#### Abstract

Excited states in ${ }^{137}$ Cs have been studied by using the near-barrier, single-proton transfer reaction ${ }^{10} \mathrm{~B}\left({ }^{136} \mathrm{Xe},{ }^{9} \mathrm{Be} \gamma\right){ }^{137} \mathrm{Cs}$ in inverse kinematics and performing particle $-\gamma$ and particle- $\gamma \gamma$ coincidence measurements. The low-spin level scheme of ${ }^{137} \mathrm{Cs}$ has been augmented: (i) The expected set of single-proton, seniority $v=1$ states has been delineated in its entirety; (ii) Another member of the $v=3$ proton $0 g_{7 / 2}$ multiplet, a low-lying $9 / 2^{+}$level, has been identified and this set of states now approaches completion; (iii) A second $9 / 2^{+}$ and a candidate $13 / 2^{+}$level have been observed. The results are discussed in the framework of shell-model calculations in the proton $2 s 1 d 0 g 0 h$ shell.

## I. INTRODUCTION

Studies of increasingly neutron-rich nuclei lead to the quest for new and improved data on single-proton states [1]. Specifically, it is desirable to use a complete set of experimentally supported single-particle proton energies, for a given valence-proton shell, when describing high-precision spectroscopic data. In the ${ }^{132} \mathrm{Sn}$ region, for example, the nuclei of interest are those from $\mathrm{Sb}(Z=51)$ up to about $\mathrm{Cs}(Z=55)$ with neutron numbers $N \geqslant 82$.

The subject of the present study is the semimagic nucleus ${ }^{137} \mathrm{Cs}$. Recent experimental studies of ${ }^{137} \mathrm{Cs}$ have been carried out with emphasis on the high-spin yrast structure, using deep-inelastic, one-proton transfer, and fusion-fission reactions [2,3] as well as spontaneous fission of ${ }^{252} \mathrm{Cf}$ [4]. The most comprehensive low-spin studies, on the other hand, date back to the nineteen-seventies using $\left(d,{ }^{3} \mathrm{He}\right)$ and $\left({ }^{3} \mathrm{He}, d\right)$ reactions [5] as well as $\beta$ decay $[6,7]$. The resulting level scheme is proposed in Ref. [8]. The present experiment utilizes a one-proton transfer reaction in inverse kinematics with a ${ }^{136} \mathrm{Xe}$ beam on a ${ }^{10} \mathrm{~B}$ target. Using the approach of Refs. [9,10], a specific targetlike fragment (TLF) is correlated with coincident $\gamma$ rays

[^0]emitted by the corresponding projectilelike fragment (PLF). New levels in ${ }^{137} \mathrm{Cs}$ as well as spin and parity assignments to previously observed states are reported. The experimental findings are compared with shell-model calculations. The overall agreement between theory and experiment is found to be satisfactory.

## II. EXPERIMENTAL CONDITIONS AND ANALYSIS PROCEDURES

The experiment introduced above was performed at the ATLAS accelerator at Argonne National Laboratory as part of a series of runs with a $560-\mathrm{MeV}{ }^{136} \mathrm{Xe}$ beam impinging on different targets. The pertinent information about these runs is summarized in Table I. The detection setup comprised Digital Gammasphere [11], with 92 Compton-shielded HPGe detectors arranged in 16 angular rings around the target [12], and the Phoswich Wall charged-particle detector array [13], located downstream from the target with a laboratory-angle coverage of $9^{\circ} \leqslant \theta_{\text {lab }} \leqslant 72^{\circ}$. The event trigger required that a Phoswich Wall element and at least two HPGe detectors fired prior to suppressing Compton-scattering signals.

In the offline analysis, a gating procedure was applied to the so-called (A,C) particle map, which makes use of the Phoswich Wall fast-plastic and $\mathrm{CsI}(\mathrm{Tl})$ signals [13], and the prompt peak of the measured particle's time spectrum with respect to the accelerator radiofrequency. The map gating condition required the presence of TLF beryllium events. A typical particle map

${ }^{\text {a }}$ Monoisotopic.
for the data obtained with the ${ }^{10} \mathrm{~B}$ target is presented in Fig. 1. The Doppler-shift correction applied to the $\gamma$-ray spectra relied on the PLF velocity vector reconstructed event-by-event for the direct reaction, and took advantage of the 256 -fold pixelation of the Phoswich Wall [13].

