## Abstract

In this study, we extensively describe experimental models, with correlating experimental conditions, which were used to investigate the enzymatic hydrolysis of bacterial cellulose (BC) to obtain nanocrystals. Cellulase from *Trichoderma reesei* was used in five enzyme/BC ratios over a period of 74 h. The turbidity data was modeled using both logistic regression and empirical regression to determine the fractal kinetics, resulting in unique kinetic patterns for the mixtures that were richest in BC and in enzymes. The evolution of the yield was inversely related to the turbidity, as confirmed through a semi-empirical approach that was adopted to model the experimental data. The yield values after 74 h of hydrolysis were higher for the substrate-rich mixtures (~20%) than for the enzyme-rich mixtures (~5%), as corroborated by cellobiose and glucose quantification. Transmission electron microscopy and atomic force microscopy analyses revealed a shift from a fibril network to a needle-like morphology (i.e., aggregated nanocrystals or individual nanocrystals ~6 nm width and 200-800 nm in length) as the enzyme/BC ratios went from lower to higher. These results were explained in terms of the heterogeneous substrate model and the erosion model. This work initiated a promising, environmental-friendly method that could serve as an alternative to the commonly used chemical hydrolysis routes.

## INTRODUCTION

The exciting structure and properties of bacterial nanocellulose (BNC), a green nanomaterial, have been widely reviewed.<sup>1</sup> Although bacterial cellulose (BC) has the same chemical composition as plant-derived cellulose, differences in the biosynthesis process lead to distinct structural properties. The most relevant aspects rely on the purity of the cellulose, which is produced by some species of acetic acid bacteria (in particular, *Komagataeibacter xylinum* and *Komagataeibacter sucrofermentans*).<sup>2</sup> Pure cellulose is free of other plant components such as hemicellulose and lignin. Deviation from purity may have tremendous technical and economic consequences in all industrial settings.

From a technical point of view, the purity of BC dramatically affects the hierarchical assembly pattern of  $\beta$ -1,4-glucan chains in the cellulose I allomorph (the form that living cells assemble); the triclinic phase ( $I_{\alpha}$ ) is the most abundant (~70% from static cultures) in BNC, while the monoclinic phase ( $I_{\beta}$ ) is found in most plant cellulose.<sup>3</sup> The highly ordered alignment and stacking of glucan chain sheets into crystal units, also known as cellulose nanocrystals, is reflected in native BC's higher inherent crystallinity (84–89%) than its plant-derived counterpart (40–60%),<sup>4,5</sup> as Sacui et al. confirmed recently using a combined CPMAS-NMR/WAXS spectroscopy approach.<sup>6</sup> This turns out to be important when considering practical uses of BC (e.g., the development of nanocomposite materials), as the crystalline structure greatly affects cellulose's mechanical and interfacial properties.<sup>7</sup> The unique mechanical anisotropy of BNC is responsible for its outstanding elastic modulus, with single-fibril measurements made by atomic force microscopy (AFM; e.g., tip bending) and Raman spectroscopy as high as ~78 GPa and 114 GPa, respectively.<sup>8,9</sup> These values further increase if the crystalline phase is voided of contributions from the amorphous regions. In particular, Reiling and Brickmann estimated the crystal modulus of polymorph  $I_{\alpha}$  as being between 128 GPa and 161 GPa,<sup>10</sup> and Eichhorn and Davies estimated it as being between 136 and 155 GPa.<sup>11</sup> Regardless of the specific absolute value, the modulus of BNC is comparable with that of high-performance

1  
2  
3 synthetic fibers such as aramid (130 GPa) and is above that of aluminum (70 GPa) and glass fibers  
4  
5 (76 GPa).<sup>12</sup>  
6

7  
8 From an economic point of view, Donini et al. compared the productivity of cellulose from  
9  
10 plants and microorganisms.<sup>13</sup> They found that the production of cellulose from 1 ha of eucalyptus (80  
11  
12 t of cellulose/ha after 7 years of cultivation) could be achieved with bacteria to a hypothetical yield  
13  
14 of 15 g/L in 50 h of culture (average of 0.3 g/h) in a bioreactor of 500 m<sup>3</sup> in approximately 22 days.  
15  
16 Moreover, obtaining high-purity BC involves a simpler procedure than obtaining plant-derived  
17  
18 cellulose. Indeed, to overcome lignocellulose's inherent recalcitrance (the resistance of cell walls to  
19  
20 deconstruction), a harsh first step is necessary to remove the lignin and hemicellulose and thus  
21  
22 facilitate the subsequent processing.<sup>14</sup> The delignification or fractionation of lignocellulose (which is  
23  
24 usually carried out using a sulfite, chlorite, diluted-acid, or alkaline solution) is a cumbersome process  
25  
26 that is also somewhat detrimental to the environment.<sup>15</sup> In spite of that, while it is possible to devise  
27  
28 an economically feasible biotechnological process for BNC production, by enzymatic hydrolysis, the  
29  
30 high selling costs associated to its production are nowadays the main hurdle that restrain BNC to  
31  
32 high-value niche markets.<sup>16</sup> The main reason for this is the low yield of the fermentation process.<sup>17</sup>  
33  
34 Depending on the operating parameters (such as type of process, growth medium, strain, pH, and  
35  
36 temperature) values ranging between 4.0 g/L and 16.0 g/L have been reported.<sup>18</sup> Concerning BCNCs,  
37  
38 yields in the range 21-38% and of ~14% have been reported for acid hydrolysis<sup>19</sup> and hydrolysis  
39  
40 mediated by ammonium persulfate,<sup>20</sup> respectively. No data has been found on the yield of BCNCs  
41  
42 obtained by enzymatic hydrolysis.  
43  
44  
45  
46  
47  
48

49 Because of BC's superior chemical purity, crystallinity, and biocompatibility, as well as its  
50  
51 ultrafine network architecture and easy handling, it performs better than other conventional natural  
52  
53 or synthesized counterparts,<sup>21</sup> making its use possible for diverse sectors. The first commercially  
54  
55 available BNC product (nata de coco) appeared in the 1990s;<sup>22</sup> since then, BNC has been used for a  
56  
57 variety of applications, including textiles, cosmetics, medical or biomedical products, and food  
58  
59 products.<sup>23</sup> Other proposed uses of BNC include reinforced polymeric materials or paper; thickening  
60

1  
2  
3 agents or food stabilizers; food packaging; biomaterials for use in manufacturing cosmetics, artificial  
4 skin, artificial blood vessels, or engineered tissues; diaphragms for loudspeakers; and materials for  
5 use in the preparation of optically transparent films, electric conductors, or magnetic materials.<sup>24</sup> To  
6 exploit BNC's full potential, it is crucial to isolate the crystalline phase from the amorphous domains,  
7 especially when bacterial cellulose nanocrystals (BCNCs) are intended to be a viable alternative to  
8 inorganic or mineral-based reinforced nanobuilding blocks for the generation of polymer  
9 nanocomposites with superior performance (e.g., mechanical, gas-barrier, and thermal performance).

