ORI), Jocelyn Claude, Romain Decoin, Anaëlle Bernard (Amis de la RNN du Lac de Remoray), Camille Barbaz, Michel Sauret (EPAGE Haut-Doubs Haute-Loue), Magalie Mazuy (CEN FC), and their respective structures. We also thank Christian Miquel for help in molecular work. CK was supported by a PhD fellowship from the Parc naturel régional du Haut-Jura the DREAL Bourgogne-Franche-Comté and ANRT (CIFRE grant number 2019/1732).

1 **Abstract**

2 Climate is a main driver of species distributions, but all species are not equally affected by
3 climate change, and their differential responses to similar climatic constraints might
4 dramatically affect the local species composition. In the context of climate warming, a better
5 knowledge of the ability of dispersal-limited and habitat-specialist species to track climate
6 change at local scale is urgently needed. Comparing the population genetic and demographic
7 impacts of past climate cycles in multiple co-distributed species with similar ecological
8 requirements help predicting the community-scale response to climate warming, but such
9 comparative studies remain rare. Here, we studied the relationship between demographic
10 history and past changes in spatial distribution of three protected peatland butterfly species
11 (*Boloria aquilonaris*, *Coenonympha tullia*, *Lycaena helle*) in the Jura massif (France), using a
12 genomic approach (ddRAD sequencing) and species distribution modeling (SDM). We found
13 a similar and narrow thermal niche among species, and shared demographic histories of post-
14 glacial decline and recent fragmentation of populations. Each species functions as a single
15 metapopulation at the regional scale, with a North-South gradient of decreasing genetic
16 diversity that fits the local dynamics of the ice cover over time. However, we found no
17 correlation between changes in the quantity or the quality of suitable areas and changes in
18 effective population size over time. This suggests that species ranges moved beyond the Jura
19 massif during the less favorable climatic periods, and/or that habitat loss and deterioration are
20 major drivers of the current dramatic decline observed in the three species. Our findings allow
21 better understanding how history events and contemporary dynamics shape local biodiversity,
22 providing valuable knowledge to identify appropriate conservation strategies.

1. Introduction

Climate has major effects on the global distribution of species, but all species are not equally vulnerable to climate change. The variety of responses is the result of differences in species biology and ecology (dispersal behavior, niche characteristics and niche breadth, physiology, phenology) together with historical contingencies (Estrada et al., 2018; Pedreschi et al., 2019). For example, butterflies were shown to be more vulnerable to climate change than birds (Devictor et al., 2012) and within butterflies, habitat specialist species generally appear to be more at risk than generalist species (Warren et al., 2001; Settele et al., 2008; Heikkinen et al., 2010; Noreika et al., 2016). In fact, habitat specialization and sedentary behavior might have negatively affected the altitudinal shift response to recent past climate change among butterfly species (Habel et al., 2023). Furthermore, in contrast to several organisms that have already shown range shifts northwards as a response to ongoing climate warming (Parmesan et al., 1999; Devictor et al., 2012), southern populations of post-glacial relict species are often trapped in isolated altitudinal habitats (Turlure et al., 2010). Given the current rate of warming, we need to evaluate the ability of dispersal-limited and habitat specialist species to track their climate niches at local scale.

The population genetic and distributional responses of species to past climate changes can give insight on their capacity to cope with ongoing warming. The Pleistocene climatic fluctuations have profoundly impacted species distributions (Hewitt, 2000; Schmitt, 2007). During the last glacial maximum (LGM), many temperate species from Europe showed range contraction towards glacial refuges in Mediterranean peninsulas where the climate remained suitable (Taberlet et al., 1998; Hewitt, 2000, 2004). However, the picture is less clear for boreo-montane species (Schmitt and Varga, 2012). Some species may have survived the last glaciation in restricted non-glaciated areas at high latitude or altitude, or as small populations at the margin of the glaciated areas (Schoville et al., 2011; Sherpa et al., 2022). Other species may have

1 benefited from cold temperature and expanded their range during the LGM (Kebaïli et al.,
2 2022). These different distributional responses of boreo-montane species are expected to result
3
4 in distinct population demographic histories; for instance, a decrease in effective population
5
6 size (Ne) during the LGM for species that remained within small ice-free refuges (Sherpa et al.,
7
8 2022), or an increase in Ne for cold-adapted species that expanded during the LGM and reduced
9
10 Ne during interglacial periods (Kebaïli et al., 2022). The current genetic diversity of populations
11
12 should reflect, in part, their demographic and biogeographic history, with decreasing genetic
13
14 diversity from the glacial refuge to the newly colonized areas (Hewitt 2004). However, very
15
16 few studies have investigated the relationship between habitat suitability and demographic
17
18 changes over time, and how currently co-distributed species with similar ecology did respond
19
20 to past climate change.
21
22
23
24
25

26 The boreo-montane species *Boloria aquilonaris* (Nymphalidae, Heliconinae),
27
28 *Coenonympha tullia* (Nymphalidae, Satyrinae) and *Lycaena helle* (Lycaenidae) have a patchy
29
30 distribution in Europe and are among the most endangered European butterflies (van Swaay et
31
32 al., 2011). The main causes of the recent decline of these peatland species are land-use changes
33
34 (peat exploitation, drainage of wetlands and conversion to crop production or urbanization) and
35
36 climate change (Settele et al., 2008; Noreika et al., 2016). The three species benefit from a high
37
38 protection status both at the Europe and local scales, and a large amount of literature is available
39
40 on their current distribution, local habitat requirements and population ecology through
41
42 conservation monitoring programs (Settele et al., 2008; Turlure et al., 2010; Habel et al., 2011;
43
44 Fisher et al., 2014; Weking et al., 2013, Noreika et al., 2016; Čelik et al., 2018; Lebigre et al.,
45
46 2022; Osborne et al., 2022). Yet little is known about their evolutionary history and past
47
48 distributions (but see Habel et al., 2010 for *L. helle*). Given that these peatland butterflies have
49
50 a similar habitat, they might show an analogous demographic history of population decline
51
52 concomitant with periods of habitat contraction. However, habitat quality rather than habitat

76 quantity might be a better predictor of local abundance, especially for habitat specialists such
77 as peatland butterflies (Dennis and Eales, 1997; Noreika et al., 2016; Čelik et al., 2018; Lebigre
78 et al., 2022). Furthermore, the three species differ in several life-history traits including larval
79 host-plant, overwintering stages and microhabitat (Settele et al., 2008), which might result in
80 slight differences in climatic niches and responses to climate change, and therefore in
81 population histories.

82 Here, we ask whether habitat specialists such as peatland butterflies, which are co-
83 distributed in the Jura massif but have distinct life-history traits, have a common demographic
84 and biogeographic history in response to the climate changes during the last glacial cycle.
85 Contrary to the Alps, the Jura massif has never been entirely covered by ice during the LGM
86 (Lhosmot et al., 2022) and might have acted as a refuge for cold-adapted species, possibly in
87 multiple distinct areas. This hypothesis has however hardly been tested so far (Sherpa et al.,
88 2022). Combining fine-scale population genomics (Jura massif) and coarse-scale predictions of
89 species distribution (Europe), we specifically address the following questions: (1) Do the three
90 species present the same population genetic structure and a shared demographic history in the
91 Jura massif? (2) Is their current distribution explained by the same climatic predictors? (3) How
92 did the spatial distribution of favorable areas change over time for each species, and has the
93 Jura massif always been a suitable area? (4) Is there a relationship between the effective
94 population size and the quantity and/or the quality of climatically suitable areas in Europe and
95 Jura since the last interglacial (LIG)?

