Glass,<sup>26</sup> Michael A. van Es,<sup>5</sup> Leonard H. van den Berg,<sup>5</sup> Ammar Al-Chalabi,<sup>22</sup> Jan Veldink<sup>5</sup> and Philip Van Damme<sup>1,2,3</sup>, on behalf of Project MinE ALS Sequencing Consortium

With the advent of gene therapies for amyotrophic lateral sclerosis (ALS), there is a surge in gene testing for this disease. Although there is ample experience with gene testing for *C9orf72*, *SOD1*, *FUS* and *TARDBP* in familial ALS, large studies exploring genetic variation in all ALS-associated genes in sporadic ALS (sALS) are still scarce. Gene testing in a diagnostic setting is challenging, given the complex genetic architecture of sALS, for which there are genetic variants with large and small effect sizes. Guidelines for the interpretation of genetic variants in gene panels and for counselling of patients are lacking.

We aimed to provide a thorough characterization of genetic variability in ALS genes by applying the American College of Medical Genetics and Genomics (ACMG) criteria on whole genome sequencing data from a large cohort of 6013 sporadic ALS patients and 2411 matched controls from Project MinE.

We studied genetic variation in 90 ALS-associated genes and applied customized ACMG-criteria to identify pathogenic and likely pathogenic variants. Variants of unknown significance were collected as well. In addition, we determined the length of repeat expansions in *C9orf72*, *ATXN1*, *ATXN2* and *NIPA1* using the ExpansionHunter tool.

We found *C9orf72* repeat expansions in 5.21% of sALS patients. In 50 ALS-associated genes, we did not identify any pathogenic or likely pathogenic variants. In 5.89%, a pathogenic or likely pathogenic variant was found, most commonly in *SOD1*, *TARDBP*, *FUS*, *NEK1*, *OPTN* or *TBK1*. Significantly more cases carried at least one pathogenic or likely pathogenic variant compared to controls (odds ratio 1.75; *P*-value  $1.64 \times 10^{-5}$ ). Isolated risk factors in *ATXN1*, *ATXN2*, *NIPA1* and/or *UNC13A* were detected in 17.33% of cases. In 71.83%, we did not find any genetic clues. A combination of variants was found in 2.88%.

This study provides an inventory of pathogenic and likely pathogenic genetic variation in a large cohort of sALS patients. Overall, we identified pathogenic and likely pathogenic variants in 11.13% of ALS patients in 38 known ALS genes. In line with the oligogenic hypothesis, we found significantly more combinations of variants in cases compared to controls. Many variants of unknown significance may contribute to ALS risk, but diagnostic algorithms to reliably identify and weigh them are lacking. This work can serve as a resource for counselling and for the assembly of gene panels for ALS. Further characterization of the genetic architecture of sALS is necessary given the growing interest in gene testing in ALS.

## Introduction

Amyotrophic lateral sclerosis (ALS) is a motor neuron disorder characterized by upper and lower motor neuron degeneration, which leads to progressive muscle weakness and wasting.<sup>1</sup> Up to 50% of patients develop extramotor symptoms, such as cognitive or behavioural dysfunction, as seen in frontotemporal dementia (FTD).<sup>1</sup> The disease is relentlessly progressive and most people die between 2 and 5 years after disease onset, as effective treatments are lacking.<sup>1,2</sup> ALS has a strong genetic component. In 5–10%, there is a familial history of ALS (fALS). Highly penetrant causal variants are found in ~70% of fALS patients, most commonly in *C9orf72*, *SOD1*, *TARDBP* and *FUS*, which are responsible for about 40%, 20%, 4% and 3% of familial cases in Western populations, respectively.<sup>3</sup> The remaining 90–95% of patients present with apparently sporadic ALS (sALS),<sup>4</sup> but mutations in the same genes are found at lower frequencies.<sup>5</sup> Twin studies suggest a heritability in sALS patients of around 60%.<sup>6</sup> Both rare variants with a variable

effect size, common variants with small effect size and combinations of such variants are thought to confer genetic risk in sALS patients, but convincing data showing this are still lacking.<sup>7,8</sup> Nevertheless, much of the genetic architecture of ALS remains unknown. Over the past few years, many efforts have been made to unravel the missing heritability. Genetic research has linked a considerable number of genes and variants to ALS through various techniques.<sup>7,9</sup> However, strong evidence for association is variable, and some findings have failed to be replicated in subsequent studies.<sup>10</sup> Furthermore, the clinical significance of individual variants is often unclear (e.g. monogenetic with high penetrance, modifier, risk factor or in linkage with causal variant), especially in sALS patients. As the risk of ALS is age-dependent, the life-time risk is in the order of 1/400 for males and 1/550 for females and since many of the reported disease-associated variants have been associated with incomplete penetrance (in fALS pedigrees), such variants will invariably also be found in control populations.<sup>11</sup> One of the difficulties in the interpretation of variants in complex genetic diseases like ALS is how to weigh the pathogenicity of variants, since

consensus criteria are not available and different methods for scoring genetic variants are used.<sup>12,13</sup>

