Abstract

We study a new kind of nonzero-sum stochastic differential game with mixed impulse/switching controls, motivated by strategic competition in commodity markets. A representative upstream firm produces a commodity that is used by a representative downstream firm to produce a final consumption good. Both firms can influence the price of the commodity. By shutting down or increasing generation capacities, the upstream firm influences the price with impulses. By switching (or not) to a substitute, the downstream firm influences the drift of the commodity price process. We study the resulting impulse-regime switching game between the two firms, focusing on explicit threshold-type equilibria. Remarkably, this class of games naturally gives rise to multiple potential Nash equilibria, which we obtain thanks to a verification-based approach. We exhibit three candidate types of equilibria depending on the ultimate number of switches by the downstream firm (zero, one or an infinite number of switches). We illustrate the diversification effect provided by vertical integration in the specific case of the crude oil market. Our analysis shows that the diversification gains strongly depend on the pass-through from the crude price to the gasoline price.

Keywords Stochastic differential games · Impulse controls · Optimal switching · Quasi-variational inequalities · Nash equilibrium · Commodity markets

1 Introduction

Since Hotelling's [20] seminal study of commodity prices, considerable efforts have been undertaken to understand the dynamics of the equilibrium price of commodities and in particular, its long-run properties. The cyclical nature of price dynamics is driven by the substitution effect, whereby consumers will switch to a different commodity if prices rise too high. In

a deterministic setting, the switching time to the substitute is simple to analyze, but with the stochastic economic cycle consumers face a huge challenge in determining when is the appropriate moment to switch. The succession of booms and busts of commodity prices complicates the switching timing. In the long run, production capacities adapt to demand and make the price oscillate around a long-term equilibrium. Indeed, the long-run behavior of commodity prices exhibits super-cycle patterns. The econometric studies in Leon and Soto [24], Erten and Ocampo [15], Jacks [21] and more recently Stuemer [31] all find the presence of super-cycles of several decades in the price of commodities. This phenomenon makes one wonder whether it is even necessary for the consumers to ever switch and whether it is not preferable to just wait for the prices to crash again.

The long-run dynamics of commodity prices not only heavily weighs on consumers' long-term decisions but is also an important driver of the industrial organization of the production (upstream) and transformation (downstream) segments. In particular, from the perspective of industrials, having one foot in each of these two sides of the commodity market is supposed to induce a natural physical hedge against the undesirable effects of super-cycles. For instance, Helfat and Teece [19] and Levin [23] find a positive hedging effect procured by vertical integration in the oil industry, while Mansur [27] and Aïd et al. [2] find the same effect in electricity markets.¹

In this paper, we design a dynamic model of competition between production and consumption of a commodity used as an intermediate good, allowing to draw conclusions on the long-run dynamics of the commodity price and its effects on vertical integration. In our model, two factors drive the price of the commodity: on the one hand, short-term but persistent shocks of demand and/or production, and on the other hand, strategic decisions of the (representative) upstream production firm and of the (representative) downstream consumer firm. The upstream producer extracts the commodity at cost c_p and sells it for a price X . The downstream industry buys the commodity and converts it into a final good that has a price P , non-decreasing in X . This framework covers a wide range of industries. One might think, for example, of the agricultural sector where soy enters as an input for the food industry to produce a large range of consumer goods. In the aluminum industry, upstream smelters produce aluminum to be used by the automotive, transportation and computer industries. In the oil industry, the crude is extracted by production firms, then transformed into gasoline and kerosene by downstream refineries, and then consumed in the retail market. For the sake of simplicity, we identify the downstream firm that transforms the commodity with the final consumer and this downstream firm's profit with the consumer's surplus.

We focus on the role of the commodity price X that intrinsically creates competition between the representative agents of producers and consumers. In a nutshell, producers prefer high price X , while consumers prefer low price X . This competition is dynamic and manifests itself through strategic price effects actuated by the two industries. Therefore, X is (partially) jointly controlled by the producers/consumers, leading to game-theoretic impacts.

On the upstream production side, the producer needs the commodity price X to be high enough to make a profit margin. We suppose that the dynamics of investment and disinvest-

¹ Vertical integration is also intensively discussed in the economic literature from the regulation perspective of vertical mergers. We refer to Perry [28] for an in-depth review and to Lafontaine and Slade [22] for an update. Briefly, from the regulation perspective, since there are markets for both the raw commodity and its transformed products, vertical integration is considered a device to increase firms' market power and foreclose competitors. There are empirical evidences of competition distortion by vertically integrated firms (see for instance the Hasting and Gilbert [18] study of the US gasoline retail market) which can be explained using a game-theoretic model of foreclosure (De Fontenay and Gans [12]). Despite the importance of the regulation perspective, we focus in this paper on the firm's interests in being or not vertically integrated for hedging purposes procured by diversification effect.

ment in upstream production is driven by *production capacity shocks* that cause *jumps* in the price X . This assumption is consistent with the theory of real options that predicts the existence of threshold prices triggering the decision of entry and the exit from the market (see MacDonald and Siegel [26] and Dixit and Pindyck [14]). It is also consistent with the observations of quick swings in investment and disinvestment in production, see, e.g., the boom and bust of commodity prices in 2008–2010.

On the downstream consumer side, consumers induce a long-term effect on the commodity price only if they switch to a substitute, and they switch to a substitute only if they anticipate that X will remain high enough for a long time. The downstream side faces slower dynamics because it involves the transformation of many local installations using the commodity. To have an example in mind, one may think of the thousands of adjustments required to change heating systems in buildings, or of the slow effect of the energy saving programs launched by OECD after the 1970s oil shocks. Thus, in our model, the downstream market for the final good can be in *contraction* or *expansion* regime. The contraction regime corresponds to a decreasing demand for the primary commodity, i.e., the market is abandoning the use of the commodity for a substitute, while the expansion mode corresponds to an increasing demand for the commodity. Depending on the state of the downstream retail market, the *drift* of the commodity price takes either a constant positive value in the expansion mode or a negative value in the contraction mode. Because such consumer shifts are slow and expensive, the state is persistent (i.e., piecewise constant in time) and changing the state of the final-good market incurs heavy switching costs. This toggling of the price trend can be interpreted as endogenous *regime switching*, a common way of modeling commodity prices through the business cycle. Indeed, since the seminal paper by Hamilton [17] on the modeling of financial time-series with regime-switching models, this type of models has been successfully applied to a large range of commodities spot prices, such as crude oil (Alizadeh et al. [4]), precious metals (Choi and Hammoudeh [11]), lumber (Chen and Insley [10]) and power (Haldrup and Nielson [16]). Beyond the impact of producers and consumers decisions, the commodity price is subject to exogenous short-term stochastic shocks, captured through a Brownian motion driving risk factor.

Our aim is to construct and characterize the dynamic equilibrium in the commodity market due to this vertical competition. Our major contribution is to provide an endogenous, game-theoretic basis for two key stylized features of commodity markets: (i) super-cycles that manifest as long-term mean-reversion; (ii) fundamental impact of supply and demand that maintains the price in a range of values rather than a single equilibrium value. Furthermore, our model allows for three potential types of equilibria depending on the number of demand switches undertaken by the consumer at equilibrium: zero, one, or an infinite number of switches. All threshold-type equilibria exhibit the latter qualitative properties. Besides, the higher the consumer's switching cost, the more she is compelled to endure an unfavorable range of prices.

We name the three types of potential equilibria in our model as *generic*, *transitory* and *preemptive*. In the *generic* equilibrium described precisely in Sect. 4.1, both the upstream and downstream representative firms act on the price perpetually: the downstream firm repeatedly switches from expansion to contraction, and the upstream firm applies investment and disinvestment impulses. This equilibrium is likely in sectors where there are easily available substitutes, e.g., for agricultural products. In the *transitory* equilibrium described in Sect. 4.2, the consumer and the producer both prefer a given regime and thus, the consumer switches at most once when the market is initialized in the opposite regime. Afterward, only the producer acts to maintain the price within her preferred range of values by appropriate investment/disinvestment actions. In the last type of equilibrium, the consumer is also stuck

forever in a regime, but it is a regime she wishes to leave. In that case described in Sect. 4.3, only the producer acts. Starting in the expansion regime, for instance, the consumer would like to switch to the contraction regime when the price reaches a threshold. But the producer, who prefers perpetual expansion, *preempts* the switch by acting just before the action of the consumer. Transitory and preemptive equilibria are likely to be observed in sectors where substitutes are hard to come by and where upstream firms dominate.

Our model relates to the vast literature on the dynamics of commodity prices. An important stream of the economic literature deals with the joint dynamics of futures and spot prices and its relation with storage. The seminal references are the papers by Deaton and Laroque [13] and Routledge et al. [30]. The monograph by Pirrong [29] provides a thorough discussion of this field of research. In this paper, our focus is to explain the cycles of commodity prices as the result of vertical competition. The paper which is the closest to our work is Cassasus et al. [8] addressing long-term competitive equilibrium of crude oil, which also exhibits mean-reversion and regime switching produced by episodes of over- and under-supply, generated by lumpy irreversible investment performed by a representative agent. Although our model shares some features with Cassasus et al. [8] (the absence of storage for instance), we get a richer set of equilibria generated by the antagonist objectives of the upstream and downstream sectors.

Along the way, we also make mathematical contributions to the literature on nonzero-sum stochastic games (see Martyr and Moriarty [25], Attard [5], De Angelis et al. [9], Aïd et al. [1]). To our knowledge ours is the first paper that: (i) considers a mixed impulse–control/switching–control stochastic game; (ii) explicitly constructs a potential impulse-switching threshold-type equilibria in nonzero-sum games; provides new verification theorems regarding best-response strategies for (iii) an impulsive agent in a regime-switching setting and (iv) switching agent with an impulsive state process. While our solution is non-exhaustive in the sense that we a priori focus on a special class of equilibria (leaving open the question of existence of other equilibrium families), it is highly tractable. Namely, we are able to provide closed-form description of the dynamic equilibrium, offering precise quantitative insights regarding the producer and consumer roles and their equilibrium behavior.

To emphasize the latter point, beyond several synthetic examples that illustrate and visualize our model features, we also present a detailed case study of the diversification effect provided by vertical integration in the crude oil market circa 2019, viewed as a competition between crude oil producers and oil refiners that convert crude into gasoline and other consumer goods. In our case study, we fitted the oil market to the generic type of equilibrium, considering that oil consumption experiences alternate phases of expansion when the price is low and contraction when the price is too high. In this setting, we consider a small downstream firm asking herself whether she has an interest in getting more vertically integrated. We show that the gains from integration are directly linked to the pass-through parameter that links the crude oil price to the retail gasoline price. The higher this pass-through, the higher production activity dominates the retail activity both in terms of expected rate of profit and the standard deviation of rate of profit.

The rest of the paper is organized as follows. Section 2 sets up the competitive producer–consumer commodity market. Section 3 then constructs the respective candidates for threshold-type impulse-switching equilibria by considering the producer and consumer best-response strategies. Section 4 illustrates and discusses the different types of emergent equilibria using toy examples. Section 5 presents the above vertical integration case study, and Sect. 6 concludes. All the proofs, as well as additional comparative statics, are delegated to Sect. 7.

2 The Model

2.1 Description

We use (X_t) to denote the (pre-equilibrium) commodity price, modeled as a continuous-time stochastic process. The two players are denoted as *p* producer and *c* consumer. In what follows sub-index *p* (resp. *c*) in the notation will always refer to the producer (resp. consumer). The market involves the original raw commodity that is being produced and the goods market (e.g., gasoline). The producer extracts the commodity at cost c_p and sells it for price x . The consumer buys it for price x , converts it into a final good, and sells it for price P .

Profit rates The price x of the commodity influences the *volume* of trade, captured by the demand function $D_p(x)$. A similar phenomenon plays out in the final-good market: the goods price P leads to sales volume $D_c(P)$. Since the consumer is in effect the intermediary between the commodity and the goods market, she will pass some of her input price shocks to the output price $P \equiv P(x)$.

We ignore the players’ fixed costs because they can be considered to be integrated in the investment costs, and concentrate on the variable costs and revenues that are driven by the respective input/output prices. Based on the above discussion, the instantaneous profit rate of the producer is

$$\pi_p(x) := (x - c_p)D_p(x). \tag{1}$$

Let c_c be the processing/conversion cost from input commodity to final good and α be the respective conversion factor, so that one unit of commodity becomes α units of the final good (e.g., barrels of crude oil, converted into barrels of gasoline). Then, the instantaneous profit rate of the consumer is

$$\pi_c(x) := D_c(P)P - \frac{D_c(P)}{\alpha}(x + c_c). \tag{2}$$

We note that while the consumer has market power, he is not the only user of the commodity (e.g., crude oil is also used by the petrochemical industry), so there is no direct link between production volume and consumption volume. Thus, while there is a physical link between the consumer input volume $D_c(P)/\alpha$ and her output volume $D_c(P)$, there is no direct link between $D_c(P)/\alpha$ and aggregate commodity demand $D_p(x)$.

We shall consider linear inverse demand

$$D_p(x) = d_0 - d_1x.$$

If we further assume that $P(x) = p_0 + p_1x$ (the price of the final good is linearly proportional to the commodity price), and $D_c(P) = d'_0 - d'_1P$ (final-good demand is linearly decreasing in its price P), the profit rate of the consumer becomes:

$$\begin{aligned} \pi_c(x) &= D_c(P(x)) \cdot \left(P(x) - \frac{(x + c_c)}{\alpha} \right) \\ &= (d'_0 - d'_1p_0) \left(p_0 - \frac{c_c}{\alpha} \right) \\ &\quad + \left((d'_0 - d'_1p_0) \left(p_1 - \frac{1}{\alpha} \right) - d'_1p_1 \left(p_0 - \frac{c_c}{\alpha} \right) \right) x + d'_1p_1 \left(\frac{1}{\alpha} - p_1 \right) x^2 \\ &=: \gamma_0 + \gamma_1x + \gamma_2x^2. \end{aligned} \tag{3}$$

The consumer profit is concave in the commodity price x , $\gamma_2 < 0$, if and only if the pass-through coefficient p_1 is higher than the conversion factor $1/\alpha$. It means that the final-good price increases faster than the need of the downstream industry to produce one more good, which is a sound economic condition for having a sustainable downstream industry. To sum up, the profit rates of both producer and consumer are concave and quadratic in x .

Market Conditions We model the commodity price process (X_t) as a controlled Itô diffusion of the form

$$dX_t = \mu_t dt + \sigma dW_t - dN_t. \tag{4}$$

The Brownian motion (W_t) captures exogenous price shocks due to random demand or production fluctuations, or pertinent economic shocks for the industry. In this sense, the model is agnostic in the reasons why the commodity price fluctuates around its mean trend. The point process $N_t := \sum_{i \geq 1} \xi_i \mathbf{1}_{\{\tau_i \leq t\}}$ captures the producer interventions at times $(\tau_i)_{i \geq 1}$ and impulses $(\xi_i)_{i \geq 1}$. A positive impulse is triggered by an investment phase and has a negative impact on the price. A negative impulse is induced by a disinvestment phase and has a positive impact on the price.

The drift process (μ_t) represents the state of the retail market for the final good. It is either in expansion or in contraction state. When in expansion, demand is growing faster than the available production capacity; hence, prices tend to rise: $\mu_t = \mu_+ > 0$. When in contraction, the demand is shrinking faster than the production capacity; thus, the price tends to decrease, and thus, $\mu_t = \mu_- < 0$. This modeling corresponds to an imperfect adjustment of the market as in a *sticky price* model in macroeconomics. The drift is fully controlled by the consumer,

$$\mu_t = \mu_+ \sum_{i=0}^{\infty} \mathbf{1}_{\{\sigma_{2i} \leq t < \sigma_{2i+1}\}} + \mu_- \sum_{i=1}^{\infty} \mathbf{1}_{\{\sigma_{2i-1} \leq t < \sigma_{2i}\}}, \quad t \geq 0,$$

where σ_i is the i -th switching instance taken by the consumer in the case $\mu_{0-} = \mu_+$ (with the convention $\sigma_0 = 0$, so that σ_1 is the first switching time) and analogously when $\mu_{0-} = \mu_-$ by interchanging odd and even switching times. Thus, both players influence (X_t) , although their actions are of distinct types, namely impulse control (N_t) by the producer and switching-drift control (μ_t) by the consumer. The resulting controlled price dynamics are denoted as $X^{(\mu, N)}$.