Acid hydrolysis is the most widely employed method for obtaining cellulose nanocrystals from  
parental, macro-sized cellulose fibers,<sup>25</sup> as also demonstrated by very recent works, where either  
hydrochloric acid or sulfuric acid were used to produce cellulose nanocrystals.<sup>26–31</sup> However,  
cellulose fibers treated with sulfuric and hydrochloric acids yield crystals with poor thermal and  
mechanical properties, which can dramatically affect the composite's final performance.<sup>32</sup> In  
addition, the use of concentrated acid solutions poses a serious environmental risk in terms of both  
disposal and energy consumption; this is in contrast with the increasing demand for innovative green  
and sustainable chemistry technologies. Therefore, it is a priority to investigate alternative CNC-  
production routes that have less environmental impact but that do not jeopardize the native cellulose's  
structural properties. Ultrasonication has been proposed to achieve this goal, but a few studies have  
highlighted that it is more convenient when used only to assist in a main chemical route's  
procedure.<sup>33–35</sup> The best-known application of enzymatic hydrolysis of cellulosic biomass is for  
biological conversion into fuels and chemicals, for which it has shown the potential to achieve higher  
yields, higher selectivity, lower energy costs, and milder operating conditions than are found in  
chemical processes.<sup>36</sup> More recently, the current global focus on refining lignocellulose biomass has  
been expanded to also include intermediate products such as nanocellulose.<sup>37</sup> Enzymatic hydrolysis  
could theoretically be employed as an approach with low environmental impact in the top-down  
reduction of cellulose to nanocrystals. In recent years, to make this process economically viable, much  
effort has been expended to increase cellulolytic enzymes' efficiency (e.g., by enhancing resistance

1  
2  
3 to operational conditions such as pH and temperature, or by increasing speed) and reduce their price.  
4  
5 As a result, a number of commercial mixtures using cellulase enzymes are available under various  
6  
7 trade names (e.g., Celluclast™, Accelerase™, Spezyme CPT™, and Viscoferm™). In fact, these  
8  
9 mixtures include a variety of enzymes that are collectively known as cellulases: i) endo-1,4-β-  
10  
11 glucanases (EGs), which target cellulose chains in random locations away from the chain ends; ii)  
12  
13 exoglucanases or cellobiohydrolases (CBHs), which degrade cellulose by splitting off molecules from  
14  
15 both ends of the chain, thus producing cellobiose dimers; and iii) β-glucosidases, which hydrolyze  
16  
17 the cellobiose units that are produced during the EG and CBH attacks, turning them into glucose.<sup>38</sup>  
18  
19 EGs, in particular, quickly degrade the amorphous regions of the cellulose chains to produce smaller  
20  
21 cellulose fragments,<sup>39</sup> whereas CBHs typically attack the short crystalline regions of the cellulose.<sup>40</sup>  
22  
23 For this reason, cellulases can be used to obtain nanocrystals in nearly the same way as is used in acid  
24  
25 hydrolysis.  
26  
27  
28  
29

30  
31 A few works in the literature already reported on the enzymatic hydrolysis of BNC. Santa-  
32  
33 Maria and Jeoh used a cellobiohydrolase (Cel7A from *Trichoderma reesei*) to investigate changes in  
34  
35 cellulose microstructure throughout the hydrolysis process by simultaneous confocal and atomic force  
36  
37 microscopy.<sup>41</sup> George et al. compared BCNC's morphological and thermal properties with those of  
38  
39 acid-processed nanocrystals, which are components in polyvinylalcohol nanocomposites.<sup>32</sup> Hu et al.  
40  
41 developed a bio-absorbable bacterial cellulose (BBC) material for wound dressing applications. The  
42  
43 biodegradation of this material was investigated by *in-vitro* biodegradability tests using different  
44  
45 enzymes (alone or in combination) as a function of pH values relevant to wound environments.<sup>42</sup> In  
46  
47 a similar study, Wang et al. evaluated the *in vitro* biodegradability of bacterial cellulose by cellulose  
48  
49 in simulated body fluid.<sup>43</sup> Domingues et al. compared CNCs obtained by acid hydrolysis of  
50  
51 eucalyptus fibers with CNCs obtained upon enzymatic hydrolysis of bacterial cellulose. The main  
52  
53 focus of this investigation was on the impact of the characteristic shape and surface chemistry of the  
54  
55 two types of CNCs at oil/water interfaces and solid surfaces (cationized silica and polystyrene films).<sup>44</sup>

3 In this work, we investigate the possibility of producing BCNCs using commercially available  
4 enzymes preparation under controlled conditions (pH, temperature, and time). We systematically  
5 discuss for the first time the effect that the enzyme/cellulose ratio has on the BCNCs' final  
6 morphological properties and also consider the yield of the water suspensions thereof. In addition,  
7 we use a modeling approach to gather information on the kinetic of the hydrolysis reaction. The  
8 information stemming from this study can be used to further clarify enzymatic hydrolysis's potential  
9 as an alternative to chemical strategies for obtaining BCNCs.

## 21 EXPERIMENTAL SECTION

### 22 *Production of the macro-sized BC*

23  
24 BC was produced by static fermentation using *Komagataeibacter sucrofermentans* DSM 15973  
25 (Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig  
26 Germany) in rectangular (630×430×115 mm<sup>3</sup>) polypropylene trays: 4 L of Hestrin and Schramm  
27 (HS) medium (glucose: 20 g/L ; peptone: 5 g/L; yeast extract: 5 g/L; Na<sub>2</sub>HPO<sub>4</sub>: 2.7 g/L; citric acid:  
28 1.15 g/L; pH 6.0) were inoculated with 0.5 L of pre-culture (HS medium, 2L Erlenmeyer flask, growth  
29 for 48 h at 30°C, 150 rpm). After 7 days at 30°C the resulting BC pellicles were removed from the  
30 cultural medium, washed with deionized water and boiled in a NaOH 1M solution for 30 min to  
31 remove the residual bacterial cells. After cycles of washing with distilled water, the cellulosic material  
32 was homogenized for 15 min with an Ultra-turrax<sup>®</sup> T25 Basic homogenizer (Ika-Werke, Stanfen,  
33 Germany) at 12,000 rpm and finally freeze-dried at -55°C and 0.63 mbar for 24 h using an ALPHA  
34 1-2 LDplus freeze dryer (Martin Christ, Osterode am Harz, Germany).