For each run, two types of two-dimensional histograms of $\gamma$-ray energies were created: (i) a $E_{\gamma}-E_{\gamma}$ matrix and (ii) a set of "angle-dependent" $E_{\gamma}(\chi)-E_{\gamma}$ (any) matrices. The matrices in (ii) allowed to determine the $\gamma$-ray anisotropies relative to the spin direction of the fragment nucleus following the procedure of Ref. [14]. Here, $\chi$ represents the angle between the emitted $\gamma$ ray and the spin direction (binned into $10^{\circ}$ increments), while "any" stands for no angle requirement. All these histograms were analyzed using the RADWARE analysis package [15].

FIG. 1. An (A,C) particle map for the ${ }^{136} \mathrm{Xe}+{ }^{10} \mathrm{~B}$ data. The study of ${ }^{137} \mathrm{Cs}$ uses the two-dimensional gate that selects beryllium events. The two other particle groups represent boron and carbon events, respectively, the former being associated with projectile Coulomb excitation. The map is for pixel 30 of the Phoswich Wall. The color scale shown on the right provides the range of $z$-axis values in this example.

FIG. 2. Representative $\gamma$-ray spectra for the $560-\mathrm{MeV}{ }^{136} \mathrm{Xe}+$ ${ }^{10} \mathrm{~B}$ reaction. (a) Total projection of a $\gamma-\gamma$ coincidence matrix gated by beryllium ions in the A-C map (see text). Transitions are labeled by their energy in keV. (b) Coincidence spectrum for ${ }^{137} \mathrm{Cs}$ obtained by gating on the $455-\mathrm{keV}$ transition. Transitions with labels in parentheses are viewed as insignificant (see text). (c) Similar to (b), but for the $1273-\mathrm{keV}$ gating transition (main panel). Inset: higher-energy extension of the spectrum of panel (b). The position of the gate is always indicated by the letter G . The $\gamma$ rays labeled by a plus sign are newly observed.

## III. EXPERIMENTAL RESULTS

This section reports the new information on the ${ }^{137}$ Cs level scheme obtained in the present experiment. Representative $\gamma$-ray spectra for the desired one-proton transfer channel leading to ${ }^{137} \mathrm{Cs}$ are provided in Figs. 2 and 3 and are used to justify the location of new transitions in the level scheme of Fig. 4. Note that the precise level and $\gamma$-ray energies are reported in Table II, together with other relevant information on each transition. The total projection in Fig. 2(a) has been produced with a beryllium gate and is dominated by the $\gamma$ rays of ${ }^{137} \mathrm{Cs}$ such as the prominent $5 / 2^{+} \rightarrow 7 / 2^{+}$ground-state transition [8]. In addition to ${ }^{137} \mathrm{Cs}$, the ${ }^{139,140} \mathrm{Ba},{ }^{139} \mathrm{La}$, and ${ }^{142} \mathrm{Ce}$ nuclei are present as well. The latter nuclei originate from incomplete fusion reactions, for which the remaining light fragments have leaked into the particle coincidence gate. Specifically, the ${ }^{136} \mathrm{Xe}+\alpha$ incomplete fusion reaction leads to the ${ }^{139} \mathrm{Ba}+\mathrm{n}$ and ${ }^{140} \mathrm{Ba}$ channels, and a ${ }^{6} \mathrm{Li}$ ion remains,

FIG. 3. Coincidence spectra for ${ }^{137} \mathrm{Cs}$ obtained by gating on the transitions with the respective energies of (a) 1114 keV (main panel) and 1109 keV (inset), (b) 1184 keV , and (c) 627 keV . The meaning of G and of the plus sign is the same as in Fig. 2. The $684-\mathrm{keV}$ assignment in panel (b) is done with less confidence than that for a stronger peak.
while the ${ }^{136} \mathrm{Xe}+{ }^{6} \mathrm{Li}$ combination produces ${ }^{139} \mathrm{La}+3 \mathrm{n}$ and is accompanied by an $\alpha$ particle. In this context, the ${ }^{142} \mathrm{Ce}$ line is attributed to a ${ }^{136} \mathrm{Xe}$ reaction on oxygen, with the latter being present due to target oxidation.

