Abstract Single photons detected by the DELPHI experiment at LEP2 in the years 1997–2000 are reanalysed to investigate the existence of a single extra dimension in a modified ADD scenario with slightly warped large extra dimensions. The data collected at centre-of-mass energies between 180 and 209 GeV for an integrated luminosity of $\sim$650 pb^{-1} agree with the predictions of the Standard Model and allow a limit to be set on graviton emission in one large extra dimension. The limit obtained on the fundamental mass scale M_D is 1.69 TeV/c^2 at 95% CL, with an expected limit of 1.71 TeV/c^2.

1 Introduction

The Standard Model (SM) has been thoroughly tested at the CERN LEP e^+e^- collider [1, 2]. No sign of statistically significant deviations from it or evidence for new physics phenomena beyond it have been found up to the highest LEP centre-of-mass energies of about 209 GeV. Yet the SM cannot be the final picture, because of several theoretical problems. One is known as the hierarchy problem and is related to the observed weakness of gravity in comparison with other interactions. This may be expressed by the observation that the reduced Planck mass, $M_{Pl} = \sqrt{1/G_N} \sim 2.4 \times 10^{15}$ TeV/c^2, where G_N is Newton's coupling constant, is much larger than the 0.1–1 TeV/c^2 scale of the electroweak symmetry breaking.

A step towards the solution of this puzzle was proposed in 1998 by Arkani-Hamed, Dimopoulos and Dvali (ADD) [3], assuming the existence of large extra spatial dimensions (ED). Models with one ED were proposed a long time ago in connection with gravity and its unification with electromagnetism in the papers of Kaluza and Klein (KK) [4–6]. More recently, with the appearance of string theory, the existence of several EDs was advocated, but their size was thought to be close to the Planck length, $R \sim 1/M_{Pl} \sim 10^{-33}$ cm. In this case EDs would be completely out of the reach of present and planned colliders. The novel suggestion of ADD was the possible existence of large EDs with a fundamental Planck mass close to the electroweak scale, in fact implying that non-trivial physics "ends" at energies of about 1 TeV. In the ADD model all the SM particles are supposed to live on a 3D brane corresponding to our usual space, while gravitons are allowed to propagate into the bulk. Thus the weakness of gravity is simply due to its dilution in the volume of the EDs.

Assuming flat EDs and compactification on a torus, Gauss' law gives:

$$M_{Pl}^2 = R^n M_D^{n+2}, \tag{1.1}$$

where R is the radius of the ED and M_D is the fundamental Planck scale in the D-dimensional space-time ($D = 4 + n$). With $M_D \sim 1$ TeV/c^2 and $n = 1$, (1.1) implies a modification of Newton's law over solar system distances which is not observed. So the possibility that $n = 1$ is usually considered to be falsified. On the other hand for $n \geq 2$, $R < 1$ mm and tests of gravity are only recently reaching these small distances [7]. For $n \geq 3$, $R < 1$ nm and no gravity test exists which can falsify the model.

The graviton, confined within flat EDs of size R, has a uniform spectrum of excitations, which, from the point of view of a 4D observer, will be seen as a KK tower of states, with masses uniformly spaced between $1/R$ ($\sim 10^{-32/n}$ TeV/c^2) and M_D. In particle collisions at accelerators and in the cosmos, gravitons can be emitted, but they escape immediately into the bulk, with momentum conservation in all the dimensions, and are therefore detectable via a missing energy signature. Each KK state is very weakly coupled, yet the number of states is very large, which turns into a sizable cross-section for graviton emission. Astrophysics yields strong constraints for $n = 2, 3$ based on observations of supernova SN1987A and on the behavior of neutron stars [8, 9]. The limits on the M_D scale vary from 20 to 40 TeV/c^2 and 2 to 3 TeV/c^2, respectively, and seem to rule out the ADD model with $M_D = 1$ TeV/c^2. They are however based on many assumptions with differences of a factor of 2–3 between different calculations. For larger n they become much weaker.