### 51 *Enzymatic hydrolysis*

52  
53 A stock dispersion of BC was prepared by adding 12 g of freeze-dried BC to 88 g of distilled water.  
54 Then, 2 g of the stock dispersion was added to 40 g of sodium acetate buffer solution (0.1 M, pH 5).  
55 The dispersion was homogenized using an Ultra-turrax<sup>®</sup> T25 Basic homogenizer (Ika-Werke,  
56  
57  
58  
59  
60

1  
2  
3 Stanfen, Germany) at 8,000 rpm for 5 min and then kept in an incubator at  $55 \pm 1^\circ\text{C}$  overnight to  
4  
5 facilitate the solvent's diffusion into the cellulose material and thus promote an even degradation of  
6  
7 the amorphous parts upon adding the enzymatic mixture. The enzymatic hydrolysis was performed  
8  
9 using cellulase from *Trichoderma reesei* (ATCC26921) in the form of lyophilized powder stock  
10  
11 (Sigma Aldrich, Milano, enzymatic activity  $\sim 6.5$  U/mg solid). A stock solution of the enzyme in water  
12  
13 (5 mg/mL) was prepared to obtain various enzyme/BC mixtures (listed in Table 1). The enzymatic  
14  
15 hydrolysis was conducted for a minimum of 2 h and a maximum of 74 h, all at  $55 \pm 1^\circ\text{C}$ .  
16

#### 45 *Analyses*

46  
47 The evolution of the enzymatic hydrolysis was monitored at 2 h or 3 h intervals in turbidity  
48  
49 experiments over a temporal window of 74 h. Spectrophotometric measurements were performed  
50  
51 using a Lambda 25 spectrophotometer (Perkin Elmer, Waltham, MA, USA) at wavelengths between  
52  
53 380 nm and 800 nm in transmittance mode. For each sample, the area under the transmittance  
54  
55 spectrum was calculated by means of PerkinElmerUV WinLab software (version 6.0.4.0738) and  
56  
57 plotted over time.  
58  
59  
60

1  
2  
3 The yield of the enzymatic process was gravimetrically determined every 2 h over a 74 h  
4 temporal window for each enzyme/BC combination collecting all the cellulosic material (Table 1).  
5  
6 More specifically, 40 mL of the enzyme/BC water dispersion was centrifuged at 4,000 rpm (2,630  
7 rcf or g-force) for 15 min using a Rotofix 32 A centrifuge (Hettich GmbH & Co. KG, Tuttlingen,  
8 Germany). The resulting pellet, made of the hydrolyzed BC, was used for gravimetric analysis with  
9  
10 a HS43S-MC halogen-lamp moisture-content analyzer (Mettler Toledo, Greifensee, Switzerland) set  
11 to 105°C.  
12

14  
15  
16  
17  
18

19 Cellobiose and glucose were the ultimate products of the enzymatic process and were quantified  
20 using high-performance liquid chromatography (HPLC). The supernatant that arose from the  
21 centrifugation of the enzyme/BC mixture (which was itself obtained after 74 h of hydrolysis)  
22 underwent a first centrifugation at 4,000 rpm (2,630 rcf or g-force) for 15 min. The supernatant of  
23 this first centrifugation was in turn centrifuged at 14,000 rpm (9,205 rcf or g-force) for 5 min to  
24 completely remove the residual particles that were still present in the solution. The HPLC analysis  
25 was performed using a Merck Hitachi L-7100 system with an Aminex HPX-87P column (300 mm ×  
26 7.8 mm; Biorad Laboratories, Hercules, CA, USA) and an evaporative light-scattering detector  
27 (Sedex 75; Sedere, Alfortville, France; conditions: He 3.5 bar, 50°C). The analysis was carried out at  
28 60°C using water (0.5 mL/min) as the eluent.  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41

42 Transmission electron microscope (TEM) was used to capture images of the BCNCs (a LEO  
43 912 AB energy-filtering transmission electron microscope operating at 80 kV; Zeiss, Oberkochen,  
44 Germany). Digital images were recorded with a ProScan 1K Slow-Scan CCD camera (ProScan,  
45 Scheuring, Germany). Samples for the TEM analyses were prepared according to the negative  
46 staining technique by drop-casting a few microliters of dispersion onto a glow-discharged Formvar-  
47 coated Cu grid (400-mesh) and letting the samples rest for 1-2 min, then blotting the excess of  
48 suspension and contrasting with uranyl acetate.  
49  
50  
51  
52  
53  
54  
55  
56  
57

58 AFM experiments were performed using a Nanoscope V Multimode (Bruker, Karlsruhe,  
59 Germany) in intermittent-contact mode after dropping 10 µL of 1:10 diluted BCNC dispersion onto  
60

1  
2  
3 a mica substrate. The images were collected at a resolution of  $512 \times 512$  pixels using silicon tips  
4  
5 (force constant: 3 N/m; resonance frequency:  $\sim 75$  kHz). Dimensional calculations for the acquired  
6  
7 images were conducted with Nanoscope software (version 7.30; Bruker, Karlsruhe, Germany). The  
8  
9 mean values reported for the BCNCs' dimensions were calculated from several images.

12 Information on the size distribution of BCNCs was obtained through photon correlation  
13  
14 spectroscopy using a dynamic light-scattering (DLS) Zetasizer ZS90 instrument (Malvern  
15  
16 Instruments Ltd., Malvern, UK). Analyses were carried out at  $25^\circ\text{C}$ , with a stabilization time of 60 s,  
17  
18 and using water's viscosity ( $\nu = 0.8872$  cP) and refractive index ( $n = 1.330$ ) values. The software  
19  
20 used the nonnegative least squares algorithm to calculate the size distribution.

23 The statistical significance of the mean values was determined via a one-way analysis of variance  
24  
25 using StatgraphicsPlus 4.0 software (STSC, Rockville, MD, USA). The mean values, where  
26  
27 appropriate, were separated using a least significant difference multiple-range test at  $p < 0.05$ .  
28  
29 Modeling of the experimental data for the turbidity and yield experiments was performed by means  
30  
31 of nonlinear regression, supported by the Levenberg–Marquardt algorithm, in Origin 8 software  
32  
33 (OriginLab Corporation, Northampton, MA, USA). The comparison between the experimental  
34  
35 transmittance data and those predicted by the models was performed using the root mean square error  
36  
37 (*RMSE*), calculated as follows:  
38  
39