Figures 2(b) and 2(c) display beryllium- and $\gamma$-gated spectra for ${ }^{137} \mathrm{Cs}$. The spectrum in coincidence with the $455-\mathrm{keV}$ transition [Fig. 2(b) and inset of Fig. 2(c)] displays the expected lines [8] and, in addition, new $\gamma$ rays with respective energies of $666,1037,1703$, and 1905 keV . Except for the $666-\mathrm{keV} \gamma$ ray, these transitions directly feed the $455-\mathrm{keV}$ first-excited state in ${ }^{137} \mathrm{Cs}$, as proposed in Fig. 4. The $666-\mathrm{keV} \gamma$ ray represents the energy difference between the 1703- and $1037-\mathrm{keV}$ transitions. These three lines determine the position of the second $1 / 2^{+}$ state more precisely than was the case in previous work (17-keV uncertainty [5,8]). Further justification of the above direct feeding of the first excited state is provided by the $1273-\mathrm{keV}$ gate of Fig. 2(c): this ground-state transition and the $455-\mathrm{keV} \gamma$ ray do not share coincidence relationships with other lines. The spectrum of Fig. 2(b) warrants two additional comments. First, the present data support the negative result of Ref. [7] on a low-lying candidate $3 / 2^{+}$level at 982 keV that had been reported in a preceding study [6]. If this level had been populated, it would likely decay to the $455-\mathrm{keV}$ state, but a corresponding $E_{\gamma} \sim 527-\mathrm{keV}$ transition is absent. Second, the presence of additional transitions feeding the $455-\mathrm{keV}$ state with respective energies of 1119,1328 , or 1461 keV [6,7] is not confirmed by the present data. Such a $1119-\mathrm{keV} \gamma$ ray would form a triplet with the 1109- and 1114-keV transitions; however, this peak does not have the unusually broad width that would suggest the presence of three close-lying transitions of comparable strength. Similarly, Fig. 2(b) is lacking evidence for possible 1328- and 1461-keV lines.

Figure 3(a) provides the coincidence spectrum gated by the $1114-\mathrm{keV}$ transition. This spectrum highlights the sequence of the prominent $455-$, $1114-$, and $298-\mathrm{keV}$ transitions. It is consistent with both the aforementioned absence of a 1119keV line (hence, absence of a higher-lying $\gamma$ ray other than that with $E_{\gamma}=298 \mathrm{keV}$ ), and the placement of the 1037-, 1109-, 1197-, 1703-, and 1905-keV lines with respect to their common final state. The inset of Fig. 3(a) displays the coincidence spectrum gated by the $1109-\mathrm{keV}$ transition and serves as a comparison, with the $298-\mathrm{keV}$ line being notably absent. Figure 3(b) provides the coincidence spectrum gated by the $1184-\mathrm{keV}$ ground-state transition, herewith focusing on the yrast sequence of the ${ }^{137} \mathrm{Cs}$ level scheme $\left(I^{\pi}>11 / 2^{+}\right)$. Strong

FIG. 4. The level scheme for ${ }^{137} \mathrm{Cs}$ obtained in the $560-\mathrm{MeV}{ }^{136} \mathrm{Xe}+{ }^{10} \mathrm{~B}$ reaction. The widths of the arrows are proportional to the measured $\gamma$-ray intensities. The energies are given in keV . The assignments given in parentheses are tentative. The transitions and the spin-parity assignments marked in red are new to this work.

evidence is found for the 487 - and 222-keV transitions from the confirmed $15 / 2^{+}$and $17 / 2^{+}$levels (see below) and for a new $627-\mathrm{keV}$ line. Additional $\gamma$ rays are those with $E_{\gamma}=373,861$, and 684 keV . The latter is weak, but its placement as a "feeder" of the 1184-keV level appears to be justified. A spectrum gated by the $627-\mathrm{keV}$ transition is presented in Fig. 3(c): of the yrast transitions it displays only the $1184-\mathrm{keV}$ line, suggesting the presence of a $1811-\mathrm{keV}$ level from which the new $\gamma$ ray decays. The weak $455-\mathrm{keV}$ peak present in this spectrum can be due to a somewhat poorer background subtraction (hence, a small fraction of the strongest $\gamma$ ray remains) or to a transition in ${ }^{139} \mathrm{Ba}$. The former possibility is more likely, since the $455-\mathrm{keV}$ gate of Fig. 2(b) does not indicate any ${ }^{139} \mathrm{Ba}$ line. In addition, there is no $E_{\gamma} \sim 730-\mathrm{keV}$ transition that would link the 1184and $455-\mathrm{keV}$ levels.

For almost all the observed levels, spin and parity assignments are proposed based on a $\gamma$-ray angular-distribution analysis. Figure 5 provides sample angular distributions for three $\gamma$ rays: a known stretched electric quadrupole ( $E 2$ ) (a) and antistretched magnetic dipole (M1) transition (b), and the $1273-\mathrm{keV}$ line, subject of a new assignment (c).