The quadratic nature of the upstream and downstream profit rate functions $\pi_p(\cdot)$ and $\pi_c(\cdot)$ implies that each player has their own natural habitat given by the intervals (x_c^1, x_c^2) and (x_p^1, x_p^2) for commodity price levels with:

$$x_p^1 := \min \left\{ c_p, \frac{d_0}{d_1} \right\}, \quad x_p^2 := \max \left\{ c_p, \frac{d_0}{d_1} \right\}, \tag{5}$$

$$x_c^1 := \min \left\{ \frac{p_0 - c_c/\alpha}{1/\alpha - p_1}, \frac{d'_0 - d'_1 p_0}{p_1 d'_1} \right\}, \quad x_c^2 := \max \left\{ \frac{p_0 - c_c/\alpha}{1/\alpha - p_1}, \frac{d'_0 - d'_1 p_0}{p_1 d'_1} \right\}. \tag{6}$$

Players make a positive profit only when the price is in the interval (x_i^1, x_i^2) , $i \in \{c, p\}$. The concavity of the profit functions implies that players have *preferred* commodity levels \bar{X}_p, \bar{X}_c that maximize their profit rates, namely:

$$\bar{X}_p := \frac{d_0 + c_p d_1}{2d_1}, \quad \bar{X}_c := -\frac{\gamma_1}{2\gamma_2}. \tag{7}$$

Typically, we expect that $\bar{X}_c < \bar{X}_p$, so that the preferred commodity price of the consumer is lower than that of the producer. The stochastic fluctuations coming from (W_t) can generate

three different market conditions:

$$\begin{aligned}
 X_t < \bar{X}_c & \text{ I: abnormally low prices;} \\
 \bar{X}_c \leq X_t \leq \bar{X}_p & \text{ II: vertical competition;} \\
 \bar{X}_p < X_t & \text{ III: abnormally high prices.}
 \end{aligned}$$

In the first and last cases, both players have the same preferences to raise or decrease X_t ; in the intermediate case, they compete against each other. Because both players can in principle push (X_t) in either direction, the market organization is influenced by their relative gain of doing so, as well as their action costs. In cases I and III, the players are in waiting mode because of the second-mover advantage, hoping that the other will act first which allows the second to benefit from the price effect without paying the cost of (dis-)investment or of switching. In case II, they are in preemption mode, with the player who moves first being able to increase her profits at the expense of the other. These dynamic shifts between waiting and preemption is an important feature of vertical competition.

Objective Functions and Admissible Strategies The objective functionals of the players consist of integrated profit rates $\pi_c(x)$, discounted at constant rate $\beta > 0$ and subtracting the control costs that are paid at respective intervention epochs. We take the investment cost function of the producer to be some convex function $K_p : \mathbb{R} \rightarrow \mathbb{R}$, and of the consumer as $H : \{\mu_-, \mu_+\} \rightarrow \mathbb{R}_+$. We denote the latter as $H(\mu_-) = h_-$, $H(\mu_+) = h_+$. Depending on the initial drift μ_0 being positive/negative, the producer’s objective function is given by:

$$J_p^\pm(x; N, \mu) := \mathbb{E} \left[\int_0^\infty e^{-\beta t} (X_t - c_p) D_p(X_t) dt - \sum_i e^{-\beta \tau_i} K_p(\xi_i) \mid \mu_0 = \mu^\pm, X_0 = x \right], \tag{8}$$

and, similarly, the representative consumer’s objective function is:

$$J_c^\pm(x; N, \mu) := \mathbb{E} \left[\int_0^\infty e^{-\beta t} (\gamma_0 + \gamma_1 X_t + \gamma_2 X_t^2) dt - \sum_j e^{-\beta \sigma_j} H(\mu_{\sigma_j}) \mid \mu_0 = \mu^\pm, X_0 = x \right]. \tag{9}$$

In order for the state variable dynamics and players’ expected payoffs to be well defined, we give the following definition of admissible strategies. To this end, let $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$ be a probability space with a filtration satisfying the usual conditions and supporting an $(\mathcal{F}_t)_{t \geq 0}$ -Brownian motion (W_t) .

Definition 1 (*Admissible strategies*) We say that $(\tau_i, \xi_i)_{i \geq 1}$ is an admissible strategy for the producer if the following properties hold:

1. $(\tau_i)_{i \geq 1}$ is a sequence of $[0, \infty]$ -valued stopping times such that $0 \leq \tau_1 < \tau_2 < \dots$ and $\lim_{i \rightarrow \infty} \tau_i = \infty$ a.s., with the convention that $\tau_i = \infty$ for some $i \geq 1$ implies $\tau_k = \infty$ for all $k \geq i$;
2. $(\xi_i)_{i \geq 1}$ is a sequence of real-valued \mathcal{F}_{τ_i} -measurable random variables;
3. the sequence $(\tau_i, \xi_i)_{i \geq 1}$ satisfies $\sum_{i \geq 1} e^{-\beta \tau_i} \xi_i \in L^2(\mathbb{P})$.

Similarly, we say that the sequence $(\sigma_j)_{j \geq 1}$ is an admissible strategy for the consumer if

4. each σ_j is a $[0, \infty]$ -valued stopping time, $0 \leq \sigma_1 < \sigma_2 < \dots$, with the convention that $\sigma_j = \infty$ for some $j \geq 1$ implies $\sigma_k = \infty$ for all $k \geq j$;
5. $\sum_{j \geq 1} e^{-\beta \sigma_j} \in L^2(\mathbb{P})$.

The set of all producer’s (resp. consumer’s) admissible strategies is denoted by \mathcal{A}_p (resp. \mathcal{A}_c).

Remark 1 Observe that the property 1 above implies that the producer intervention times do not accumulate in finite time, so that for all $t > 0$ the process $N_t = \sum_{i \geq 1} \xi_i \mathbf{1}_{\{\tau_i \leq t\}}$, $t \geq 0$, is well defined, adapted and finite-valued. Moreover, the integrability condition in 5 gives that $\sigma_j \rightarrow \infty$ (as $j \rightarrow \infty$), i.e., the switching times of the consumer do not accumulate in finite time either, so that the dynamics of the controlled state variable (4) is well defined too. Regarding the expected profits of the players, they are both finite due to integrability properties in 3 and 5 above.

Remark 2 According to the definition of admissibility above, neither player can intervene more than once at a time. However, simultaneous interventions coming from both of them are not excluded. As discussed, the dynamics of the intervention in upstream production is much faster than the switching of the consumption regime for final good. Thus, in case both players try to act simultaneously, we assume that the producer has priority. This avoids unnecessary technicalities and allows for a consistent modeling of the vertical competition.

2.2 Equilibrium

Using this notion of admissible strategies, we give the definition of Nash equilibrium.

Definition 2 (*Nash equilibrium*) A Nash equilibrium is any pair $((\xi_i, \tau_i)_{i \geq 1}, (\sigma_j)_{j \geq 1}) \in \mathcal{A}_p \times \mathcal{A}_c$ satisfying the following property:

$$J_p^\pm(x; N', \mu) \leq J_p^\pm(x; N, \mu), \quad J_c^\pm(x; N, \mu') \leq J_c^\pm(x; N, \mu), \quad \forall x \in \mathbb{R},$$

for any other pair of strategies $((\xi'_i, \tau'_i)_{i \geq 1}, (\sigma'_j)_{j \geq 1}) \in \mathcal{A}_p \times \mathcal{A}_c$, where in the payoffs $J_r^-(x; \cdot), r \in \{c, p\}$, above we have $N'_t = \sum_{i \geq 1} \xi'_i \mathbf{1}_{\{\tau'_i \leq t\}}$ and $\mu'_t = \mu_+ \sum_{i=0}^\infty \mathbf{1}_{\{\sigma'_{2i} \leq t < \sigma'_{2i+1}\}} + \mu_- \sum_{i=1}^\infty \mathbf{1}_{\{\sigma'_{2i-1} \leq t < \sigma'_{2i}\}}$ for $t \geq 0$, $\mu'_{0-} = \mu_+$ and the convention $\sigma'_0 = 0$ (analogously in the other case $\mu'_{0-} = \mu_-$ by interchanging odd and even switching times).

In line with the envisioned Markovian structure and in order to maximize tractability, we concentrate on a specific class of dynamic equilibria. Namely, we aim to construct threshold-type feedback Nash equilibria which are of the form

$$\tau_0 = 0, \quad \tau_i = \inf\{t > \tau_{i-1} : X_t \in \Gamma_p(t-)\}, \quad i \geq 1, \quad \xi_i = \delta(X_{\tau_i}, \mu_{\tau_i-}), \quad (10)$$

and

$$\sigma_0 = 0, \quad \sigma_j = \inf\{t > \sigma_{j-1} : X_t \in \Gamma_c(t)\}, \quad j \geq 1, \quad (11)$$

where

$$\Gamma_r(t) = \Gamma_r^+ \mathbf{1}_{\{\mu_t = \mu_+\}} + \Gamma_r^- \mathbf{1}_{\{\mu_t = \mu_-\}}, \quad r \in \{c, p\},$$

for some measurable function $\delta : \mathbb{R} \rightarrow \mathbb{R}$ and some suitable Borel sets $\Gamma_p^\pm, \Gamma_c^\pm \subset \mathbb{R}$. Thus, (10), (11) imply that players act based solely on the current price (X_t) and demand regime (μ_t), ruling out history-dependent strategies, and moreover, the strategies are characterized through fixed action regions $\Gamma_p^\pm, \Gamma_c^\pm$ and impulse maps $\delta(\cdot)$. We will denote by τ'_k the aggregated intervention times coming jointly from the two players. The fact that in (10) producer's intervention times τ_i are defined via $\Gamma_p(t-)$ translates the assumption that in case of simultaneous interventions, the producer plays first and so her thresholds naturally depend on the drift μ_{t-} just before her and consumer's actions (compare to Remark 2).

The action regions $\Gamma_p^\pm, \Gamma_c^\pm$ are expected to be as follows. The impulse intervention region of the upstream production $\Gamma_p^\pm = (x_\ell^\pm, x_h^\pm)$ is two-sided: the producer will act whenever X_t reaches x_h^\pm from below or drops to x_ℓ^\pm from above. Note that these thresholds x_ℓ^\pm, x_h^\pm are μ -dependent. On the consumption side, when $\mu_t = \mu_+$ (expansion regime), the consumer will switch to μ_- if X_t gets too high: $\Gamma_c^+ = (y_h, \infty)$. Similarly when $\mu_t = \mu_-$ (contraction regime), she will switch to μ_+ if X_t gets too low $\Gamma_c^- = (-\infty, y_\ell)$. Finally, when the producer intervenes, he will bring X_t to her impulse level $x_r^{\pm*}$ so that the impulse amount is $\xi_r^\pm = x_r^\pm - x_r^{\pm*}$. The natural ordering we expect is the producer impulses toward \bar{X}_p

$$x_\ell^\pm < x_\ell^{\pm*} \quad \text{and} \quad x_h^{\pm*} < x_h^\pm, \tag{12}$$

and the consumer switches toward \bar{X}_c ,

$$y_\ell < \bar{X}_c < y_h, \tag{13}$$

so that when acting both players try to move X toward their preferred levels. However, the precise ordering between the impulse thresholds $x_r^{\pm*}$ and the switching thresholds y 's is not clear a priori and will emerge as part of the overall equilibrium construction.

2.3 Illustration of Competitive Dynamics

To further understand the market evolution under competition of the producer and consumer, we focus on the case where both players are active. The producer's strategy is summarized via a 2×4 matrix C_p which lists the thresholds x_ℓ^\pm, x_h^\pm and the target levels $x_\ell^{\pm*}, x_h^{\pm*}$. Thus, the no-intervention regions are $[x_\ell^\pm, x_h^\pm]$ and impulse amounts are $x_h^\pm - x_h^{\pm*}, x_\ell^{\pm*} - x_\ell^\pm$:

$$C_p = \begin{bmatrix} x_\ell^+, x_\ell^{+*}, x_h^{+*}, x_h^+ \\ x_\ell^-, x_\ell^{-*}, x_h^{-*}, x_h^- \end{bmatrix}. \tag{14}$$

The consumer has two switching thresholds y_ℓ, y_h ; in a typical setup, we expect them to satisfy the following ordering

$$x_\ell^- < y_\ell < y_h < x_h^+. \tag{15}$$

Note that in the expansion regime (drift μ_+), we assume that $y_h < x_h^+$. Therefore, coming from below, X_t^* hits y_h first, causing the consumer to switch into the contraction regime with drift μ_- . As a result, the impulse threshold x_h^+ is not effective, i.e., it will never get triggered along an equilibrium path of (X_t) . Similar argument implies that x_ℓ^- is *not effective* either if $x_\ell^- < y_\ell$. In the left panel of Fig. 1, we illustrate such threshold-based vertical competition among the two players.

To illustrate competitive dynamics, the right panel of Fig. 1 shows a sample trajectory of (X_t^*) (the superscript emphasizing the fact that we are now looking at equilibrium) with producer and consumer strategies

$$C_p = \begin{bmatrix} 1.0, 1.3, 1.7, 2.0 \\ 1.0, 1.3, 1.7, 2.0 \end{bmatrix}, \quad (y_\ell, y_h) = (1.2, 1.8).$$

According to the above discussion, the effective thresholds are (x_ℓ^+, y_h) when $\mu_t = \mu_+$, or (y_ℓ, x_h^-) when $\mu_t = \mu_-$. In other words, in the expansion regime, (X_t) will be between $[1.0, 1.8]$ and in the contraction regime it will be between $[1.2, 2.0]$. In Fig. 1 (Right), we start in the contraction regime with $X_0 = 1.5$ and $\mu_0 = \mu_-$. On this trajectory, (X_t^*) moves down until it touches the consumer's threshold y_ℓ , where the consumer switches

Fig. 1 Left panel: dynamic competition between producer and consumer. The blue arrows represent drift-switching controls exercised by the consumer at levels y_ℓ and y_h , while the red curved arrows represent impulse controls exercised by the producer at levels x_ℓ^{+*} , x_h^{-*} that instantaneously push X_t to x_ℓ^{+*} and x_h^{-*} , respectively. Right: A sample path of the controlled commodity price (X_t^*) under competitive equilibrium. Observe that $X_t^* \in [1, 2]$ for all t

to a positive drift to draw the price up. Nevertheless, the price keeps decreasing and hits $x_\ell^+ = 1.0$, whereby the producer intervenes and pushes it to $x_\ell^{+*} = 1.3$. Prices then continue to rise up to $y_h = 1.8$ at which point the consumer switches again and starts pushing them back down (supposedly she wishes to keep them somewhere around 1.5). This cyclic behavior continues ad infinitum, yielding a stationary distribution for the pair (X_t^*, μ_t^*) . Note that the consumer uses her switching control to keep X_t^* from going too high or too low, essentially cycling between y_ℓ and y_h . Indeed, starting at $X_t^* = y_\ell$, the consumer switches to expansion which causes prices to trend up; once they hit y_h , the consumer switches to contraction, causing prices to trend down. As a result, μ_t alternates between μ_+ , μ_- generating a mean-reverting behavior. Throughout, the producer acts as a “back-up,” explicitly forcing prices from becoming extreme (namely from falling in the expansion regime, or rising in the contraction regime). These additional interventions by the producer make the domain of (X_t^*) bounded.

It is also possible that, say, $x_h^+ < y_h$ so that in the expansion regime the producer will act first both when (X_t^*) falls (impulse threshold x_ℓ^+) and when (X_t^*) rises (x_h^+), making the consumer *inactive*. In that case it is plain to see that the drift $\mu_t \equiv \mu_+$ will stay positive forever; (X_t) will be forced to a bounded domain but will not have mean-reverting dynamics since the drift is constant. Instead, it will experience repeated impulses downward to counteract the upward trend due to ongoing consumption growth.

3 Best-Response Functions

To obtain a threshold-type feedback Nash equilibrium, we view it as a fixed point of the producer and consumer *best-response maps*. Therefore, our overall strategy is to (i) characterize threshold-type switching strategies for the consumer given a pre-specified, threshold-type behavior by the producer; (ii) characterize threshold-type impulse strategies for the producer who faces a pre-specified regime-switching behavior of (X_t) ; (iii) employ *tâtonnement*, i.e., iteratively apply the best-response controls alternating between the two players to construct an *interior, non-preemptive* equilibrium satisfying the ordering (15).

To analyze best-response strategies, we utilize stochastic control theory, rephrasing the related dynamic optimization objectives through *variational inequalities* (VI) for the jump-diffusion dynamics (4). The competitor thresholds then act as boundary conditions in the VIs. To establish the desired equilibrium, we need to verify that the best response is also of threshold-type and solves the expected systems of equations. We note that all three pieces above are new and we have not been able to find precise analogues of the needed verification theorems in the extant literature. Nevertheless, they do build upon similar single-agent control formulations, so the overall technique is conceptually clear.

3.1 Consumer Best Response

Fixing impulse thresholds x_r^\pm ($r = h, l$), the consumer faces a two-state switching control problem on the bounded domain (x_ℓ^\pm, x_h^\pm) . Namely, given a producer’s impulse strategy $(\tau_i, \xi_i)_{i \geq 1}$ with $\tau = \inf\{t : X_t \notin [x_\ell^\pm, x_h^\pm]\}$, we expect the following stochastic representation for her value functions $w^\pm(x)$ with $x \in [x_\ell^\pm, x_h^\pm]$

$$w^\pm(x) = \sup_{\sigma \in \mathcal{T}} \mathbb{E}_{x, \pm} \left[\int_0^{\tau \wedge \sigma} e^{-\beta t} \pi_c(X_t) dt + e^{-\beta \tau} \mathbb{1}_{\{\tau < \sigma\}} \left(w^\pm(X_\tau - \xi) \right) + e^{-\beta \tau} \mathbb{1}_{\{\tau > \sigma\}} \left(w^\mp(X_\sigma) - h_\pm \right) \right], \tag{16}$$

where $\mathbb{E}_{x, \pm}$ denotes expectation with respect to $\mu_t \in \{\mu_-, \mu_+\}$ and h_\pm are the fixed intervention costs of the consumer. The above is a system of two coupled equations, which locally resembles an optimal stopping problem with running payoff $\pi_c(\cdot)$, reward $w^\mp(\cdot)$ (last term), and stop-loss payoff (middle term) $w^\mp(\cdot)$ due to the producer impulse at τ . This is *almost* the formulation as considered in [3] except with two modifications:

- The domain is bounded on both sides (previously there was a one-sided stop-loss region).
- The boundary condition $w^+(x_\ell) = w^+(x_\ell^{+*})$ is autonomous but non-local. Therefore, the two stopping-type VIs for the consumer are coupled only through the free boundaries, not through the stop-loss thresholds as in [3].