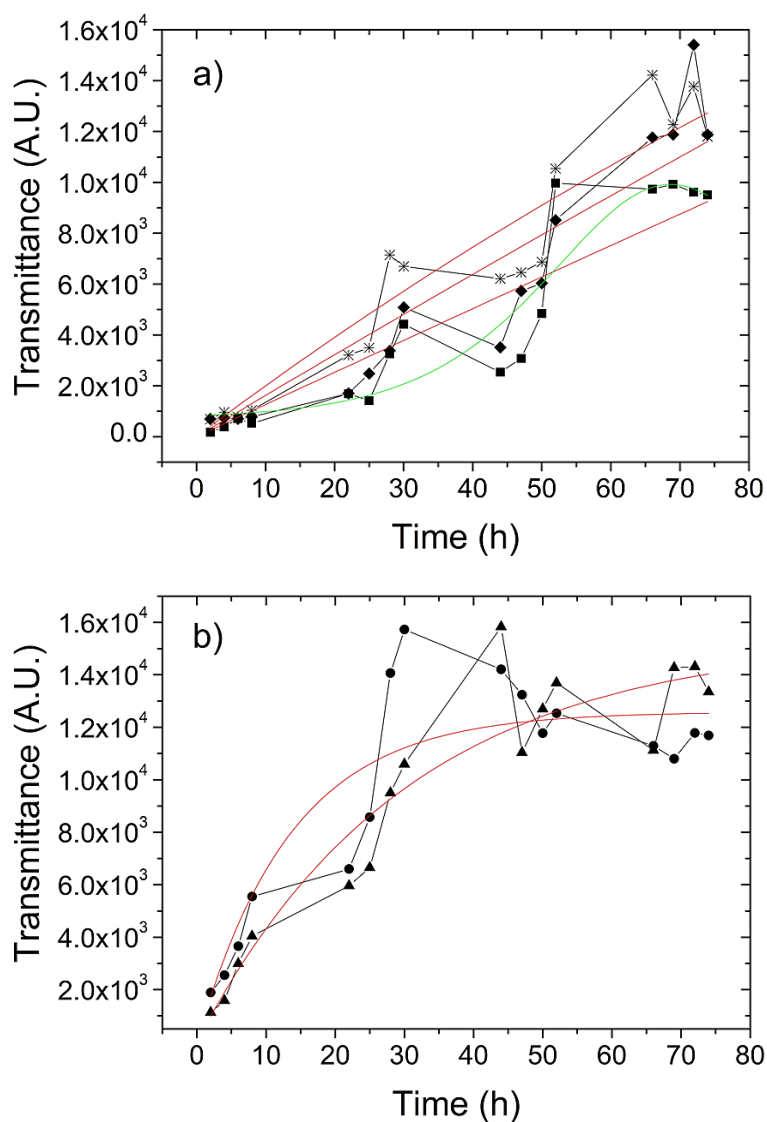

$$41 \quad 42 \quad 43 \quad 44 \quad 45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 51 \quad 52 \quad 53 \quad 54 \quad 55 \quad 56 \quad 57 \quad 58 \quad 59 \quad 60$$
$$RMSE = \sqrt{\frac{\sum_{i=1}^n (x_{\text{exp},i} - x_{\text{pred},i})^2}{n}} \quad (1)$$

where  $x_{\text{exp},i}$  is the observed (measured) value,  $x_{\text{pred},i}$  is the value predicted by the model, and  $n$  the  
number of the experimental measurements. *RMSE* is a widely used parameter to estimate the quality  
of model fitting as well as to compare the individual model performance. If *RMSE* tends toward 0 or  
is very close to the experimental error, it means that model is able to represent the experimental data.

## RESULTS AND DISCUSSION

### *Turbidity and hydrolysis kinetic analyses*

Turbidity experiments were carried out to monitor the evolution of the enzymatic hydrolysis. More specifically, decreased turbidity (i.e., increased transmittance) was expected for extended hydrolysis times as a consequence of reduced size of the BC fibrils. A decrease in size to the nanoscale level would reduce effect of the scattering phenomenon (and thus the turbidity of the BC water solution), as the wavelength of the incident light would be greater than or equal to the size of the newly formed BCNCs. As depicted in [Figure 1](#), over time, the transmittance increased for all the enzyme/BC ratios until an apparent steady state was reached; this is a clear evidence of a decreased rate during the process, which is a typical feature of cellulose hydrolysis.<sup>37</sup> Inhibition by cellobiose and glucose, enzyme deactivation, decreased substrate reactivity, decreased substrate accessibility, and decreased synergism between cellulases (among other factors) were reported as being the most relevant rate-relenting factors.<sup>45</sup> However, some obvious differences among the samples were detected in evolution of the transmittance and two different patterns were detected among the five transmittance-versus-time curves depending on the enzyme concentration. While the plots of the 1:4, 1:3, and 1:2 mixtures showed an initial lag phase followed by a rising phase ([Figure 1a](#)), the curves obtained from the 1:1 and 2:1 mixtures exhibited an immediate climbing trend ([Figure 1b](#)). It is noteworthy that the BC-containing water dispersions' initial transmittance value (i.e., after 2 h) was proportionally higher for the mixtures that had lower amounts of enzymes; this demonstrates that, even after only 2 h, the enzymatic hydrolysis produced an appreciable outcome for the mixtures richest in enzymes (1:1 and 2:1). In addition, the maximum transmittance for the 1:1 and 2:1 mixtures was achieved after ~30 and 45 h, respectively, after which a decrease was observed; the decrease was more marked for the 2:1 mixture. This decrease in transmittance (i.e., increase in turbidity) was probably due to the newly formed nanocrystals beginning to reaggregate after the completion of the hydrolysis reaction due to the extensive hydrogen bonding between the chemically unmodified (i.e., -OH rich) cellulose molecules.

**Figure 1.** Evolution of transmittance (expressed as the area under each spectrum) during 74 h of hydrolysis for the enzyme/BC ratios of: (a) 1:4 (—■—), 1:3 (—◆—), and 1:2 (—\*—); (b) 1:1 (—▲—) and 2:1 (—●—). The black lines connecting the experimental points are only to ensure clarity. The red and green lines are the fitting curves obtained from a nonlinear regression of the experimental data according to eq. 2 and eq. 3 (see the main text for details).

The two hydrolysis kinetics patterns described previously can be more clearly demonstrated by modeling the experimental transmittance data using the empirical model that Väljamäe et al. proposed for fractal kinetics, which are spatially heterogeneous reactions that are diffusion-limited, dimensionally restricted, or occurring on fractal surfaces:<sup>46</sup>

$$p(t) = [S]_0 \cdot [1 - \exp(-k \cdot t^{(1-h)})], \quad (2)$$

where  $p(t)$  is the concentration of released cellobiose (in  $\mu\text{M}$ );  $[S]_0$  is the initial concentration of the cellulose substrate, as represented as cellobiose units ( $\mu\text{M}$ );  $t$  is time; and  $k$  and  $h$  are empirical constants. To apply eq. 2 to our turbidity data, the product concentration and transparency were assumed to follow the same evolution; that is, in the time course of insoluble cellulose's enzymatic degradation, as the concentration of cellobiose increases, the transparency increases (or the turbidity decreases) proportionally. It must be pointed out that eq. 2 was used only for fitting purposes—to provide clear evidence of the two patterns observed during the native BC hydrolysis reaction for the various cellulose/enzyme ratios. Therefore, no physical meaning was assigned to the constants  $k$  and  $h$ . As shown in [Figure 1](#), the nonlinear regression of the hydrolysis data (expressed as transparency evolution) using eq. 2 yielded two prediction patterns, which is consistent with the experimental points. These two patterns are represented by the red lines of both panel (a) and panel (b) of [Figure 1](#). In particular, the prediction for the 2:1 and 1:1 enzyme/BC mixtures followed the typical trend for the enzymatic hydrolysis of BC, with an initial increase and subsequent decrease in the reaction rate ([Figure 1b](#)). The prediction for the remaining mixtures (1:2, 1:3, and 1:4) provided by the same fractal model is instead represented by a straight line that denotes a different hydrolysis kinetics pattern for the mixtures containing a lower amount of enzyme ([Figure 1a](#)). This is further corroborated by the fact that a better prediction for the data sets of the 1:2, 1:3, and 1:4 mixtures was obtained using a logistic regression model (see the green line for the 1:4 mixture in [Figure 1a](#)):