These have been fitted with a standard Legendre polynomial expression and the fit results are included in the figure. The characteristic $A_{2} / A_{0}$ and $A_{4} / A_{0}$ coefficients derived from the fits are reported in the last two columns of Table II. The values obtained for the known transitions [Figs. 5(a) and 5(b)] are in line with expectations for the present analysis, using the spinalignment method, where stretched (or antistretched) dipole and quadrupole transitions have positive and negative $A_{2} / A_{0}$ coefficients, respectively. The positive-parity assignment for the state associated with the $455-\mathrm{keV}$ transition (hence, of $M 1$ character) is adopted from Ref. [5]: this level has been shown to contain most of the $d_{5 / 2}$ single-particle strength.

The $849-$ and $1273-\mathrm{keV}$ antistretched and stretched dipole transitions to the ground state have not only positive $A_{2} / A_{0}$ coefficients, but also nonzero $A_{4} / A_{0}$ ones indicative of a mixed multipole character of the $M 1+E 2$ type. The $849-\mathrm{keV}$ transition is bypassed by the $393-\mathrm{keV} \gamma$ ray, the latter having a negative $A_{2} / A_{0}$ coefficient. For the common $E=849-\mathrm{keV}$ initial state, a $5 / 2_{2}^{+}$assignment follows since the angular distribution of the $393-\mathrm{keV} \gamma$ ray is consistent with that of an unstretched-dipole transition (no spin change). For the

FIG. 5. Representative $\gamma$-ray angular distributions, with respect to the spin direction, for transitions in ${ }^{137} \mathrm{Cs}$. Panels (a-c) are for the 1184-, 455-, and $1273-\mathrm{keV}$ transitions, respectively. The former two cases are established stretched-quadrupole (E2) and antistretched magnetic-dipole (M1) transitions, respectively.

1273-keV transition, a stretched-dipole assignment is preferred over an antistretched one; otherwise one must invoke the rather unlikely scenario of the presence a third low-lying 5/2+ state. Hence, a $9 / 2^{+}$assignment is proposed for the $1273-\mathrm{keV}$ level. For the $1612-\mathrm{keV}$ transition, which decays to the first excited state, different considerations apply, and its angular distribution is provided in Fig. 6(a). This transition has $A_{2} / A_{0}$ and $A_{4} / A_{0}$ coefficients, suggesting a $3 / 2^{+}$assignment for the initial state at 2067 keV . Specifically, the $A_{4} / A_{0}$ coefficient is consistent with 0 and, thus, favors the $3 / 2^{+}$assignment over the $7 / 2^{+}$alternative [16]. This new assignment removes the previous $\left(3 / 2^{+}, 5 / 2^{+}\right)$ambiguity for the $E=2067-\mathrm{keV}$ level [8], in particular, a $5 / 2^{+}$assignment is ruled out.

Among the other prominent transitions feeding the $E=$ $455-\mathrm{keV}, 5 / 2^{+}$state are the $1037-$ and $1703-\mathrm{keV} \gamma$ rays, which are both isotropic as indicated by $A_{2} / A_{0}$ coefficients consistent with 0 . This observation supports the assignment for the $E=1492$ - and $2158-\mathrm{keV}$ levels as the first and second $1 / 2^{+}$state, respectively [8]. The $666-\mathrm{keV} \gamma$ ray connecting these levels is too weak to enable an additional angulardistribution measurement. Nevertheless, the observation of this $\gamma$ ray in the presence of the bypassing $1703-\mathrm{keV}$ E2

FIG. 6. Similar to Fig. 5, but for the (a) 1612-, (b) 1114-, and (c) $298-\mathrm{keV}$ transitions. For all these transitions, new spin-parity assignments are proposed.
transition is in line with the $1 / 2_{1,2}^{+}$assignments; these states have apparently similar wavefunctions. The $1197-\mathrm{keV} \gamma$ ray feeding the $E=455-\mathrm{keV}, 5 / 2^{+}$state has a negative $A_{2} / A_{0}$ coefficient and, thus, can be either of stretched-quadrupole or unstretched-dipole character. The corresponding level at 1652 keV is tentatively assigned (5/2, 9/2), indicating that its spin cannot be unambiguously determined. For the 1109- and the weak $1905-\mathrm{keV} \gamma$ rays, no angular distribution is available.

