn as solid curves in this figure, display clearly a tripartite structure. First, around

$W = 0$, a prominent peak is apparent whose width in this figure is entirely due to the convolved Gaussian. Second, a quadratic decay is appreciated for slightly larger values of W . The probability distribution in this region is thus Gaussian in nature. Third, the tails of the distribution have a manifestly exponential character: the coarse-grained curve displays a prominent kink where the exponential tail meets the Gaussian part of the distribution.

It is worth discussing the validity of our coarse-graining approach. We have verified that the discussion above is not modified significantly when the function used to coarse-grain is changed from a Gaussian or a Lorentzian, or when the width of this function is changed within reason. A final check we performed was to construct the cumulative distribution function $\int_{-\infty}^W dw P(w)$. This function was interpolated and smoothed, and then differentiated to give a continuous version of $P(W)$. Once again, the conclusions we drew above were left unmodified. It is possible to attach a physical meaning to the coarse-graining of $P(W)$ as follows. Should the probability distribution be measured using any realistic apparatus, the measurement results will not be infinitely sharp, and will be distributed according to some distribution, usually assumed to be Gaussian. Such an experiment would directly yield the coarse-grained distribution we calculate and display in figure 4. Another way of getting a smooth, continuous distribution would be to take the classical limit for the dynamics of both the optical and mechanical system, which would then result in a stochastically frequency-shifted harmonic oscillator [20]. While this approach would not entail the enforcement of any smoothing procedure, its study would deserve a full-fledged analysis that goes beyond the scopes of this work.

We have shown, both analytically and numerically, that despite turning on a nonlinear interaction between the two modes, on average there is no net production of work. This feature contrasts both with the case of a quench in the frequency of the harmonic potential of a single oscillator [21], and of the linear interaction between two bosonic modes [10], where net work is produced on average. We shall return to this point in the next subsection, where we discuss the physical origin of this fact and demonstrate a method for producing non-zero average work.

Using equation (13) we can easily compute the evolution of the initial Gibbs state, as defined by $\hat{Q}(t) = e^{-\frac{i}{\hbar}t\hat{H}_F} \hat{Q}_\beta^{(c)} \otimes \hat{Q}_\beta^{(m)} e^{\frac{i}{\hbar}t\hat{H}_F}$. In our case, it is easily seen that this always leads to a separable state, where any correlations between the optical and mechanical modes are fully classical. The dynamics is periodic in time: at $t = 2\pi r/\omega_m$ ($r \in \mathbb{Z}$), the system goes back to the initially factorized state, while for $t = (2r + 1)\pi/\omega_m$ ($r \in \mathbb{Z}$), one gets the maximally (classically) correlated state.

Equation (13) also allows us to compute the partition function of the system, via a suitable Wick rotation of the argument, i.e., $u \rightarrow -i\hbar\beta$, which effectively identifies the imaginary time as an inverse temperature. For the initial state of the system the partition function factorizes in two canonical contributions $\mathcal{Z}_I = \mathcal{Z}_\beta^{(c)} \mathcal{Z}_\beta^{(m)} \equiv [(1 - e^{-\hbar\beta\omega_c})(1 - e^{-\hbar\beta\omega_m})]^{-1}$, while for the coupled system we obtain

$$\mathcal{Z}_F = \left(1 - e^{-\hbar\beta\omega_m}\right)^{-1} \sum_{n=0}^{\infty} e^{-\hbar\beta\omega_c n} e^{\hbar\beta(g^2/\omega_m)n^2}. \quad (19)$$

The free energy difference is correspondingly given by

$$\Delta F = -\frac{1}{\beta} \ln \left[\sum_{n=0}^{\infty} \frac{N_c^n}{(1 + N_c)^{n+1}} e^{\hbar\beta(g^2/\omega_m)n^2} \right] = -\frac{1}{\beta} \ln [1 - e^{-\hbar\beta\omega_c}] - \frac{1}{\beta} \ln \left[\sum_{n=0}^{\infty} e^{-\hbar\beta\omega_c n} e^{\hbar\beta \frac{g^2 n^2}{\omega_m}} \right],$$