96 97 **2. Material and Methods**

98 **2.1 Studied species**

99 In the Jura massif, the three species are univoltine and on-wing in May-June. They all are small
100 butterflies with limited dispersal found in wetlands, but they differ in their larval-host plant,

101 overwintering stages and microhabitat. The Cranberry Fritillary *B. aquilonaris* is found in
102 raised bogs (European Nature Information System (EUNIS) code: D1.1;
103 <https://www.eea.europa.eu/data-and-maps/data/eunis-habitat-classification-1>) and wet heaths,
104 in sheltered places at the edges of woods or in clearings. Eggs are laid on *Vaccinium oxycoccos*,
105 the larval host-plant, but the caterpillar overwinters in the moss layer just after hatching and
106 starts feeding only the following year: the summer thermal buffering of the *Sphagnum*
107 hummocks appear to be as important as the presence of the host plant for larval survival (Settele
108 et al., 2008; Turlure et al., 2010). The Violet Copper *L. helle* lives in moist or wet eutrophic and
109 mesotrophic grasslands (EUNIS code: 3.4) and uses *Bistorta officinalis* as larval foodplant, and
110 overwinters as a pupa (Habel et al., 2011; Fisher et al., 2014). *Lycaena helle* dispersal is limited
111 by both forests and fully open habitats as this butterfly prefers wind-sheltered stands (Fischer
112 et al., 1999; Bauerfeind et al., 2009; Chuluunbaatar et al., 2009; Lebigre, 2022). The Large
113 Heath *C. tullia* is a specialist of good-quality lowland fens with water table at or just below the
114 surface (Lebigre et al., 2022), typically found in poor fens and soft-water spring mires (EUNIS
115 code: D2.2). Unlike the two other species, the caterpillar can feed on many different grasses
116 (Clarke, 2022) but it feeds on *Carex* sp. in limestone Jura Mountains (Decoin et al., 2021). The
117 third instar caterpillars hibernate in the tussocks of the foodplant and actively escape from
118 flooding by climbing up so that winter vegetation structure is a major constrain for this species
119 (Joy and Pullin, 1997; Weking et al., 2013; Čelik et al., 2018; Osborne et al., 2022).

121 **2.2 Study area and sample collection**

122 The study area covers the Jura massif, on the border between France and Switzerland (Figure
123 1). Sampling localities were distributed into three main geographical regions in France: Haut-
124 Jura (HJ); Doubs and Drugeon valleys (DDV); plateau of Russey (RUS) (Figure 1;
125 Supplementary Table S1). The sampling was performed by qualified personnel from:

126 Conservatoire Botanique Nationale de Franche-Comté – Observatoire des Invertébrés
127 (CBNFC–ORI); Conservatoire d’Espaces Naturels de Franche-Comté (CEN FC); Réserve
128 Naturelle du Lac de Remoray; Établissement Public d’Aménagement et de Gestion de l’Eau
129 Haut-Doubs Haute-Loue (EPAGE HDHL); Parc naturel régional du Haut-Jura (PNRHJ). The
130 experimental protocols were validated by the French authorities (authorization number:
131 DDPP01-21-052) and by the Swiss Canton of Vaud authorities (authorization number: 2021-
132 3539). For each locality, one to nine butterflies were captured using hand-nets, and one hind
133 leg was collected before immediate release. This method was shown to cause low disturbance
134 on post-release flight behavior and survival in butterflies (Koscinski et al., 2011), thus
135 minimizing the impact of sampling on vulnerable populations of protected species. We sampled
136 52 individuals from 11 localities for *B. aquilonaris*, 100 individuals from 18 localities for *C.*
137 *tullia* and 236 individuals from 67 localities for *L. helle*. For *L. helle*, two additional localities
138 were sampled in the Canton de Vaud, Switzerland (Supplementary Table S1). The sampling
139 was performed during the flight period in 2018, 2020 and 2021. Collected tissues were stored
140 at -20°C until DNA extraction.

141 142 **2.3 DNA extraction and ddRAD-seq libraries preparation**

143 DNA was extracted (DNEasy Blood & Tissue kit, Qiagen) and 50 ng was double-digested with
144 *SbfI*-HF and *MspI* restriction enzymes (New England Biolabs) and individually tagged during
145 ligation to P1 and P2 adapters as described in Kebaïli et al. (2021). After a first purification step
146 with 1.5 volumes of NucleoMag NGS Clean-up and Size Selected (Macherey-Nagel SAS), the
147 adapters-ligated DNA fragments were size-selected for a length of 200–600 bp (Pippin-Prep
148 2% gel cassette; Sage Science Inc). Libraries were amplified in 10 independent replicates,
149 which were pooled and purified with 1 volume of NucleoMag NGS Clean-up and Size Selected
150 (Macherey-Nagel SAS) (see Kebaïli et al., 2022 for PCR conditions). The libraries were

151 sequenced on Illumina HiSeq 2500 ($2 \times 125\text{bp}$) in 2018 and Illumina NovaSeq 6000 ($2 \times 150\text{bp}$)
152 in 2020 and 2021.

153

154 **2.4 Genomic data treatment**

155 After trimming adapters (BBDuk from the BBTools package; Bushnell, 2014), the assembly of
156 ddRAD loci and SNP calling were performed using the Stacks v2.2 *de novo* pipeline (Rochette
157 et al., 2019). Reads were demultiplexed, filtered based on quality and cut to 110bp
158 (*process_radtags*). Loci reconstruction was performed for each species separately, using a
159 maximum of eight mismatches to merge two stacks into a polymorphic locus within an
160 individual (*ustacks*) and between individuals (*cstacks*). Single-end catalog loci (*sstacks*) were
161 merged into single loci (*gstacks*) and SNP datasets included all biallelic variant positions
162 (*populations*).

163 SNPs were filtered using VCFtools v1.16 (Danecek et al., 2011), following a modified
164 approach of the one proposed by O’Leary et al. (2018). We removed SNPs with read coverage
165 $\leq 5X$ and mean read coverage among individuals $\leq 15X$. To minimize the amount of missing
166 data in final datasets ($< 15\%$), we discarded individuals with high percentage of missing data:
167 six for *B. aquilonaris*; thirteen for *C. tullia*; eighteen for *L. helle* (Supplementary Table S2). To
168 maximize the number of SNPs, we applied different filtering parameters for each species,
169 retaining SNPs with $< 30\%$ missing data for *C. tullia* and *L. helle*, and SNPs with $< 50\%$ missing
170 data for *B. aquilonaris*. Finally, we retained one random SNP per locus.

171

172 **2.5 Genetic diversity and population structure**

173 Population genetic structure and diversity analyses were performed after filtering the SNP
174 datasets for low frequency variants (minor allele frequency, $\text{MAF} \leq 1\%$). We first inferred
175 individual ancestry coefficients using the program ADMIXTURE v1.3 (Alexander et al., 2009).

176 The optimal number of K genetic clusters was determined based on the lowest error rate from
177 a 10-fold cross-validation (CVE). To evaluate the level of genetic differentiation between
178 sampling localities, we calculated pairwise F_{ST} using the *hierfstat* package v0.5-10 (Goudet,
179 2005) in R (R Core Team, 2022).

180 The *hierfstat* R package was also used to calculate population genetic diversity,
181 including observed heterozygosity (H_o), expected heterozygosity (H_e), inbreeding coefficient
182 (F_{IS}), and differentiation between a given locality and all the localities in the study area
183 (population-specific F_{ST}). For H_o , H_e and F_{IS} , 95% confidence intervals (CI95) were estimated
184 from 1,000 bootstraps of the data, and 100 bootstraps for the population-specific F_{ST} . Spatial
185 patterns of genetic diversity were inferred using the program EEMS (Petkova et al., 2016). We
186 computed genetic dissimilarities on a spatial grid of 600 demes for each species. The analysis
187 was repeated independently three times, with 4,000,000 MCMC iterations, a burn-in of
188 1,000,000 and a thinning interval of 10,000. The average posterior distributions of within-deme
189 genetic variability were represented on maps using the *rEEMSplots* R package (Petkova et al.,
190 2016).