With the advent of precision medicine for genetic subtypes of ALS, the interest in gene testing is increasing. It is common practice to offer gene testing for fALS, but much less so for sALS. Large studies systematically describing the genetic variation in sALS are rare.<sup>14,15</sup> However, a better insight in the level of pathogenicity of single variants is essential for the interpretation of variants in a diagnostic setting, for counselling of patients and their families and for use in clinical drug trials.

We analysed whole genome data of a large cohort of 6013 sporadic ALS patients and focused on a set of 90 genes reported to be associated with causing ALS.<sup>16</sup> We implemented an automatic pipeline for classification of variants using modified criteria of the American College of Medical Genetics and Genomics (ACMG) to adjudicate the variants.<sup>17</sup> Here, we present a comprehensive overview of the pathogenic and likely pathogenic variants encountered in these ALS-associated genes, simultaneously validating the association of some of these genes with ALS in our cohort. In light of the oligogenic inheritance model of ALS, we also searched for the occurrence of combinations of such variants.

## Materials and methods

### Patient selection

This study used whole genome sequencing (WGS) data of a total of 9600 samples of ALS cases and age- and sex- matched controls from Project MinE. Samples were mostly of people of European descent and collected from 17 centres across 13 countries: Belgium, The Netherlands, Switzerland, Spain, France, UK, Ireland, Israel, Italy, Portugal, Sweden, Turkey, and USA. The diagnosis of ALS was made based on the revised El Escorial criteria in the including centre, which also provided clinical information. Case/control ratio was two to one. For more detailed information on patient and control selection we refer to the pilot study of Project MinE.<sup>16</sup> A set of 8940 genomes passed quality control, of which 6529 unrelated ALS index patients and 2411 unrelated healthy controls. fALS patients, defined as having a family member with ALS in the first or second degree, were excluded for this analysis ( $n=301$ ). Patients with primary lateral sclerosis ( $n=74$ ), progressive muscular atrophy ( $n=90$ ) and progressive bulbar palsy ( $n=51$ ) were also excluded. Our final cohort consisted therefore of 6013 sALS patients and 2411 controls.

### Whole genome sequencing and bioinformatics analysis

DNA was extracted and sequenced on the Illumina HiSeq 2000 and HiSeq X platforms. Sequencing data was then aligned to GRCh37 using the iSAAC Aligner, and variants called using the iSAAC variant caller; both the aligner and caller are standard to Illumina's aligning and calling pipeline. Lifter to GRCh38 was performed using picard LifterVcf (v2.20.2-SNAPSHOT). Quality control was performed at sample and variant level as described previously.<sup>18</sup>

### Gene selection

A list of 'ALS-associated genes' was selected from four databases (search conducted on 28 April 2021): OMIM (search term 'amyotrophic lateral sclerosis'), the neuromuscular homepage (NMHP), the online version of the gene table and ALSod (genes with definitive and strong evidence).<sup>19–22</sup> All genes were included to provide

an unbiased selection, regardless of the evidence that was available for an association with ALS. This resulted in a set of 91 genes (Supplementary Table 1). For one gene, NOTCH2NLC, the liftover to GRCh38 failed because of mappability issues, excluding this gene from further analysis. This brought the total number of eligible genes to 90. Additionally, we randomly selected 90 genes with expression in brain as obtained from the GTEx Portal for comparison (Supplementary Table 2).<sup>23</sup>

The exact genomic regions corresponding to these genes were extracted from Ensembl (version 96), to which we added a buffer region of 2500 base pairs both upstream and downstream.<sup>24</sup> For each gene, we selected the canonical transcript (Supplementary Table 1).

### Variant extraction and annotation

We extracted all sequencing variants located in the genomic region of the selected genes from WGS data of patients and controls. Variants were annotated using nsemble-vep (v96.0-0). Vcfanno (v0.3.1) was used to add precalculated scores of the dbnsfp (v4.1a) and dbcsnv (v1.1) databases and add the allele frequency from Gnomad (v2.1.1 liftover\_grch38).