which, as can be verified, agrees with the Jarzynski equality $\Delta F = -\frac{1}{\beta} \ln \chi(i\beta)$. Upon close inspection, it is readily apparent that the series involved in the latter expression is actually divergent. Indeed, for every finite value of β , g/ω_m , and ω_c/ω_m , there exists $\bar{n} = \bar{n}(g, r)$ such that $\forall n > \bar{n}$, we have that $g^2 n > r$. This causes the sum to diverge exponentially, such that ΔF is formally undefined. This divergent term can be traced back to the part of \hat{H}_F that reads $\omega_c \hat{a}^\dagger \hat{a} - g^2/\omega_m (\hat{a}^\dagger \hat{a})^2$. As is apparent, the spectrum of this Hamiltonian is not bounded from below. Occupation of levels with $n \geq \bar{n}$, which occurs naturally for any non-zero β , can thus be mapped into a negative temperature with respect to \hat{H}_F . To resolve this issue, we impose a cutoff on the number of terms in the series; when g/ω_m approaches or even exceeds unity, with the system entering the interesting strong-coupling regime of optomechanics, we must truncate the series to correspondingly small photon numbers in order to prevent dynamical instability, and the ensuing divergence of ΔF , upon quenching the system. Alternatively, one can also devise ad hoc mechanisms to stabilize the divergent character of free energy difference. For example, one may add to the Hamiltonian \hat{H}_I a quadratic term in the photon number operator $\hbar \epsilon (\hat{a}^\dagger \hat{a})^2$; this can be done by adding a Kerr-like medium into the cavity, along the lines of [22]. When $\epsilon \geq g^2/\omega_m$ this contribution will compensate the divergent one, ensuring the convergence of ΔF . Another possibility is quenching both the linear and the quadratic terms in the mechanical displacement i.e., retaining both the contributions $k = 1, 2$ in equation (9); for the mechanical oscillator this would imply—beside a displacement and an energy shift both dependent on n —also a renormalization of the frequency (dependent on the photon number as well, see section 3.3) which eventually allow for the convergence of series for suitable values of the parameters involved. However it must be stressed that in both cases the regularization comes at the expense of modifying the probability distribution of the work and henceforth, for the rest of this work, we will therefore restrict ourselves to the physical domain in which the series does converge, leaving a quantitative study of the modification entailed by the additions mentioned above to further studies.

An explicit calculation of ΔF , as illustrated in figure 5, shows that the free energy difference is negative, in agreement with the statement of the second law $\Delta F \leq \langle W \rangle \equiv 0$. Moreover, the irreversible work reduces to $W_{\text{irr}} = -\Delta F$. Upon moving towards lower temperatures, both the evolved state and the reference thermal state tend to collapse onto the ground state, leading to vanishing values of the irreversible work, as is apparent from the figure. On the other hand, upon increasing the coupling g/ω_m , the free energy difference grows in modulus.

Finally we point out that, in the spirit of [23], the divergence of the free energy difference is related, via the Jarzynski equality equation (7), to the divergence of exponentiated average work $\int_{\mathbb{R}} dW P(W) e^{-\beta W}$, which in turn imposes some constraint on the behavior of the tails of the work probability distribution. In our case a divergent ΔF would imply a sub-exponential decay of the tails of the distribution.

3.2. Initial displacement of the mechanical oscillator

In the previous subsection we observed how $\langle W \rangle = 0$ for an initial thermal state of the Hamiltonian H_I , independently of the strength of the quench. The fact can be seen as a direct consequence of the symmetry of the interaction which, being proportional to \hat{x} , is an odd function in the mechanical field operators, such that

$$\langle W \rangle = -g N_c \text{Tr} \left\{ \left(\hat{b} + \hat{b}^\dagger \right) \hat{Q}_\beta^{(m)} \right\} = 0. \quad (20)$$

In other words, the average work generated by this kind of quench will be zero. In order to remedy this, we now add an initial displacement of amplitude \mathcal{E} $\omega_m \in \mathbb{R}$ to the mechanical mode \hat{b} of the Hamiltonian (9) so that the