Now, given a producer strategy \mathcal{C}_p , if the consumer’s response is such that $y_\ell < x_\ell^-$ and $x_h^+ < y_h$, the consumer will be stuck forever in the initial regime because the price touches x_ℓ^- before y_ℓ in the contraction regime and x_h^+ before y_h in the expansion regime. In this case, the price will oscillate between x_ℓ^- and x_h^- if the initial market is in the contraction regime, and between x_ℓ^+ and x_h^+ in the expansion regime.

In the case where the consumer’s response satisfies $y_\ell < x_\ell^-$ and $y_h < x_h^+$, depending on the initial state, the consumer will switch once to the expansion regime or will be stuck in the initial expansion regime. If the initial regime is μ_+ , the price will touch y_h , the regime will switch to contraction, the price will never touch y_ℓ and will oscillate between x_ℓ^- and x_h^- . If the initial state is already μ_+ , no switch of regime will ever occur. The same reasoning applies for the symmetric case where $x_\ell^- < y_\ell$ and $x_h^+ < y_h$.

Finally, if the consumer’s response satisfies $x_\ell^- < y_\ell$ and $y_h < x_h^+$, then whatever the initial regime, the state (μ_t) will switch many times between the two regimes.

The best response of the consumer consists in picking the best response among the three possible ones above. Thus, we distinguish three cases:

- (a) *No-Switch* The consumer is completely inactive and simply collects her payoff based on the strategy $(x_{\ell, h}^\pm)$.

(b) *Single Switch* The consumer always prefers one regime to the other. Then, she is inactive (like in case (a) above) in the preferred regime and faces an optimal stopping (since there is only a single switch to consider) problem in the other regime.

(c) *Multiple Switch* The consumer switches back and forth between both regimes: the continuation region is (y_ℓ, y_h) .

Proposition 1 provides the value function of the consumer in case (a). The system (24) characterizes the game payoff in case (b), and Proposition 2 provides the value function of the consumer in case (c).

3.1.1 No-Switch

Regardless of the consumer strategy, in the continuation region, a direct application of the Feynman–Kac formula on (16) shows that her value function solves the following ordinary differential equation (ODE)

$$-\beta w + \mu_\pm w_x + \frac{1}{2}\sigma^2 w_{xx} + \pi_c(x) = 0. \tag{17}$$

Solving this inhomogeneous second-order ODE, we obtain $w^\pm(x) = \widehat{w}^\pm(x) + u^\pm(x)$, where letting $\theta_2^\pm < 0 < \theta_1^\pm$ be the two real roots of the quadratic equation $-\beta + \mu_\pm z + \frac{1}{2}\sigma^2 z^2 = 0$,

- $u^\pm(x) = \lambda_1^\pm e^{\theta_1^\pm x} + \lambda_2^\pm e^{\theta_2^\pm x}$ solves the homogeneous ODE $-\beta u + \mu_\pm u_x + \frac{1}{2}\sigma^2 u_{xx} = 0$ and $\lambda_{i,0}^\pm, i = 1, 2$ are to be determined from appropriate boundary conditions;
- $\widehat{w}^\pm(x)$ is a particular solution to (17), given by

$$\widehat{w}^\pm(x) = Ex^2 + F_\pm x + G_\pm \quad \text{where} \\ E = \frac{\gamma_2}{\beta}, \quad F_\pm = \frac{1}{\beta} \left(\gamma_1 + 2\mu_\pm \frac{\gamma_2}{\beta} \right), \quad G_\pm = \frac{1}{\beta} \left(\gamma_0 + \sigma^2 \frac{\gamma_2}{\beta} + \mu_\pm F_\pm \right). \tag{18}$$

When the consumer is inactive (denoted by w_0^\pm), the continuation region is $[x_\ell^\pm, x_h^\pm]$ with the boundary conditions at the impulse levels

$$w_0^\pm(x_r^\pm) = w_0^\pm(x_r^{\pm*}), \quad r \in \{\ell, h\}. \tag{19}$$

From (19) the respective coefficients $\lambda_{1,0}^\pm, \lambda_{2,0}^\pm$ are solved from the following uncoupled linear system:

$$\lambda_{1,0}^\pm \cdot [e^{\theta_1^\pm x_\ell^\pm} - e^{\theta_1^\pm x_\ell^{\pm*}}] + \lambda_{2,0}^\pm \cdot [e^{\theta_2^\pm x_\ell^\pm} - e^{\theta_2^\pm x_\ell^{\pm*}}] = \widehat{w}^\pm(x_\ell^{\pm*}) - \widehat{w}^\pm(x_\ell^\pm), \tag{20}$$

$$\lambda_{1,0}^\pm \cdot [e^{\theta_1^\pm x_h^\pm} - e^{\theta_1^\pm x_h^{\pm*}}] + \lambda_{2,0}^\pm \cdot [e^{\theta_2^\pm x_h^\pm} - e^{\theta_2^\pm x_h^{\pm*}}] = \widehat{w}^\pm(x_h^{\pm*}) - \widehat{w}^\pm(x_h^\pm). \tag{21}$$

For $x > x_h^\pm$, we take $w_0^\pm(x) = w_0^\pm(x_h^{\pm*})$ and similarly in the contraction regime, we take $w_0^\pm(x) = w_0^\pm(x_\ell^{\pm*})$ for $x < x_\ell^\pm$.

Proposition 1 *Let $(\lambda_{1,0}^\pm, \lambda_{2,0}^\pm) \in \mathbb{R}^4$ be the solution to the system (20), (21). Then the functions $w_0^\pm(x), x \in [x_\ell^\pm, x_h^\pm]$, are the value functions for an inactive consumer, i.e., $w_0^\pm(x) = J_c^\pm(x; N, \mu^\pm)$, where N is the producer impulse strategy associated with the thresholds $(x_\ell^\pm, x_\ell^{\pm*}; x_h^\pm, x_h^{\pm*})$ with $x_\ell^\pm < x_h^\pm$.*

The role of $w_0^\pm(\cdot)$ is important for judging the other two cases, and moreover for deciding whether the best response ought to be of threshold-type.

3.1.2 Single Switch

We next consider the situation where the payoff in the expansion regime is higher than the contraction one for any price x , so that the consumer is never incentivized to switch to the contraction regime. We then expect the consumer’s corresponding best response to be either a single-switch strategy (to the preferred regime) or no-switch (if already there). Economically, this corresponds to $y_h > x_h^+$ so that as the price rises, the producer impulses (X_t) down, and the consumer is not intervening to decrease her demand. As a result, the consumer never switches (except perhaps the first time from negative to positive drift) and $\lim_{t \rightarrow \infty} \mu_t = \mu_+$. This can be observed when demand switching is very expensive, so that the producer has full market power and is able to keep prices consistently low. The consumer is forced to be in the expansion regime forever, and she is not able to influence (X_t).

Suppose that the consumer prefers expansion regime ($\mu_t = \mu_+$) and adopts threshold-type strategies. Given C_p , her strategy is summarized by

$$y_\ell > x_\ell^-, \quad y_h = +\infty,$$

and the resulting contraction-regime value function w^- should be a solution to the variational inequality

$$\sup \left\{ -\beta w^- + \mu_- w_x^- + \frac{1}{2} \sigma^2 w_{xx}^- + \pi_c; w_0^+ - h_- - w^- \right\} = 0, \tag{22}$$

where w_0^+ is from Proposition 1 and the continuation region is $[y_\ell, x_h^-]$. This is a standard optimal stopping problem. Note that while the above equation for w^- depends on w_0^+ , the equation for w_0^+ is autonomous—the system of equations becomes decoupled because the two regimes of (μ_t) no longer communicate.

To solve (22), we posit that her best response is of the form

$$w^-(x) = \begin{cases} w_0^+(x) - h_-, & x \leq y_\ell, \\ \widehat{w}^-(x) + \lambda_1^- e^{\theta_1^- x} + \lambda_2^- e^{\theta_2^- x}, & y_\ell < x < x_h^-, \\ w^-(x_h^{*-}), & x_h^- \leq x, \end{cases} \tag{23}$$

with the smooth-pasting and boundary conditions:

$$\begin{cases} \widehat{w}^-(y_\ell) + \lambda_1^- e^{\theta_1^- y_\ell} + \lambda_2^- e^{\theta_2^- y_\ell} = \widehat{w}^+(y_\ell) + \lambda_{1,0}^+ e^{\theta_1^+ y_\ell} + \lambda_{2,0}^+ e^{\theta_2^+ y_\ell} - h_-, & (C^0 \text{ at } y_\ell) \\ \widehat{w}^-(x_h^-) + \lambda_1^- e^{\theta_1^- x_h^-} + \lambda_2^- e^{\theta_2^- x_h^-} = \widehat{w}^-(x_h^{*-}) + \lambda_1^- e^{\theta_1^- x_h^{*-}} + \lambda_2^- e^{\theta_2^- x_h^{*-}}, & (C^0 \text{ at } x_h^-) \\ \widehat{w}_x^-(y_\ell) + \lambda_1^- \theta_1^- e^{\theta_1^- y_\ell} + \lambda_2^- \theta_2^- e^{\theta_2^- y_\ell} = \widehat{w}_x^+(y_\ell) + \lambda_{1,0}^+ \theta_1^+ e^{\theta_1^+ y_\ell} + \lambda_{2,0}^+ \theta_2^+ e^{\theta_2^+ y_\ell}. & (C^1 \text{ at } y_\ell) \end{cases} \tag{24}$$

The system (24) is to be solved for the three unknowns $y_\ell, \lambda_1^-, \lambda_2^-$, while $\lambda_{1,0}^+, \lambda_{2,0}^+$ are the coefficients of the consumer’s payoff associated with the no-switch strategy in the μ_+ regime, see previous subsection. We can re-write it as first solving for $\lambda_{1,2}^-$ from the linear system

$$\begin{bmatrix} e^{\theta_1^- y_\ell} & e^{\theta_2^- y_\ell} \\ e^{\theta_1^- x_h^-} - e^{\theta_1^- x_h^{*-}} & e^{\theta_2^- x_h^-} - e^{\theta_2^- x_h^{*-}} \end{bmatrix} \cdot \begin{bmatrix} \lambda_1^- \\ \lambda_2^- \end{bmatrix} = \begin{bmatrix} w_0^+(y_\ell) - \widehat{w}^-(y_\ell) - h_- \\ \widehat{w}^-(x_h^{*-}) - \widehat{w}^-(x_h^-) \end{bmatrix} \tag{25}$$

and then determining y_ℓ from the smooth pasting C^1 -regularity

$$w_x^-(y_\ell) = w_{0,x}^+(y_\ell). \tag{26}$$

The case of a single switch from expansion to contraction regime can be treated analogously in a symmetric way.

3.1.3 Double Switch

Finally, we consider the main case where the consumer adopts *threshold-type* switches, i.e., the ordering in (15) holds. Given C_p , the w^\pm are then supposed to be a solution to the coupled variational inequalities

$$\sup \left\{ -\beta w^+ + \mu_+ w_x^+ + \frac{1}{2} \sigma^2 w_{xx}^+ + \pi_c; \max\{w^- - h_+, w^+\} - w^+ \right\} = 0, \tag{27}$$

$$\sup \left\{ -\beta w^- + \mu_- w_x^- + \frac{1}{2} \sigma^2 w_{xx}^- + \pi_c; \max\{w^+ - h_-, w^-\} - w^- \right\} = 0, \tag{28}$$

where we expect continuation regions of the form (x_ℓ^+, y_h) and (y_ℓ, x_h^-) . To set up a verification argument for the consumer’s best response, we make the ansatz

$$w^+(x) = \begin{cases} w^+(x_\ell^{+*}), & x \leq x_\ell^+, \\ \widehat{w}^+(x) + \lambda_1^+ e^{\theta_1^+ x} + \lambda_2^+ e^{\theta_2^+ x}, & x_\ell^+ < x < y_h, \\ w^-(x) - h_+, & x \geq y_h, \end{cases} \tag{29a}$$

$$w^-(x) = \begin{cases} w^+(x) - h_-, & x \leq y_\ell, \\ \widehat{w}^-(x) + \lambda_1^- e^{\theta_1^- x} + \lambda_2^- e^{\theta_2^- x}, & y_\ell < x < x_h^-, \\ w^-(x_h^{-*}), & x \geq x_h^-. \end{cases} \tag{29b}$$

This yields 6 equations:

$$\begin{cases} \widehat{w}^+(y_\ell) + \lambda_1^+ e^{\theta_1^+ y_\ell} + \lambda_2^+ e^{\theta_2^+ y_\ell} - h_- = \widehat{w}^-(y_\ell) + \lambda_1^- e^{\theta_1^- y_\ell} + \lambda_2^- e^{\theta_2^- y_\ell}, & (C^0 \text{ at } y_\ell) \\ \widehat{w}^+(x_\ell^+) + \lambda_1^+ e^{\theta_1^+ x_\ell^+} + \lambda_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{w}^+(x_\ell^{+*}) + \lambda_1^+ e^{\theta_1^+ x_\ell^{+*}} + \lambda_2^+ e^{\theta_2^+ x_\ell^{+*}}, & (C^0 \text{ at } x_\ell^+) \\ \widehat{w}^-(y_h) + \lambda_1^- e^{\theta_1^- y_h} + \lambda_2^- e^{\theta_2^- y_h} - h_+ = \widehat{w}^+(y_h) + \lambda_1^+ e^{\theta_1^+ y_h} + \lambda_2^+ e^{\theta_2^+ y_h}, & (C^0 \text{ at } y_h) \\ \widehat{w}^-(x_h^-) + \lambda_1^- e^{\theta_1^- x_h^-} + \lambda_2^- e^{\theta_2^- x_h^-} = \widehat{w}^-(x_h^{-*}) + \lambda_1^- e^{\theta_1^- x_h^{-*}} + \lambda_2^- e^{\theta_2^- x_h^{-*}}, & (C^0 \text{ at } x_h^-) \\ \widehat{w}_x^+(y_\ell) + \lambda_1^+ \theta_1^+ e^{\theta_1^+ y_\ell} + \lambda_2^+ \theta_2^+ e^{\theta_2^+ y_\ell} = \widehat{w}_x^-(y_\ell) + \lambda_1^- \theta_1^- e^{\theta_1^- y_\ell} + \lambda_2^- \theta_2^- e^{\theta_2^- y_\ell}, & (C^1 \text{ at } y_\ell) \\ \widehat{w}_x^-(y_h) + \lambda_1^- \theta_1^- e^{\theta_1^- y_h} + \lambda_2^- \theta_2^- e^{\theta_2^- y_h} = \widehat{w}_x^+(y_h) + \lambda_1^+ \theta_1^+ e^{\theta_1^+ y_h} + \lambda_2^+ \theta_2^+ e^{\theta_2^+ y_h}. & (C^1 \text{ at } y_h) \end{cases} \tag{30}$$

The six equations can be split into a linear system for the four coefficients $\lambda_{1,2}^\pm$ ’s

$$\begin{bmatrix} e^{\theta_1^+ y_\ell} & e^{\theta_2^+ y_\ell} & -e^{\theta_1^- y_\ell} & -e^{\theta_2^- y_\ell} \\ e^{\theta_1^+ x_\ell^+} - e^{\theta_1^+ x_\ell^{+*}} & e^{\theta_2^+ x_\ell^+} - e^{\theta_2^+ x_\ell^{+*}} & 0 & 0 \\ -e^{\theta_1^+ y_h} & -e^{\theta_2^+ y_h} & e^{\theta_1^- y_h} & e^{\theta_2^- y_h} \\ 0 & 0 & e^{\theta_1^- x_h^-} - e^{\theta_1^- x_h^{-*}} & e^{\theta_2^- x_h^-} - e^{\theta_2^- x_h^{-*}} \end{bmatrix} \cdot \begin{bmatrix} \lambda_1^+ \\ \lambda_2^+ \\ \lambda_1^- \\ \lambda_2^- \end{bmatrix} = \begin{bmatrix} \widehat{w}^-(y_\ell) - \widehat{w}^+(y_\ell) - h_+ \\ \widehat{w}^+(x_\ell^{+*}) - \widehat{w}^+(x_\ell^+) \\ \widehat{w}^+(y_h) - \widehat{w}^-(y_h) - h_- \\ \widehat{w}^-(x_h^{-*}) - \widehat{w}^-(x_h^-) \end{bmatrix} \tag{31}$$

and the smooth-pasting conditions determining the two switching thresholds $y_{\ell,h}$ (viewed as free boundaries)

$$w_x^+(y_r) = w_x^-(y_r), \quad r \in \{\ell, h\}. \tag{32}$$

Fig. 2 Value functions w_0^\pm , w_1^\pm and w_2^\pm of the consumer given the producer’s strategy (a)

Proposition 2 Let the 6-tuple $(\lambda_1^\pm, \lambda_2^\pm, y_h, y_\ell)$ be a solution to the system (31), (32) such that the order in (15) is fulfilled. Then, the functions defined in (29) give the best-response payoffs of consumer, and a best-response strategy is given by $(\hat{\sigma}_i)_{i \geq 1}$, where

$$\hat{\sigma}_0 = 0, \quad \hat{\sigma}_i = \inf \{t > \hat{\sigma}_{i-1} : X_t \in \Gamma_c(t)\}, \quad i \geq 1,$$

with $\Gamma_c^+ = [y_\ell, +\infty)$ and $\Gamma_c^- = (-\infty, y_h]$.