The spin-parity assignments for the $1570-$ and $1868-\mathrm{keV}$ levels share certain considerations and, thus, are discussed together. The angular distributions of some of the $\gamma$ rays involved in the deexcitation of the two states, those with $E_{\gamma}=1114$ and 298 keV , are presented in Figs. 6(b) and 6(c), respectively. The $1114-\mathrm{keV} \gamma$ ray and its bypassing $1570-\mathrm{keV}$ transition to the ground state have sets of $A_{2} / A_{0}$ and $A_{4} / A_{0}$ coefficients suggesting a $9 / 2_{2}^{+}$or a $5 / 2_{3}^{+}$assignment for the $E=1570-\mathrm{keV}$ initial state. Both the 298 - and $594-\mathrm{keV} \gamma$ rays are characterized by a $A_{2} / A_{0}$ coefficient compatible with a stretched-dipole assignment and, furthermore, by a $A_{4} / A_{0}$ coefficient consistent with 0 . This common feature suggests that the 298 - and $594-\mathrm{keV}$ dipole transitions are rather pure and, thus, of the $E 1$ type (negligible $M 2$ components). In addition to the angular-distribution analysis, the following considerations apply: (i) Only the $9 / 2_{2}^{+}$and $11 / 2^{-}$assignments
for the respective $1570-$ and $1868-\mathrm{keV}$ levels appear to be consistent with the $\gamma$-ray coincidence relationships; a scenario invoking instead a $5 / 2_{3}^{+}$and, accordingly, a $7 / 2^{-}$level would imply that a $E_{\gamma} \sim 1413-\mathrm{keV}$ transition between the $E=1868$ and $455-\mathrm{keV}$ levels should be present, and this possibility is excluded as can be seen in the spectrum of Fig. 2(b); (ii) The scenario with a $E=1868-\mathrm{keV}, 7 / 2^{-}$level also leads to a $E_{\gamma} \sim 1868-\mathrm{keV}$ ground-state transition; although such a $\gamma$ ray (without a coincidence relationship with any other line) is hard to identify, there is no hint for a $\sim 1868-\mathrm{keV}$ photon, and this weakens the possible alternative further. On the other hand, the lack of evidence for a $\sim 1868-\mathrm{keV} \gamma$ ray also supports the $11 / 2^{-}$assignment for the $1868-\mathrm{keV}$ level: the corresponding ground-state transition would be of $M 2$ character and would be a rather unlikely competitor of the other decay branches. It should be pointed out that there is some ambiguity in the literature regarding the spin-parity quantum numbers for the $1868-\mathrm{keV}$ state. This level was originally characterized as a $\ell=5$ (i.e., $h_{11 / 2}$ ) state in Ref. [5]. This result was subsequently adopted in Refs. [6,7], but the compilation of Ref. [8] assigned spin-parity $9 / 2^{-}$without providing a basis for the assignment. The new evidence presented here requires $11 / 2^{-}$quantum numbers for the $1868-\mathrm{keV}$ level, in line with Ref. [5].

In the present study, the assignments of some of the yrast transitions [3] have been confirmed as well. The $A_{2} / A_{0}$ coefficients of the $1184-$ and $487-\mathrm{keV}$ lines indicate that both transitions are of $E 2$ character, whereas the set of $A_{2} / A_{0}$ and $A_{4} / A_{0}$ values obtained for the $222-\mathrm{keV} \gamma$ ray suggests that the next higher yrast transition is of the $M 1+E 2$ type (although the $A_{4} / A_{0}$ coefficient is not much different from 0 ). The $1811-\mathrm{keV}$ level is assigned a $13 / 2$ spin, primarily based on the positive $A_{2} / A_{0}$ coefficient obtained for the angular distribution of the $627-\mathrm{keV}$ transition (Table II). An alternative $9 / 2$ assignment is excluded, as it would imply the possibility of a bypassing $E_{\gamma} \sim 1811-\mathrm{keV}$ ground-state transition, which can be ruled out. Due to the large error of the $A_{4} / A_{0}$ coefficient for the new transition, no parity assignment is proposed. Nevertheless, the near-yrast 1811-keV level can be viewed as a candidate for the $13 / 2^{+}$state (see Sec. IV).