$$y = a + 4b \cdot n / (1 + n)^2, \quad (3)$$

where  $n = \exp(-(x - c) / d)$ ;  $a$ ,  $b$ ,  $c$ , and  $d$  are empirical parameters. Detailed information on the modeling of the experimental data using both eq. 2 and eq. 3 is reported in [Figures S1–S5](#) of [Supporting Information](#), together with the relevant statistical parameters arising from the fitting procedure ([Table S1](#)).

This study's logistic model is a sigmoid function that has been used to interpolate S-shaped data distributions for studies on topics such as tumor growth,<sup>47</sup> toxicity and cytotoxicity,<sup>48–50</sup>

1  
2  
3 biodegradability,<sup>51</sup> catalysis,<sup>52</sup> microbial growth,<sup>53</sup> biotechnological processes,<sup>54</sup> and food-texture  
4 evolution.<sup>55</sup> In this work, the logistic regression model suggests that, for high substrate/enzyme ratios,  
5 the course of BC's enzymatic hydrolysis stays in a silent phase for the first approximately 6-8 h,  
6  
7  
8  
9 contrary to what was observed for the mixtures richest in enzymes (i.e., the 1:1 and 2:1 mixtures).

10  
11  
12 These observations have a mechanistic explanation. Enzymatic hydrolysis of cellulosic biomass  
13 is a heterogeneous reaction that occurs on the surface of a substrate that is large enough to  
14 accommodate a large number of enzyme molecules.<sup>45</sup> After the first adsorption of cellulases onto the  
15 substrate (phase 1),<sup>56</sup> the two following steps more directly affect the hydrolysis rate: the location of  
16 a bond that is susceptible to hydrolysis on the substrate surface (phase 2)<sup>57</sup> and the formation of an  
17 enzyme-substrate complex (phase 3).<sup>58</sup> Therefore, as the enzyme/cellulose ratio increases (and the  
18 amount of enzyme adsorbed on the cellulose surface increases), the hydrolytic reaction speeds up  
19 (given that the cellulosic substrate has the same characteristics in terms of, e.g., composition and  
20 crystallinity). The initial lag phase observed for the 1:4, 1:3, and 1:2 mixtures can thus be plausibly  
21 explained by considering the extended time that is necessary for phase 2 and phase 3 to take place  
22 due to the lower initial enzyme concentrations for those phases. In addition, the interaction between  
23 endo-type and exo-type enzymes must be considered. The most established mechanism is a sequential  
24 synergistic action whereby EGs initiate the attack on the cellulose by forming new chain ends, which  
25 then serve as attack sites for the endwise-acting CBHs' processive hydrolysis.<sup>59</sup> This means that, for  
26 the mixtures with the fewest enzymes, an extended time is expected to elapse before the hydrolysis  
27 of BC can actively occur because the EGs must generate the new chain ends before the CBHs can  
28 start to processively hydrolyze the cellulose chains.

### 51 52 53 *Yield of the hydrolysis process*

54  
55  
56 The yield of the parental freeze-dried BC's hydrolysis reaction over 74 h is displayed in [Figure 2a](#) for  
57 all five enzyme/BC mixtures used in this work. The evolution of the yield is inversely related to the  
58 results of the turbidity experiments (i.e., the transmittance evolution is an indirect indication of the  
59  
60

1  
2  
3 hydrolysis rate), as shown in [Figure 1](#). The yield for the substrate-rich mixtures (i.e., 1:4 and 1:3)  
4  
5 apparently decreased only slightly during the first ~20 h, reflecting the lag phase that was also  
6  
7 observed in the turbidity experiments. After this time, the yield decreased more rapidly, indicating a  
8  
9 more intensive hydrolysis reaction. By contrast, for the enzyme-rich mixtures (i.e., 1:1 and 2:1), the  
10  
11 yield decreased rapidly during the first ~10 h before decreasing, suggesting that the hydrolysis  
12  
13 reaction had approached completion. A similar, though less pronounced, hydrolysis reaction was  
14  
15 apparent for the 1:2 mixture.  
16  
17  
18

19  
20 Quantitative information on the yield evolution was obtained through a semi-empirical  
21  
22 approach. The experimental yields collected during the 74 h period of analysis were first modeled via  
23  
24 nonlinear regression, with the goal of obtaining a simple but adequate analytical expression (and its  
25  
26 first derivative). In particular, a first-order (eq. 4) decay function was used for the 1:2 mixture, a  
27  
28 second-order (eq. 5) decay function was used for the 1:1 and 2:1 mixtures, and a simple power  
29  
30 function (eq. 6) was used for the 1:3 and 1:4 mixtures:  
31  
32