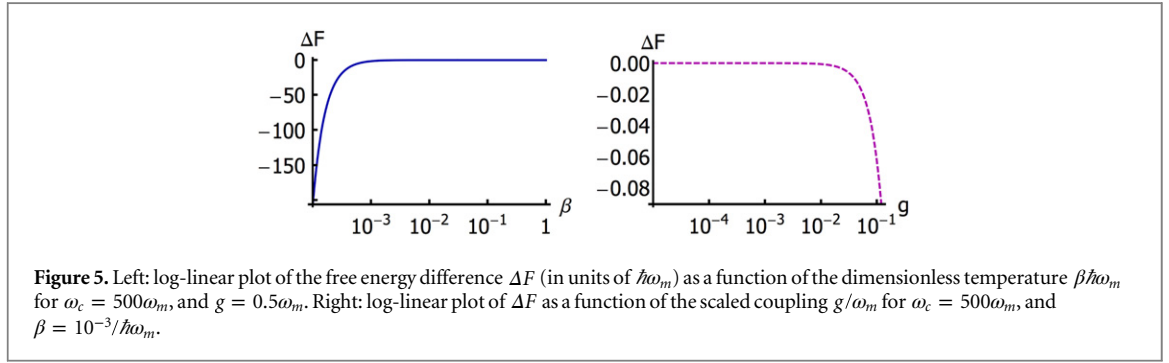

Figure 5. Left: log-linear plot of the free energy difference ΔF (in units of $\hbar\omega_m$) as a function of the dimensionless temperature $\beta\hbar\omega_m$ for $\omega_c = 500\omega_m$, and $g = 0.5\omega_m$. Right: log-linear plot of ΔF as a function of the scaled coupling g/ω_m for $\omega_c = 500\omega_m$, and $\beta = 10^{-3}/\hbar\omega_m$.

initial and final Hamiltonians will now read $\hat{H}_{I,F,\mathcal{E}} = \hat{H}_{I,F} + \hbar \mathcal{E} \omega_m (\hat{b} + \hat{b}^\dagger)$. It can be shown that $\hat{H}_{I,\mathcal{E}} = \hat{D}(\mathcal{E})\hat{H}_I\hat{D}^\dagger(\mathcal{E})$ and $\hat{H}_{F,\mathcal{E}} = \hat{D}(\mathcal{E})(\hat{H}_F + 2\hbar g \mathcal{E}\hat{a}^\dagger\hat{a})\hat{D}^\dagger(\mathcal{E})$ with $\hat{D}(\mathcal{E})$ a local displacement of amplitude \mathcal{E} . Proceeding as before, the characteristic function of the work distribution can be computed as

$$\chi(u) = \sum_{n=0}^{\infty} \frac{N_c^n}{(1+N_c)^{n+1}} e^{-i(g/\omega_m)^2 n^2 (\omega_m u - \sin \omega_m u)} e^{-(g/\omega_m)^2 n^2 (1+2N_m)(1-\cos \omega_m u)} e^{2i\text{gn}\mathcal{E}u}, \quad (21)$$

which differs from equation (15) by a phase factor. This extra factor is actually responsible for positive derivative of the imaginary part $\text{Im}[\chi(u, \mathcal{E})]$ at the origin and hence to a non-zero value of the average work. Indeed, applying equation (4), one finds that the average work done by quenching the optomechanical interaction is given by

$$\langle W \rangle = 2\hbar g \mathcal{E} N_c, \quad (22)$$

which depends linearly on the displacement \mathcal{E} , on the number of thermal photons populating the cavity, and on the quenching parameter.

Finally, the free energy difference for this model is given by

$$\Delta F = -\frac{1}{\beta} \ln \left[\sum_{n=0}^{\infty} \frac{N_c^n}{(1+N_c)^{n+1}} e^{\hbar\beta\frac{g^2 n^2}{\omega_m^2} - 2\hbar\beta\text{gn}\mathcal{E}} \right]. \quad (23)$$

The behavior of the irreversible work W_{irr} is reported in figure 6, with respect to the inverse temperature and the magnitude of the displacement.

3.3. Quenched quadratic optomechanical interaction

We will consider now the case where the photon number operator of the cavity field is coupled to the square of the position operator of the mirror. As before, we will concentrate on the single-photon regime where the interaction of a single photon with the mechanical mode is enough to appreciably change its frequency and also squeeze its state. In this instance, we can introduce the single-photon coupling strength κ through the relation $G^{(2)} = \kappa/x_{\text{zpf}}^2$, in analogy with the linear case. The initial Hamiltonian H_I is unmodified and still given by equation (11), whereas the the post-quench Hamiltonian now reads

$$\hat{H}_F = \hat{H}_I + \hbar \kappa \hat{a}^\dagger \hat{a} (\hat{b} + \hat{b}^\dagger)^2. \quad (24)$$