For $n \geq 2$ limits on graviton emission have been obtained at the LEP collider [10–13] and at the Tevatron [14, 15]. At LEP the direct graviton emission reaction $e^+e^- \to G\gamma$ (GZ) has been studied: for $n \geq 2$ the photon spectrum peaks at low energies and at small emission angles [16]. No excess with respect to the SM predictions has been found and a combination of the LEP results yielded $M_D > 1.60$ (0.80) TeV/c^2 for $n = 2$ (6) at the 95% Confidence Level (CL) [17].

Recently the ADD model has been reconsidered by Giudice, Plehn and Strumia (GPS) [18], who have focused on the infrared (IR) behavior of the model in connection with limits at colliders versus gravity and astrophysics constraints. They considered a distorted version of the ADD model with the same properties in the ultraviolet (UV) region, but satisfying observational and astrophysical limits in the large distance regime. They showed that the introduction of an IR cut-off in the ADD model evades the constraints from astrophysics and gravity for small n, including $n = 1$, given the energy resolution of the collider experiments. This IR cut-off is equivalent to a slight deformation or warping of the otherwise flat EDs. They started from the Randall and Sundrum type 1 model (RS1) [19] and considered the limit of slightly warped but large ED, resulting in a moderately large total warp factor. In RS1 the visible brane is located

[a] e-mail: jan.timmermans@cern.ch

[b] Deceased.

at $y = 0$, where y is the coordinate in the extra dimension, and the Planck brane at $y = \pi R$. The line element is non-factorisable due to the warping factor

$$ds^2 = e^{2\sigma(y)} \eta_{\mu\nu} dx^\mu dx^\nu + dy^2 \qquad (1.2)$$

with $\sigma(y) = \mu|y|$. Here μ is a mass parameter due to the warp, which has a value $50 \text{ MeV}/c^2 \leq \mu \ll 1 \text{ TeV}/c^2$ and introduces an IR cut-off. This cut-off implies a mass of the graviton which is inaccessible for cosmological processes, but which has no significant implications for the high energy collider signal in the UV region of the KK spectra. In particular, the relation between the fundamental mass scale in 5 dimensions and the 4D Planck mass becomes

$$M_{Pl}^2 = \frac{M_5^3}{2\mu\pi}(e^{2\mu R\pi} - 1), \qquad (1.3)$$

where R is the radius of the compactified ED. Hence the one ED can still be large, but unobserved as a modification of Newton's law or in the cosmological low energy processes. In this model the hierarchy between the Fermi and Planck scales is generated by two factors, the large ED and warping. It can be seen that for $\mu \ll R^{-1}$ the ADD limit, (1.1), is obtained.

Since a search for graviton emission with $n = 1$ was not performed in the previous publication [11] and since the results cannot be inferred from the limits already given for $n \geq 2$ because the photon energy spectra differ noticeably for different values of n [16, 18], the DELPHI data were re-analysed and the results will be presented here. The paper is organized as follows: Sect. 2 recalls briefly the experimental details, the analysis is discussed in Sect. 3, Sect. 4 presents the results and the conclusions are given in Sect. 5.

2 Detector and data preselection

The general criteria for the selection of single-photon events are based mainly on the electromagnetic calorimeters and on the tracking system of the DELPHI detector [20, 21]. All the three major electromagnetic calorimeters in DEL-PHI, the High density Projection Chamber (HPC), the Forward ElectroMagnetic Calorimeter (FEMC) and the Small angle TIle Calorimeter (STIC), have been used in the single-photon reconstruction. The STIC accepted photons at very small polar angle,[1] the FEMC covered intermediate angles, and large angles with respect to the beams were covered by the HPC. Hermeticity Taggers were used to ensure detector hermeticity for additional neutral particles in the angular region around 45° between HPC and FEMC, not covered by

---

[1]In the DELPHI coordinate system, the z axis is along the electron beam direction and the polar angle to the z axis is called θ.

the calorimeters. The DELPHI tracking system and the taggers were used as a veto. A detailed description of the trigger conditions and efficiencies of the calorimeters is given in a previous publication [11], where the rejection of events in which charged particles were produced is also discussed.