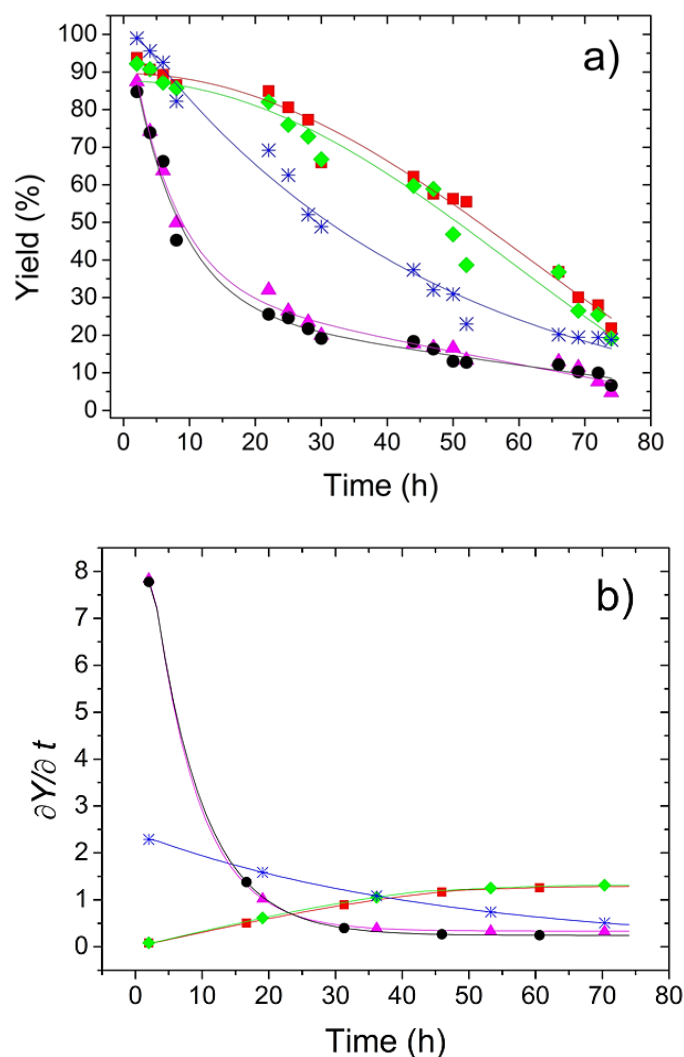

$$y = y_0 + a_1 \exp(-x/b_1) \quad (4)$$

$$y = y_0 + a_1 \exp(-x/b_1) + a_2 \exp(-x/b_2) \quad (5)$$

$$y = (a + bx^2)^2 \quad (6)$$

33  
34  
35  
36  
37  
38  
39  
40 As shown in [Figure 2a](#) (solid lines), the selected functions fit the experimental data satisfactorily,  
41  
42 which further supports the various kinetics that underlie the yield evolution and, in turn, the hydrolysis  
43  
44 reaction. From a quantitative point of view, the first derivatives of the above functions provided  
45  
46 indications of the process's rate. The yield rate decreased steeply from the beginning for the 1:1 and  
47  
48 2:1 mixtures, suggesting that the hydrolysis reaction was fully active after 2 h of incubation. After  
49  
50 ~30 h, the yield rate approached a quasi-steady state, again denoting the completion of the process.  
51  
52 A similar trend pertained to the 1:2 mixture, though it is worth noting that the initial rate in this  
53  
54 mixture was almost four times lower than those of the 1:1 and 2:1 mixtures.  
55  
56  
57  
58  
59  
60

**Figure 2.** (a) Experimental (symbols) and predicted (solid lines) yield values of the various enzyme/BC ratios, according to eq. 4 (1:2 [ $-\ast-$ ] mixture), eq. 5 (1:1 [ $-\blacktriangle-$ ] and 2:1 [ $-\bullet-$ ] mixtures), and eq. 6 (1:3 [ $-\blacklozenge-$ ] and 1:4 [ $-\blacksquare-$ ] mixtures). (b) First derivative of the fitting curves shown in panel (a). The symbols are only to aid in identification.

Interestingly, the first derivative of eq. 6, which was used to interpolate the experimental yield data of the 1:3 and 1:4 mixtures, started at a zero-speed-rate state, further corroborating the presence of an initial latency phase in hydrolysis reactions involving substrate-rich mixtures. The rate slowly increased until reaching a steady state after  $\sim 50$  h, and the resulting value was, in any case, much lower than the maximum rates recorded for the 1:1 and 2:1 mixtures (which were in the early stages of the hydrolysis process). These results demonstrate that the hydrolysis of BC at high substrate

1  
2  
3 concentrations (the 1:3 and 1:4 mixtures) was not as efficient as for the enzyme-rich mixtures (the  
4 1:1 and 2:1 mixtures). However, after 74 h, the absolute yield was higher for the substrate-rich  
5 1:1 and 2:1 mixtures). However, after 74 h, the absolute yield was higher for the substrate-rich  
6 1:1 and 2:1 mixtures). However, after 74 h, the absolute yield was higher for the substrate-rich  
7 1:1 and 2:1 mixtures). However, after 74 h, the absolute yield was higher for the substrate-rich  
8 1:1 and 2:1 mixtures). However, after 74 h, the absolute yield was higher for the substrate-rich  
9 1:1 and 2:1 mixtures). However, after 74 h, the absolute yield was higher for the substrate-rich  
10 hydrolysis process the occurred for the dispersions that contained the most enzymes (1:1 and 2:1).

11  
12 The appearance of the water dispersions that contained hydrolyzed BC was markedly different  
13 from that of the initial mixture that contained the parental BC (Figure 3). After 74 h of hydrolysis, all  
14 the mixtures were slightly hazy and fully homogeneous (i.e., without any macroscopic cellulosic  
15 aggregate), especially the mixtures with the 1:1 and 2:1 enzyme/BC ratios. This strongly suggests  
16 that all samples decreased in size, though at different time scales (after approximately 50 h of  
17 hydrolysis for the 1:4, 1:3, and 1:2 mixtures and approximately 30 h for the 1:1 and 2:1 mixtures).

43 **Figure 3.** Photos of parental BC before hydrolysis (left) and of the enzyme/BC mixtures after 74 h  
44 of hydrolysis (right). Note the flakes in the parental dispersion and the decreasing hazy appearance  
45 moving from the 1:4 mixture to the 2:1 mixture.

#### 51 52 *Cellobiose and glucose quantification*

53  
54 The outcome of the HPLC analysis is reported in Figure 4. The concentrations of cellobiose and  
55 glucose were inversely related as a function of the enzyme/BC ratio; the disaccharide concentration  
56 decreased as the ratio decreased, whereas the hexose concentration increased monotonically as the  
57  
58  
59  
60

amount of enzyme increased. These results confirm that more intense hydrolytic activity occurred at higher concentrations of enzyme. In addition, the conversion of cellobiose into glucose after 74 h (mostly by the  $\beta$ -glucosidases) was higher for the mixtures that were richer in enzymes, insomuch as no cellobiose was detected in the supernatant of the 2:1 mixture. Finally, the quantitative analysis of cellobiose and glucose was in agreement with the yields calculated for the five enzyme/BC mixtures: lower yields were associated with higher concentrations of glucose after 74 h of hydrolysis.

**Figure 4.** Cellobiose and glucose concentrations at the end of the 74 h BC hydrolysis reaction. Error bars represent the standard deviation around the mean value. The superscripts in italics refer to statistically significant differences within the same group ( $p < 0.05$ ). <sup>a</sup>Aqueous solution (5 mg/g; see main text for details). <sup>b</sup>Aqueous dispersion (12% by weight; see main text for details). N.D.: Not determined.