Figure 2 illustrates the shapes of the consumer’s value function in the different case of best response. For the strategy given, we have a dominant function in the contraction regime (w_0^-) and a dominant function in the expansion regime (w_0^+).

Remark For comparison purposes, it is also useful to know the continuation region of the consumer when she *alone* controls the market price (X_t). As usual, this region is $(-\infty, y_h)$ in the expansion regime and $(y_\ell, +\infty)$ in the contraction regime, with the natural ordering $y_\ell < y_h$. The value functions w^\pm satisfy:

$$\sup \left\{ -\beta w^+ + \mu_+ w_x^+ + \frac{1}{2} \sigma^2 w_{xx}^+ + \pi_c; w^- - h_+ \right\} = 0, \tag{33}$$

$$\sup \left\{ -\beta w^- + \mu_- w_x^- + \frac{1}{2} \sigma^2 w_{xx}^- + \pi_c; w^+ - h_- \right\} = 0. \tag{34}$$

To set up a verification argument for the consumer’s best response, we make the ansatz

$$w^+(x) = \begin{cases} w^-(y_h) - h_+, & x \geq y_h, \\ \hat{w}^+(x) + \lambda_{1,0}^+ e^{\theta_1^+ x} + \lambda_{2,0}^+ e^{\theta_2^+ x}, & x < y_h, \end{cases} \tag{35a}$$

$$w^-(x) = \begin{cases} \hat{w}^-(x) + \lambda_{1,0}^- e^{\theta_1^- x} + \lambda_{2,0}^- e^{\theta_2^- x}, & x > y_\ell, \\ w^+(y_\ell) - h_-, & x \leq y_\ell. \end{cases} \tag{35b}$$

Furthermore, in the expansion regime, to keep $w^+(x)$ bounded as $x \rightarrow -\infty$ we must have $\lambda_{2,0}^+ = 0$ because $\theta_2^+ < 0$. In the contraction regime, a similar argument gives $\lambda_{1,0}^- = 0$. We are left with the four unknowns y_ℓ, y_h and $\lambda_{1,0}^p$ and $\lambda_{2,0}^-$ determined from the following

smooth-pasting conditions:

$$\begin{cases} \widehat{\omega}^-(y_\ell) + \lambda_{2,0}^- e^{\theta_2^- y_\ell} = \widehat{\omega}^+(y_\ell) + \lambda_{1,0}^+ e^{\theta_1^+ y_\ell} - h_-, & (C^0 \text{ at } y_\ell) \\ \widehat{\omega}^+(y_h) + \lambda_{1,0}^+ e^{\theta_1^+ y_h} = \widehat{\omega}^-(y_h) + \lambda_{2,0}^- e^{\theta_2^- y_h} - h_+, & (C^0 \text{ at } y_h) \\ \widehat{\omega}_x^-(y_\ell) + \lambda_{2,0}^- \theta_2^- e^{\theta_2^- y_\ell} = \widehat{\omega}_x^+(y_\ell) + \lambda_{1,0}^+ \theta_1^+ e^{\theta_1^+ y_\ell}, & (C^1 \text{ at } y_\ell) \\ \widehat{\omega}_x^+(y_h) + \lambda_{1,0}^+ \theta_1^+ e^{\theta_1^+ y_h} = \widehat{\omega}_x^-(y_h) + \lambda_{2,0}^- \theta_2^- e^{\theta_2^- y_h}. & (C^1 \text{ at } y_h) \end{cases} \tag{36}$$

□

3.2 Producer Best Response

We now consider the best response of the producer, given the consumer’s switching strategy denoted by $C_c := [y_\ell, y_h]$. Once again, we face three cases:

1. The producer is a monopolist, i.e., the consumer is completely inactive;
2. The consumer adopts a single-switch strategy;
3. The consumer adopts a double-switch strategy.

3.2.1 Producer as Sole Optimizer

To begin with, we determine the monopoly-like strategy of the producer assuming the consumer adopts a no-switch strategy. In that case, μ_t is constant throughout and the functions v^\pm of the producer satisfy the variational inequality (VI):

$$\sup \left\{ -\beta v^\pm + \mu_\pm v_x^\pm + \frac{1}{2} \sigma^2 v_{xx}^\pm + \pi_p, \sup_\xi \{ v^\pm(\cdot + \xi) - v^\pm(\cdot) - K_p(\xi) \} \right\} = 0. \tag{37}$$

Note that the two VIs for v^+ and v^- are autonomous, hence uncoupled from each other. In the continuation region, the general solution of the ODE

$$-\beta v + \mu_\pm v_x + \frac{1}{2} \sigma^2 v_{xx} + \pi_p(x) = 0$$

is of the form $v^\pm(x) = \widehat{v}^\pm(x) + u^\pm(x)$, where $u^\pm = v_1^\pm e^{\theta_1^\pm x} + v_2^\pm e^{\theta_2^\pm x}$, with $\theta_1^\pm, \theta_2^\pm$ as before, satisfies the homogenous ODE $-\beta u + \mu_\pm u_x + \frac{1}{2} \sigma^2 u_{xx} = 0$, and $\widehat{v}^\pm(x)$ is a particular solution given by

$$\widehat{v}^\pm(x) = Ax^2 + B_\pm x + C_\pm, \tag{38}$$

where the coefficients A, B_\pm, C_\pm are identified as:

$$A = -\frac{d_1}{\beta}, \quad B_\pm = \frac{1}{\beta} \left(d_0 - \frac{2\mu_\pm d_1}{\beta} + c_p d_1 \right), \quad C_\pm = \frac{1}{\beta} (\mu_\pm B_\pm + A\sigma^2 - c_p d_0).$$

Assuming the producer adopts threshold-type impulse strategies defined by $\xi^*(x)$ in the intervention region, her expected payoff is of the form:

$$v^\pm(x) = \begin{cases} v^\pm(x_h^{\pm*}) - K_p(\xi^*(x)) & x \geq x_h^\pm, \\ \widehat{v}^\pm(x) + v_1^\pm e^{\theta_1^\pm x} + v_2^\pm e^{\theta_2^\pm x}, & x_\ell^\pm < x < x_h^\pm, \\ v^\pm(x_\ell^{\pm*}) - K_p(\xi^*(x)) & x \leq x_\ell^\pm. \end{cases} \tag{39}$$

When applying the optimal impulse $\xi^{\pm*}(x)$ at the threshold x_r^{\pm} , $r = \ell, h$, the producer brings X_t back to the price level $x_r^{\pm*} := x_r^{\pm} - \xi^{\pm*}(x_r^{\pm})$. For optimality, the respective impulse amounts satisfy the first order conditions

$$v_x^{\pm}(x_h^{\pm*}) = -\partial_{\xi} K_p(\xi^*(x_h^{\pm})), \quad v_x^{\pm}(x_{\ell}^{\pm*}) = -\partial_{\xi} K_p(\xi^*(x_{\ell}^{\pm})). \tag{40}$$

We reinterpret the above as the equation to be satisfied by $\xi^*(x_r^{\pm})$ which are treated temporarily as unknowns and plugged into further equations. To ensure that the value function is continuous at x_r^{\pm} , we further need

$$v^{\pm}(x_r^{\pm}) = v^{\pm}(x_r^{\pm*}) - K_p(\xi_r^{\pm*}). \tag{41}$$

Finally, making the hypothesis that the value function is differentiable at the borders of the intervention region, we have:

$$v_x^{\pm}(x_{\ell}^{\pm}) = v_x^{\pm}(x_{\ell}^{\pm*}) - \partial_{\xi} K_p(\xi^*(x_{\ell}^{\pm})), \tag{42a}$$

$$v_x^{\pm}(x_h^{\pm}) = v_x^{\pm}(x_h^{\pm*}) - \partial_{\xi} K_p(\xi^*(x_h^{\pm})). \tag{42b}$$

We consider two cases of impulse costs: (i) constant $K_p(\xi) = \kappa_0$ and (ii) linear $K_p(\xi) = \kappa_0 + \kappa_1|\xi|$. In case (i), because the impulse cost is independent of the intervention amount there will be an optimal impulse level $x_r^{\pm*}$ so that for any x in the intervention region the strategy is to impulse back to $x_r^{\pm*}$ which is the same at the two thresholds. In case (ii), $\partial_{\xi} K_p = \pm\kappa_1$ and all the smooth pasting and boundary conditions can be gathered in the following system:

$$\begin{cases} \widehat{v}^{\pm}(x_h^{\pm}) + v_1^{\pm} e^{\theta_1^{\pm} x_h^{\pm}} + v_2^{\pm} e^{\theta_2^{\pm} x_h^{\pm}} = \widehat{v}^{\pm}(x_h^{\pm*}) + v_1^{\pm} e^{\theta_1^{\pm} x_h^{\pm*}} + v_2^{\pm} e^{\theta_2^{\pm} x_h^{\pm*}} - \kappa_0 - \kappa_1(x_h^{\pm} - x_h^{\pm*}), & (\mathcal{C}^0 \text{ at } x_h^{\pm}) \\ \widehat{v}^{\pm}(x_{\ell}^{\pm}) + v_1^{\pm} e^{\theta_1^{\pm} x_{\ell}^{\pm}} + v_2^{\pm} e^{\theta_2^{\pm} x_{\ell}^{\pm}} = \widehat{v}^{\pm}(x_{\ell}^{\pm*}) + v_1^{\pm} e^{\theta_1^{\pm} x_{\ell}^{\pm*}} + v_2^{\pm} e^{\theta_2^{\pm} x_{\ell}^{\pm*}} - \kappa_0 - \kappa_1(x_{\ell}^{\pm*} - x_{\ell}^{\pm}), & (\mathcal{C}^0 \text{ at } x_{\ell}^{\pm}) \\ \widehat{v}_x^{\pm}(x_h^{\pm*}) + v_1^{\pm} \theta_1^{\pm} e^{\theta_1^{\pm} x_h^{\pm*}} + v_2^{\pm} \theta_2^{\pm} e^{\theta_2^{\pm} x_h^{\pm*}} = -\kappa_1 & (\mathcal{C}^1 \text{ at } x_h^{\pm*}) \\ \widehat{v}_x^{\pm}(x_{\ell}^{\pm*}) + v_1^{\pm} \theta_1^{\pm} e^{\theta_1^{\pm} x_{\ell}^{\pm*}} + v_2^{\pm} \theta_2^{\pm} e^{\theta_2^{\pm} x_{\ell}^{\pm*}} = \kappa_1, & (\mathcal{C}^1 \text{ at } x_{\ell}^{\pm*}) \\ \widehat{v}_x^{\pm}(x_h^{\pm}) + v_1^{\pm} \theta_1^{\pm} e^{\theta_1^{\pm} x_h^{\pm}} + v_2^{\pm} \theta_2^{\pm} e^{\theta_2^{\pm} x_h^{\pm}} = \widehat{v}_x^{\pm}(x_h^{\pm*}) + v_1^{\pm} \theta_1^{\pm} e^{\theta_1^{\pm} x_h^{\pm*}} + v_2^{\pm} \theta_2^{\pm} e^{\theta_2^{\pm} x_h^{\pm*}} - \kappa_1, & (\mathcal{C}^1 \text{ at } x_h^{\pm}) \\ \widehat{v}_x^{\pm}(x_{\ell}^{\pm}) + v_1^{\pm} \theta_1^{\pm} e^{\theta_1^{\pm} x_{\ell}^{\pm}} + v_2^{\pm} \theta_2^{\pm} e^{\theta_2^{\pm} x_{\ell}^{\pm}} = \widehat{v}_x^{\pm}(x_{\ell}^{\pm*}) + v_1^{\pm} \theta_1^{\pm} e^{\theta_1^{\pm} x_{\ell}^{\pm*}} + v_2^{\pm} \theta_2^{\pm} e^{\theta_2^{\pm} x_{\ell}^{\pm*}} + \kappa_1. & (\mathcal{C}^1 \text{ at } x_{\ell}^{\pm}) \end{cases} \tag{43}$$

Note that there are two uncoupled linear systems for v^+ and v^- . The \mathcal{C}^0 conditions are from (41), the first two \mathcal{C}^1 conditions are from (40) which determines the optimal impulse destination, and the last two \mathcal{C}^1 conditions are from (42).

By a standard verification argument, one can show that if both systems above admit solutions $v_{1,2}^{\pm}$ and $x_{\ell,h}^{\pm}$, where the latter satisfy the order condition $x_{\ell}^{\pm} < x_h^{\pm}$, then the functions $v^{\pm}(x)$ as in (39) are the value functions of the producer and his optimal strategies are given by the thresholds $x_{\ell,h}^{\pm}$ and impulse amounts $\xi^*(x_{\ell,h}^{\pm})$. This can be done by following exactly the arguments in, e.g., [7] (see also their Remark 2.1), which are very standard in the literature of impulse control problems. Therefore, details are omitted.

3.2.2 Non-Preemptive Response

Suppose the following ordering, which is similar to (15), holds:

$$x_{\ell}^{\pm} < y_l < y_h < x_h^{\pm}. \tag{44}$$

We then expect v^{\pm} to solve the VIs

$$\begin{cases} \sup \{ -\beta v^+ + \mu_+ v_x^+ + \frac{1}{2} \sigma^2 v_{xx}^+ + \pi_p ; \sup_{\xi} (v^+(\cdot - \xi) - v^+ - K_p(\xi)) \} = 0, \\ \sup \{ -\beta v^- + \mu_- v_x^- + \frac{1}{2} \sigma^2 v_{xx}^- + \pi_p ; \sup_{\xi} (v^-(\cdot - \xi) - v^- - K_p(\xi)) \} = 0. \end{cases} \tag{45}$$

To obtain the producer best response, it suffices to identify the two active impulse thresholds x_ℓ^+, x_h^- and the respective target levels x_ℓ^{+*}, x_h^{-*} . The other two boundary conditions take place at the consumer thresholds y_ℓ, y_h , so that the strategy (see (47)) is $C_p = \left[\begin{matrix} x_\ell^+, x_\ell^{+*}, -, +\infty \\ -\infty, -, x_h^{-*}, x_h^- \end{matrix} \right]$. The game coupling shows up in the additional *boundary* condition that when the consumer switches, the producer’s value is unaffected:

$$v^+(y) = v^-(y), \quad y \in (-\infty, y_\ell] \cup [y_h, +\infty). \tag{46}$$

Accordingly, our ansatz is

$$v^-(x) = \begin{cases} v^-(x_h^{-*}) - K_p(\xi^*(x)), & x \geq x_h^-, \\ \widehat{v}^-(x) + v_1^- e^{\theta_1^- x} + v_2^- e^{\theta_2^- x}, & y_\ell < x < x_h^-, \\ v^+(x), & x \leq y_\ell, \end{cases} \tag{47a}$$

$$v^+(x) = \begin{cases} v^-(x), & x \geq y_h, \\ \widehat{v}^+(x) + v_1^+ e^{\theta_1^+ x} + v_2^+ e^{\theta_2^+ x}, & x_\ell^+ < x < y_h, \\ v^+(x_\ell^{+*}) - K_p(\xi^*(x)), & x \leq x_\ell^+. \end{cases} \tag{47b}$$

To simplify the presentation, let us concentrate on the proportional impulse costs $K_p(\xi) = \kappa_0 + \kappa_1|\xi|$. We have the smooth pasting C^1 and boundary conditions:

$$\begin{cases} \widehat{v}^+(y_\ell) + v_1^+ e^{\theta_1^+ y_\ell} + v_2^+ e^{\theta_2^+ y_\ell} = \widehat{v}^-(y_\ell) + v_1^- e^{\theta_1^- y_\ell} + v_2^- e^{\theta_2^- y_\ell}, & (C^0 \text{ at } y_\ell) \\ \widehat{v}^-(y_h) + v_1^- e^{\theta_1^- y_h} + v_2^- e^{\theta_2^- y_h} = \widehat{v}^+(y_h) + v_1^+ e^{\theta_1^+ y_h} + v_2^+ e^{\theta_2^+ y_h}, & (C^0 \text{ at } y_h) \\ \widehat{v}^+(x_\ell^+) + v_1^+ e^{\theta_1^+ x_\ell^+} + v_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{v}^+(x_\ell^{+*}) + v_1^+ e^{\theta_1^+ x_\ell^{+*}} + v_2^+ e^{\theta_2^+ x_\ell^{+*}} - K_p(\xi^*(x_\ell^+)), & (C^0 \text{ at } x_\ell^+) \\ \widehat{v}^-(x_h^-) + v_1^- e^{\theta_1^- x_h^-} + v_2^- e^{\theta_2^- x_h^-} = \widehat{v}^-(x_h^{-*}) + v_1^- e^{\theta_1^- x_h^{-*}} + v_2^- e^{\theta_2^- x_h^{-*}} - K_p(\xi^*(x_h^-)), & (C^0 \text{ at } x_h^-) \\ \widehat{v}_x^+(x_\ell^+) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^+} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{v}_x^+(x_\ell^{+*}) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^{+*}} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^{+*}} - \kappa_1, & (C^1 \text{ at } x_\ell^+) \\ \widehat{v}_x^-(x_h^-) + v_1^- \theta_1^- e^{\theta_1^- x_h^-} + v_2^- \theta_2^- e^{\theta_2^- x_h^-} = \widehat{v}_x^-(x_h^{-*}) + v_1^- \theta_1^- e^{\theta_1^- x_h^{-*}} + v_2^- \theta_2^- e^{\theta_2^- x_h^{-*}} + \kappa_1, & (C^1 \text{ at } x_h^-) \\ \widehat{v}_x^+(x_\ell^{+*}) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^{+*}} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^{+*}} = -\kappa_1 & (C^1 \text{ at } x_\ell^{+*}) \\ \widehat{v}_x^-(x_h^{-*}) + v_1^- \theta_1^- e^{\theta_1^- x_h^{-*}} + v_2^- \theta_2^- e^{\theta_2^- x_h^{-*}} = \kappa_1, & (C^1 \text{ at } x_h^{-*}) \end{cases} \tag{48}$$