Repeat expansions in *C9orf72* (the GGGGCC-repeat sequence in intron 1a) and *NIPA1*, as well as intermediate repeat expansions in *ATXN1* and *ATXN2*, were identified in our WGS data using the ExpansionHunter tool.<sup>25</sup> Cut-offs used were repeat lengths: 30 for *C9orf72*, 39 for *ATXN1*, 33 for *ATXN2* and 10 for *NIPA1*. Expanded means that the lower bound of the estimated repeat length range is higher or equal to the cut-off. Normal means that the upper bound of the range is lower than the cut-off. Intermediate means that the result is in between 'expanded' and 'normal'. Where available, results from ExpansionHunter were compared with wet lab results (repeat primed PCR). Inconsistent means that a discrepancy between the result from ExpansionHunter and the wet lab was found. Unknown means the length of the repeat could not be determined. The single nucleotide polymorphism (SNP) rs12608932 in *UNC13A* is a known risk factor for ALS.<sup>26</sup> Frequency of the CC genotype was distilled from our data.

### Attribution of variant pathogenicity

To predict variant pathogenicity we used the software tool CharGer (Characterization of Germline variants), an open-source framework conducting a fully automated variant interpretation based on the ACMG-criteria, enriched with custom modules and a user-adjustable scoring system.<sup>27</sup> We partially customized the criteria and included some changes to make them more suitable for complex diseases. A summary of how we customized the ACMG criteria can be found in Supplementary Figs 1 and 2 and Supplementary Tables 1 and 3. After applying these modified criteria on the extracted sequencing variants, we selected all variants with a classification of pathogenic (class V) or likely pathogenic (class IV).

Expansions in *ATXN1*, *ATXN2* and *NIPA1* and the SNP rs12608932 in *UNC13A* were not considered pathogenic but were logged as risk factors.

### Known mutations associated with ALS

We extracted variants associated with ALS in the 90 genes of interest from two databases: ClinVar and the NMHP.<sup>20,28</sup> We reclassified these variants as described in Supplementary Fig. 1 and selected the variants with a final classification as pathogenic and likely pathogenic as 'known ALS-associated mutations'. An overview of

the number of variants reclassified per gene is provided in [Supplementary Table 4](#).

### Statistical analysis

R (v3.6.3) was used to perform Fisher exact tests to compare variant frequency between cases and controls in our dataset assuming a dominant model. Odds ratios (ORs) with zero cell counts in the control population were estimated by assuming the control population had a count of one, these ORs are denoted with a tilde. Multiple testing correction was performed using the Holm method as implemented in `p.adjust`. For comparison between patients with and patients without pathogenic and likely pathogenic variants  $\chi^2$  test was performed for categorical variables and a t-test for continuous variables.

### GnomAD

To calculate ORs compared to GnomAD v3, the variants that passed quality control were downloaded from <https://gnomad.broadinstitute.org> and processed through our modified ACMG criteria, retaining only the pathogenic and likely pathogenic variants.<sup>29</sup> These were compared to the pathogenic and likely pathogenic variants present in our ALS cohort after removing the variants that were also removed in GnomAD. Fisher's exact test was then used as described above.

### Graphical representation

Graphical representations called 'lollipop plots' were created in R (version 3.6.0) using the Bioconductor package `trackViewer` (version 1.20.5).<sup>27,30</sup>

### Ethical approval

The study was approved by the national ethical committees of the participating centres. All participants signed an informed consent, which also included permission to publish scientific results at the group level. The Commission of medical ethics of UZ KU Leuven gave permission for sample collections (S50354) and for exome/genome sequencing (S52853).

### Data availability

The data that support the findings of this study are available on request from the corresponding author. The data are not publicly available due to privacy restrictions.

## Results

Our final cohort consisted of 6013 sALS patients and 2411 controls. The MinE project was set up to discover new ALS genes, so patients with known causal mutations might be underrepresented. The main characteristics of the cohort are summarized in [Table 1](#).