191

192 **2.6 Climate niche models**

193 To determine the best climatic predictors of the distribution of each of the three species at the
194 European scale, we performed species distribution models (SDMs) using the *biomod2* R
195 package v4.2.2 (Thuiller et al., 2016). Species presences were extracted from the Global
196 Biodiversity Information Facility database (GBIF, 2022). We selected human observations after
197 1970 with coordinate precision < 5 km. We added the geo-reference of all our sampling
198 localities (Supplementary Table S1) and of local managers population monitoring data recorded
199 after 1970. In total, we obtained 11,432 occurrences for *B. aquilonaris*, 16,106 for *C. tullia* and
200 4,932 for *L. helle*. To reduce sampling bias, one occurrence was randomly selected within a

1 raster cell of 1 km (Fourcade et al., 2014), resulting in 2,944, 1,515 and 603 occurrences,
2 respectively. We selected six bioclimatic variables for 1970–2000 from the WorldClim
3 database v2.1 (2.5 arc-minutes; Fick and Hijmans, 2017) that were shown to be important
4
5 203 predictors for another co-distributed butterfly (Sherpa et al., 2022): mean annual temperature
6
7 204 (BIO1); mean diurnal range (BIO2); isothermality (BIO3); mean temperature of the wettest
8
9 205 quarter (BIO8); annual precipitation (BIO12); precipitation seasonality (BIO15).
10
11
12 206

13
14 207 SDMs included five statistical models: generalized linear (GLM), additive (GAM), and
15
16 208 boosting (GBM) models; maximum entropy (MAXENT); random forest (RF) (Araújo and
17
18 209 New, 2007; Marmion et al., 2009). A dataset of 10,000 random pseudo-absences was produced
19
20 210 using a surface range envelope model. Training data included 70% of the occurrences randomly
21
22 211 sampled, and the remaining 30% were used to evaluate model performance with two metrics:
23
24 212 the true skill statistic (TSS) and the area under the curve (AUC). We performed a three-fold
25
26 213 internal cross-validation, resulting in a total of 45 models that were merged using the weighted
27
28 214 sum of probabilities (EMwmeanByTSS) or the committee averaging (EMcaByTSS) methods.
29
30 215 For each bioclimatic variable, we calculated the importance of its contribution to the model (see
31
32 216 Thuiller et al., 2009) and variable importance was normalized to the model for comparison
33
34 217 among species.
35
36
37
38
39
40
41
42

43 219 **2.7 Demographic inferences**

44 220 Changes in effective population size (N_e) over time were inferred using the Stairway Plot
45
46 221 method v2 (Liu and Fu, 2020) based on the site frequency spectrum (SFS). The SFS was
47
48 222 calculated from all SNP positions (no filter on MAF) and imputed genotypes. Missing data was
49
50 223 imputed to the most likely genotype using the LEA R package v3.0.0 (*impute* function; Frichot
51
52 224 et al., 2014), and a number of ancestral populations corresponding to the number of
53
54 225 geographical areas: $N = 5$ for *B. aquilonaris* and *C. tullia*; $N = 8$ for *L. helle* (Supplementary
55
56
57
58
59
60
61
62
63
64
65

226 Table S1). We used a mutation rate of 2.10^{-9} based on previous studies in butterflies (Keightley
227 et al., 2015; Kebaili et al., 2022; Sherpa et al., 2022) and a generation time of one year, all
228 species being univoltine. The total sequence length accounted for both polymorphic and
229 monomorphic loci. Two-epoch models were built with 67% of segregating sites used for
230 training and break points following authors' recommendation. Median estimates of N_e and
231 CI_{95} were obtained from 200 bootstrap replicates. Stairway Plot analyses were carried out at:
232 (1) the population level based on population genetics results; (2) the species level including all
233 48 individuals for *B. aquilonaris* and down-sampling randomly the *C. tullia* and *L. helle*
234 datasets to the same sample size.

235 Divergence times between the three main geographical areas (HJ, DDV, and RUS) were
236 inferred using DIYABC v2.1.0 (Cornuet et al., 2014), using the SNP datasets of 48 individuals
237 filtered for $MAF \leq 1\%$. Two series of analyses determined the time period and mode of
238 divergence. The first analyses compared three scenarios of synchronous divergence: (1) during
239 an ancient decrease in N_e (Split-1D); (2) during a recent decrease in N_e (Split-2D); (3) during
240 an ancient increase in N_e (Split-Exp) (Supplementary Table S3). The second analyses
241 compared: (1) synchronous divergence times (Synch-Split); (2) an early divergence of RUS
242 followed by HJ and DDV (Asynch-Split1); (3) an early divergence of HJ followed by RUS and
243 DDV (Asynch-Split2) (Supplementary Table S3). We ran 100,000 simulations for each
244 scenario, using the mean genetic diversities within populations, F_{ST} and Nei's distances among
245 populations as summary statistics. The 1% of simulated data closest to the observed data were
246 used to calculate the posterior probabilities of scenarios (logistic regression) and the posterior
247 distribution of demographic parameters. Confidence in scenario choice (Type I and Type II
248 errors) was evaluated from 100 newly simulated datasets.

251 To characterize the changes in species potential distribution over time, we projected SDMs into
252 current climate (1970–2000) and eight palaeoclimates: Late Holocene (LatH: 0.3–4.2 kya); Mid
253 Holocene (MidH: 4.2–8.3 kya); Early Holocene (EarH: 8.3–11.7 kya); Younger Dryas Stadial
254 (YDS: 11.7–12.9 kya); Bølling-Allerød (BA: 12.9–14.7 kya); Heinrich Stadial 1 (HS: 14.7–
255 17.0 kya); Last Glacial Maximum (LGM: ca. 21 kya); Last Interglacial (LIG: ca. 130 kya).
256 Palaeoclimate data was retrieved from the PaleoClim database (2.5 arc-minutes; Brown et al.,
257 2018; Karger et al., 2020). Palaeoclimate projections were resampled to a 1×1 km resolution,
258 using the k-nearest neighbors method in QGIS v3.22.3 (QGIS Development Team, 2022).

259 The availability of suitable habitats at each of the nine time periods was characterized
260 by two metrics. First, we calculated the average predicted probability of presence (pp) across
261 all cells (hereinafter habitat quality). Second, we used the pp threshold that maximizes the TSS
262 score (ppTSS) for each species model and calculated the total area with predicted presence: pp
263 > ppTSS (hereinafter habitat quantity). These two metrics were calculated at the European scale
264 as well as at the scale of the Jura massif, by working on the geographic subset of SDM
265 projections corresponding to the massif. Raster manipulation and indices were calculated using
266 QGIS. To evaluate the impact of past climate fluctuations on the species demography history,
267 we combined our results of climate niche and demographic models. We tested the relationship
268 between changes in habitat quality and habitat quantity over time, and changes in Ne over time.
269 For a given time period, the Ne corresponded to the mean of the inferred median Ne in this
270 period based on species demographic history (all populations combined) using the Stairway
271 Plot method. The relationships between Ne and habitat metrics, both at European and Jura
272 massif scales, were tested using Spearman correlations in R.

274 **3. Results**

275 **3.1 Genetic datasets**

276 We obtained an average of 0.46 ± 0.28 (SD; standard deviation) million reads per individual
277 for *B. aquilonaris* (Ba), 0.56 ± 0.46 million reads for *C. tullia* (Ct) and 0.78 ± 0.79 million reads
278 for *L. helle* (Lh) after quality filtering (Supplementary Table S2). After dropping individuals
279 with a high proportion of missing data, the final sample sizes (N) for the three species were N_{Ba}
280 = 48, $N_{Ct} = 87$ and $N_{Lh} = 218$. After applying the missing data and physical linkage filters, the
281 number of loci was 380 for *B. aquilonaris*, 1,305 for *C. tullia* and 1,569 for *L. helle*, which were
282 used for Stairway Plot analyses. After filtering for low frequency variants, the datasets included
283 380 SNPs for *B. aquilonaris*, 1,293 SNPs for *C. tullia* and 1,455 SNPs for *L. helle*, which were
284 used for population structure and diversity analyses, and divergence time estimations
285 (DIYABC). The average percentage of missing data among individuals per locus was $10.76 \pm$
286 7.97 for *B. aquilonaris*, 12.44 ± 8.85 for *C. tullia* and 11.78 ± 7.77 for *L. helle* (Supplementary
287 Table S2).