Unlike the single-agent setting (43), Eq. (48) are coupled. The coefficients $v_{1,2}^\pm$ are the solution to the linear system

$$\begin{bmatrix} e^{\theta_1^+ y_\ell} & e^{\theta_2^+ y_\ell} & -e^{\theta_1^- y_\ell} & -e^{\theta_2^- y_\ell} \\ e^{\theta_1^+ x_\ell^+} - e^{\theta_1^+ x_\ell^{+*}} & e^{\theta_2^+ x_\ell^+} - e^{\theta_2^+ x_\ell^{+*}} & 0 & 0 \\ -e^{\theta_1^+ y_h} & -e^{\theta_2^+ y_h} & e^{\theta_1^- y_h} & e^{\theta_2^- y_h} \\ 0 & 0 & e^{\theta_1^- x_h^-} - e^{\theta_1^- x_h^{-*}} & e^{\theta_2^- x_h^-} - e^{\theta_2^- x_h^{-*}} \end{bmatrix} \cdot \begin{bmatrix} v_1^+ \\ v_2^+ \\ v_1^- \\ v_2^- \end{bmatrix} = \begin{bmatrix} \widehat{v}^-(y_\ell) - \widehat{v}^+(y_\ell) \\ \widehat{v}^+(x_\ell^{+*}) - \widehat{v}^+(x_\ell^+) - K_p \\ \widehat{v}^+(y_h) - \widehat{v}^-(y_h) \\ \widehat{v}^-(x_h^{-*}) - \widehat{v}^-(x_h^-) - K_p \end{bmatrix} \tag{49}$$

and the thresholds x_h^+, x_ℓ^- are determined by the C^1 smooth pasting (recall that $x_h^{-*} = x_h^- - \xi^*(x_h^-), x_\ell^{+*} = x_\ell^+ - \xi^*(x_\ell^+)$):

$$\begin{cases} v_x^-(x_h^-) = v_x^-(x_h^{-*}), \\ v_x^+(x_\ell^+) = v_x^+(x_\ell^{+*}), \end{cases} \tag{50}$$

and the first order conditions (FOCs) giving the optimal impulses:

$$v_x^-(x_h^{-*}) = -\partial_\xi K_p(\xi^*(x_h^{-})) \quad v_x^+(x_\ell^{+*}) = -\partial_\xi K_p(\xi^*(x_\ell^{+})). \tag{51}$$

Proposition 3 *Let the 8-tuple $(v_1^\pm, v_2^\pm, x_h^+, x_\ell^-, x_h^{+*}, x_\ell^{-*})$ be a solution to the system (48), such that the order in (44) is fulfilled and $x_\ell^+ < x_\ell^{+*}, x_h^{-*} < x_h^-$. Let v^\pm be defined in (47) and assume*

$$v_{xx}^+(x_\ell^{+*}) < 0, \quad v_{xx}^-(x_h^{-*}) < 0. \tag{52}$$

Then, the functions v^\pm are the best-response payoffs of the producer, and a best-response strategy is given by

$$\tau_0^* = 0, \quad \tau_i^* = \inf \{t > \tau_{i-1}^* : X_t^* \in \Gamma_p(t-)\}, \tag{53}$$

$$\xi_i^*(x_\ell^+) = x_\ell^{+*} - x_\ell^+, \quad \xi_i^*(x_h^-) = x_h^- - x_h^{-*}, \quad i \geq 1, \tag{54}$$

with $\Gamma_p(t) = \Gamma_p^+ \mathbf{1}_{\{\mu_t = \mu_+\}} + \Gamma_p^- \mathbf{1}_{\{\mu_t = \mu_-\}}$, where $\Gamma_p^+ = (-\infty, x_\ell^+]$ and $\Gamma_p^- = [x_h^-, +\infty)$, while (X_t^) follows the dynamics corresponding to the consumer’s strategy $(\sigma_i)_{i \geq 1}$ and the producer’s impulse strategy $(\tau_i^*, \xi_i^*)_{i \geq 1}$.*

We remark that while we do not have a direct result regarding existence of solutions to (48), we provide nonetheless a verification theorem that connects a solution 8-tuple to a best-response strategy.

3.2.3 Preemptive Response

It is possible that the static discounted future profit of the producer satisfies, say, $v^+(x) \geq v^-(x)$ for any x , so that he always prefers expansion regime to contraction regime.

In that case, the consumer switching at y_h from expansion to contraction hurts the producer and one possible strategy for him is to *preempt* in order to prevent the consumer from switching the drift to μ_- . This situation could be viewed as looking for best $x_h^+ < y_h$, given y_h . In the latter case the constrained solution could be $x_h^+ = y_h -$, whereby the system (43) does not hold and the best response is to impulse (X_t) right before it hits y_h , $x_h^+ = y_h -$. This strategy is not well defined (i.e., the supremum is not achieved on the open interval (x_ℓ^+, y_h)), but the resulting preemptive best-response value in the μ_+ regime can be obtained by using the ansatz (where we slightly abuse the notation to write $x_h^{+*} = y_h - \xi^*(y_h)$ for the target impulse level at y_h)

$$v^+(x) = \begin{cases} v^+(x_h^{+*}) - K_p(\xi^*(x)), & x \geq y_h, \\ \widehat{v}^+(x) + v_1^+ e^{\theta_1^+ x} + v_2^+ e^{\theta_2^+ x}, & x_\ell^+ < x < y_h, \\ v^+(x_\ell^{+*}) - K_p(\xi^*(x)), & x \leq x_\ell^+, \end{cases} \tag{55}$$

and the boundary conditions for determining the target impulse levels

$$v_x^+(x_h^{+*}) = -\kappa_1, \quad v_x^+(x_\ell^{+*}) = +\kappa_1. \tag{56}$$

Note that we now have 5 unknowns, $v_{1,2}^+, x_\ell^+, x_\ell^{+*}, x_h^{+*}$ rather than six as we “fixed” $x_h^+ = y_h$. This yields the following system

$$\begin{cases} \widehat{v}^+(y_h) + v_1^+ e^{\theta_1^+ y_h} + v_2^+ e^{\theta_2^+ y_h} = \widehat{v}^+(x_h^{+*}) + v_1^+ e^{\theta_1^+ (x_h^{+*})} + v_2^+ e^{\theta_2^+ (x_h^{+*})} - K_p(\xi^*(y_h)) & (C^0 \text{ at } y_h) \\ \widehat{v}^+(x_\ell^+) + v_1^+ e^{\theta_1^+ x_\ell^+} + v_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{v}^+(x_\ell^{+*}) + v_1^+ e^{\theta_1^+ (x_\ell^{+*})} + v_2^+ e^{\theta_2^+ (x_\ell^{+*})} - K_p(\xi^*(x_\ell^+)) & (C^0 \text{ at } x_\ell^+) \\ \widehat{v}_x^+(x_\ell^+) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^+} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{v}_x^+(x_\ell^{+*}) + v_1^+ \theta_1^+ e^{\theta_1^+ (x_\ell^{+*})} + v_2^+ \theta_2^+ e^{\theta_2^+ (x_\ell^{+*})} + \kappa_1 & (C^1 \text{ at } x_\ell^+) \\ \widehat{v}_x^+(x_h^{+*}) + v_1^+ \theta_1^+ e^{\theta_1^+ x_h^{+*}} + v_2^+ \theta_2^+ e^{\theta_2^+ x_h^{+*}} = -\kappa_1 & (C^1 \text{ at } x_h^{+*}) \\ \widehat{v}_x^+(x_\ell^{+*}) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^{+*}} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^{+*}} = \kappa_1. & (C^1 \text{ at } x_\ell^{+*}) \end{cases} \tag{57}$$

Fig. 3 Value functions v_0^\pm , v_1^\pm , and v_{pre}^\pm of the producer given the consumer’s strategy $C_c = (3, 4)$.

Preemption in the contraction regime writes in a symmetric way.

In general, we need to manually verify whether $x_h^+ > y_h$ (the “normal” case) or $x_h^+ = y_h$ (the preemptive case) whenever we consider the producer best response. The two situations lead to different boundary conditions at the upper threshold, and hence cannot be directly compared. Considering the optimization problem for x_h^+ , we expect his value function to increase in x_h^+ on (x_ℓ^+, y_h) and experience a positive jump at y_h , i.e., conditional on someone acting, the producer prefers the consumer’s switch to applying his impulse. However, if this is not the case, the consumer action hurts the producer and assuming the impulse costs are low, the best response is $x_h^+ = y_h$. This corner solution arises due to the underlying discontinuity: on (x_ℓ^+, y_h) the producer compares the value of waiting to the value of doing an optimal impulse, but at y_h he compares the value of switching to that of doing an optimal impulse. So it could be that “waiting” $>$ impulsing $>$ switching at y_h , leading to preemptive impulse to prevent the worst (for the producer) outcome.

Proposition 4 Assume $\mu_{0-} = \mu_+$. Let the 5-tuple $(v_1^+, v_2^+, x_\ell^{+*}, x_h^{+*}, x_h^{+*})$ be a solution to the system (57), such that the order in (44) is fulfilled and $x_\ell^{+*} < x_h^{+*}, x_h^{+*} < y_h$. Let v^+ be defined as in (55) and assume

$$v_{xx}^+(x_\ell^{+*}) < 0, \quad v_{xx}^+(x_h^{+*}) < 0. \tag{58}$$

Then, the function v^+ is the best-response payoff of the producer in the expansion regime, and a best-response strategy is given by

$$\tau_0^* = 0, \quad \tau_i^* = \inf\{t > \tau_{i-1}^* : X_t \in \Gamma_p(t-)\}, \tag{59}$$

$$\xi_i^*(x_\ell^+) = x_\ell^{+*} - x_\ell^+, \quad \xi_i^*(y_h) = y_h - x_h^{+*}, \quad i \geq 1, \tag{60}$$

with $\Gamma_p(t) = \Gamma_p^+(t) = (-\infty, x_\ell^+] \cup [y_h, +\infty)$, while X^* follows the dynamics corresponding to the producer’s impulse strategy $(\tau_i^*, \xi_i^*)_{i \geq 1}$.

Figure 3 illustrates the shapes of the producer’s value function in the different cases of best response. For the given consumer strategy, we have a dominant function in the contraction regime (v_1^-) and a dominant function in the expansion regime (v_1^+).

4 Equilibria

The best-response functions defined in Sect. 3 lead to three types of potential market equilibria, depending on the equilibrium behavior of the consumer and characterized by the relative positions of the consumer and producer thresholds:

- Type I—generic: $y_\ell \leq x_h^-$ and $x_\ell^+ \leq y_h$.
- Type II—transitory: $-\infty = y_\ell \leq x_\ell^-$ and $x_\ell^+ \leq y_h$; or $y_\ell \leq x_h^-$ and $y_h = +\infty$.
- Type III—preemptive: $y_\ell \leq x_h^-$ and $x_\ell^+ = y_h$; or $y_\ell = x_h^-$ and $x_\ell^+ \leq y_h$.

In equilibrium type I, the consumer switches back and forth forever between the two expansion and contraction regimes. The optimal policy of the consumer is given by the threshold y_ℓ in the contraction regime and y_h in the expansion regime, while the optimal policy of the producer is formed by the pair $(x_\ell^+, x_\ell^{+,*})$ in the expansion regime and symmetrically by the pair $(x_h^{+,*}, x_h^-)$ in the contraction regime. We anticipate this to be the most common equilibrium type; it is precisely described and illustrated in Sect. 4.1.

In equilibrium type II, the consumer and the producer both prefer a given regime and thus, the consumer switches at most once when the market is initialized in the opposite regime. Afterward, only the producer acts to maintain the price between (x_ℓ, x_h) . Consider the case of a single switch from expansion to contraction; the consumer’s optimal policy consists then in only one threshold, y_h . The optimal policy of the producer is more complicated: in the expansion regime, it consists of the pair $(x_\ell^+, x_\ell^{+,*})$ and in the contraction regime, it consists of a quadruplet $(x_\ell^-, x_\ell^{-,*}, x_h^{-,*}, x_h^-)$. The same reasoning applies in the other single switch case. This equilibrium is described in Sect. 4.2.

The last type of equilibrium, named type III, resembles the preceding one in the sense that at most one switch can be observed. But it differs because here the consumer is stuck forever in a state she wishes to leave. In that case described in Sect. 4.3, only the producer acts. Starting in the expansion regime, for instance, the consumer would like to switch to the contraction regime when the price reaches a threshold y_h . But the producer, who prefers perpetual expansion, *preempts* the switch by acting at the threshold y_h^- , just before the action of the consumer.

Threshold-type equilibria offer analytical tractability to describe the long-run market behavior. The latter can be summarized by the stationary distribution of the commodity price (X_t^*) and the consumer regimes (μ_t^*) as induced by the equilibrium strategies (N_t^*, μ_t^*) . To quantify these effects, we define an auxiliary discrete-time jump chain $(M_n^*)_{n=0}^\infty$ which takes values in the state space

$$E := \{S_+, S_-, I_\ell^-, I_h^-, I_\ell^+, I_h^+\}. \tag{61}$$

The chain M^* keeps track of the sequential actions of the players, where S_\pm represents the switches of the consumer (“ S_+ ” stands for the switch $\mu_- \rightarrow \mu_+$ and “ S_- ” for $\mu_+ \rightarrow \mu_-$) and I_r^\pm the impulses (up/down at the two impulse boundaries) of the producer. Thus, M^* summarizes the sequence of market interventions stored within τ_i, σ_i stopping times. Note that states $M_n^* \in \{S_+, I_{\ell h}^+\}$ imply a positive drift μ_+ of X^* , while the rest imply a negative drift μ_- . Moreover, if the consumer adopts a double-switch strategy and the producer adopts a non-preemptive strategy as discussed in Sect. 4.1, then the thresholds x_h^+ and x_ℓ^- will be hit at most once by X^* and therefore the corresponding states I_h^+ and I_ℓ^- of M_n^* are transient.

Because the dynamics of X^* between interventions are always Brownian motion (BM) with drift, the transition probabilities of M^* can be described in terms of hitting probabilities of a BM. This offers closed-form expressions for the transition probability matrix \mathbf{P} of M^* , and its invariant distribution denoted by $\bar{\Pi}$. Moreover, the sojourn times of M^* correspond

Table 1 Model parameters for Sect. 4.1

	Market	Consumer		Producer	
β	0.1	x_c^1	1	x_p^1	2
σ	0.25	x_c^2	5	x_p^2	6
μ_+	0.1	a_c	0.75	a_p	0.25
μ_-	-0.1	h_{\pm}	10	κ_0	3
				κ_1	0

Fig. 4 Producer’s and consumer’s profit rates as a function of x

to (X_t^*) hitting the various thresholds (in terms of the original continuous-time “ t ”) and are similarly linked to BM first passage times. Combining the above ideas, we can then derive a complete description of (μ_t^*) , namely the long-run proportion of time that the commodity demand is in expansion/contraction regimes and the respective expected switching time, see (71).

In the following section otherwise stated, we use the parameter values in Table 1, such that $\pi_i(x) = a_i(x - x_i^1)(x_i^2 - x)$, $i \in \{c, p\}$. This yields consumer and producer preferred price levels of $\bar{X}_c = 3$, $\bar{X}_p = 4$. The same set of parameters yields an equilibrium of each type, showing the non-uniqueness of equilibria in this model.

We remark that while our verification results in Propositions 2–4 rigorously characterize player strategies, we do not have any existence results for the game equilibrium itself. In particular, we do not have existence results for the corresponding large systems of equations that describe all the thresholds. Global existence (i.e., for any admissible competitor strategy) seems to be out of reach, and it is challenging to formulate any algebraic conditions that would hold in equilibrium and ensure existence (Fig. 4). Thus, ultimately we numerically find a fixed point to the (specific type of) best-response strategy maps and then view it as an approximate (up to numerical round-off error, since we cannot show existence directly) threshold-type equilibrium. Consequently, technically our discussion below concerns candidate equilibria that satisfy the equilibrium equations up to machine precision.

Fig. 5 A sample path of the controlled market price (X_t^*) under a type I equilibrium (left), type II (center) and type III (right) together with $\mathbb{E}[X_t^*]$ (black solid curve). The colors along the x -axis indicate the corresponding μ_t^* . We start with $\mu_0^* = \mu_+$

4.1 Type I—Generic

We look for an *interior, non-preemptive* equilibrium satisfying the ordering (15), i.e., a pair of consumer and producer strategies of the form (y_ℓ^*, y_h^*) and $(x_\ell^+, x_\ell^{+*}, x_h^{-*}, x_h^-)$. To construct this equilibrium, we employ tâtonnement, i.e., iteratively apply the best-response controls alternating between the two players. This corresponds to the interpretation of Nash equilibrium as a *fixed point of best-response maps* BR . The equilibrium is obtained using two different fixed-point algorithms. Given strategies C_p^0 and C_c^0 , we have either an asynchronous or synchronous algorithm, namely

$$\begin{aligned}
 C_p^{k+1} &= BR(C_c^k), & C_p^{k+1} &= BR(C_c^k), \\
 C_c^{k+1} &= BR(C_p^{k+1}), & C_c^{k+1} &= BR(C_p^k), \\
 &\text{asynchronous} & &\text{synchronous.}
 \end{aligned}$$

The resulting equilibrium found using both algorithms is the same and is

$$C_p^{I,*} = \left[\begin{matrix} 2.0, & 3.6, & -, & +\infty \\ -\infty, & -, & 4.5, & 6.1 \end{matrix} \right], \quad C_c^{I,*} = [2.2, 4.4]. \tag{62}$$

The dynamic equilibrium of the commodity price X^* is illustrated in Fig. 5 (Left). The market starts in the expansion regime, $\mu_0^* = \mu_+$. We observe that x_h^{-*} is close to y_h^* , implying that once the price has reached the switching level y_h^* , it is likely to touch soon thereafter the threshold x_h^{-*} , making the price drop to x_h^{-*} . The producer “backs up” this mean-reversion by impulsing down if prices rise too much and impulsing up if they drop too much. Otherwise, she lets the consumer be in charge via switching control that benefits him as well.