Using the ExpansionHunter tool, we identified 313 cases (5.21%) with a C9orf72 hexanucleotide repeat expansion. Looking at the 90 genes, we identified 365 pathogenic and likely pathogenic sequencing variants in 354 (5.89%) cases and 87 pathogenic and likely pathogenic sequencing variants in 83 controls (3.44%) ([Table 2](#), [Supplementary Table 5](#) and [Supplementary Table 6](#)). Significantly more cases carried at least one pathogenic or likely pathogenic sequencing variant compared to controls (OR 1.75; P-value  $1.64 \times 10^{-5}$ ). Pathogenic and likely pathogenic sequencing variants were observed in 40 of the 90 genes, that is in 38 genes in cases and in

24 genes in controls ([Table 2](#), [Supplementary Table 5](#), [Fig. 1](#) and [Supplementary Fig. 3](#)). In 25 genes, a higher proportion of patients carried at least one pathogenic or likely pathogenic variant compared to controls. For 10 genes, the OR for carrying a pathogenic or likely pathogenic variant was higher than two, with a P-value below the significance threshold of 0.05 for the genes *NEK1* (OR 21.84; P-value  $2.57 \times 10^{-7}$ ), *SOD1* (OR 7.66; P-value  $3.15 \times 10^{-4}$ ), *FUS* (OR ~6.43; P-value  $9.40 \times 10^{-3}$ ), *OPTN* (OR 4.83; P-value  $1.58 \times 10^{-2}$ ) and *TARDBP* (OR ~5.22; P-value  $2.59 \times 10^{-2}$ ). P-values remained below the adjusted significance threshold only for *NEK1* and *SOD1* after correcting for multiple testing. However, by increasing the size of the control population by taking data from gnomAD, we could confirm these top five genes, obtaining even lower P-values. Some other genes also reached P-values below the significance threshold when compared to gnomAD after correction for multiple testing. However, only *TBK1* could be added to the list of significant genes using a more stringent genome wide correction for the  $\pm 20\,000$  genes in the genome. The ORs and their 95% confidence interval after comparison to gnomAD are illustrated in [Fig. 2](#). The known Asp91Ala (D91A) variant in *SOD1* was discarded by our pipeline, because rule BS1 was triggered (allele frequency higher than expected for the disorder). We extracted the frequencies in a separate analysis and found 19 sALS patients with a heterozygous *SOD1* D91A variant, 21 with a homozygous variant and five controls with a heterozygous variant. In 15 genes, a higher proportion of controls

**Table 1 Summary of the main characteristics of the MinE cohort**

	Cases (n = 6013)	Controls (n = 2411)
<b>Sex</b>

List of the first 20 of 40 genes in which pathogenic or likely pathogenic variants were found in cases and/or controls (sorted on increasing P-value). On the left, the absolute number of ALS patients and controls of our cohort with minimal one pathogenic or likely pathogenic variant in that gene is indicated along with the proportion of total cases ( $n = 6013$ ) and controls ( $n = 2411$ ) as a percentage in brackets. P-value, adjusted (Adj.) P-value after correction for multiple testing, estimated odds ratio and 95% confidence interval are shown in separate columns. To the right, a comparison with controls of the gnomAD database. Repeat expansions and SNP rs12608932 in *UNC13A* are not included in this table. The full table with all 40 genes can be found in the [Supplementary material \(Supplementary Table 5\)](#). Adj = adjusted; CI = confidence interval; Est = estimated; Inf = infinity; NMHP = neuromuscular homepage; OR = odds ratio.

carried at least one pathogenic or likely pathogenic variant. The P-value was below the significance threshold of 0.05 only in *NEFH* (OR 0.30; P-value  $3.26 \times 10^{-2}$ ) but did not survive correction for multiple testing and was also not significant when controls from gnomAD were added. In 50 genes, we did not find any pathogenic or likely pathogenic variant. Variants of unknown significance (VUS) are listed in [Supplementary Table 7](#). Patients with pathogenic and likely pathogenic variants were more often diagnosed with FTD (32.41% versus 21.56% of patients with data available, P-value  $1.70 \times 10^{-2}$ ) and had younger age of onset (58.62 years versus 60.56 years, P-value  $1.17 \times 10^{-4}$ ) ([Supplementary Table 8](#)). In the set of 90 randomly selected genes, we did not find significantly more pathogenic variants in cases or controls, neither in total nor at the individual gene level (OR 1.46; P-value  $3.39 \times 10^{-1}$ ) ([Supplementary Table 9](#)). Of the variants associated with ALS in ClinVar and the NMHP, 367 were reclassified as likely pathogenic or pathogenic by applying our modified ACMG criteria. These variants were considered 'known ALS-associated mutations'. In our cohort, 60 (23.0%) of the unique identified variants in cases were known ALS-associated mutations, the majority were novel variants.