3.2 Population genetic structure and diversity

290 The level of population differentiation in the Jura massif varied among species. The optimal
291 number of genetic clusters from ADMIXTURE analysis was $K = 1$ for *B. aquilonaris* and *C.*
292 *tullia*, and $K = 3$ for *L. helle* (Supplementary Figure S1). Investigating higher values of K did
293 not reveal a clear geographic structuring for *B. aquilonaris* (Figure 3; Supplementary Figure
294 S2). For $K = 3$ genetic groups, the two southern localities of the HJ region (mainly dark red
295 cluster) differentiated from the four northern localities of the RUS region (mainly orange
296 cluster). However, most localities showed a high number of admixed individuals. For *C. tullia*,
297 all localities in the RUS region showed genetic differentiation with those of the HJ and DDV
298 regions for $K = 2$, and these two last regions were further separated for $K = 3$ (Figure 3;
299 Supplementary Figure S3). For *L. helle*, the optimal number of $K = 3$ groups revealed
300 population structure largely corresponding to the three geographical regions but with substantial

1 admixture (Figure 3; Supplementary Figure S4). Increasing K up to 6 further separated localities
2 from the HJ and DDV regions according to their geography, with three areas in HJ: southern
3 HJ, Northern HJ and Grandvaux-Malvaux; two areas in DDV: Haut-Doubs and Dugeon basin
4
5 303 HJ, Northern HJ and Grandvaux-Malvaux; two areas in DDV: Haut-Doubs and Dugeon basin
6
7 304 (Figure 3; Supplementary Table S1).

8
9 305 The three regions exhibited different spatial patterns of genetic diversity. The HJ region
10 was the less genetically diversified in all the three species, and the RUS region had the highest
11 diversity for *B. aquilonaris* and *C. tullia* but it was the DDV region for *L. helle* (Figure 2A;
12 306 Table1). In accordance, significant spatial genetic dissimilarities were detected for *B.*
13
14 307 *aquilonaris* and *C. tullia*, with a decreasing gradient of diversity from North to South, whereas
15
16 308 *L. helle* rather showed a diverse population in the center of the study area and a reduction of
17
18 309 diversity at extreme North and South localities (Figure 2B).

20
21 310
22
23 311
24
25 312 For most regions, the distribution of heterozygosity (observed, H_o ; expected, H_e) was
26
27 313 bimodal, indicating two groups of localities: a group with a high genetic diversity and a group
28
29 314 with a lower genetic diversity (Figure 2A). This pattern is typical of a metapopulation system,
30
31 315 with some well-connected and highly diversified localities corresponding to the core (or source)
32
33 316 population, and more isolated (sink) populations suffering from drift and genetic erosion.
34
35 317 Accordingly, population-specific F_{ST} were significantly positive (indicative of the effect of
36
37 318 genetic drift) for all localities in all regions but lower in the most diverse regions for *C. tullia*
38
39 319 (RUS) and for *L. helle* (DDV) (Table 1). Another indication of a dynamic, non-equilibrium,
40
41 320 metapopulation functioning in the three species is the significantly positive inbreeding
42
43 321 coefficient F_{IS} observed in all localities, which is especially high in *C. tullia* (Table 1). The
44
45 322 average pairwise F_{ST} among localities within regions revealed spatial variation in the level of
46
47 323 population differentiation. In *B. aquilonaris*, the most diversified RUS region showed the
48
49 324 lowest genetic differentiation among localities ($F_{ST} = 0.085 \pm 0.05$) compared to differentiation
50
51 325 within HJ ($F_{ST} = 0.227 \pm 0.04$) and within DDV ($F_{ST} = 0.199 \pm 0.03$) (Supplementary Table

326 S5). For the two other species, the localities within the DDV region were the less differentiated,
327 with an average pairwise $F_{ST} = 0.067 \pm 0.04$ compared to the HJ ($F_{ST} = 0.111 \pm 0.07$) and RUS
328 ($F_{ST} = 0.116 \pm 0.06$) regions in *C. tullia* and $F_{ST} = 0.048 \pm 0.04$ compared to the HJ ($F_{ST} = 0.116$
329 ± 0.06) and RUS ($F_{ST} = 0.096 \pm 0.08$) in *L. helle* (Supplementary Tables S6 and S7).

331 **3.3 Species demographic history**

332 The demographic history of populations in the Jura massif revealed consistent patterns among
333 the three regions and for the three species (Supplementary Figure S5). Given the
334 metapopulation functioning of each species suggested by population structure and diversity
335 analyses, we inferred the changes in effective population size (N_e) over time at the species level
336 including individuals from all the three regions (Figure 4A). Two species (*C. tullia* and *L. helle*)
337 showed an ancient demographic expansion, with an increase in N_e between 1 Mya and 200 kya.
338 All species showed a relatively recent decrease in N_e , which started during the last glacial
339 period (approximately 25 kya) for *B. aquilonaris* and *L. helle*, and more recently (6 kya) for *C.*
340 *tullia*.

341 The three species showed similar time and mode of divergence between regions in the
342 Jura massif (Figure 4B). For the first DIYABC analysis testing the period of divergence (ancient
343 vs. recent), the most likely scenario was a recent split between the HJ, RUS and DDV regions
344 (scenario Split-2D; Table 2). For the second DIYABC analysis testing the mode of divergence
345 (synchronous vs. asynchronous), the most likely scenario was a first divergence of the RUS
346 region, followed by the divergence between the southern regions DDV and HJ (scenario
347 Asynch-Split2; Table 2). The first population split (S1) occurred during Mid Holocene (7.0
348 kya) for *C. tullia* and *L. helle* and more recently during Late Holocene (2.1 kya) for *B.*
349 *aquilonaris* (Figures 4C; Supplementary Table S8). The second split (S2) was estimated during
350 the Late Holocene, approximately 1.4 kya, 0.8 kya and 2.6 kya for *B. aquilonaris*, *C. tullia* and

351 *L. helle*, respectively. While the S1 split is subsequent to the ancient decrease (D1) in N_e in the
352 ancestral populations (no overlap between S1 and D1), the S2 split occurred at the same time
353 as the more recent decrease (D2) in N_e (overlap between S2, D2R and D2HD).

3.4 Species current climate distribution

354
355
356 Species distribution model (SDM) evaluation statistics revealed a good performance of all
357 models on average for *B. aquilonaris* (TSS = 0.72; AUC = 0.94), *C. tullia* (TSS = 0.85; AUC
358 = 0.98) and *L. helle* (TSS = 0.82; AUC = 0.97). The main climatic predictor of the current
359 distribution of the three species was the mean annual temperature (BIO1; > 40%, Table 3). At
360 the European scale, the thermal niche of the three species was extremely narrow and at their
361 highest limit in the Jura massif (Table 3), *L. helle* being the most narrow-range and thermophilic
362 species with a BIO1 range excluding negative temperatures. Isothermality (BIO3) and
363 precipitation seasonality (BIO15) were also two important predictors of the three species
364 distribution, while total annual precipitation (BIO12) was the least important predictor. SDMs
365 further revealed differences in climatic preferences between the three species. Temperature of
366 the wettest quarter (BIO8) was important only for *B. aquilonaris* and *C. tullia*, and diurnal range
367 (BIO2) only for *C. tullia* (Table 3).

368 SDM projections under current climate conditions revealed the largest predicted
369 distribution in Western Europe for *B. aquilonaris* (1,426,977 km²), mainly in Scandinavia
370 (Figure 5A). Its southern potential distribution was more fragmented on plateaus and mountains
371 including very isolated patches. The two other species had a more restricted distribution.
372 Climatically suitable areas for *C. tullia* (581,681 km²) were mainly located in Northern Europe,
373 the UK, as well as few patches in the Alps and the Jura massif (Figure 5B). The last species *L.*
374 *helle* (325,135 km²) had the smallest Scandinavian distribution, but encountered suitable areas
375 in most of southern mountain ranges (Figure 5C). In the Jura massif, *B. aquilonaris* and *L. helle*

376 had similar predicted distributions composed of a large suitable area in high altitudes (> 900
377 masl), with a potential distribution range of 8,418 km² and 7,466 km², respectively (Figures 5D
378 and 5E). The predicted distribution range of *C. tullia* was reduced to 2,106 km² at altitudes
379 <900m (Figure 5F).