We choose to work with a non-negative κ , since $\kappa < 0$ can introduce post-quench instabilities similar to the one noted for the linear case. The $\kappa > 0$ case exhibits no such instabilities. Yet again, we see that this interaction preserves the photon number $\hat{a}^\dagger \hat{a}$, so that it proves convenient to write $\hat{H}_F = \bigoplus_{n=0}^{\infty} \hat{H}_{F,n}$ where each $\hat{H}_{F,n}$ can be cast in the form

$$\hat{H}_{F,n} = \left[\hbar\omega_c n + \hbar\Omega_n \left(\hat{b}^\dagger \hat{b} + \frac{1}{2} \right) + \hbar\Sigma_n \left(\hat{b}^{\dagger 2} + \hat{b}^2 \right) \right] |n\rangle\langle n|_c, \quad (25)$$

where $\Omega_n \equiv \omega_m + 2\kappa n$ and $\Sigma_n \equiv 2\kappa n$. Within each such fixed photon-number manifold, we notice the appearance of a modified mechanical frequency, together with a squeezing operator for the mechanical mode whose argument is conditioned on the photon number. The evolution operator relative to the post-quench Hamiltonian can subsequently be expressed as

$$e^{-\frac{i}{\hbar}\hat{H}_F u} = \sum_{n=0}^{\infty} e^{-iu \left[\omega_c n + \Omega_n \left(\hat{b}^\dagger \hat{b} + \frac{1}{2} \right) + \Sigma_n \left(\hat{b}^{\dagger 2} + \hat{b}^2 \right) \right]} |n\rangle \langle n|_c. \quad (26)$$

Our next task is to disentangle each exponential operator in the sum. By using the commutation relations between the operators involved in equation (26), which provide a two-excitation realization of the $\mathfrak{su}(1, 1)$ algebra [24], we find

$$e^{-\frac{i}{\hbar}\hat{H}_F u} = e^{\frac{i}{2} \left[\xi_n^* \hat{b}^2 - \xi_n \hat{b}^{\dagger 2} \right]} e^{-i\eta_n \left(\hat{b}^\dagger \hat{b} + \frac{1}{2} \right)} e^{-i\omega_c u n} |n\rangle \langle n|_c, \quad (27)$$

where

$$\eta_n \equiv \arctan \left[\frac{1 + 2\tilde{\kappa}n}{\sqrt{1 + 4\tilde{\kappa}n}} \tan(\omega_m u \sqrt{1 + 4\tilde{\kappa}n}) \right] \quad (28)$$

with $\tilde{\kappa} \equiv \kappa/\omega_m$ being a dimensionless quench parameter. We further have the complex quantity $\xi_n \equiv |\xi_n| e^{i\phi_n}$ whose phase is $\phi_n \equiv \eta_n + \frac{\pi}{2}$ and modulus

$$|\xi_n| \equiv \operatorname{arcsinh} \left[\frac{2\tilde{\kappa}n}{\sqrt{1 + 4\tilde{\kappa}n}} \sin(\omega_m u \sqrt{1 + 4\tilde{\kappa}n}) \right]. \quad (29)$$

Armed with this tool we can thus compute the characteristic function of the work distribution, which reads

$$\chi(u) = \sum_{n=0}^{\infty} \frac{N_c^n}{(1 + N_c)^{n+1}} \frac{1}{\sqrt{\sum_{j=0}^2 \chi_{n,j} N_m^j}}, \quad (30)$$

and comes in the form of a thermal average with respect to the cavity distribution—as in equation (15)—of algebraic functions. Each of the latter is the reciprocal of the square-root of a second degree polynomial in the mean number of phonons N_m , whose coefficients are concisely related to each other. Indeed, we can split $\chi_{n,0}$ into its real and imaginary parts, which read

$$\operatorname{Re}(\chi_{n,0}) = \cos(\omega_m u) \cos(\omega_m u \sqrt{1 + 4\tilde{\kappa}n}) + \frac{1 + 2\tilde{\kappa}n}{\sqrt{1 + 4\tilde{\kappa}n}} \sin(\omega_m u) \sin(\omega_m u \sqrt{1 + 4\tilde{\kappa}n}), \quad (31)$$

and

$$\operatorname{Im}(\chi_{n,0}) = \sin(\omega_m u) \cos(\omega_m u \sqrt{1 + 4\tilde{\kappa}n}) - \frac{1 + 2\tilde{\kappa}n}{\sqrt{1 + 4\tilde{\kappa}n}} \cos(\omega_m u) \sin(\omega_m u \sqrt{1 + 4\tilde{\kappa}n}). \quad (32)$$