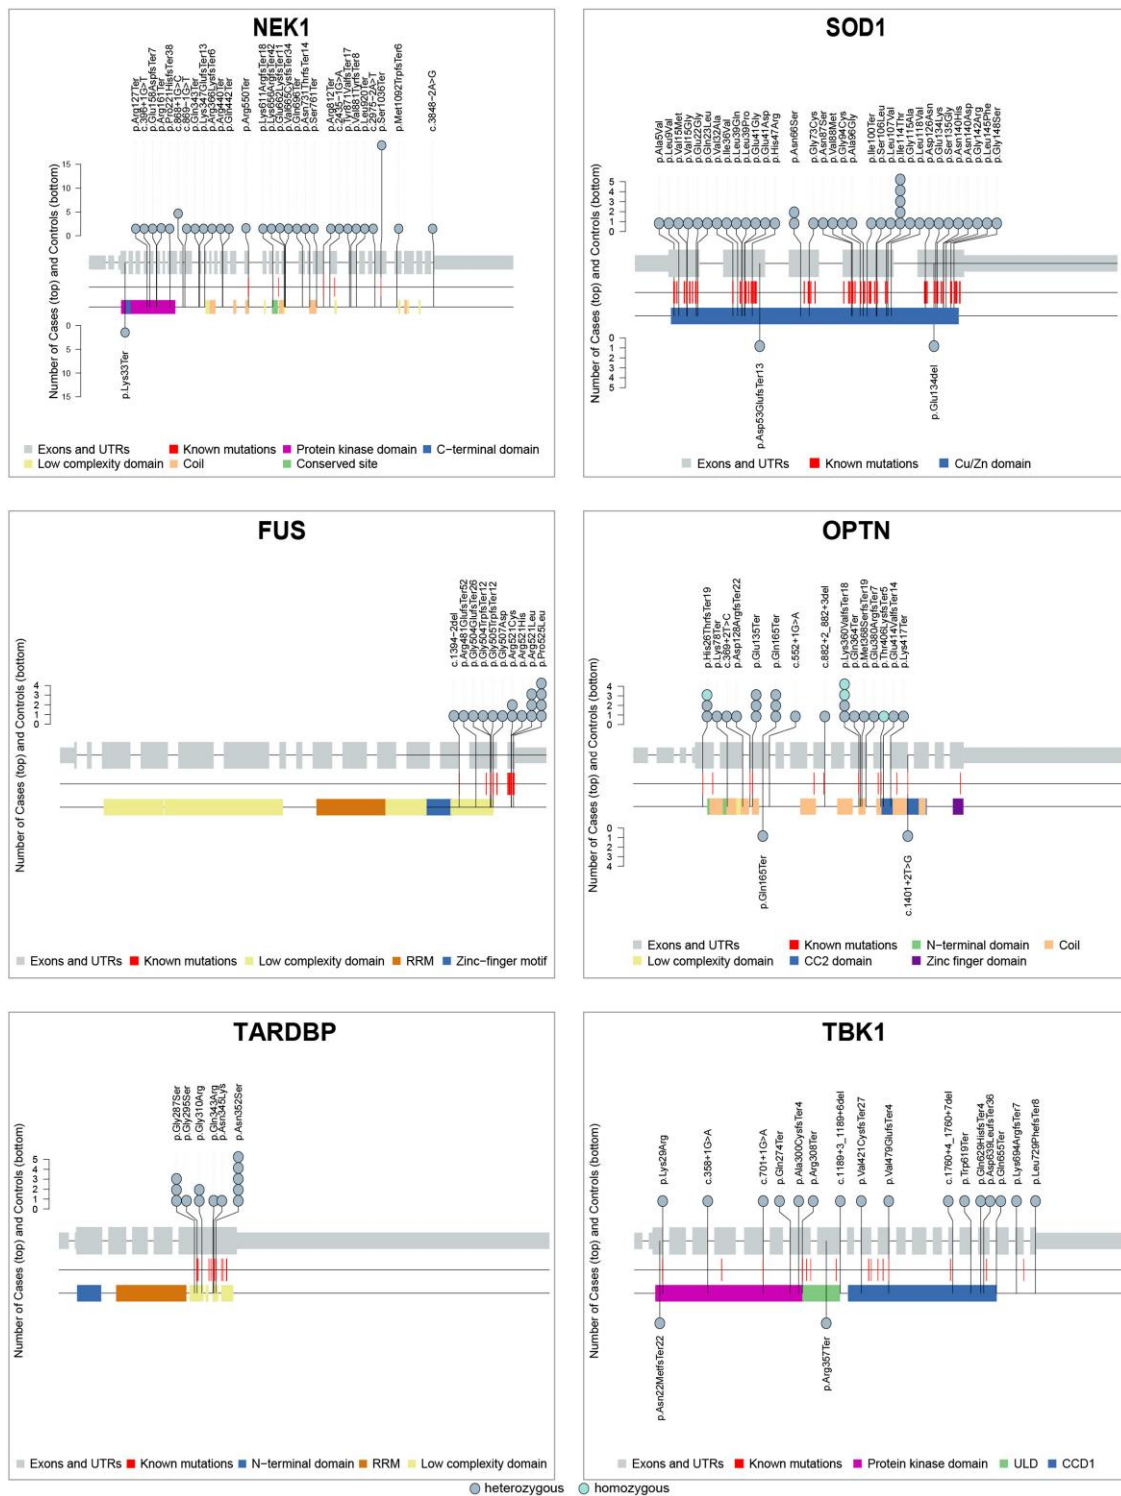

Taken together, 313 cases (5.21%) were explained by a *C9orf72* hexanucleotide repeat expansion. A pathogenic or likely pathogenic sequencing variant was observed in *SOD1*, *FUS*, *TARDBP*, *NEK1*, *OPTN* and *TBK1* in 38 (0.63%), 16 (0.27%), 13 (0.22%), 54 (0.90%) and 24 (0.40%) and 16 (0.27%), respectively. Of the remaining cases, 179 (2.98%) had a mutation in one of the outstanding genes. In the remaining part of the cohort, we detected one or more susceptibility factors in 1042 (17.33%) cases. In the other 4319 (71.83%) cases, we did not find any genetic clue. In the control cohort, a *C9orf72* hexanucleotide repeat expansion was observed in seven (0.29%)

controls. Pathogenic or likely pathogenic sequencing variants were observed in *SOD1*, *NEK1*, *OPTN* and *TBK1* in two (0.08%), one (0.04%), one (0.04%) and one (0.04%) control, respectively. Pathogenic or likely pathogenic sequencing variants in the other genes were found in 76 (3.15%) controls [not statistically different from the proportion of 2.98% in cases (P-value 0.72)]. We found only susceptibility factors in 387 (16.05%) controls. No variants of interest were found in 1934 (80.22%) controls.

To evaluate the incidence of combinations of variants, we took following variants into account: pathogenic and likely pathogenic sequencing variants, *C9orf72* repeat expansions and ALS susceptibility factors including *ATXN1* and *ATXN2* intermediate repeat expansions, *NIPA1* repeat expansions and homozygosity for the C-allele of rs12608932 in *UNC13A*. A combination of two of these variants was found in 164 (2.73%) cases and 34 (1.41%) controls (OR 1.96; P-value  $2.31 \times 10^{-4}$ ) and a combination of three variants in nine (0.15%) cases and in two (0.08%) controls (OR 1.81; P-value 0.74) ([Fig. 3](#) and [Supplementary Table 10](#)).