#### *Morphological characterization of hydrolyzed BC*

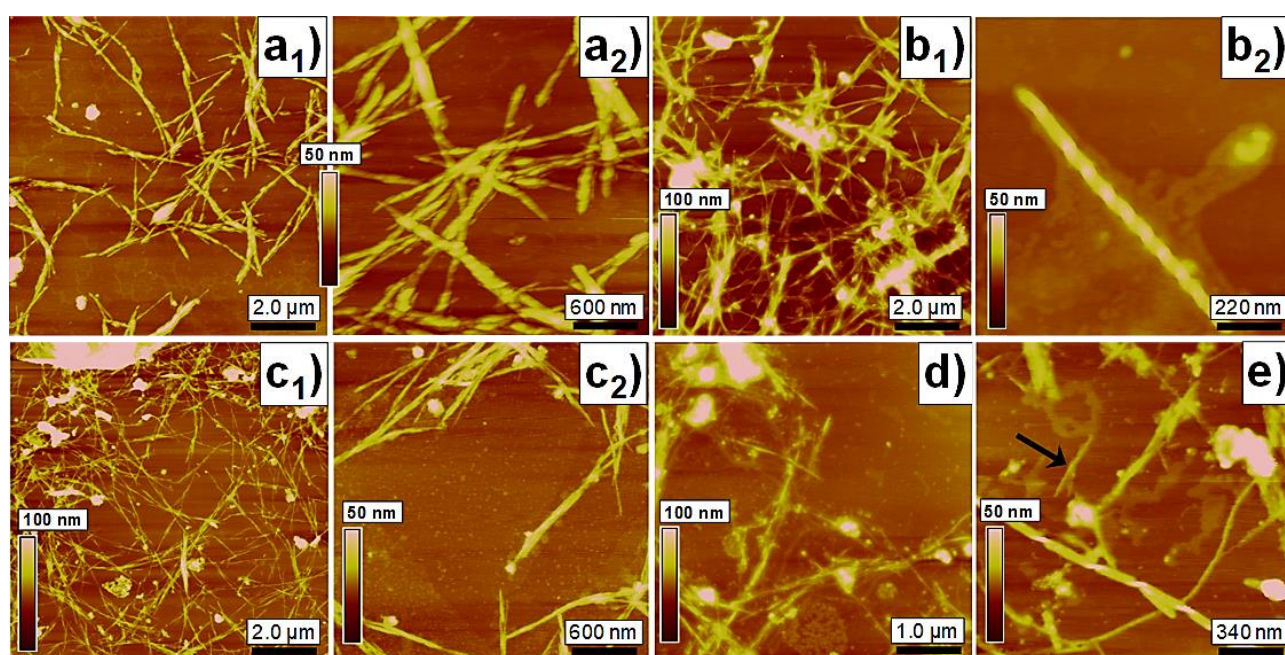

Cellulose has a unique structure, as it is organized in a hierarchical fashion, with plant-derived cellulose and BC having quite distinct features due to certain differences in their respective biosynthesis processes.<sup>60</sup> At a basic level, adjacent molecules interact via van der Waals forces and

intermolecular hydrogen bonding promoting the arrangement of cellulose chains in elementary fibrils. Within these cellulose fibrils there are regions where the cellulose chains are organized in a highly ordered (crystalline) structure, and regions that are disordered (amorphous-like).<sup>61</sup> Although the interplay and spatial organization of these two phases has yet to be clarified, according to the existing literature it is likely that the amorphous phase is randomly distributed along and across the contour of the fibril. The crystalline domains are made of crystal units (known as cellulose nanocrystals) of 3–10 nm in width (depending on the source), i.e., highly ordered domains whereby cellulose chains adopt parallel configurations according to the specific hydrogen-bonding pattern of BC's allomorph  $I_{\alpha}$ .<sup>62</sup> The next structural level involves the assembly of elementary fibrils to form cellulose nanofibrils (also called microfibrils) of 20–100 nm in width.<sup>63,64</sup> Self-assembly of these nanofibrils leads to a third level of structural organization, which, for BC, involves flat ribbons with rectangular cross-sections.<sup>65,66</sup>

**Figure 5.** Transmission electron microscopy images of hydrolyzed bacterial cellulose after 74 h according to the following enzyme/BC ratios: (a) 1:4, (b<sub>1</sub> and b<sub>2</sub>) 1:3, (c) 1:2, (d) 1:1, and (e) 2:1.

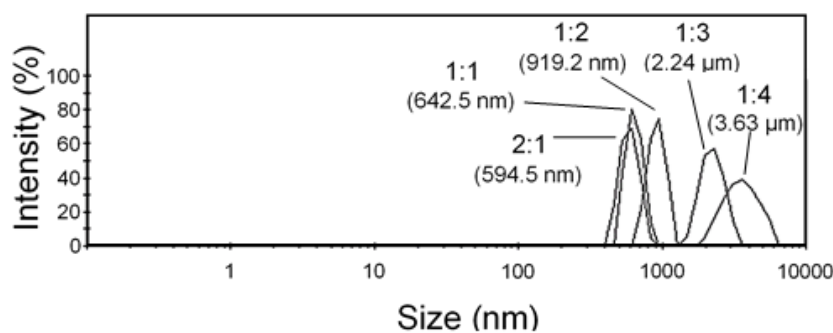

The enzymatic hydrolysis yielded different morphologies depending on the enzyme/BC ratio, as seen in Figures 5 and 6, which show representative TEM and AFM images, respectively. A shift occurs from a network of fibrils at lower enzyme/BC ratios to a thinner morphology at higher ratios (e.g., see panels a through e of Figure 5). In particular, flat ribbons of variable width in the range of 50–100 nm were observed for the 1:4 and 1:3 mixtures (Figures 5a and 5b<sub>1</sub>), with bundles of ribbons still present in the 1:4 mixture. A markedly different morphology was observed for the 1:2 enzyme/BC ratio, for which thin nanofibrils were tightly connected, forming a bundle rather than isolated particles (Figure 5c). This change in morphology was accompanied by a marked reduction in size (compare panels a<sub>1</sub> and a<sub>2</sub> with panels c<sub>1</sub> and c<sub>2</sub> in Figure 6), whereby thinner particles (although of similar length) were obtained from the 1:2 mixture (Figure 6c).

**Figure 6.** Atomic force microscopy height images of hydrolyzed BC after 74 h according to the following enzyme/BC ratios: (a) 1:4 at  $10 \times 10 \mu\text{m}^2$  (a<sub>1</sub>) and  $5 \times 5 \mu\text{m}^2$  (a<sub>2</sub>); (b) 1:3 at  $10 \times 10 \mu\text{m}^2$  (b<sub>1</sub>) and  $1 \times 1 \mu\text{m}^2$  (b<sub>2</sub>); (c) 1:2 at  $10 \times 10 \mu\text{m}^2$  (c<sub>1</sub>) and  $3 \times 3 \mu\text{m}^2$  (c<sub>2</sub>); (d) 1:1 at  $5 \times 5 \mu\text{m}^2$ ; and (e) 2:1 at  $1.7 \times 1.7 \mu\text{m}^2$ .