At equilibrium, the price X^* fluctuates in a range of values where neither the producer nor the consumer have negative profit rate. If alone in the market, the optimal monopolistic strategies of the producer and the consumer are

$$C_p^m := \left[\begin{matrix} 1.9, & 3.5, & 3.5, & 5.6 \\ 2.4, & 4.5, & 4.5, & 6.1 \end{matrix} \right], \quad C_c^m := [1.7, 4.3]. \tag{63}$$

We see that the equilibrium strategy of the producer $C_p^{I,*}$ is quite close to what he would have done if alone in the market. On his side, the consumer-induced equilibrium price range is wider than he would prefer (2.6 against 2.2 if alone). In equilibrium, it is as if the producer lets the consumer do the job of bringing back the price to his preferred level \bar{X}_p . The producer intervenes only if X_t^* drops too low or gets too high, after the regime switching has occurred.

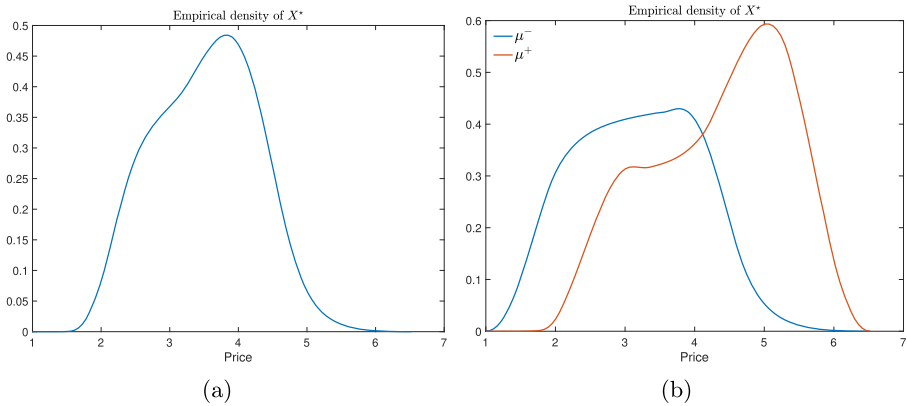

Fig. 6 Estimated long-run densities ϕ^* of X^* in a double-switch and one-sided impulse equilibrium. Panel **a** overall kernel smoothed $\phi^*(\cdot)$. **b** long-run distributions ϕ_{\pm}^* of X^* conditional on $\mu(t) = \mu_+$ (resp. $\mu(t) = \mu_-$). Recall that the domain of X_t^* depends on the current regime, so the support of the two densities differs

But, in the long run, the average price $\lim_{t \rightarrow \infty} \mathbb{E}[X_t^*]$ is close to 3.5, which is the mid-value between \bar{X}_p and \bar{X}_c .

The players’ equilibrium strategy profile yields a stationary distribution for the pair (X_t^*, μ_t^*) . The macro-market μ^* switches between the expansion and the contraction regimes back and forth, while the jointly controlled price (X_t^*) is bounded in the range $[x_\ell^+, x_h^-]$ and fluctuates in a *mean-reverting* pattern due to alternating signs of its drift. These stylized features can be broadly traced in the world commodity markets which undergo cyclical Expansion/Contraction patterns.

Dynamics of (X_t^) in the Equilibrium* The dynamics of the commodity price (X_t^*) are less tractable due to the impulses applied by the producer. Let $\phi^*(\cdot)$ denote the long-run (i.e., stationary) distribution of (X_t^*) . In Fig. 6, we show ϕ^* obtained from an empirical density based on a long trajectory of (X_t^*) , relying on Monte Carlo simulations and the ergodicity of the recurrent, bounded process (X_t^*) . For additional interpretability, we also plot the invariant distributions ϕ_{\pm}^* conditional on $\mu_t = \mu_{\pm}$.

4.2 Type II—Transitory

In another type of equilibrium, the consumer switches only in one regime, with the other being absorbing. For this reason, we name it *transitory*. To fix ideas, suppose that the consumer only switches from expansion regime to contraction regime. In that case, the producer effectively acts like a profit maximizing monopoly in the contraction regime with two-sided impulses; in the expansion regime, she will apply a one-sided impulse as in the equilibrium type I.

To solve for such equilibrium, we first compute the producer strategy in the contraction regime which is a decoupled VI as in (39) leading to the 6 equations in (43) but only for v^-, x_r^-, x_r^{*-} , $r \in \{\ell, h\}$. This solution induces the corresponding no-switch solution ω_0^- of the consumer as in (20), (21). Both v^-, ω_0^- are then fixed and act as source terms to solve for the equilibrium in the expansion regime. For the latter, we need to compute $v^+(\cdot)$ and the associated thresholds x_ℓ^+, x_ℓ^{*+} (only one threshold), as well as $\omega^+(x)$ and the switching threshold y_h (note that there is no y_ℓ). The boundary conditions are $v^+(y_h) = v^-(y_h)$, $\omega^+(y_h) = \omega^-(y_h) - h_0$.

This reasoning leads to the following algorithm. If x_ℓ^+ and $x_\ell^{+,*}$ are fixed, we compute the best response of the consumer by solving the variational problem for the consumer value function ω^+ such that:

$$w^+(x) = \begin{cases} w_0^-(x) - h_0, & y_h \leq x, \\ \widehat{\omega}^+(x) + \lambda_1^+ e^{\theta_1^+ x} + \lambda_2^+ e^{\theta_2^+ x}, & x_\ell^+ < x < y_h, \\ w^+(x_\ell^{+,*}), & x \leq x_\ell^+. \end{cases}$$

This is exactly the best response in the single-switch case with the solution given by the system (24) and which provides the consumer’s threshold y_h . Now, if we consider that y_h is fixed, we can compute the best response of the producer by solving a VI for the value function v^+ that satisfies

$$v^+(x) = \begin{cases} v^-(x), & y_h \leq x, \\ \widehat{v}^+(x) + v_1^+ e^{\theta_1^+ x} + v_2^+ e^{\theta_2^+ x}, & x_\ell^+ < x < y_h, \\ v^+(x_\ell^{+,*}) - \kappa_0 - \kappa_1(x_\ell^{+,*} - x), & x \leq x_\ell^+. \end{cases}$$

The boundary conditions giving the four unknowns $(x_\ell^+, x_\ell^{+,*}, v_1^+, v_2^+)$ are:

$$\begin{cases} v^-(y_h) = \widehat{v}^+(y_h) + v_1^+ e^{\theta_1^+ y_h} + v_2^+ e^{\theta_2^+ y_h}, & (C^0 \text{ at } y_h) \\ \widehat{v}^+(x_\ell^+) + v_1^+ e^{\theta_1^+ x_\ell^+} + v_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{v}^+(x_\ell^{+,*}) + v_1^+ e^{\theta_1^+ x_\ell^{+,*}} + v_2^+ e^{\theta_2^+ x_\ell^{+,*}} - \kappa_0 - \kappa_1(x_\ell^{+,*} - x_\ell^+), & (C^0 \text{ at } x_\ell^+) \\ \widehat{v}_x^+(x_\ell^+) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^+} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^+} = \widehat{v}_x^+(x_\ell^{+,*}) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^{+,*}} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^{+,*}} + \kappa_1, & (C^1 \text{ at } x_\ell^+) \\ \widehat{v}_x^+(x_\ell^{+,*}) + v_1^+ \theta_1^+ e^{\theta_1^+ x_\ell^{+,*}} + v_2^+ \theta_2^+ e^{\theta_2^+ x_\ell^{+,*}} = \kappa_1. & (C^1 \text{ at } x_\ell^{+,*}) \end{cases} \tag{64}$$

Now, we can perform the iterations $y_h^0 \rightarrow (x_\ell^{+, (0)}, x_\ell^{+,* (0)}) \rightarrow y_h^1 \rightarrow (x_\ell^{+, (1)}, x_\ell^{+,* (1)}) \dots$

We find the following fixed point of the best-response functions of the producer and the consumer:

$$C_p^{II,*} = \left[1.9, 3.6, -, +\infty \right], \quad C_c^{II,*} = [-\infty, 4.3], \tag{65}$$

The system starts in the expansion regime, and once the price reaches level $X_t^* = 4.3$, the consumer switches to contraction and the systems remains in that state forever. After that, she relies on the producer to impulse (X_t^*) up/down when prices get too low/too high but never reverts to the expansion regime. Thus, in the long run (X_t^*) is simply a Brownian motion with negative drift μ_- that has two impulse boundaries $x_\ell^- = 2.4, x_h^- = 6.1$.

Compared to the double-switch equilibrium of the previous section, the above market equilibrium in (65) has two important differences. First, as $t \rightarrow \infty$ we have that $\mu_t^* \rightarrow \mu_-$ so that in the long run the market will be in the contraction regime and the consumer becomes inactive. Second, because the producer eventually “takes over,” she will intervene much more frequently (see center panel of Fig. 5), benefiting himself and reducing consumer value.

4.3 Type III—Preemptive

The producer may have an interest to preempt the switch, say, from the expansion regime to the contraction regime to avoid decline in the consumption of the commodity he produces. In this case, the equilibrium is a fixed point of the best-response function of the producer described in Sect. 3.2.3 and the best-response function of the consumer described in Sect. 3.1.2. We look for an equilibrium where the consumer would like to switch at y_h in the expansion

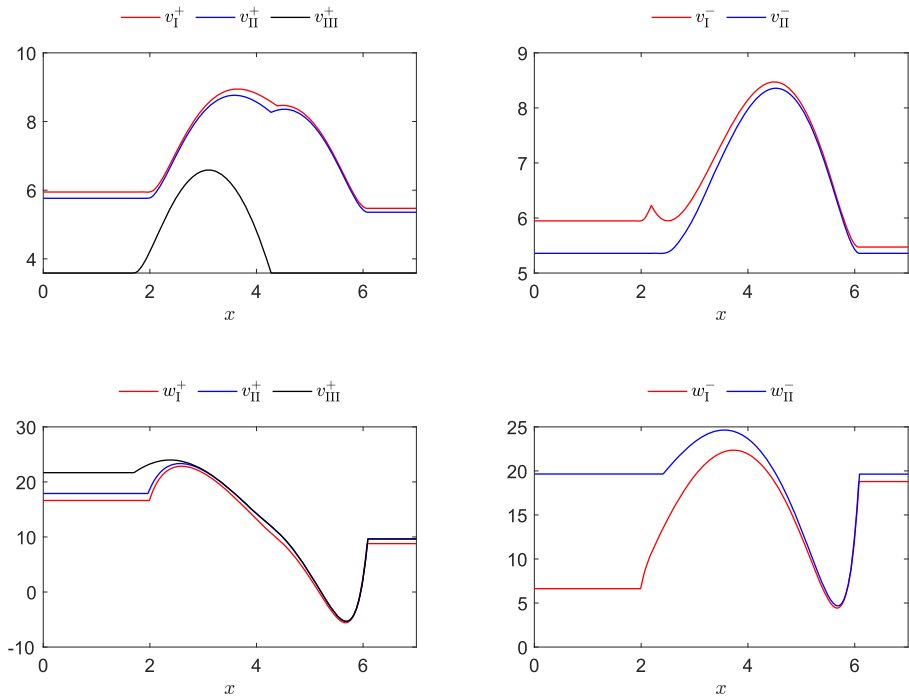

Fig. 7 Producer and consumer value functions in the different equilibria

regime, but where the producer makes y_h his own intervention threshold to impulse the price down.

Using the same protocol as in type I and type II equilibrium research, we find the following threshold strategy for the producer and the consumer:

$$C_p^{III,*} := \begin{bmatrix} 1.7, 3.1, 3.1, 4.3 \\ -, -, -, - \end{bmatrix}, \quad C_c^{III,*} := [-, 4.3]. \tag{66}$$

In the preemptive equilibrium, the price fluctuates in a narrower range than the other two equilibria. Here, (X_t^*) oscillates between $x_\ell^+ = 1.7$ and $x_h^+ = y_h = 4.3$.

4.4 Equilibrium Non-Uniqueness

There are at least three potential equilibria. A natural question is thus whether one of them is preferable to the others. Figure 7 shows the value functions of the producer and of the consumer in the two market regimes (expansion and contraction) and for the different equilibria from type I to type III. We observe that the producer would prefer to live in a type I equilibrium. The function v_1^\pm dominates all the other ones (note that there is no v_3^- because in equilibrium type III contraction never happens). However, the consumer would rather be in the preemptive equilibrium type III: her value function w_3^+ dominates the other two. Intuitively, we may think that the switching costs she saves by letting the producer do all the work of maintaining the price around its long-term average value compensate for the inconvenience of having prices that are higher than preferred.

Table 2 Long-run mean and variance of X^* , long-run profit rates, and frequency of regime switches as market volatility σ changes (APOO in parentheses)

	σ	$\mathbb{E}_{\phi^*}[X^*]$	$\text{Var}_{\phi^*}(X^*)$	$\mathbb{E}_{\phi^*}[\pi_p]$	$\mathbb{E}_{\phi^*}[\pi_c]$	Switch (per yr)
Type I	0.25	3.52	0.73	0.81 (80%)	2.4 (80%)	0.021
	0.3	3.62	0.80	0.80 (79%)	2.2 (73%)	0.021
	0.4	3.77	0.94	0.76 (75%)	1.90 (62%)	0.020
Type II	0.25	3.73	0.68	0.87 (85%)	2.3 (74%)	0.020
	0.3	3.76	0.74	0.85 (84%)	2.2 (71%)	0.020
	0.4	3.81	0.85	0.81 (80%)	1.95 (64%)	0.020
Type III	0.25	3.41	0.45	0.86 (85%)	2.7 (90%)	0.0
	0.3	3.35	0.51	0.83 (82%)	2.7 (90%)	0.0
	0.4	3.28	0.61	0.78 (77%)	2.7 (88%)	0.0

4.5 Impact of Market Volatility

As one example of comparative statistics that are possible in our model, we investigate the impact of volatility parameter σ of X on the equilibrium profits and behavior of X^* . In Table 2, we list statistics of ϕ^* for a range of market volatilities σ . We also quantify the profitability of the two players through their average percentage of optimality (APOO)

$$\text{APOO} := \frac{\int_{\mathcal{D}} \pi_r(x)\phi^*(dx)}{\pi_r(\bar{X}_r)},$$

which is the ratio between average profit rate $\pi_r(X_r^*)$ in equilibrium and the maximum profit that could be hypothetically obtained at the first-best level $\pi_r(\bar{X}_r)$, $r \in \{c, p\}$.

In all types of equilibria, both players are worse off in terms of expected profit rate as σ increase. This occurs even though in type I and in type II equilibria the average price $\mathbb{E}[X^*]$ increases. However, that gain is dominated by the losses due to higher $\text{Var}(X^*)$ which implies that prices tend to be further from their preferred levels \bar{X}_r , decreasing $\mathbb{E}_{\phi^*}[\pi_r]$.

4.6 Effect of Consumer’s Switching Cost

A key parameter that controls which equilibrium type we face is the consumer’s switching cost h_0 . Starting from the double-switch situation, as h_0 increases (> 0.6), the consumer is less incentivized to switch from μ^+ to μ^- and we enter the single-switch scenario of Sect. 3.1.2. Consequently, she receives the no-switch payoff $\omega_0^+(x)$ when $\mu_t = \mu^+$ and solving for her best-response boils down to solve for y_h only. Once h_0 gets very large, her best response is simply the no-switch response ω_0^\pm . Conversely, as $h_0 \downarrow 0$ her actions become free. In that situation, we can reduce the producer problem to a single, piecewise VI with a free boundary \tilde{X}_c :

$$\sup \left\{ -\beta v(x) + \mu_- v_x + \frac{1}{2}\sigma^2 v_{xx} + \pi_p(x) ; \sup_{\xi} \{v(x + \xi) - v(x) - K_p(\xi)\} \right\} = 0 \quad x > \tilde{X}_c, \tag{67}$$

$$\sup \left\{ -\beta v(x) + \mu_+ v_x + \frac{1}{2}\sigma^2 v_{xx} + \pi_p(x) ; \sup_{\xi} \{v(x + \xi) - v(x) - K_p(\xi)\} \right\} = 0 \quad x < \tilde{X}_c, \tag{68}$$

Fig. 8 Equilibrium thresholds as a function of consumer switching cost h_0 given parameter values in Table 1. We show the consumer thresholds y_l, y_h , the producer thresholds x_l^+, x_h^- and respective impulse target levels $x_l^{*,+}, x_h^{*, -}$

with the C^0 regularity at \tilde{X}_c : $\lim_{x \uparrow \tilde{X}_c} v(x) = \lim_{x \downarrow \tilde{X}_c} v(x)$.