## Discussion

We here present a comprehensive genetic profile of a large sALS cohort. In total, 10.85% of the studied cases with sALS diagnosis had a pathogenic variant—5.21% had a pathogenic repeat expansion in *C9orf72* and 2.66% a pathogenic or likely pathogenic mutation in either *SOD1*, *TARDBP*, *FUS*, *NEK1*, *OPTN* or *TBK1*. We observed potentially causative variants in other ALS-associated genes in an additional 3.26% of sALS patients (in 2.98% when patients carrying a combination with a *C9orf72* hexanucleotide repeat expansion or with variants in *SOD1*, *FUS*, *TARDBP*, *NEK1*,

**Figure 1** Lollipop plots showing pathogenic and likely pathogenic variants encountered in *NEK1*, *SOD1*, *FUS*, *OPTN*, *TARDBP* and *TBK1* in cases and controls. Lollipop plots showing the mutational spectra of the displayed genes in cases ( $n = 6013$ ) and controls ( $n = 2411$ ). For each gene, exons and untranslated regions are represented as grey bars, connected by introns shown as grey lines (reduced with a factor 1/100). Protein domains and motifs are shown as coloured bars. Each lollipop represents a pathogenic or likely pathogenic variant encountered in cases (top) or controls (bottom). The absolute number of cases and controls with the variant is reflected by the height of the lollipop. Known ALS-associated mutations (from ClinVar and the NMHP) are shown as red lines. AXH = ataxin-1/HBP1 domain; CCD1 = coiled-coil domain 1; NMHP = neuromuscular homepage; RRM = RNA recognition motif; ULD = ubiquitin-like domain; UTR = untranslated region.