The study was done with data taken during the 1997–2000 runs at e^+e^- centre-of-mass energies from 180 to 209 GeV, corresponding to an integrated luminosity of $\sim 650 \text{ pb}^{-1}$, with the subdetectors relevant for the analysis all fully operational.

The single-photon events were selected in two stages. In the first stage events with only one detected photon were preselected and compared to the SM process $e^+e^- \to \nu\bar{\nu}\gamma$. A likelihood ratio method was then used to maximize the sensitivity in the search for graviton production with $n = 1$.

Events with a photon in the HPC were selected by requiring a shower having a scaled energy $x_\gamma = E_\gamma / E_{beam} > 0.06$, θ between 45° and 135°, and no charged particle tracks. Photons in the FEMC were required to have a scaled energy $x_\gamma > 0.10$ and a polar angle in the intervals $12° < \theta < 32°$ $(148° < \theta < 168°)$. Single photons in the STIC were preselected by requiring one shower with a scaled energy $x_\gamma > 0.30$ and with $3.8° < \theta < 8°$ $(172° < \theta < 176.2°)$. Additional details about the preselection are given in [11]. In the single-photon event preselection events with more than one photon were accepted only if the other photons were at low angle $(\theta_\gamma < 2.2°)$, low energy $(E_\gamma < 0.8 \text{ GeV})$ or within 3°, 15°, 20° from the highest energy photon in the STIC, FEMC and HPC respectively.

3 Single-photon analysis

The single-photon analysis has been discussed in detail in [11], here we will recall the main points and underline the differences in the present analysis.

Single-photon events can be faked by the QED reaction $e^+e^- \to e^+e^-\gamma$ if the two electrons escape undetected along the beampipe or if the electrons are in the detector acceptance but are not detected by the experiment. This process has a very high cross-section, decreasing rapidly with increasing energy and polar angle of the photon. Its behavior together with the rapid variation of efficiencies at low photon energy motivates the different calorimeter energy cuts in the preselection and additional energy-dependent cuts on the polar angle in the FEMC and STIC.

The remaining background from the $e^+e^- \to e^+e^-\gamma$ process was calculated with the Monte Carlo program TEEG by D. Karlen [22] and two different event topologies were found to contribute, giving background at low and high photon energy respectively. Either both electrons were below the STIC acceptance or one of the electrons was in the DEL-PHI acceptance where it was wrongly identified as a pho-

ton, while the photon was lost for example in the gaps between the electromagnetic calorimeters not covered by the Hermeticity Taggers, or in masked crystals in the FEMC.

The contribution from other processes has also been calculated: cosmic ray events, $\gamma\gamma$ collisions using PYTHIA 6.1 [23] and BDK [24, 25], $e^+e^- \to \gamma\gamma(\gamma)$ according to Berends et al. [26–28], $e^+e^- \to \mu\mu(\gamma)$ and $e^+e^- \to \tau\tau(\gamma)$ with KORALZ [29, 30], and four-fermion events with EXCALIBUR [31] and Grc4f [32].

The $e^+e^- \to \nu\bar{\nu}\gamma(\gamma)$ process was simulated by the KORALZ [29, 30] program. A comparison of the cross-section predicted by KORALZ 4.02 with that predicted by NUNUGPV [33, 34] and KK 4.19 [35] showed agreement at the percent level. This difference is negligible with respect to the statistical and systematic uncertainties in the present measurement.

Simulated events for the irreducible contribution from $\nu\bar{\nu}\gamma$ production and other SM backgrounds were generated at the different centre-of-mass energies and passed through the full DELPHI simulation and reconstruction chain [20, 21].

Figure 3.1 shows the x_γ distribution of all preselected single-photon events. As discussed in the previous paper [11], only single photon events in the HPC and FEMC were used for the subsequent analysis, since the E_γ cuts in the STIC, needed to reduce the radiative Bhabha background, reject a large part of the ED signal even in the case $n = 1$.