380

381 **3.5 Species past climate distribution**

382 SDM projections under the eight paleoclimates revealed similar responses among the three
383 species at the European scale (Figure 6A; Supplementary Figures S6 to S8). During the LIG,
384 the distribution of climatically suitable areas included northern Europe and mountain chains,
385 with a larger predicted distribution for *C. tullia* and *B. aquilonaris* than for *L. helle*. During the
386 LGM, the projected distributions predicted an increase in habitat quantity for all species
387 compared to LIG, but an increase in habitat quality only for *B. aquilonaris* and *L. helle*. This
388 predicted geographic expansion was associated with a cooling of the climate and high values
389 of isothermality overlapping well the species temperature requirements (Figure 6A). After the
390 LGM, the quantity of habitats strongly decreased for all species, especially for *C. tullia* and *L.*
391 *helle* whereas suitable habitats for *B. aquilonaris* were more abundant. Predicted habitat quality
392 and quantity slightly increased since the late Holocene.

393 The changes in the quality and the quantity of habitats over time in the Jura massif were
394 completely different from those observed at the European scale, with a decrease between LIG
395 and HS similarly for the three species when the ice sheet covered a large area (Figure 6B). The
396 changes in the distribution of climatically suitable areas over time were relatively similar for *B.*
397 *aquilonaris* and *L. helle* (Figures 5D and 5F). During the LGM, the South of the Jura massif
398 was covered by ice, which restricted the suitable areas for *B. aquilonaris* and *L. helle* in
399 lowlands to the North of the massif. This LGM reduction of the distribution range was even
400 more dramatic for *C. tullia*, with suitable areas only in the West of the massif (Figure 5E). Since

401 the HS period, the warming of the climate and ice retreat created new suitable habitats for *B.*
402 *aquilonaris* and *L. helle*, which remained nearly constant until present days (Figures 5D, 5F
403 and 6A). However, the projected distributions suggested an absence of suitable habitats for *C.*
404 *tullia* in the Jura from the HS until the Mid Holocene (Figures 5E and 6A).

405 406 **3.6 Effect of past climate changes on species demographic history**

407 Our assessment of the impact of past climate fluctuations on the effective population size of
408 peatland butterflies currently found in the Jura massif revealed two contrasting patterns between
409 habitat quantity and quality. All the Spearman correlation tests between changes in the quantity
410 of suitable habitats and N_e over time were non-significant for *B. aquilonaris* (Europe: $\rho = 0.58$,
411 $P = 0.108$; Jura: $\rho = -0.23$, $P = 0.552$), for *C. tullia* (Europe: $\rho = 0.17$, $P = 0.678$; Jura: $\rho = -0.12$,
412 $P = 0.764$) and *L. helle* (Europe: $\rho = 0.60$, $P = 0.097$; Jura: $\rho = 0.09$, $P = 0.814$). Although not
413 all significant, we found positive relationships between changes in habitat quality and N_e over
414 time at the European scale (*B. aquilonaris*: $\rho = 0.62$, $P = 0.076$; *C. tullia*: $\rho = 0.63$, $p = 0.068$;
415 *L. helle*: $\rho = 0.71$, $P = 0.033$) but not in the Jura massif (*B. aquilonaris*: $\rho = -0.02$, $P = 0.982$; *C.*
416 *tullia*: $\rho = -0.04$, $p = 931$; *L. helle*: $\rho = -0.15$, $P = 0.708$). The decrease in mean temperatures
417 and increase in isothermality coincided with a reduction in N_e by 1.6 for the three species
418 (Figures 4 and 6). Climatically suitable areas remained nearly stable (*B. aquilonaris*) or slightly
419 increased (*C. tullia* and *L. helle*) between the end of the Holocene and current days (Figure 6).
420 However, in the same period, N_e changes revealed dramatic population declines for *B.*
421 *aquilonaris* (decrease factor ~ 47) and *C. tullia* (decrease factor ~ 83), and a decline of lower
422 amplitude in *L. helle* (decrease factor ~ 3).

423 424 **4. Discussion**

425 **4.1 Same past history but different metapopulation functioning**

426 The reconstructions of species demographic history show a common pattern of recent post-
427 glacial population decline and fragmentation among the three species. Despite the ice covered
428 most of their current range during the LGM, and habitat quality and quantity strongly varied at
429 the Europe and Jura scales from the LIG to the Mid-Holocene (~6 kya), the effective population
430 size remained nearly constant or only moderately decreased (by 1.6-fold) over this period
431 (Figure 4). This suggests that the local populations have been able to track their thermal niche
432 over time, probably by moving northward or upslope with glacier retreat (Figure 6;
433 Supplementary Figures S6 to S8). Yet, our assessment of the effect of past climate changes on
434 species demographic history revealed a positive relationship between the changes in habitat
435 quality and the changes in effective population size over time at the European scale, which
436 support a global-scale relationship between climate suitability and population size
437 (Chattopadhyay et al., 2019). After the LGM, glacier retreat opened new habitats in northern
438 Europe while the potential distribution of the three species progressively fragmented into small
439 mountain areas in the South.

440 The Jura massif corresponds to one of the small areas at the warm range margin (Figures
441 5 and 6). Contrary to the general warming in many areas of Europe, the temperature continued
442 to decrease in the Jura massif until 14–17 kya (Figure 5 and 6). During the LGM, the northern
443 part of the massif was free of ice, with highly favorable habitats restricted to the margin of the
444 ice sheet (Figure 5; Lhosmot et al., 2022). However, these habitats rapidly became less
445 favorable for the presence of the three species, which might have partly moved their distribution
446 further West. The lack of relationship between climate suitability and population size at the
447 scale of the Jura massif supports the hypothesis that local populations shifted their distribution
448 to track suitable habitats while maintaining nearly constant population size. Since 13–14 kya,
449 the warming created new and more suitable habitats in the Jura massif for *B. aquilonaris* and
450 *L. helle*, whereas habitat quantity and quality remained low elsewhere in Europe (Figure 6).

451 This result suggests that the Jura massif has provided a climatic refuge for these two species,
452 but not for *C. tullia*, as habitat quality and quantity remained low until 6 kya. The North-to-
453 South gradient of decreasing genetic diversity observed for *B. aquilonaris* and *C. tullia*, together
454 with a more ancient divergence of populations in the northern region of the massif (RUS)
455 common to all species, support a progressive re-colonization of the Jura massif from the
456 northern deglaciated area. This confirms the position of the North of the Jura massif as a glacial
457 refuge for boreo-montane butterflies (Sherpa et al., 2022). Finally, during the Holocene, we
458 found an increase in habitat quality and quantity for all species, probably linked to the formation
459 of peatlands in parallel with the progressive retreat of the Jura glaciers (from 5.8 to 12.9 kya;
460 Gauthier et al., 2019; Lhosmot et al 2022). However, the three species kept declining during
461 this period (Figures 4 and 6), which could reflect the influence of micro-climatic conditions and
462 land uses by humans rather than global climate in recent times (Settele et al., 2008; Noreika et
463 al., 2016).

464 The spatial distribution of genetic diversity reveals different metapopulation source-sink
465 dynamics between species (Figure 2; Table 1; Supplementary Table S4). Contrary to *B.*
466 *aquilonaris* and *C. tullia* (diverse pool in the North), the most diverse populations of *L. helle*
467 are currently found in the central region of the massif (DDV; see also Habel et al., 2010), while
468 the relictual northern populations are experiencing genetic erosion. Furthermore, populations
469 of *C. tullia* and *L. helle* in this central region show high genetic connectivity, suggesting that
470 the core of the metapopulation is shifting from RUS to DDV, which is confirmed by genetic
471 differentiation indices (F_{ST}) (Supplementary Table S6 and S8) and field estimates of population
472 density (Duflo et al., 2017). Most populations are not at drift-migration equilibrium (positive
473 population-specific F_{ST} and F_{IS}). As the three species are short dispersers (Baguette, 2003;
474 Gorbach, 2011; Turlure et al., 2014; Wainwright, 2005), small changes in the level of
475 population connectivity can break down the metapopulation functioning, by reducing the

476 colonization probability of empty patches of habitat, and by increasing the extinction risk in
477 highly isolated patches through genetic drift and inbreeding depression (Hansson, 1991; Hess,
478 1996; Gaggiotti, 2003; Perry and Lee, 2019).