It is worthwhile to mention that the $E=1893-\mathrm{keV}, 17 / 2^{+}$ level is the highest-spin state observed with the present reaction. For example, the rather prominent $890-\mathrm{keV}, 21 / 2^{+} \rightarrow$ $17 / 2^{+}$yrast transition of Refs. [2-4] is absent [cf. Fig. 3(b)]. Evidently, the single-proton transfer reaction favors the population of sets of low-spin, non-yrast states in ${ }^{137} \mathrm{Cs}$, which are, thus, complementary to those studied in Refs. [2-4].

## IV. DISCUSSION

In this section, a comparison is made between the low-spin $(I \leqslant 17 / 2)$ levels of ${ }^{137} \mathrm{Cs}$ and the results of shell-model calculations for this nucleus. In addition, level systematics for ${ }^{137} \mathrm{Cs}$ and neighboring $N=82$ nuclei are presented as a function of proton number.

Table III compares the calculated level energies with those obtained from the present experiment. In these calculations, a ${ }^{132} \mathrm{Sn}$ closed core was chosen and the valence-proton space included the single-particle orbitals of the $50-82$ shell; i.e., $0 g_{7 / 2}, 1 d_{5 / 2}, 1 d_{3 / 2}, 2 s_{1 / 2}$, and $0 h_{11 / 2}$. The calculations em-

TABLE III. A comparison of calculated and experimental level energies in ${ }^{137} \mathrm{Cs}$. The calculations have been performed assuming a ${ }^{132} \mathrm{Sn}$ core. The reduced transition probabilities reported in footnotes a and b have been obtained using g factors $\mathrm{g}_{l}=1.2$ and $\mathrm{g}_{s}=0.7 \mathrm{~g}_{s, \text { free }}$. The configuration listed in the third column represents a coupling between the $0_{1}^{+}, 0_{2}^{+}, 2_{1}^{+}, 4_{1}^{+}$, or $6_{1}^{+}$states of ${ }^{136} \mathrm{Xe}$ and a valence proton (see text).

${ }^{\text {a }}$ Strong $9 / 2_{2}^{+} \rightarrow 7 / 2_{2}^{+}$transition predicted $\left[B(M 1)=0.3 \mu_{N}^{2}\right]$.
${ }^{\mathrm{b}}$ Strong $3 / 2_{2}^{+} \rightarrow 5 / 2_{1}^{+}$transition predicted $\left[B(M 1)=0.9 \mu_{N}^{2}\right]$.
${ }^{\text {c }}$ Mixed configuration (the two components contribute about equally to the total wave function).
ployed the two-body effective Hamiltonian of Ref. [17] with the matrix elements derived from the CD-Bonn nucleonnucleon potential [18], and the single-particle energies taken from the experimental spectrum of ${ }^{133} \mathrm{Sb}$, except for the $2 s_{1 / 2}$ orbital, which was not identified in this nucleus. The $2 s_{1 / 2}$ energy was based on the more precisely determined $1 / 2_{2}^{+}$level of ${ }^{137} \mathrm{Cs}$ reported in Table II.

In addition to the calculated level energies, the table specifies, in the third column, the dominant configuration of the state, which typically represents $\geqslant 65 \%$ of the total amplitude of the wavefunction (the higher-lying $3 / 2^{+}$states are the exception). The configuration is expressed as a coupling between, on the one hand, the ground state or one of the lowest-lying excited states of the even-mass ${ }^{136} \mathrm{Xe}$ isotone and, on the other, the single-particle state of the remaining valence proton. Here, the couplings involving the $0_{1}^{+}$state of ${ }^{136} \mathrm{Xe}$ represent the single-proton states, all the other cases are associated with 3 "unpaired" protons (see discussion below).