Table 3.1 shows the total number of observed and expected events in the HPC and FEMC. The numbers are integrated over the LEP energies from 180 to 209 GeV and correspond to an overall luminosity of ~650 pb^{-1}.
A likelihood ratio method was used to select the final sample of single-photon events. This method allows the final selection to be optimized for excluding the cross section of a given signal assuming that no signal is present in the data sample. Hence the method optimizes the background suppression for a given signal efficiency [36]. The likelihood ratio function used in this analysis is given by:

$$\mathcal{L}_R = \frac{\mathcal{L}_S}{\mathcal{L}_B} = \frac{P_S(E_\gamma)}{P_B(E_\gamma)}. \tag{3.1}$$

The probability density functions ($P_{i=S,B}$) used to construct $\mathcal{L}_R$ were produced from the normalized photon energy distributions of the expected ED and SM background events, after passing through the same selection criteria. A low pass filter was also used to eliminate the high frequency statistical fluctuations from the final P_i functions. An event was then selected as a candidate event if it passed the requirement $\mathcal{L}_R > \mathcal{L}_R^{CUT}$. The value of $\mathcal{L}_R^{CUT}$ was determined by minimizing the expected excluded cross section in the absence of a signal:

$$\sigma^{min}(\mathcal{L}_R^{CUT}) = \frac{N_{95}^{min}(\mathcal{L}_R^{CUT})}{\epsilon^{max}(\mathcal{L}_R^{CUT}) \times L}, \tag{3.2}$$

where N_{95}^{min} is the upper limit on the number of signal events at 95% CL computed with the mono-channel version of the Bayesian method in [37]. ϵ^{max} is the efficiency for the signal and L is the integrated luminosity. The values of N_{95}^{min} and ϵ^{max} both decrease with an increasing value of $\mathcal{L}_R^{CUT}$. Their derivatives, however, behave differently which results in a well defined minimum of $\sigma^{min}(\mathcal{L}_R^{CUT})$.

The data collected at different centre-of-mass energies were analysed separately and different analyses were made depending on the electromagnetic calorimeter in which the photon was recorded. The $\mathcal{L}_R^{CUT}$ values obtained showed a variation of around 0.7 ± 0.1, though all the final selections contained a rejected region in the energy spectra that covered most of the Z-peak, as expected. In some cases the selection also implied slightly stronger criteria for the overall minimum photon energy. Out of the preselected FEMC events, 262 passed the final selection with 250.6 expected and from the HPC events, 255 were selected with 263.5 expected. The signal efficiency of the final selection was between 85% and 90% with respect to preselection level. The final experimental limit was obtained using a Bayesian multi-channel method [37] which combined the results of

Fig. 3.1 x_γ of selected single photons. The *light shaded area* is the expected distribution from $e^+e^- \to \nu\bar{\nu}\gamma(\gamma)$ and the *dark shaded area* is the total background from other sources. Indicated in the plot is also the signal expected from $e^+e^- \to G\gamma$ for $n = 1$ and $M_D = 1.25$ TeV/c^2

Table 3.1 The number of selected and expected single-photon events

	$N_{observed}$	$N_{e^+e^- \to \nu\bar{\nu}(\gamma)}$	$N_{other\ SM\ background}$
FEMC	705	626 ± 3	49.1
HPC	498	540 ± 4	0.6

the 20 analyses, the data for the two calorimeters being grouped into 10 datasets between 180 and 209 GeV centre-of-mass energy. The method takes into account all the available information (such as the fraction of the signal and the average background in each subdetector and in each data subsample) in order to properly calculate the final limit.