480 **4.2 Close climatic niches but species-specific requirements**

481 Species climate niche models reveal that the presence of *B. aquilonaris*, *C. tullia* and *L. helle*
482 is determined by the same bioclimatic predictors, which can be explained by their common
483 habitat requirements. These cold-adapted butterflies all live in cold and humid habitats, such as
484 bogs, mires or their margins (Turlure et al., 2010; Habel et al., 2011; Weking et al., 2013).
485 Accordingly, two common predictors of their geographic distribution include a low mean
486 annual temperature (BIO1 < 11°C) and a weak to moderate temperature variability within an
487 average month relative to the year (BIO3). Over their life cycle, the three species need a range
488 of temperatures compatible with (1) the maintenance of soil water saturation for larval
489 development, in relation to the ecology of their host-plants that grow on waterlogged soils
490 (Čelik and Vreš, 2018; Goffart et al., 2014; Price et al., 1998; Schweingruber et al., 2020;
491 Turlure et al., 2010), and (2) imagos thermoregulation activities during the flight period,
492 essential for reproduction success (Kingsolver, 1983; Saastamoinen and Hanski, 2008). They
493 are also equally constrained to areas with even precipitations throughout the year (BIO15),
494 required to maintain the hydrological quality of their habitat (Čelik and Vreš, 2018; Goffart et
495 al., 2014; Turlure et al., 2013).

496 Each species occupies a slightly distinct climatic niche despite large overlap in
497 temperature (70%) and precipitation seasonality (90%) ranges. For instance, mean temperature
498 of the wettest quarter (BIO8) was the third relevant predictor for the presence of *B. aquilonaris*
499 and *C. tullia*. However, their niche is quite different (only ~40% of overlap) as *B. aquilonaris*
500 tolerates more negative temperatures than *C. tullia* (Table 3), which can be explained by

40
501 differences in their biology and ecology. *B. aquilonaris* overwintering 1st instar caterpillars are
502 buffered from negative temperature inside *Sphagnum* hummocks (Turlure et al., 2010; Turlure
503 et al., 2013). In contrast, during flooding events, 3rd instar *C. tullia* caterpillars must actively
504 climb up the stem of the host-plant (Joy and Pullin, 1997; Joy and Pullin, 1999), which requires
505 temperature warm enough. The climatic niche of *C. tullia* also appears to be more constrained
506 than the two other species, as five of the six variables used in SDMs contribute to its predicted
507 distribution by more than 10% (Table 3). The geographic distribution of *C. tullia* excludes
508 elevated areas (> 1,000 masl), where the mean diurnal temperature range is too high (BIO2 >
509 6°C). By contrast, *L. helle* overwinters as a pupa, with no less than 300 days spent at this stage.
510 Pupal stage microclimatic requirements are not well known (Turlure et al., 2014) but our results
511 suggest that it needs to be shielded from frost (Table 3). Such conditions are found under the
512 vegetation litter where the last stage caterpillar shelters to pupate (Fisher et al., 2014). Out of
513 the three species, *L. helle* is the most thermophilic (BIO1 > 0°C) and the less dependent on soil
514 water saturation as its host-plant, *B. officinalis*, is widely distributed. Our demographic
515 inferences also suggest that this species is the less vulnerable to habitat degradation and climate
516 change, as its population has experienced much more limited decline as compared to the two
517 other species.

The Jura massif constituted a thermal refuge for the three butterfly species during the
last glacial cycle and continues in the current context of global warming. The massif included
suitable areas for *B. aquilonaris* and *L. helle* over time since the LIG, suggesting they have
persisted locally throughout the last glacial cycle (Figure 5). However, for *C. tullia*, local
conditions were unfavorable from 17,0 to 4,2 kya (Figure 6). This species is currently found in
the massif in fenlands mainly composed of *Carex spp.*, that are more abundant in warmer
peatlands than in cold ombrotrophic bogs characterized by plant community dominated by
Sphagnum spp. (Dieleman et al., 2015). The formation of fenlands, which requires sufficiently

526 high temperature, were probably not encountered locally until the Mid-Holocene in the Jura
527 massif, explaining that local conditions were unfavorable for *C. tullia*. Although the three
528 species probably responded to Pleistocene climatic events by shifting their distribution, the
529 improvement of climate conditions over the past 4,000 years in the Jura massif, and the
530 associated increase in habitat availability, did not slow down the prolonged and ongoing decline
531 of populations. Furthermore, they currently occupy habitats in which temperature conditions
532 correspond to the upper limits of their respective thermal niches. Together, these results suggest
533 that boreo-montane species are somehow trapped in isolated areas (south margin) and in their
534 specific habitat (fragmented patches) (see also Sherpa et al., 2022). This implies that species
535 might not be able to respond to future climate change, especially for dispersal-limited and
536 habitat specialist species (Habel et al., 2023), and that further habitat degradation threaten the
537 persistence of populations.

539 **4.3 Conservation implications**

540 The three species under study are not equally vulnerable to climate change. Based on population
541 genomics analyses and ecological models, *C. tullia* appears to be more affected than *B.*
542 *aquilonaris* and *L. helle*. Interestingly, their conservation status at the European scale ranks
543 differently, in accordance to their predicted range in Europe: *L. helle* is classified by the IUCN
544 (<https://www.iucnredlist.org>) as endangered (EN), *C. tullia* as vulnerable (VU) while *B.*
545 *aquilonaris* is of least concern (LC). As one of the last areas sheltering *B. aquilonaris*, *C. tullia*
546 and *L. helle* in South-Western Europe, the French Jura region is of priority concern. All species
547 are currently experiencing a dramatic decline in this region, which justifies the integration of
548 management measures into the national and regional action plans for their conservation (Houard
549 and Jaulin, 2018; Jacquot et al., 2022).

550 Species conservation relies on two main axes: the restoration/improvement of habitat
1
2 551 buffering against climate change and of landscape connectivity to ensure a dynamic
3
4 552 metapopulation functioning (Bennett et al., 2021). In this context, the present multi-taxa study
5
6
7 553 represents a major step towards a better knowledge on the evolutionary history, species-specific
8
9 554 ecological requirements, and local dynamics of populations. The genetic erosion and
10
11
12 555 geographic isolation of populations in the Jura massif make them particularly vulnerable to
13
14 556 ongoing climate change. For instance, the karstic nature of the massif ground makes it more
15
16
17 557 sensitive to droughts (Bidault et al., 1990). The repetition of dry summers these last years could
18
19 558 strongly affect the hydrological equilibrium of the species habitats, and the vegetation structures
20
21
22 559 protecting them from extreme temperatures during summer and winter. In addition to climate
23
24 560 conditions, human activities and infrastructures development are other drivers of population
25
26
27 561 trends, as peat cutting, the modification of waterbeds, and the installation of drainage systems
28
29 562 to develop agriculture in the massif, which disturb bogs hydrological functioning and peat
30
31
32 563 ecosystems (Gauthier et al., 2019). Indeed, the degradation of wetlands is well documented
33
34 564 throughout Europe, due to increased global demand for land and water, pollution, and climate
35
36
37 565 change. Their role as biodiversity hotspots and their contribution for many ecosystem services,
38
39 566 such as carbon sequestration and climate change adaptation, stress an urgent need to protect
40
41
42 567 and restore these fragile ecosystems (Kimmel and Mander, 2010; Joosten, 2015; Cartwright,
43
44 568 2019). Measures impeding global warming effects on the hydrological functioning of species
45
46 569 habitat are essential, especially with the accumulation of drought events. Concrete solutions
47
48
49 570 include avoidance of additional water withdrawals in peatlands by obliteration of drainage
50
51 571 ditches and restoration of historical streambeds.