Overall, there is a satisfactory correspondence between calculated and observed levels, with discrepancies of 150 keV or less, except for the $1 / 2_{1}^{+}$and $3 / 2_{2}^{+}$states. The largest discrepancy ( 293 keV ) occurs for the $3 / 2_{2}^{+}$level, where the
calculated energy is also lower than the observed one. This appears to be the result of dealing with a strongly mixed configuration (cf. footnote c of Table III). The overall picture validates the choice of ${ }^{132} \mathrm{Sn}$ as the inert core. Two additional comments on specific states can be made.
(i) The $3 / 2^{+}$states and a related issue: The calculated $3 / 2_{1}^{+}$ level remains unobserved, and the $3 / 2_{2}^{+}$state is calculated to be of mixed $0_{1}^{+} \otimes 1 d_{3 / 2}$ and $2_{1}^{+} \otimes 1 d_{5 / 2}$ character. On the other hand, the $B(M 1)$ values calculated in the course of the present study predict the $3 / 2_{2}^{+} \rightarrow 5 / 2_{1}^{+}$transition to be comparatively strong (see footnote b of Table III), as the initial- and final-state wave functions have significant $0_{1}^{+} \otimes 1 d_{3 / 2}$ and $0_{1}^{+} \otimes 1 d_{5 / 2}$ components, respectively. Unfortunately, the present data do not provide valuable lifetime information. Nevertheless, the corresponding $1612-\mathrm{keV} \gamma$ ray is one of the strongest $M 1$ transitions in the spectra, and this observation appears to be consistent with the above prediction. Also, a possible $9 / 2_{2}^{+} \rightarrow$ $7 / 2_{2}^{+}$transition has a calculated large $B(M 1)$ value (footnote a of Table III). While a $7 / 2_{2}^{+}$state could not be firmly established, the $1564-\mathrm{keV}$ level of Fig. 4 is a possible candidate for this excitation. In this scenario, the transition under consideration would not be observed due to its low energy, in agreement with the present data.
(ii) The $13 / 2^{+}$state: The observed $1811-\mathrm{keV}$ level is a good candidate for association with the computed $13 / 2^{+}$state due to the proposed spin assignment and an energy difference between the data and calculations of 142 keV . One of the nearby $N=82$ isotones, ${ }^{141} \mathrm{Pr}$, also has a low-lying $(E=$ 1768 keV ) $13 / 2^{+}$level [19], and it is interesting to compare the decay branches from the $13 / 2^{+}$states in both nuclei. The ${ }^{141} \mathrm{Pr}$ nucleus has a low-lying $(E=1118 \mathrm{keV}) 11 / 2^{-}$ state to which the $13 / 2^{+}$level decays most strongly, but the $13 / 2^{+} \rightarrow 11 / 2^{+}$transition is the next strongest decay branch. Such a $11 / 2^{-}$level is not an option for a de-excitation in ${ }^{137} \mathrm{Cs}$ $(E=1868 \mathrm{keV})$, and the $13 / 2 \rightarrow 11 / 2^{+}, 627-\mathrm{keV}$ decay path thus mirrors the ${ }^{141} \mathrm{Pr}$ observation, herewith increasing the confidence in the proposed spin assignment for the 1811-keV level.

As is customary for a semimagic nucleus, most of the ${ }^{137}$ Cs low-spin levels can be grouped according their seniority [20]. These are, in principle, the (i) single-proton, seniority $v=1$ states, and $v=3$ excitations with a $0 g_{7 / 2}$ broken pair coupled to a proton in the (ii) $0 g_{7 / 2}$ or (iii) $1 d_{5 / 2}$ orbital; the latter are called $v=30 g_{7 / 2}$ and $v=30 g_{7 / 2} 1 d_{5 / 2}$ multiplets, respectively. In order to confirm that the seniority scheme is appropriate, a separate set of shell-model calculations for ${ }^{137} \mathrm{Cs}$ was performed, from which the expected seniority composition of the wavefunctions under discussion was validated. These findings can be summarized as follows: (i) States that are characterized by a large $(>90 \%) v=1$ component are the $7 / 2^{+}$ground state and the $1 / 2_{2}^{+}, 5 / 2_{1}^{+}$, and $11 / 2^{-}$levels of Table III. As far as the $3 / 2_{2}^{+}$state is concerned, it turns out that this is a mixture of the $v=1$ component and the $v=30 g_{7 / 2} 1 d_{5 / 2}$ multiplet. (ii) The $v=30 g_{7 / 2}$ multiplet contains the $3 / 2_{1}^{+}, 5 / 2_{2}^{+}, 9 / 2_{1}^{+}, 11 / 2_{1}^{+}$, and $15 / 2_{1}^{+}$states where the corresponding compositions are typically $\sim 90 \%$ (e.g., for $3 / 2_{1}^{+}, 5 / 2_{2}^{+}$). (iii) The $v=30 g_{7 / 2} 1 d_{5 / 2}$ multiplet involves the $1 / 2_{1}^{+}, 5 / 2_{3}^{+}, 7 / 2_{2}^{+}, 9 / 2_{2}^{+}, 11 / 2_{2}^{+}, 13 / 2^{+}, 15 / 2_{2}^{+}$, and $17 / 2^{+}$ levels with typical compositions of $\sim 80 \%$ (e.g., for $1 / 2_{1}^{+}$).