We thus have $\chi_{n,1} = 2(\chi_{n,0} - 1)$ and $\chi_{n,2} = 2[\operatorname{Re}(\chi_{n,0}) - 1]$. As before, since the Fourier transform of equation (30) cannot be directly evaluated, in order to compute the probability distribution of the work equation (2) we proceed by diagonalizing the post-quench Hamiltonian \hat{H}_F . First, we keep in mind that \hat{H}_I is the same as before. However, within any fixed photon number manifold, $\hat{H}_{F,n}$ be diagonalized via a squeezing operation $\hat{S}(z) = \exp(z^* \hat{b}^2/2 - z \hat{b}^{\dagger 2}/2)$ on the mechanical mode conditioned on the photon number n [25, 26]. Once again denoting the post-quench quantities with a prime, and expressing the states in the eigenbasis of \hat{H}_I , we find eigenstates $\hat{H}_{F,n} |n'\rangle_c \otimes \hat{S}(\zeta_{n'}) |k'\rangle_m = E_{n',k'} |n'\rangle_c \otimes \hat{S}(\zeta_{n'}) |k'\rangle_m$, where the squeezing parameter is given by $\zeta_{n'} \equiv \frac{1}{4} \log[1 + 4(\kappa/\omega_m)n']$, and the eigenvalue

$$E_{n',k'} = \hbar\omega_c n' + \hbar\omega_m \sqrt{1 + 4(\kappa/\omega_m)n'} \left(k' + \frac{1}{2} \right). \quad (33)$$

As sketched in figure 7, for the manifold corresponding to n' photons, the quench results in a modification of the oscillation frequency which is multiplied by a factor $\sqrt{1 + 4(\kappa/\omega_m)n'}$, a relative shift of the mechanical levels by $\hbar\omega_m[\sqrt{1 + 4(\kappa/\omega_m)n'} - 1]$, and a squeezing of the state by a factor $\zeta_{n'}$. Putting everything together, the probability distribution of the work is thus given by

$$\begin{aligned}
 P(W) &= \sum_{n,n',k,k'} P_n^{(c)} P_k^{(m)} \left| \langle k' | S(\zeta_{n'}) | k \rangle \right|^2 \delta \left[W - (E_{n',k'} - E_{n,k}) \right] \delta_{n,n'} \\
 &= \sum_{n,k,k'} P_n^{(c)} P_k^{(m)} \frac{k! k'}{(\cosh \zeta_n)^{2k+1}} \left[S(k, k', \zeta_n) \right]^2 \delta \left\{ W - \hbar\omega_m \left[\sqrt{1 + \frac{4n\kappa}{\omega_m}} k' - k \right] \right\}, \quad (34)
 \end{aligned}$$

where $S(k, k', \zeta_n)$ is given by

$$S(k, k', \zeta_n) = \sum_{m=0}^{\lfloor \frac{k'}{2} \rfloor} \sum_{l=0}^{\lfloor \frac{k}{2} \rfloor} \frac{(-1)^{3m+2l} (\tanh \zeta_n)^{m+l}}{2^{m+l} m! l! (k-2l)!} (\cosh \zeta_n)^{2l} \delta_{k'-2m, k-2l}, \quad (35)$$

being $\lfloor x \rfloor$ the floor function of argument x , which yields the largest integer not greater than x .

The probability distribution for the work done on the oscillator in the case of a quadratic interaction, as derived in this section, is illustrated for some representative cases in figures 8 and 9. In order to characterize quantitatively the key features of the distribution of work, here we mention that the average work generated by a quench of the quadratic optomechanical Hamiltonian is different from zero and is then given by