53 572 Our study, combining population genomics analyses and species distribution modeling,
54
55
56 573 confirms the power of these approaches to provide valuable regional-scale recommendations
57
58 574 for protecting species (Forester et al., 2013; Supple and Shapiro, 2018). First, genomics (as
59
60
61
62
63
64
65

1 575 opposed to genetics based on a few markers) is particularly precious in conservation biology
2 576 that focuses on endangered species with low population sizes, because it allows low local
3
4 577 sampling size. The low number of individuals collected per locality is compensated by the high
5
6
7 578 number of loci genotyped: instead of averaging heterozygosity across individuals for a few
8
9 579 markers to estimate genetic diversity, heterozygosity is averaged across loci, which allows a
10
11 580 more precise (lower variance) estimation of local genetic diversity, even when only few
12
13 581 individuals are sampled (Nazareno et al., 2017; Després et al., 2019). Contrary to global genetic
14
15 582 parameters, the estimation of effective population size requires larger sample sizes, especially
16
17 583 for recent demographic events (Robinson et al., 2014; Nunziata and Weisrock, 2018;
18
19 584 McLaughlin and Winker, 2020). For this purpose, we considered the species-level (96 gene
20
21 585 copies) estimates of site frequency spectrum to infer demographic dynamics, but we also show
22
23 586 that robust inference can be obtained with smaller sample sizes (Figure S5). Second, we identify
24
25 587 several groups of isolated populations suffering from drift and genetic erosion in the Jura
26
27 588 massif, especially in the southernmost region where populations might be more vulnerable to
28
29 589 extinction. Because the northernmost region harbors the highest population diversity for two of
30
31 590 the studied species, conservation actions may focus on habitat restoration to maintain these
32
33 591 diverse gene pools, and on improving landscape connectivity to allow migration to southern
34
35 592 recipients. More precise management recommendations may arise from a fine scale study to
36
37 593 identify functional ecological corridors (i.e., landscape factors that favor gene flow) and new
38
39 594 or former suitable habitat patches for future colonization, which can guide population
40
41 595 management (Savary et al., 2021; Osborne et al., 2022), especially improving landscape
42
43 596 connectivity to promote the natural movement of species, which can be combined with the
44
45 597 reinforcement or reintroduction of populations via assisted migration (Andersen et al., 2014;
46
47 598 Descimon and Bachelard, 2014).

600 **5. Conclusions**

1
2 601 The use of genomics in conservation is still limited and usually tackles single species, which is
3
4
5 602 only part of larger conservation activities aiming to restore and conserve entire habitats
6
7 603 (Suchácková Bartonová et al., 2023). The analyses of population genomes and species
8
9 604 distributions are powerful tools to better understand the genomic and demographic
10
11
12 605 consequences of climate changes over time and to inform conservation decisions. By
13
14 606 integrating the output of both approaches, our study sheds light not only on the current
15
16
17 607 population dynamics, but also on the species abilities to respond to past climate changes, and
18
19 608 therefore on their vulnerability to ongoing climate change. Furthermore, we determine that
20
21 609 multiple co-distributed species have a shared demographic and biogeographic history, due to
22
23
24 610 similar habitat and climate niche, and recolonization history. Such knowledge is essential to
25
26
27 611 better predict community-scale responses to climate warming, and to implement conservation
28
29 612 actions that can benefit multiple species. Nonetheless, we also found idiosyncratic responses to
30
31 613 habitat fragmentation at the local scale, which might be explained by specific species traits and
32
33
34 614 distinct metapopulation dynamics. This allows identifying the species that might be more
35
36 615 vulnerable to extinction and areas that might act as diversity reservoirs. Incorporating our
37
38
39 616 comparative approach with time series genomic data (Díez-del-Molino et al., 2018; Clark et al.,
40
41 617 2023) can further help evaluating the effect of management practices on population connectivity
42
43 618 and effective size over time, and/or identify source/sink populations for future reintroduction
44
45
46 619 or reinforcement actions.

Data accessibility

The ddRAD sequences (fastq) are available at the European Nucleotide Archive repository (<http://www.ebi.ac.uk/ena>) and accessible under study accession numbers PRJEB65448. The SNP datasets are available at Dryad Digital Repository (DOI: 10.5061/dryad.pk0p2ngt1). In accordance with the French regulation regarding protected species (article L.124-4 of the environment code), the precision of coordinates of the localities sampled in the Jura massif was degraded to 10 × 10 km uncertainty but are available from authors upon request. The GBIF occurrence datasets are available at <https://doi.org/10.15468/dl.3gc8xu> (*C. tullia*), <https://doi.org/10.15468/dl.cjnunz> (*B. aquilonaris*) and <https://doi.org/10.15468/dl.tbwmfm> (*L. helle*).

Figures and figure captions

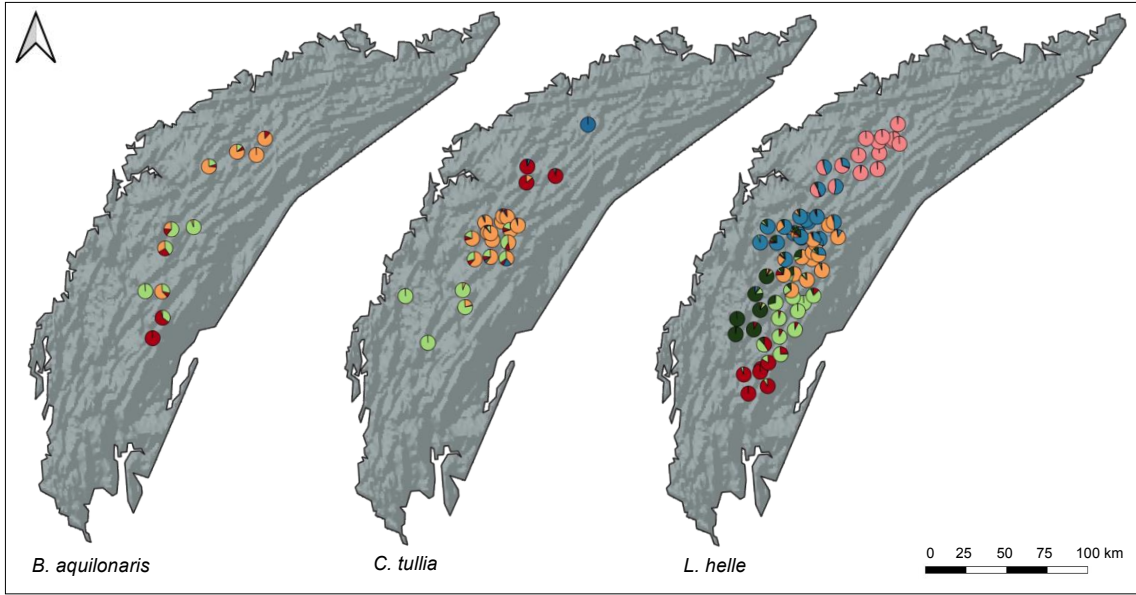

947 **Figure 1. Study area and location of sample sites for the three species.** The top left map
948 shows the context of the study area, locating the Jura massif on the border between France (FR)
949 and Switzerland (CH). The enlarged map shows the Jura massif with the three main study
950 regions (HJ; RUS; DDV) in different transparent fill colors. Symbol shape and colors represent
951 the location of sample sites for each species. Photos credits: *B. aquilonaris*, Frédéric Mora; *C.*
952 *tullia*, Mathilde Poussin; *L. helle*, Pierre Durllet.