FIG. 7. The lowest-spin levels in the $N=82{ }^{133} \mathrm{Sb},{ }^{135} \mathrm{I}$, and ${ }^{137} \mathrm{Cs}$ nuclei. The information on the former two isotones is adopted from Ref. [21]. States with spins above $11 / 2$ in ${ }^{133} \mathrm{Sb}$ and $15 / 2$ in ${ }^{135} \mathrm{I}$ and ${ }^{137} \mathrm{Cs}$ have been omitted. The spins and parities given in parentheses represent tentative assignments. The sets of levels in black are part of the seniority $v=30 g_{7 / 2}$ (full line) and $v=30 g_{7 / 2} 1 d_{5 / 2}$ multiplets (dashed line). The levels in color are single-proton $(v=1)$ states, and their configurations are given on the right-hand side. See text for details.

This seniority description is illustrated in Fig. 7, where a compilation of the lowest-spin levels in ${ }^{137} \mathrm{Cs}$ and in the lighter $N=82$ isotones can be found. Note that, for ${ }^{137} \mathrm{Cs}$, only states with firmly established spin and parity have been compiled, whereas for ${ }^{135} \mathrm{I}$ and ${ }^{133} \mathrm{Sb}$, any state with a proposed spin value is considered. The $v=1$ states in ${ }^{137} \mathrm{Cs}$ have all been observed and their decay modes characterized. Similarly, the observation of the $v=30 g_{7 / 2}$ multiplet in ${ }^{137} \mathrm{Cs}$ approaches completion; i.e., only the $3 / 2^{+}$member remains unobserved. With respect to the remaining ${ }^{137} \mathrm{Cs}$ levels, an additional comment is warranted. The $1 / 2_{1}^{+}$and $7 / 2_{2}^{+}$states are part of the $v=30 g_{7 / 2} 1 d_{5 / 2}$ multiplet, and the $13 / 2$ and $17 / 2^{+}$levels (cf. Fig. 4) that are also associated with this group (Fig. 7) have been omitted in the last figure only to simplify the presentation. The sets of levels for ${ }^{135} \mathrm{I}$ and ${ }^{133} \mathrm{Sb}$ (Fig. 7) illustrate the sparsity of experimental information as one moves towards nuclei with a larger neutron excess. Hence, this compilation establishes only the trend of the $5 / 2_{1}^{+}$level as a function of proton number.

## V. CONCLUSIONS

A significantly improved low-spin level scheme for ${ }^{137} \mathrm{Cs}$ has been established from an experiment with a ${ }^{136} \mathrm{Xe}$ beam and a ${ }^{10} \mathrm{~B}$ target, where particle $-\gamma$ coincidence measurements with the PhoswichWall and the Digital Gammasphere detector arrays were carried out. As a result, knowledge on the sets of positive-parity levels associated with the single-particle proton states of the $50-82$ shell and with the members of the $v=3 g_{7 / 2}$ multiplet has been considerably increased. In addition, new states have been observed including a candidate $13 / 2^{+}$level. Two long-standing issues have been identified. First, among the positive-parity states, a predicted low-lying $(E \lesssim 1200 \mathrm{keV}) 3 / 2^{+}$state is still missing. Second, the $E=$ $1868-\mathrm{keV}$ level has been reassigned as $I^{\pi}=11 / 2^{-}$(i.e., $h_{11 / 2}$ ) and this concurs with the $\ell=5$ characterization of the state in earlier transfer-reaction work. Shell-model calculations performed in the course of this study reproduce the features of the detailed level scheme satisfactorily. A comparison of the ${ }^{137} \mathrm{Cs}$
levels with those of the lighter odd-proton, neutron-magic nuclei was presented, resulting in suggestions for follow-up $\gamma$-ray spectroscopic studies of these isotones.

## ACKNOWLEDGMENTS

[16] An inspection of T. Yamazaki, Nucl. Data Tables A 3, 1 (1967) indicates that the $B 4 F 4$ values (representing the $A_{4}$ parameter) are zero for $3 / 2 \rightarrow 5 / 2(L 1=L 2=1)$ and $3 / 2 \rightarrow$ $5 / 2(L 1=L 2=2)$ transitions ( $L 1$ and $L 2$ representing the angular momenta of the corresponding transition), but nonzero for the $7 / 2 \rightarrow 5 / 2(L 1=L 2=1)$ and $7 / 2 \rightarrow 5 / 2(L 1=$ $L 2=2$ ) cases. The use of the spin-alignment method in the present study implies that the angular-distribution coefficients have opposite signs compared to those in Yamazaki's tables.