**Figure 2** Odds ratios and their 95% confidence intervals. Illustration of the odds ratios and their 95% confidence intervals for the 40 genes with pathogenic or likely pathogenic variants in. Odds ratios are calculated compared to gnomAD v3.

OPTN and TBK1 were excluded). In 17.33%, we found isolated risk factors, but of importance, in 71.83%, no genetic significant variants were detected.

Until now, similar projects have mainly focused on fALS patients. Here we describe the genetic landscape of a large cohort of sporadic ALS patients.<sup>13</sup> An overview of the genetic findings in ALS patients is a first step to get better understanding of the genetic architecture of ALS. Especially in the era of next generation sequencing and with the advent of gene-specific therapies, genetic screening is offered to an increasing number of patients. Therefore, a comprehensive genetic characterization of sALS patients is indispensable for informed counselling of these patients. Evidence on the strength of association of genes with ALS is also valuable for the development and analysis of gene panels.

Overall, when we analysed genetic variation in 90 genes for which association with ALS has been reported, we observed an enrichment of pathogenic and likely pathogenic sequencing variants in cases compared to controls. In *NEK1*, *SOD1*, *FUS*, *OPTN* and *TARDBP* enrichment was significant. That these genes end up as top genes is not surprising since it is known that 2–3% of sALS patients carry pathogenic mutations in these genes.<sup>5</sup> That only *NEK1* and *SOD1* survived multiple testing is probably due to the low numbers of variants per individual gene. This strongly reduces statistical power, even though this is the largest sALS cohort

described to date. Using data from the gnomAD database to supplement our control data, all five originally significant genes were confirmed with higher significance levels. The low statistical power might also provide an explanation for the non-significant results in some of the 33 other genes with pathogenic and likely pathogenic variants, as illustrated by *TBK1*. For most of these genes without significant enrichment however, especially for the ones with ORs close to 1, we suspect that the probability of an association with ALS is rather low. The same is true for the 52 genes without pathogenic or likely pathogenic variants detected in cases. Nevertheless, we cannot exclude that some of these genes harbour truly pathogenic mutations in only a small minority of sALS patients which are therefore not detected in our cohort. Genes conferring moderate risk for ALS are also not reliably identified by our pipeline, as is illustrated by the known polymorphism in *UNC13A*.

The yield of WGS (combined gene panel analysis and *C9orf72* repeat expansion detection in WGS data) in sALS patients was 11.09% overall and 7.87% when only taking *C9orf72* repeat expansions, *SOD1*, *FUS*, *TARDBP*, *NEK1*, *OPTN* and *TBK1* into consideration. This is lower than what is reported by others, but in those studies less stringent variant selection was performed (e.g. all novel and rare variants and/or *ATXN2* intermediate expansions were reported in the yield) and a different number of genes was sequenced.<sup>15,31</sup> In 71.83% of sALS patients, we did not find any pathogenic or likely

**Figure 3 Waterfall plot: combinations of variants.** A waterfall plot shows for all cases (left) and controls (right) which variants they carry: repeat expansions in *C9orf72*; pathogenic or likely pathogenic sequencing variants in *NEK1*, *SOD1*, *FUS*, *OPTN*, *TARDBP*, *TBK1* or in one of the other ALS-associated genes; risk factors such as (intermediate) repeat expansions in *ATXN1*, *ATXN2* and *NIPA1* or the CC-genotype of the SNP rs12608932 in *UNC13A*. Brown = repeat expansions; grey = pathogenic (P) and likely pathogenic (LP) sequencing variants; purple = non-repeat expansion risk variants.