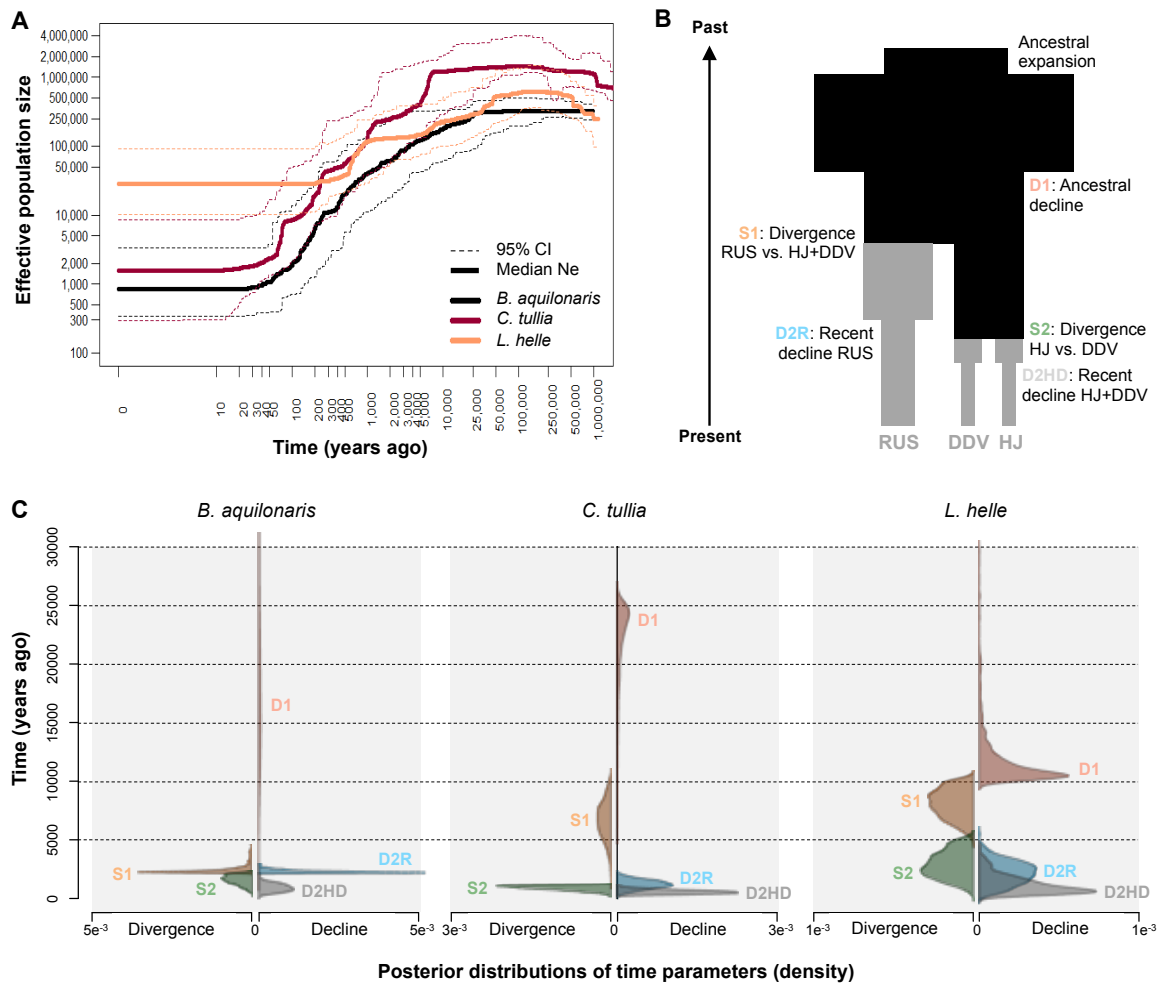

953 **Figure 2. Spatial patterns in genetic diversity.** A) Density and distribution of observed (H_o)
 954 and expected (H_e) heterozygosity (scaled and centered separately for each species) among the
 955 three regions, from North (RUS) to South (HJ). B) EEMS contour plots of the average posterior
 956 distribution of diversity rates q (\log_{10} scale). Darker font colors show significantly high (blue)
 957 or low (brown) within-deme genetic dissimilarities.

968 **Figure 5. Changes in species potential distribution over time in the Jura massif.** Species
 969 potential distribution at the European scale based on six bioclim variables (BIO1, BIO2, BIO3,
 970 BIO8, BIO12, BIO15) under current conditions for A) *B. aquilonaris* B) *C. tullia* and C) *L.*
 971 *helle*. Predicted distributions under current climate (Cur) and palaeoclimates in the Jura massif
 972 (predicted distributions at the European scale are in Supplementary Figures S6 to S8) for D) *B.*
 973 *aquilonaris* E) *C. tullia* and F) *L. helle*. Paleoclimates (in kya): Late Holocene (LatH); Mid
 974 Holocen (MidH); Early Holocene (EarH); Younger Dryas Stadial (YDS); Bølling-Allerød
 975 (BA); Heinrich Stadial 1 (HS); Last Glacial Maximum (LGM); Last Interglacial (LIG).

976 **Figure 6. Changes in climate suitability over time in (A) Europe and (B) the Jura massif.**

977 From top to bottom: changes in habitat quantity (full line), in habitat quality (dashed line), and
 978 in climate conditions for the two temperature variables important for the current distribution of
 979 species: mean annual temperature (BIO1) and isothermality (BIO3) over the nine time periods
 980 considered. Cur: 1970–2000; LatH: 0.3–4.2 kya; MidH: 4.2–8.3 kya; EarH: 8.3–11.7 kya; YDS:
 981 11.7–12.9 kya; BA: 12.9–14.7 kya; HS: 14.7–17.0 kya; LGM: 21 kya; LIG: 130 kya.

Tables

Table 1. Regional genetic diversity. Regions: Haut-Jura (HJ); Doubs-Druegeon valleys (DDV); plateau of Russey (RUS); and their sample sizes (N). Diversity indices: observed heterozygosity (Ho); expected heterozygosity (He); inbreeding coefficient (F_{IS}); population-specific differentiation (F_{ST}). 95% confidence intervals (CIs) based on bootstraps of the data.

Species	Region	N	Ho		He		F _{IS}		F _{ST}	
			value	95% CI	value	95% CI	value	95% CI	value	95% CI

5 **Table 2. Identification of the best divergence scenarios between regions for each species.** Analysis 1 tested the period (ancient vs. recent) and
6 the mode (during increase vs. decrease in N_e) of divergence; all synchronous. Analysis 2 tested the simultaneous divergence of the three populations
7 or whether one population diverged first. Prior and posterior distributions of parameters are in supplementary Tables S3 and S5, respectively, and
8 schematic representation of split times and sequence in Figure 4B.

Analysis 1. Period and factor of divergence						
Species	Split-Exp	Split-1D	Split-2D	Best scenario	Type I error	Type II error
<i>B. aquilonaris</i>	no tested	0.000 [0.000-0.000]	1.000 [1.000-1.000]	Recent split / Decline	0.05	0.05
<i>C. tulla</i>	0.000 [0.000-0.000]	0.005 [0.001-0.009]	0.999 [0.999-1.000]	Recent split / Decline	0.04	0.00 / 0.04
<i>L. helle</i>	0.000 [0.000-0.000]	0.000 [0.000-0.001]	0.999 [0.999-1.000]	Recent split / Decline	0.06	0.00 / 0.06
Analysis 2. Divergence sequence						
Species	Synch-Split	Asynch-Split1	Asynch-Split2	Best scenario	Type I error	Type II error
<i>B. aquilonaris</i>	0.000 [0.000-0.000]	0.001 [0.000-0.002]	0.999 [0.998-0.999]	Asynchronous / RUS first	0.03	0.02 / 0.01
<i>C. tulla</i>	0.001 [0.000-0.001]	0.000 [0.000-0.001]	0.999 [0.999-1.000]	Asynchronous / RUS first	0.08	0.08 / 0.00
<i>L. helle</i>	0.001 [0.000-0.001]	0.000 [0.000-0.001]	0.999 [0.999-1.000]	Asynchronous / RUS first	0.12	0.11 / 0.01

9 **Table 3. Species climatic requirements.** For each of the six bioclimate variables included in SDMs, the range is given for any variable having a
10 relative importance >10% and represents the range observed in predicted areas with high presence probability of the species (pp > ppTSS) at the
11 European scale and in the Jura massif. BIO1: Mean annual temperature; BIO2: Mean diurnal range; BIO3: isothermality; BIO8: mean temperature
12 of the wettest quarter; BIO12: annual precipitation; BIO15: precipitation seasonality.

Bioclimate variable	Relative importance			Range of variable			Western Europe			Jura massif