4 Limit on the production of gravitons

The differential cross-section for $e^+e^- \to G\gamma$ has been calculated in [16, 18] and is given by:

$$\frac{d^2\sigma}{dx_\gamma d\cos\theta_\gamma} = \frac{\alpha}{32s} \frac{\pi^{\frac{n}{2}}}{\Gamma(\frac{n}{2})} \left(\frac{\sqrt{s}}{M_D}\right)^{n+2} f(x_\gamma, \cos\theta_\gamma), \quad (4.1)$$

with

$$f(x, y) = \frac{2(1-x)^{\frac{n}{2}-1}}{x(1-y^2)}[(2-x)^2(1-x+x^2)$$
$$- 3y^2x^2(1-x) - y^4x^4]. \quad (4.2)$$

Initial state radiation can produce additional photons that would cause a signal event to be rejected in a single-photon analysis. The expected signal cross-section has therefore been corrected with a radiator approximation method [38].

For $n > 1$ the differential distribution, (4.2), is peaked at small E_γ and θ_γ, for $n = 1$ instead a singularity is present at $x_\gamma = 1$, which makes the distribution qualitatively different from the others. For instance the ratio of the cross-sections, (4.1) and (4.2), for $n = 1$ and $n = 2$ is independent of θ_γ, and increases from ~ 1.5 at small x_γ to ~ 22 at $x_\gamma = 0.995$ for $M_D = 1$ TeV/c^2 and $\sqrt{s} = 208$ GeV. In order to take into account detector effects, the theoretical ED cross-section has been corrected for efficiency and energy resolution in the calorimeters, using a parameterization developed in the $\nu\bar{\nu}\gamma$ analysis. The theoretical energy distributions for $n = 1$ and 2 smeared in the HPC and FEMC are shown in Fig. 4.1.

As can be seen in Fig. 3.1, the single photon data measured by DELPHI were well compatible with expectations from SM processes and no evidence for graviton production was found.

All DELPHI data with $\sqrt{s} > 180$ GeV were used and a dedicated selection for each bin in $\sqrt{s}$ was made as described in the previous section. These results were combined to give a 95% CL cross-section limit for one extra dimension of 0.171 pb at 208 GeV, with an expected limit of 0.166 pb. In terms of the parameter $p = (1/M_D)^3$, to which the $n = 1$ signal cross-section is proportional, the combined log-likelihood function of the Bayesian formula was practically parabolic. p is estimated to be (0.009 ± 0.098) (TeV/c^2)$^{-3}$ and is therefore consistent with zero. The obtained limit on the fundamental mass scale is $M_D > 1.69$ TeV/c^2 at 95%

**Fig. 4.1** x_γ of expected single photons in the HPC and FEMC from $e^+e^- \to G\gamma$ with $n = 1$, $M_D = 1.25$ TeV/c^2 and $n = 2$, $M_D = 1$ TeV/c^2, corrected for calorimeter efficiency and resolution. MC expectations are normalized to the luminosity of the combined data set in Fig. 3.1

CL (with 1.71 TeV/c^2 expected limit) in the $n = 1$ analysis. As a comparison, the cross-section limits in the previous analysis for $n = 2$–6 varied between 0.14 and 0.18 pb, and the obtained limits for M_D between 1.31 TeV/c^2 ($n = 2$) and 0.58 TeV/c^2 ($n = 6$). Since the characteristic peak of the $n = 1$ photon spectrum at $x_\gamma = 1$ is less prominent after including detector effects, the cross section limit is similar to those obtained for $n > 1$. The same systematic errors were considered as in the previous analysis [11], namely trigger and identification efficiency, calorimeter energy scale and background, and the effect on the M_D limit from the systematic errors in the $n = 1$ analysis was estimated to be less than 4%.

5 Conclusions

We have re-analysed single-photon events detected with DELPHI at LEP2 during 1997–2000 at centre-of-mass energies between 180 and 209 GeV to study graviton production with $n = 1$ large extra dimensions, motivated by the model of Giudice, Plehn and Strumia [18]. Since the measured single-photon cross-sections are in agreement with the expectations from the SM process $e^+e^- \to \nu\bar{\nu}\gamma(\gamma)$, the absence of an excess of events has been used to set a limit of 1.69 TeV/c^2 at 95% CL on the fundamental mass scale for $n = 1$ ED.