Figure 8 shows that for low h_0 , $x_h^{+,*} < y_l$ and x_h^+ is greater but close to y_h . Thus, when consumption switches from expansion to contraction, it is very likely that the price touches x_h^+ soon thereafter and is impulsed back to $x_h^{+,*}$ and thus, the regime rapidly switches back to expansion again. When the switching cost increases, this solution disappears.

Remark 3 It is possible for the impulse amounts to be so large as to lead to a double simultaneous control: producer’s impulse instantaneously followed by the consumer switching. In this setting, the producer effectively forces the consumer to switch the regime by impulsing X^* hard enough. This situation corresponds to $x_h^{+,*} < y_l$, so that the impulse in the contraction regime moves X^* into the respective switching region $(-\infty, y_l)$, and as a result the consumer immediately switches to the expansion regime. This situation occurs if, for instance, the drifts are $\mu^- = 0.01, \mu^+ = 0.1$, so that the consumer is not able to ever efficiently lower prices. Consequently, the producer is forced to fully control price reduction. We observe in the above situation the equilibrium thresholds of $x_h^{+,*} = 3.04 < y_l = 3.69$. \square

5 Case Study: Diversification Effect of Vertical Integration

In this section, we accordingly study whether or not downstream or upstream firms have an interest in being vertically integrated. To this end, we consider a small firm that has no market power regarding the commodity price X and focus on the case of the market equilibrium type I (generic case). We then investigate whether the firm can benefit from a diversification effect by having activity both in the downstream consumer side and the upstream conversion side.

To make the case study concrete, we consider a simplified version of the crude oil and gasoline markets, the latter a shorthand for refined products, calibrated to the ballpark of the 2019 state of the world. Currently, world oil consumption is about 100 Mb/d (millions of barrels per day), normalized to 1 “barrel” per day. We take as a nominal initial price $X_0 =$

Fig. 9 The curve $\lambda \mapsto (\sigma(\pi_\lambda), \mathbb{E}[\pi_\lambda])$ as a function of the pass-through parameter p_1

50 USD/b and a nominal volatility of crude $\sigma = 10$ USD/b. To calibrate our model, we consider that crude oil producers have a preferred range of prices that goes from $x_p^1 = 30$ USD/b to $x_p^2 = 100$ USD/b and that the average cost of oil extraction is $c_p = 30$ USD/b. This leads to a demand function $D_p(x) = 1 - 0.01x$, which captures the low sensitivity of the demand of crude to prices. The crude is transformed into gasoline with a small amount of losses 5%, so that the conversion factor is $\alpha = 0.95$.

We set the transfer function of crude oil price to average price of gasoline to $P(x) = 10 + 1.1x$, where $P(x)$ is also expressed in USD/b. There is evidence that the (pre-tax) price of gasoline is a linear function of the crude. For instance, using monthly data of the Energy Information Agency of the US Department of Energy on refined products prices from January 1983 to November 2019,² we regressed the US Total gasoline Retail sales by refineries \hat{P} to the monthly crude oil price \hat{X} and found a linear relation

$$\hat{P}_m = 1.2\hat{X}_m + 14 + \epsilon_m$$

with a regression $R^2 = 95\%$. Considering that the basket of refined products includes not just gasoline (even if it accounts for the largest share), we simplified the relation. Note that the condition $p_1 \geq \alpha$ for having a downstream convex profit function holds. Furthermore, refinery costs c_c are highly variable between 4 to 10 USD/b. We take the higher value of $c_c = 10$. Finally, we consider that the demand function for refined products, $D_c(P) = d'_0 - d'_1 P$ is such that $d'_0 = 5$ b/d of crude equivalent refined products and $d'_1 = 0.05$. With these parameters, the preferred range of crude prices for the consumer is between $x_c^1 = 11$ and $x_c^2 = 82$ USD/b. We consider fixed action costs both for the production firm and the downstream firm. We consider that the producer and the downstream firm lose two years of profit at optimal price to change state making $\kappa_0 = 2\pi_p(\bar{X}_p)$ and $h_0 = 2\pi_c(\bar{X}_c)$. Finally, we take $\mu_{\pm} = \pm 0.15$ per year, which implies that it takes 10 years for the crude price to increase by 1.5 USD.

The resulting equilibrium type I producer impulse strategy $C_p^{1,*}$ and consumer’s switching strategy $C_c^{1,*}$ associated with the calibration summarized in Table 3 are given by

$$C_p^{1,*} = \left[\begin{array}{cccc} 26, & 62, & -, & +\infty \\ -\infty, & -, & 69, & 104 \end{array} \right], \quad C_c^{1,*} = [22.5, 87]. \tag{69}$$

Thus, in equilibrium, the crude price X^* fluctuates between 22.5 and 87 USD/b, with potential excursions up to 104 or down to 26 USD/b at which point producers intervene.

² Data available at http://www.eia.gov/dnav/pet/pet_pri_refoth_dc_u_nus_m.htm.

Table 3 Nominal values for model parameters for the crude oil case study

	Value	Interpretation	Units
β	0.1	Discount rate	%/year
X_0	50	Initial oil price	USD/b
d_0	1	Demand function for oil: intercept	Mb/d
d_1	0.01	Demand function for oil: slope	Mb/d/(USD/b)
d'_0	5	Demand function for gasoline: intercept	Mb/d
d'_1	0.05	Demand function for gasoline: slope	Mb/d/(USD/b)
α	0.95	Transformation rate	dimensionless
p_0	10	Crude–gasoline price function: intercept	USD/b
p_1	1.1	Crude–gasoline transfer price function: slope	USD/b/(USD/b)
c_p	30	Oil production cost	USD/b
c_c	5	Refining cost	USD/b
μ_{\pm}	± 0.15	Annualized crude drift parameters	USD/b
σ	10	Annualized crude volatility	USD/b
h_0	$2\pi_c(\bar{X}_c) = 29$	Consumption switching cost	USD
κ_0	$2\pi_p(\bar{X}_p) = 24.5$	Production switching cost: fixed	USD
κ_1	0	Production switching cost: proportional	USD/b

Fig. 10 Left: profit rate function of the consumer $\pi_c(x)$ (red) as the pass-through parameter p_1 is varied, as well as the fixed producer profit rate $\pi_p(x)$ (blue). Middle: respective equilibrium strategy thresholds y_ℓ, y_h (red) and x_ℓ^+, x_h^- (blue) as a function of p_1 . We also plot \bar{X}_c and $\mathbb{E}_{\phi^*}[X^*]$, shading the typical commodity price range $[\mathbb{E}_{\phi^*}[X^*] \pm \sigma_{\phi^*}(X^*)]$. Right: risk-minimizing integration level λ^* as a function of p_1

Now let us consider a small firm engaging in a fraction $\lambda \in (0, 1)$ of activity in the downstream sector and $1 - \lambda$ in the upstream sector. Her profit rate is thus $\pi_\lambda := \lambda\pi_c + (1 - \lambda)\pi_p$. The firm is vertically integrated when $0 < \lambda < 1$. Denote by $\sigma(\pi_\lambda)$ the standard deviation of her profit rate $\pi_\lambda(\cdot)$ integrated against the stationary distribution ϕ^* of X^* , and by $\mathbb{E}[\pi_\lambda] = \int \pi_\lambda(x)\phi^*(dx)$ the respective expected profit rate. To fix ideas and because the analysis is symmetric, we are interested in situations where a pure downstream firm ($\lambda = 0$) would be better off having part of her activity in the upstream sector. This will take place when the upstream activity provides a higher expected profit rate and/or a lower risk as measured by $\sigma(\pi_\lambda)$. Figure 9 presents the risk–return curves $\lambda \mapsto (\sigma(\pi_\lambda), \mathbb{E}[\pi_\lambda])$ as the pass-through parameter p_1 increases from the nominal value of 1.1 to 1.18. We observe that for low values of p_1 diversification gains are limited: expected profit rate goes up, but risk also increases. For moderate p_1 , a pure downstream firm unambiguously benefits from some upstream activity: she can achieve the same level of risk with a higher expected profit. For

high p_1 , the upstream sector dominates completely with lower risk and higher average profit. Figure 10 (right) shows the critical integration level λ^* that minimizes the risk $\sigma(\pi_\lambda)$ and captures the “variance–minimal” business model.

We observe that for high enough pass-through values, being a producer ($\lambda = 1$) dominates any other combination of activity. This phenomenon happens even though the maximum profit rate of the downstream firm $\pi_c(\bar{X}_c)$ increases and gets higher than the producer’s maximum profit rate function $\pi_p(\bar{X}_p)$ as shown in the left panel of Fig. 10. As shown by the evolution of equilibrium price range in Fig. 10 (Middle), as p_1 increases, the equilibrium is getting more and more detrimental to the downstream firm. The shaded salmon area represents the interval $[\mathbb{E}_{\phi^*}[X^*] - \sigma_{\phi^*}(X^*), \mathbb{E}_{\phi^*}[X^*] + \sigma_{\phi^*}(X^*)]$ where commodity prices tend to reside. The average commodity price remains stable around 65 USD/b, and its standard deviation is not affected much by p_1 either, while \bar{X}_c is steadily decreasing. Thus, since the expected profit rate of the integrated firm is a function of the expected price and its standard deviation, it does not change much. But its variance grows as a function of p_1 and thus increases significantly. To conclude, in our model we do observe a diversification effect obtained by mixing upstream and downstream activities; however, the integration gains depend closely on the pass-through parameter p_1 which serves as a transmission channel of the volatility of the commodity price to the retail price.

6 Conclusion

We showed how a simple model of competition between upstream and downstream representative firms having different pace of intervention can lead to a rich variety of equilibria, potentially non-unique. The fact that the upstream firm can impact the price more rapidly than the downstream firm gives the producer a significant advantage, enabling him to lock the consumer in the producer’s preferred range of prices. Further, in the case of the crude oil market and its refinery products, we stressed how the pass-through parameter p_1 plays a key role for the diversification effect induced by vertical integration. Vertical integration is beneficial for low values of p_1 , while for higher values, production dominates downstream activity both in terms of expected profit rate and profit standard deviation.

7 Proofs

7.1 Proof of Proposition 1

Proof The proof is standard; nonetheless, we give some details for the reader’s convenience. To ease the notation, let us consider only the case $\mu = \mu_+$, the other case being identical. Let $w_0^+(x) = \hat{w}^+(x) + u^+(x)$, where the parameters $(\lambda_{1,0}^+, \lambda_{2,0}^+) \in \mathbb{R}$ solve the system (20), (21). By construction, the function w_0^+ is of class C^2 everywhere. Hence we can apply Itô’s formula to $e^{-\beta s} w_0^+(X_s)$ on the time interval $[0, t \wedge \zeta_n)$, yielding

$$\begin{aligned}
 e^{-\beta(t \wedge \zeta_n)} w_0^+(X_{t \wedge \zeta_n}) &= w_0^+(x) + \int_{0+}^{t \wedge \zeta_n} e^{-\beta s} [w_0^{+'}(X_{s-})(\mu_+ ds + \sigma dW_s - dN_s) - \beta w_0^+(X_{s-}) ds] \\
 &\quad + \frac{\sigma^2}{2} \int_{0+}^{t \wedge \zeta_n} e^{-\beta s} w_0^{+''}(X_{s-}) ds + \sum_{0 < s \leq t \wedge \zeta_n} e^{-\beta s} [\Delta w_0^+(X_s) + w_0^{+'}(X_{s-}) \Delta N_s],
 \end{aligned}$$

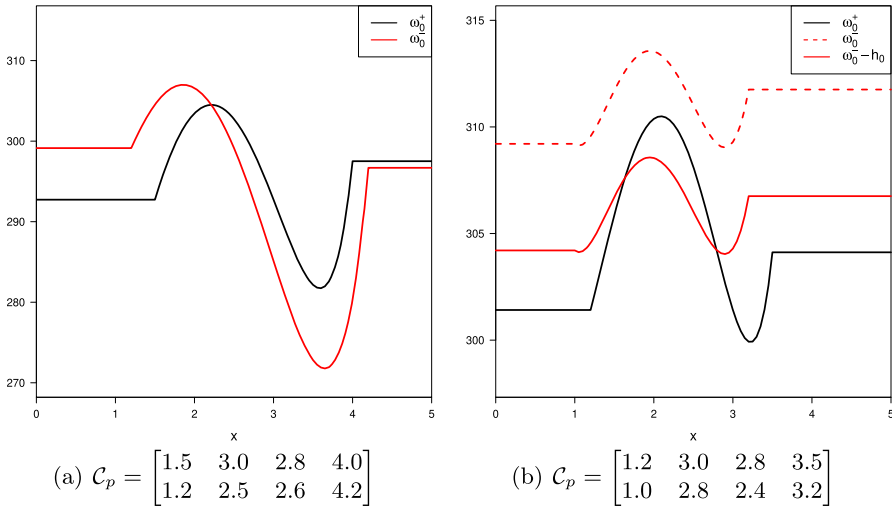

Fig. 11 No-switch payoffs $\omega_0^\pm(x)$ of the consumer given the producer's strategy C_p

where $(\zeta_n)_{n \geq 1}$ is a localizing sequence of stopping times along which the local martingale part above is in fact a true martingale. We use the notation ' and '' for, respectively, the first and second derivative in x . Taking expectations on both sides, using the fact that w_0^+ solves the ordinary differential Eq. (17) and letting $n \rightarrow \infty$, we obtain

$$\mathbb{E} \left[e^{-\beta t} w_0^+(X_t) \right] = w_0^+(x) - \mathbb{E} \left[\int_{0+}^t e^{-\beta s} \pi_c(X_s) ds + \sum_{0 < s \leq t} \Delta w_0^+(X_s) \right].$$

Now, notice that on the jumps of X we have $\Delta w_0^+(X_s) = w_0^+(x_r^{+*}) - w_0^+(x_r^+)$, which is zero by the boundary conditions (19), hence the jump part in the equation above vanishes. Moreover, being $X_t \in [x_\ell^+, x_h^+]$ for all $t \geq 0$, we have by dominated convergence that $\mathbb{E} \left[e^{-\beta t} w_0^+(X_t) \right] \rightarrow 0$ as $t \rightarrow \infty$. Therefore, letting $t \rightarrow \infty$ we can conclude that $w_0^+(x) = J_c^+(x; N, \mu^+)$ for all $x \in [x_\ell^+, x_h^+]$. \square

Figure 11a illustrates the fact that a threshold switching strategy might not be optimal in all potential situations by considering the shape of $w_0^\pm(x)$. In the right panel, we have comonotonicity between w^+ and w^- : the consumer is incentivized to switch to μ^+ when X_t is low and to μ^- when X_t is high. In that situation, we expect that a threshold-type strategy is a best response. In contrast, on the left panel two other cases are illustrated. First, we see that it is possible that $w^+(\cdot) \ll w^-(\cdot)$; in other words, the consumer has a strong preference to one regime over the other. In that case, the expansion regime could be absorbing, i.e., it is optimal to never switch to μ_- . In the plot, this would happen if h_0 is low (dashed line), whereby $w^-(x) > w^+(x) - h_0$ and it is optimal to switch to μ_- at any x (therefore μ_+ would never be observed in the resulting game evolution). At the same time, we see that if h_0 is moderate (the solid line), then the region where $w_0^-(x) > w_0^+(x) - h_0$ is disconnected, so it is likely that a two-threshold switching strategy is an optimal response.

7.2 Proof of Proposition 2

Proof of Proposition 2 By construction, the functions $w^\pm(x)$ in (29) solve the system of VIs in (27), (28) and satisfy $w^+ \in \mathcal{C}^2((x_\ell^+, x_h^+) \setminus \{y_\ell\}) \cap \mathcal{C}^1((x_\ell^+, x_h^+)) \cap \mathcal{C}^0(\mathbb{R})$ and $w^- \in \mathcal{C}^2((x_\ell^-, x_h^-) \setminus \{y_h\}) \cap \mathcal{C}^1((x_\ell^-, x_h^-)) \cap \mathcal{C}^0(\mathbb{R})$. Let N denote the pure jump component in X 's dynamics associated with the producer's strategy with thresholds $(x_\ell^\pm, x_\ell^{\pm*}; x_h^\pm, x_h^{\pm*})$. The proof is structured in two steps.