$$\langle W \rangle = \hbar\kappa N_c (1 + 2N_m), \quad (36)$$

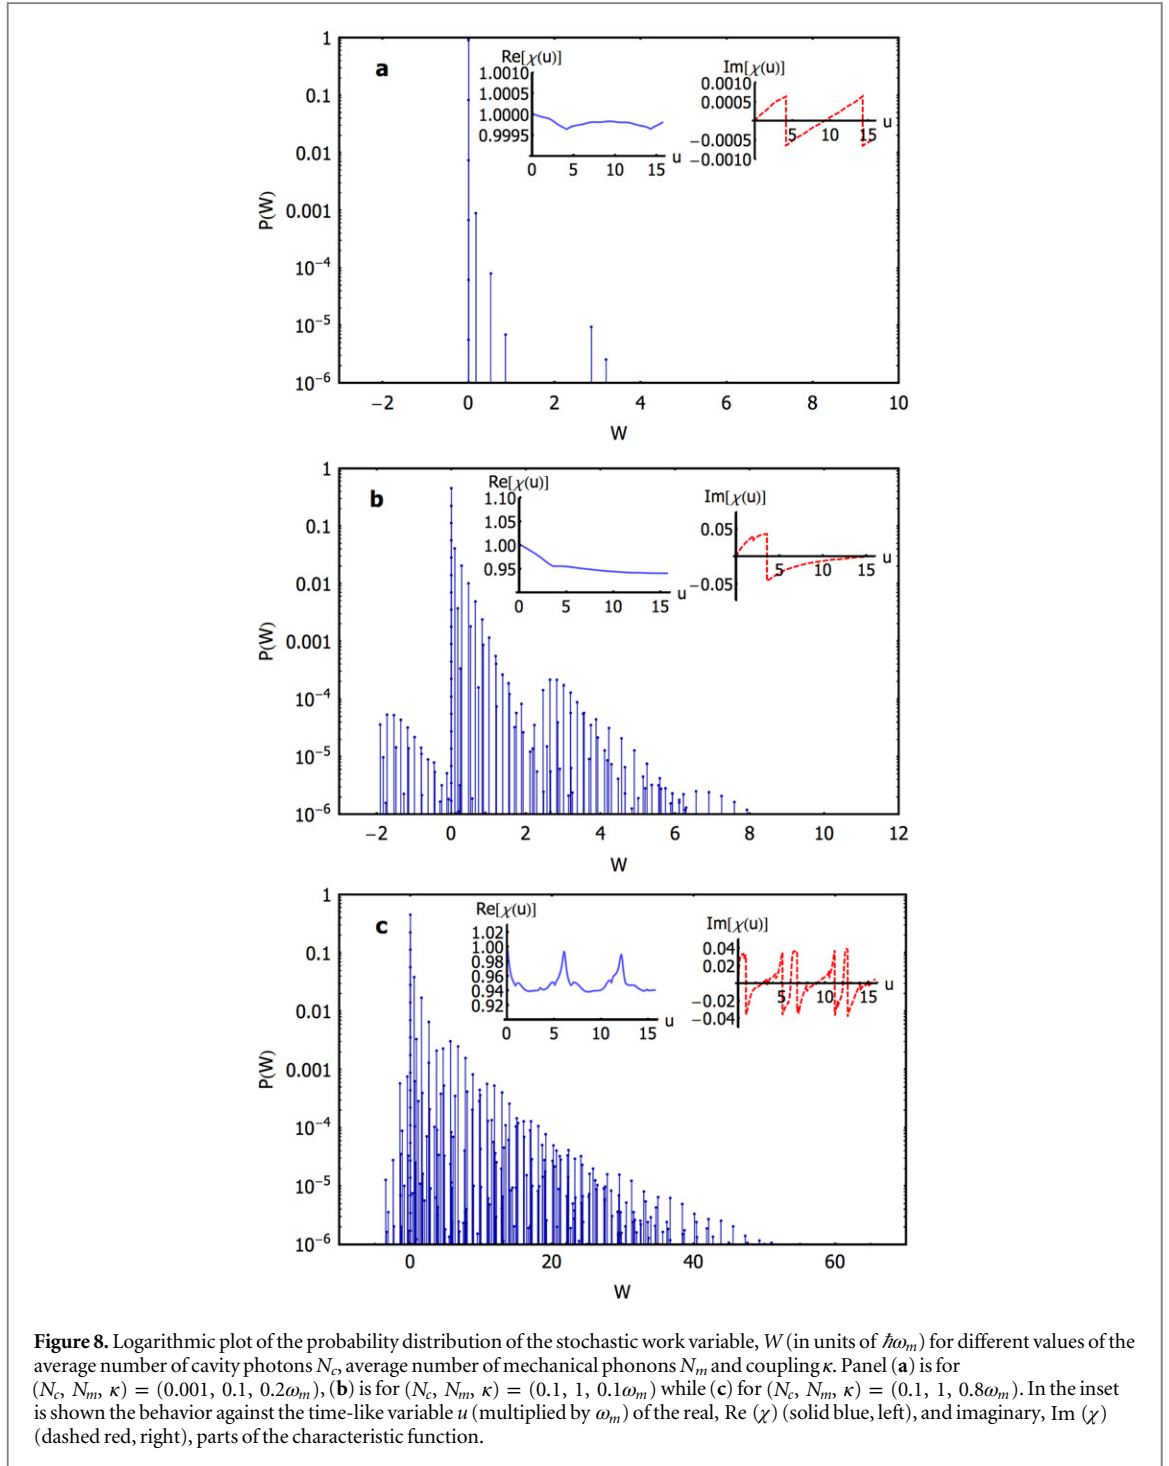

hence increasing with respect the occupation numbers of both the cavity and the mechanical mode, as made apparent by inspecting the different panels in figure 8. The variance of the distribution reads

$$\langle W^2 \rangle - \langle W \rangle^2 = \hbar^2 \kappa^2 N_c (3 + 5N_c) (1 + 2N_m)^2. \quad (37)$$

Finally, the most striking feature of the probability distribution in the case of a quadratic quench is that it is very asymmetrical, fact witnessed by its skewness

$$\gamma = \frac{4 + 8N_c + (g/\omega_m) (15 + 81N_c + 74N_c^2) (1 + 2N_m)^2}{(g/\omega_m) \sqrt{N_c} (3 + 5N_c)^{3/2} (1 + 2N_m)^2}. \quad (38)$$

We note that, for $N_m \gg 1$, it acquires the values $5/\sqrt{3N_c}$ for $N_c \ll 1$ and $74/5\sqrt{5}$ for $N_c \gg 1$; both these values are independent of the strength of the quench. As for the linear case the dynamics brings the initial bipartite state of cavity and mechanical mode into a separable state, given by $\hat{\rho}(t) = e^{-\frac{i}{\hbar} t \hat{H}_F} \hat{\rho}_\beta^{(c)} \otimes \hat{\rho}_\beta^{(m)} e^{\frac{i}{\hbar} t \hat{H}_F}$

$\sum_n p_n^{(c)} |n\rangle\langle n|_c \otimes \int d^2\alpha \mathcal{P}^{(m)}(\alpha) |e^{i\eta_n}\alpha, \xi_n\rangle\langle e^{i\eta_n}\alpha, \xi_n|_m$, where $|e^{i\eta_n}\alpha, \xi_n\rangle_m = \hat{S}(\xi_n)\hat{D}(e^{i\eta_n}\alpha)|0\rangle_m$ is a squeezed coherent state of the mechanical mode, and hence no entanglement is generated between the two modes. Proceeding in the same manner as before, we can show that the free energy can be cast in the form

$$\Delta F = -\frac{1}{\beta} \ln \left[\sinh\left(\frac{\beta}{2}\right) \right] - \frac{1}{\beta} \ln \left[\sum_{n=0}^{\infty} \frac{N_c^n \text{cosech}\left(\sqrt{1 + \frac{4n\kappa}{\omega_m} \frac{\beta}{2}}\right)}{(1 + N_c)^{n+1}} \right]. \quad (39)$$

In this case, too, a suitable Wick-like rotation to imaginary u can be performed to obtain ΔF from $\chi(u)$. In practice, however, this calculation is fraught with technical difficulties and it is far easier to compute ΔF from an explicit diagonalization of the Hamiltonian, as was done above. The behavior of the irreversible work for this

Figure 9. Logarithmic plot of the probability distribution of work (in units of $\hbar\omega_m$) corresponding to the parameters $(N_c, N_m, \kappa) = (0.19, 9, 0.7\omega_m)$. We also show the coarse grained version of the work distribution (solid magenta line). The coarse graining is realized by convolving the discrete distribution with a Gaussian function of standard deviation $0.9\hbar\omega_m$.

case has been shown in figure 10, and once again we can see how it drops lowering the temperature and increases by increasing the coupling strength.