1  
2  
3 This confirmed the results of both the turbidity experiments and the yield experiments, as the 1:2  
4 enzyme/BC ratio led to a unique hydrolysis kinetic pattern that was reflected in the hydrolyzed BC's  
5 ultimate structural characteristics.  
6  
7  
8

9  
10 For the 1:1 and 2:1 mixtures, a progressive thinning was observed by increasing the enzyme  
11 concentration, with individual nanocrystals as thin as ~6 nm (means:  $12.1 \pm 4.9$  nm and  $8.6 \pm 1.3$  nm  
12 for the 1:1 and 1:2 mixtures, respectively) and of 200–800 nm in length (mean:  $345 \pm 7$  nm for the  
13 1:2 mixture; see [Figures 5d and 5e](#)). For the 2:1 mixture, a tendency toward reaggregation of the  
14 individual nanocrystals was detected ([Figure 5e](#)), which would explain the decreasing trend in the  
15 final part of the transmittance curve during the turbidity experiments (see [Figure 1](#)). In general, while  
16 the morphology of the hydrolyzed BC tended to thinner particles, the simultaneous presence of large  
17 particles was observed even for the enzyme-richest mixtures, confirming the larger polydispersity of  
18 BC-derived nanoparticles over the plant-derived counterpart.<sup>10,62</sup> The progressive reduction in size  
19 was confirmed via a particle-size analysis ([Figure 7](#)). Although we are aware of the inadequacy of  
20 the DLS technique in determining the absolute size distribution of nonspherical particles, we decided  
21 to use this analysis in this work to gather relative information on the size reduction of hydrolyzed BC  
22 as a function of the enzyme/BC ratio. Therefore, though the absolute size values reported here should  
23 be considered with caution, a clear shift toward a lower size occurred as the enzyme/BC ratio  
24 decreased. Interestingly, the peaks pertaining to the 1:1 and 2:1 mixtures almost overlapped,  
25 providing further indication that the BCNCs reaggregated in the mixtures that were richest in  
26 enzymes. The thinning of the hydrolyzed BC particles when the enzyme concentration increases  
27 seems to suggest a peripheral attack of the enzyme, which would align with the model that Martínez-  
28 Sanz et al. proposed, according to which BC ribbons can be considered two-phase systems composed  
29 of a core of solvent-impermeable crystallites and an outer shell of paracrystalline and amorphous  
30 cellulose.<sup>60</sup>

**Figure 7.** Size-distribution intensity plot of hydrolyzed BC after 74 h, using dynamic light-scattering, for the 1:4, 1:3, 1:2, 1:1, and 2:1 enzyme/BC ratios. The mean particle sizes are in parentheses.

Notably, long particles in the form of fibrils or flat ribbons were also observed in the enzyme-rich mixtures (Figures 6d and 6e), though to a lesser extent than in the 1:4, 1:3, and 1:2 mixtures. This clearly shows that the enzymatic hydrolysis generates a certain degree of unevenness, that is, some very smooth and well-defined nanoparticles but also remaining bundles. The simultaneous presence of nanocrystals (see the arrow in Figure 6e) and bigger particles seems to corroborate the heterogeneous substrate model, which assumes a natural heterogeneity of cellulose structure in which hydrolysis only changes the proportions of structural elements with different structural properties. At the same time, the various BCNC morphologies and the high glucose concentrations, especially in the 1:1 and 2:1 mixtures, lead us to consider the surface-erosion model as a plausible way to describe the random action of cellulases on the surfaces of crystalline domains.<sup>63</sup> In addition, as was postulated for the 2:1 mixture after the turbidity experiments, the random erosion of the crystalline surface was the probable reason for the observed reaggregation of microfibril bundles;<sup>67</sup> this was confirmed via microscopy analyses.

Finally, it is interesting to note that twisted ribbons with various sizes and periodicities were observed in all samples (see Figure 5b<sub>2</sub> and Figures 6b<sub>2</sub> and 6e). This feature of BC is known,<sup>68</sup> though it is not clear whether the twists are biological in origin (caused by rotational movements of bacteria or enzyme complexes), physical (caused by the chiral nature of cellulose), or a combination

1  
2  
3 of these.<sup>69</sup> Similar morphologies have been extensively described for fibrillar proteins (e.g., amyloid  
4  
5 fibrils), the structural features of which strongly depend on the mechanisms of fibrillation.<sup>70</sup>  
6  
7  
8

## 9 10 CONCLUSIONS

11  
12 Enzymatic hydrolysis of BC is a feasible route for obtaining nanocrystals. Pinpointing the optimal  
13  
14 enzyme concentration, especially with respect to the amount of substrate that takes part in the  
15  
16 reaction, is necessary for efficient downsizing of the parental macroscopic fibers. However, the  
17  
18 simultaneous presence of particles with various morphologies (i.e., those with varied sizes and aspect  
19  
20 ratios) confirmed the heterogeneous nature of the enzymatic hydrolysis. In addition, although the  
21  
22 mixtures that were richest in enzymes provided the best outcome in terms of BCNCs, they were also  
23  
24 characterized by very low yields, demonstrating the high intensity of EGs' and CBHs' hydrolytic  
25  
26 action when performed in synergy, even for cellulose's crystalline regions. In this sense, the use of  
27  
28 endoglucanases that selectively attack only the cellulose nanofibrils' amorphous domains could  
29  
30 represent a step toward a more efficient process. At the same time, in line with the circular economy  
31  
32 principles, the glucose that results from the hydrolytic process can be reused as fuel in the growth  
33  
34 medium for the acid bacteria that produce BC.  
35  
36  
37  
38

39  
40 After this investigation, we would suggest setting the hydrolysis process at the 2:1 enzyme/BC  
41  
42 ratio up to 30 hours of reaction or, alternatively, the 1:1 enzyme/BC ratio up to ~ 45 hours. After  
43  
44 these temporal windows, it is possible to achieve a yield approaching 25% with a final morphology  
45  
46 mostly represented by BCNCs. However, the zero net electrical charge on the surface of the BCNCs  
47  
48 resulting from the enzymatic process has to be addressed in order to obtain stable suspensions over  
49  
50 time. In this regard, using surfactants and/or polyelectrolytes to act as spacers, or inducing surface  
51  
52 modifications on the cellulose backbone could be valid options.  
53  
54

55  
56 The information gathered in this study is primarily meant to benefit the scientific community,  
57  
58 particularly materials scientists who are looking for an alternative approach for obtaining cellulose  
59  
60 nanocrystals that is greener than chemical hydrolysis routes. This study's ultimate impact is of general

1  
2  
3 interest, as cellulose nanocrystals are increasingly being considered for applications in various fields,  
4 including medical/biomedical devices, purification/cleaning systems (e.g., membranes), displays,  
5 green building materials (e.g., insulating panels), and packaging solutions.

### 10 Graphical Abstract

### Synopsis

Cellulose nanocrystals can be extracted from bacterial cellulose by enzymatic hydrolysis, which represents an alternative green method to the most widely adopted chemical (e.g., acid) hydrolysis.