pathogenic variants, so genetic determinants in this patient group remain unknown. Possible explanations are the presence of variants in as yet unidentified genes, variants in noncoding regions of the genome, multiple polygenic additive contributions or epigenetic variation. Another possible reason is an oligogenic architecture where multiple less penetrant variants together constitute the risk of ALS in these patients. Such variants are not easily identified using the ACMG criteria. However, the fact that we found a significantly higher incidence of combinations in cases compared to controls could be a hint to a complex inheritance of (risk) variants in multiple genes.<sup>8</sup> Furthermore, the presence of pathogenic and likely pathogenic variants in our control cohort points towards a reduced penetrance, which also fits with the oligogenic model. Even in *SOD1*, we found two controls carrying a pathogenic variant (0.08%), which is higher than the expected frequency (0.0025%) in controls, assuming a lifetime risk for ALS of 1/400 and a frequency of 1% *SOD1* mutations in sporadic patients.<sup>32</sup> This illustrates that the penetrance at the population level is lower than what is expected based on smaller clinical cohorts, as has been shown for other neurodegenerative disorders before.<sup>33,34</sup> Probably other genetic and environmental factors play a role and explain why some mutation carriers seem more resistant to developing a clinical phenotype. That we found a higher frequency of variants in controls (3.15%) compared to cases (2.98%) in the remaining genes after excluding repeat expansions in *C9orf72* and variants in *SOD1*, *FUS*, *TARDBP*, *NEK1*, *OPTN* and *TBK1* can have multiple explanations: not all genes are robustly associated with ALS, some variants have a low penetrance or there is an overrepresentation of some variants because of populations stratification in a small control cohort. The occurrence of pathogenic and likely pathogenic variants in 3.44% of controls might thus be indicative for reduced penetrance and oligogenic inheritance but should be interpreted with

caution because of the reasons mentioned above. It is important to acknowledge that the finding of a likely pathogenic or pathogenic variant in an ALS gene does not automatically imply Mendelian inheritance of ALS. It would be interesting to follow up controls with these variants longitudinally, as well as controls with a *C9orf72* repeat expansion, however this is not intended in the design of Project MinE. Further exploration of the penetrance of variants and the meaning of the presence of variants in the control population is of great importance since this dramatically influences genetic counselling in patients.

One of the problems in the analysis and interpretation of variants in complex genetic disorders such as ALS is the lack of adequate scoring systems to assess the pathogenicity of variants. Frequently used criteria such as the ACMG guidelines are designed for Mendelian disorders and less applicable for diseases where variants might have low penetrance, be risk factors or might only be pathogenic in certain combinations.<sup>17,35</sup> Furthermore, these criteria are often vaguely defined, and standard algorithms for implementing them are lacking, which leads to leeway and subjectivity in their practical implementation.<sup>17,36</sup> This makes an automated implementation on large datasets challenging. Since better classification systems are lacking, there is no consensus on how to assess the pathogenicity for variants in complex disorders, and different methods are used through literature.<sup>12,13</sup> International attempts to correct this, such as ClinGen Gene Curation Expert Panels and Variant Curation Expert Panels, may represent a way forward. For this project, we used the software tool CharGer applying modified ACMG-criteria.<sup>27</sup> Despite our modifications, our criteria still favour the identification of more deleterious variants (e.g. nonsense and truncating variants) that are more often encountered in Mendelian disorders. On the other hand, some of the identified variants are equally present in cases

and controls. Although the classification of pathogenic and likely pathogenic variants already entails many challenges, the interpretation of VUS variants is even more complicated. This underlines the need for better classification systems for variants in complex diseases.

There are some limitations to this study. Since Project MinE is a multicentre study, our cohort is composed of samples from different countries. Patients are mostly of European descent, which makes it a good reference work for this population, but caution is needed for the extrapolation to other populations. Although the control population was matched for the different populations included, the size of the control population was too small to calculate robust ORs for every single variant. Furthermore, the samples were not included according to strict criteria other than the revised El Escorial criteria, which might have led to small differences in inclusion criteria per centre. Lastly, the definition of ‘familial ALS’ has been slippery over the years.<sup>37</sup> Extensive data about the familial history was not (always) available (e.g. occurrence of FTD in the family, ALS in third degree family members), so only the more ‘obvious’ fALS cases were excluded in this study, possibly leading to an overinflation of sALS cases.

In conclusion, this paper constitutes an inventory of pathogenic variation in a large cohort of European-ancestry sALS patients, which can serve as a valuable resource for genetic counselling and for the design of ALS gene panels. We could not provide evidence for association with ALS for all genes. However, further research is needed to exclude very rare pathogenic variants or variants with moderate risk factors in these genes. To better explore the oligogenic hypothesis, even larger cohorts are needed to reach acceptable statistical power. A challenging journey lies ahead to obtain reliable comprehensive gene testing and counselling of sALS patients. However, it is a priority for clinical trial design and therapy development in ALS.