As in the linear case, is easier to extract a physical meaning behind the various features of these plots by inspecting the respective coarse-grained distributions. First, we see that the positive- W tail still exhibits an approximately exponential decay. It is also apparent that the distribution is, in this case, significantly more skewed towards the right than in the linear case, which can be understood simply through the fact that the post-quench mechanical oscillator frequency is always *larger* even for the case when $k' = k$, therefore, which at least for small κ/ω_m has a large probability of occurring, the work done is positive.

4. Conclusions and outlook

The exploration of out-of-equilibrium features of small systems working in the quantum regime is attracting ever-increasing attention. Optomechanical systems, more so than other systems, offer the tantalizing perspective of naturally bridging the study of quantum thermodynamics with the macroscopic domain. We actually believe that this class of systems offers the possibility of a captivating analogy: movable mirrors and cavity fields closely resemble pistons and working media in a piston–chamber engine; in turn, this embodies the archetypal example of a thermal machine. In this sense, such systems may serve as the paradigm for understanding a new class of machines, operating both in the quantum regime and far from equilibrium. However, an adequate description of optomechanical systems involves a fully quantum treatment, and a detailed analysis of the thermodynamical properties of them, carried out at a fundamental level and retaining the full nonlinearity of the interaction, has not been conducted thus far. In this work we discussed the generation of work induced by a non-equilibrium transformation in an isolated optomechanical system, quantitatively assessing how an instantaneous quench of the light–matter coupling affects the thermodynamical response of the system. Our study was grounded through several analytic results, presenting expressions for both the characteristic function of the work distribution and the full statistics of the work generated for two different situations of much relevance for current and future optomechanical experiments. For a quench of linear coupling between light and the position of an oscillator, we found that no work is generated on average, whilst quenching a quadratically-coupled optomechanical interaction requires work to be performed on the system.

Besides being interesting in itself, and allowing for a full analytical treatment, the scenario we addressed comprises the fundamental ingredients necessary in order to gain knowledge about the microscopic origin of the work generated by quenching an optomechanical interaction, from a fully quantum perspective. An in-depth understanding of the thermodynamical response of such an isolated quantum system represents the cornerstone for future investigations. For instance, the implementation of protocols for extracting work out of such systems will require benchmarks based on the analysis that we have performed here, which will in turn be necessary to help uncover fundamental advantages or limitations for possible future thermal machines working in the quantum regime and that exploit the optomechanical interaction.

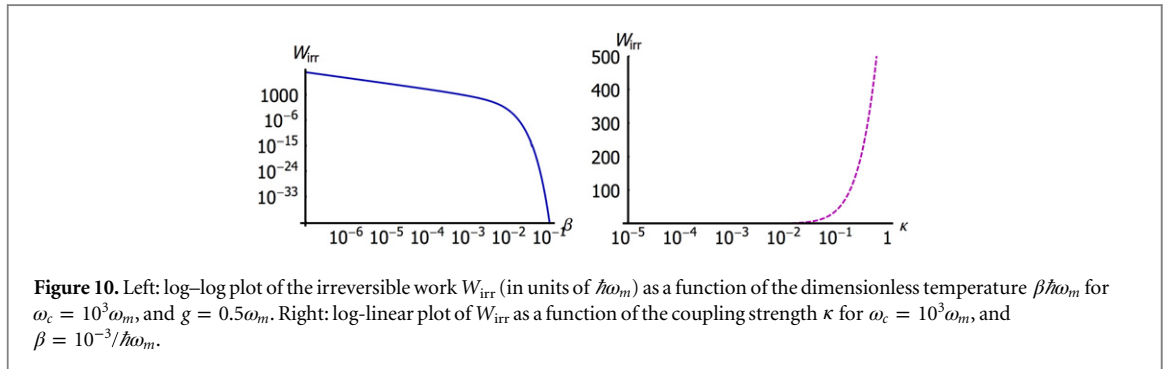

Figure 10. Left: log–log plot of the irreversible work W_{irr} (in units of $\hbar\omega_m$) as a function of the dimensionless temperature $\beta\hbar\omega_m$ for $\omega_c = 10^3\omega_m$, and $g = 0.5\omega_m$. Right: log–linear plot of W_{irr} as a function of the coupling strength κ for $\omega_c = 10^3\omega_m$, and $\beta = 10^{-3}/\hbar\omega_m$.