Step 1: optimality The following verification argument proves that such functions coincide with the best-response payoffs of the consumer and that the switching times $\hat{\sigma}_i$ as in the statement are optimal provided they are admissible. First, by an approximation procedure as in the first part of the proof in [1, Theorem 3.3], we can assume without loss of generality that $w^+ \in \mathcal{C}^2((x_\ell^+, x_h^+)) \cap \mathcal{C}^0(\mathbb{R})$. Let $\mu_{0-} = \mu_+$. Consider two consecutive switching times of any consumer admissible strategy, say σ_{2i} and σ_{2i+1} , for $i \geq 0$ with the convention $\sigma_0 = 0$, and recall that over $[\sigma_{2i}, \sigma_{2i+1})$ the state process X has drift μ_+ . Applying Itô's formula to $e^{-\beta t} w^+(X_t)$ over the interval $[\sigma_{2i} \wedge T, \sigma_{2i+1} \wedge T)$, for some finite $T > 0$, we obtain

$$\begin{aligned} e^{-\beta(\sigma_{2i+1} \wedge T)} w^+(X_{\sigma_{2i+1} \wedge T}) &= e^{-\beta(\sigma_{2i} \wedge T)} w^+(X_{\sigma_{2i} \wedge T}) \\ &+ \int_{\sigma_{2i} \wedge T}^{\sigma_{2i+1} \wedge T} e^{-\beta s} \left\{ w_x^+(X_s) dX_s + \frac{\sigma^2}{2} \omega_{xx}^+(X_s) ds - \beta X_s ds \right\} \\ &+ \sum_{\sigma_{2i} \wedge T < u \leq \sigma_{2i+1} \wedge T} e^{-\beta s} \{ \Delta w^+(X_s) + w_x^+(X_s) \Delta N_s \}. \end{aligned}$$

Using the dynamics $dX_s = \mu_+ ds + \sigma dW_s - dN_s$ between the two switching times above, localizing the martingale part through a suitable sequence of stopping times ζ_n and taking expectation on both sides, we obtain

$$\begin{aligned} \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i+1}} w^+(X_{\zeta_{n,T}^{2i+1}}) \right] &= \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i}} w^+(X_{\zeta_{n,T}^{2i}}) \right] \\ &+ \mathbb{E} \left[\int_{\zeta_{n,T}^{2i}}^{\zeta_{n,T}^{2i+1}} e^{-\beta s} \left\{ w_x^+(X_s) \mu_+ + \frac{\sigma^2}{2} w_{xx}^+(X_s) - \beta X_s \right\} ds \right] \\ &+ \mathbb{E} \left[\sum_{\zeta_{n,T}^{2i} \leq s < \zeta_{n,T}^{2i+1}} e^{-\beta s} \Delta w^+(X_s) \right], \end{aligned}$$

where we set $\zeta_{n,T}^k := \sigma_k \wedge \zeta_n \wedge T$. Notice first that the third summand above vanishes since between σ_{2i} and σ_{2i+1} , the state process X can jump only due to the impulses of the producer; hence, at any of such jumps the \mathcal{C}^0 -pasting condition at x_h^+ yields

$$\Delta w^+(X_s) = (w^+(X_s) - w^+(X_{s-})) \mathbf{1}_{(\Delta X_s \neq 0)} = (w^+(x_h^*) - w^+(x_h^+)) \mathbf{1}_{(\Delta X_s \neq 0)} = 0.$$

Regarding the second summand, we use the variational inequality (27) so that we can write

$$\mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i+1}} w^+(X_{\zeta_{n,T}^{2i+1}}) \right] \leq \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i}} w^+(X_{\zeta_{n,T}^{2i}}) \right] - \mathbb{E} \left[\int_{\zeta_{n,T}^{2i}}^{\zeta_{n,T}^{2i+1}} e^{-\beta s} \pi_c(X_s) ds \right].$$

Now, letting $n \rightarrow \infty$ we obtain by dominated convergence that

$$\mathbb{E} \left[e^{-\beta \sigma_{2i+1} \wedge T} w^+(X_{\sigma_{2i+1} \wedge T}) \right] \leq \mathbb{E} \left[e^{-\beta \sigma_{2i} \wedge T} w^+(X_{\sigma_{2i} \wedge T}) \right]$$

$$-\mathbb{E} \left[\int_{\sigma_{2i}}^{\sigma_{2i+1}} e^{-\beta s} \pi_c(X_{s \wedge T}) ds \right], \quad i \geq 0.$$

Analogously, we can get the same inequality between the switching times σ_{2i-1} and σ_{2i} for $i \geq 1$ with w^- replacing w^+ , so summing them all up we have

$$-\mathbb{E} \left[\int_0^{(\sup_i \sigma_i) \wedge T} \pi_c(X_s) ds \right] \geq \sum_{i \geq 0} \mathbb{E} \left[e^{-\beta \sigma_{2i+1} \wedge T} w^+(X_{\sigma_{2i+1} \wedge T}) - e^{-\beta \sigma_{2i} \wedge T} w^+(X_{\sigma_{2i} \wedge T}) \right] + \sum_{i \geq 1} \mathbb{E} \left[e^{-\beta \sigma_{2i} \wedge T} w^-(X_{\sigma_{2i} \wedge T}) - e^{-\beta \sigma_{2i-1} \wedge T} w^-(X_{\sigma_{2i-1} \wedge T}) \right].$$

Note that by admissibility $\sum_{i \geq 1} e^{-\beta \sigma_i} \in L^2(\mathbb{P})$, which implies $\sup_{i \geq 1} \sigma_i = +\infty$ almost surely. Then, using the C^0 -pasting conditions in (30) and letting $T \rightarrow \infty$, we finally obtain

$$\mathbb{E} \left[\int_0^{+\infty} \pi_c(X_s) ds \right] + \sum_{i \geq 1} \mathbb{E} \left[e^{-\beta \sigma_i} h_0 \right] \leq w^+(x),$$

for any admissible consumer strategy (σ_i) . Applying the same arguments to the sequence $(\hat{\sigma}_i)$ we would get equalities instead of inequalities everywhere. The proof for the case $\mu_0^- = \mu_-$ is analogous and therefore is omitted.

Step 2: admissibility To conclude we show that the switching times $\hat{\sigma}_i$ are admissible, i.e., they belong to the set \mathcal{A}_c . To do so, notice first that $(\hat{\sigma}_i)$ is a sequence of $[0, \infty)$ -valued stopping times. Hence, it remains to show that a.s. $\hat{\sigma}_i < \hat{\sigma}_{i+1}$ for all $i \geq 0$, and $\sum_{i \geq 1} e^{-\beta \hat{\sigma}_i} \in L^2(\mathbb{P})$. The former follows from $y_\ell < y_h$. For the latter, we can proceed as in the proof of [1, Prop. 4.7], whose main idea is to write each σ_i as a sum of independent exit times for some (scaled) Brownian motion with possibly different drifts and initial conditions. First, let us denote $(\tau'_k)_{k \geq 1}$ the increasing sequence of stopping times exhausting the intervention times of both players. Therefore, we have

$$\begin{aligned} \mathbb{E} \left[\left(\sum_{i \geq 1} e^{-\beta \sigma_i} \right)^2 \right] &\leq \mathbb{E} \left[\left(\sum_{k \geq 1} e^{-\beta \tau'_k} \right)^2 \right] \leq \lim_{m \rightarrow \infty} 2 \mathbb{E} \left[\sum_{1 \leq k \leq r \leq m} e^{-\beta(\tau'_r + \tau'_k)} \right] \\ &\leq \lim_{m \rightarrow \infty} 2 \mathbb{E} \left[\sum_{1 \leq k \leq m} e^{-2\beta \tau'_k} \right] = 2 \mathbb{E} \left[\sum_{k \geq 1} e^{-2\beta \tau'_k} \right], \end{aligned}$$

hence it suffices to prove that $\sum_{k \geq 1} e^{-2\beta \tau'_k} \in L^1(\mathbb{P})$. Now, notice that $\tau'_k, k \geq 1$, can be represented as $\sum_{r=1}^k \zeta_r$, where ζ_r is a sequence of independent random variables distributed as the exit time, say $\zeta^{z, \mu}$, of one of the processes $z + \mu t + \sigma W_t$ with

$$(z, \mu) \in \mathcal{Z}^\pm := \{(y_h, \mu_+), (y_\ell, \mu_-), (x_h^{+*}, \mu_+), (x_\ell^{-*}, \mu_-)\},$$

from the respective intervals

$$(-\infty, y_h), (y_\ell, +\infty), (-\infty, x_h^{+*}), (x_\ell^{-*}, +\infty).$$

Due to the independence of the sequence ζ_r , we have

$$\mathbb{E} \left[\sum_{k \geq 1} e^{-2\beta \tau'_k} \right] = \sum_{k \geq 1} \prod_{r=1}^k \mathbb{E} \left[e^{-2\beta \zeta_r} \right] \leq \sum_{k \geq 1} \left(\mathbb{E} \left[e^{-2\beta \min_{(z, \mu) \in \mathcal{Z}^\pm} \zeta^{z, \mu}} \right] \right)^k,$$

which is a convergent geometric series, due to $\beta > 0$ and the fact that $\zeta^{z,\mu} > 0$ almost surely for all $(z, \mu) \in \mathcal{Z}^\pm$. This shows that sequence of switching times $\hat{\sigma}_i$ is an admissible consumer’s strategy and concludes the proof. \square

7.3 Proofs of Propositions 3 and 4

Proof of Proposition 3 Let $v : \{\mu_-, \mu_+\} \times \mathbb{R} \rightarrow \mathbb{R}$ be the function defined as $v(\mu_\pm, x) = v^\pm(x)$, with v^\pm as in (47). By construction, the functions (v^+, v^-) solve the system of VIs in (45) and moreover $v^\pm \in \mathcal{C}^2((x_\ell^+, x_h^-) \setminus \{y_\ell, y_h\}) \cap \mathcal{C}^0(\mathbb{R})$, hence not necessarily \mathcal{C}^1 at the points y_ℓ, y_h . Recall that $\mu_t = \mu_+ \sum_{i=0}^\infty \mathbf{1}_{\{\sigma_{2i} \leq t < \sigma_{2i+1}\}} + \mu_- \sum_{i=1}^\infty \mathbf{1}_{\{\sigma_{2i-1} \leq t < \sigma_{2i}\}}, t \geq 0$, where without loss of generality we can assume σ_i is the i -th switching instance taken by the consumer in the case $\mu_{0-} = \mu_+$ (remember the convention $\sigma_0 = 0$). The other case $\mu_{0-} = \mu_-$ can be treated in a similar way, it is therefore omitted. We split the rest of the proof in two steps.

Step 1: optimality The following verification argument proves that such functions coincide with the best-response payoffs of the producer and that the impulse strategy as in the statement is optimal provided it is admissible. First, by an approximation procedure as in the first part of the proof in [1, Theorem 3.3], we can assume without loss of generality that $v^\pm \in \mathcal{C}^2((x_\ell^+, x_h^-) \cap \mathcal{C}^0(\mathbb{R}))$. Consider any producer admissible strategy $(\tau_i, \xi_i)_{i \geq 1}$ as in the first part of Definition 1. Applying Itô’s formula to $e^{-\beta t} v(\mu_t, X_t)$ over the interval $[\sigma_{2i} \wedge T, \sigma_{2i+1} \wedge T)$, for some finite $T > 0$, we obtain

$$\begin{aligned} e^{-\beta(\sigma_{2i+1} \wedge T)} v(\mu_{\sigma_{2i+1} \wedge T}, X_{\sigma_{2i+1} \wedge T}) &= e^{-\beta(\sigma_{2i+1} \wedge T)} v^+(X_{\sigma_{2i+1} \wedge T}) \\ &= e^{-\beta(\sigma_{2i} \wedge T)} v^+(X_{\sigma_{2i} \wedge T}) \\ &\quad + \int_{\sigma_{2i} \wedge T}^{\sigma_{2i+1} \wedge T} e^{-\beta s} \left\{ v_x^+(X_s) dX_s + \frac{\sigma^2}{2} v_{xx}^+(X_s) ds - \beta v^+(X_s) ds \right\} \\ &\quad + \sum_{\sigma_{2i} \wedge T < s \leq \sigma_{2i+1} \wedge T} e^{-\beta s} \left\{ \Delta v^+(X_s) + v_x^+(X_s) \Delta N_s \right\}, \end{aligned}$$

where the first equality comes from the fact that over $[\sigma_{2i} \wedge T, \sigma_{2i+1} \wedge T)$, the drift equals μ_+ (remember that $\mu_{0-} = \mu_+$). Using the dynamics $dd_s = \mu_+ ds + \sigma dW_s - dN_s$, with $N_t := \sum_{i \geq 1} \xi_i \mathbf{1}_{\{\tau_i \leq t\}}$, between the two switching times above, localizing the martingale part through a suitable sequence of stopping times ζ_n and taking expectation on both sides, we obtain

$$\begin{aligned} \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i+1}} v^+(X_{\zeta_{n,T}^{2i+1}}) \right] &= \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i}} v^+(X_{\zeta_{n,T}^{2i}}) \right] \\ &\quad + \mathbb{E} \left[\int_{\zeta_{n,T}^{2i}}^{\zeta_{n,T}^{2i+1}} e^{-\beta s} \left\{ v_x^+(X_s) \mu_+ + \frac{\sigma^2}{2} v_{xx}^+(X_s) - \beta v^+(X_s) \right\} ds \right] \\ &\quad + \mathbb{E} \left[\sum_{\zeta_{n,T}^{2i} \leq s < \zeta_{n,T}^{2i+1}} e^{-\beta s} \Delta v^+(X_s) \right], \end{aligned}$$

where we set $\zeta_{n,T}^k := \sigma_k \wedge \zeta_n \wedge T$. For the third summand above, notice that between σ_{2i} and σ_{2i+1} , due to the non-local term in the variational inequality (45), the state process X can jump only due to the impulses of the producer and at any of such jumps we have

$$\Delta v^+(X_{\tau_i}) \leq -K_p(\xi_i), \quad i \geq 0,$$

implying

$$\mathbb{E} \left[\sum_{\zeta_{n,T}^{2i} \leq s < \zeta_{n,T}^{2i+1}} e^{-\beta s} \Delta v^+(X_s) \right] \leq \mathbb{E} \left[\sum_{j: \zeta_{n,T}^{2i} \leq \tau_j < \zeta_{n,T}^{2i+1}} e^{-\beta s} K_p(\xi_j) \right].$$

Regarding the second summand, we use the variational inequality (45) so that we can write

$$\begin{aligned} \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i+1}} v^+(X_{\zeta_{n,T}^{2i+1}}) \right] &\leq \mathbb{E} \left[e^{-\beta \zeta_{n,T}^{2i}} v^+(X_{\zeta_{n,T}^{2i}}) \right] - \mathbb{E} \left[\int_{\zeta_{n,T}^{2i}}^{\zeta_{n,T}^{2i+1}} e^{-\beta s} \pi_p(X_s) ds \right] \\ &\quad + \mathbb{E} \left[\sum_{j: \zeta_{n,T}^{2i} \leq \tau_j < \zeta_{n,T}^{2i+1}} e^{-\beta s} K_p(\xi_j) \right]. \end{aligned}$$

Now, due to $X_t \in [x_\ell^+, x_h^-]$ for all $t \geq 0$, letting $n \rightarrow \infty$ we obtain by dominated convergence that

$$\begin{aligned} \mathbb{E} \left[e^{-\beta \sigma_{2i+1} \wedge T} v^+(X_{\sigma_{2i+1} \wedge T}) \right] &\leq \mathbb{E} \left[e^{-\beta \sigma_{2i} \wedge T} v^+(X_{\sigma_{2i} \wedge T}) \right] - \mathbb{E} \left[\int_{\sigma_{2i}}^{\sigma_{2i+1}} e^{-\beta s} \pi_p(X_s \wedge T) ds \right] \\ &\quad + \mathbb{E} \left[\sum_{j: \sigma_{2i} \leq \tau_j < \sigma_{2i+1}} e^{-\beta s} K_p(\xi_j) \right], \quad i \geq 0. \end{aligned}$$

Analogously, we can get the same inequality between the switching times σ_{2i-1} and σ_{2i} for $i \geq 1$ with v^- replacing v^+ , so summing them all up we have

$$\begin{aligned} -\mathbb{E} \left[\int_0^{(\sup_i \sigma_i) \wedge T} \pi_p(X_s) ds \right] &\geq \sum_{i \geq 0} \mathbb{E} \left[e^{-\beta \sigma_{2i+1} \wedge T} v^+(X_{\sigma_{2i+1} \wedge T}) - e^{-\beta \sigma_{2i} \wedge T} v^+(X_{\sigma_{2i} \wedge T}) \right] \\ &\quad + \sum_{i \geq 1} \mathbb{E} \left[e^{-\beta \sigma_{2i} \wedge T} v^-(X_{\sigma_{2i} \wedge T}) - e^{-\beta \sigma_{2i-1} \wedge T} v^-(X_{\sigma_{2i-1} \wedge T}) \right]. \end{aligned} \tag{70}$$

Note that by admissibility $\sum_{i \geq 1} e^{-\beta \sigma_i} \in L^2(\mathbb{P})$, which implies $\sup_{i \geq 0} \sigma_i = +\infty$ almost surely. Then, using the C^0 -pasting conditions in (48) and letting $T \rightarrow \infty$, we finally obtain

$$\mathbb{E} \left[\int_0^{+\infty} \pi_p(X_s) ds \right] + \sum_{i \geq 1} \mathbb{E} \left[e^{-\beta \tau_i} K_p(\xi_i) \right] \leq v^+(x),$$

for any admissible producer’s strategy $(\tau_i, \xi_i)_{i \geq 1}$. Applying the same arguments to the impulse strategy $(\tau_i^*, \xi_i^*)_{i \geq 1}$ as in the statement we would get equalities instead of inequalities everywhere. Notice that the second-order conditions (52) guarantee the optimality of the impulses ξ_i^* .

Step 2: admissibility To conclude the proof, we need to show that the impulse strategy $(\tau_i^*, \xi_i^*)_{i \geq 1}$ is admissible as in the first part of Definition 1. Property 1 is granted by the dynamics of the state variable X and the fact that producer’s thresholds satisfy $x_\ell^+ < x_\ell^{+*}, x_h^{-*} < x_h^-$.

Property 2 is obviously satisfied by definition of the optimal impulses ξ_i^* as in the statement. Hence, we are left with showing property 3, i.e., $\sum_{i \geq 1} e^{-\beta \tau_i^*} \xi_i^* \in L^2(\mathbb{P})$. We can proceed once more as in the proof of [1, Prop. 4.7] and in the second part of Proposition 2’s proof. We provide all details for reader’s convenience. First, let us denote $(\tau_k')_{k \geq 1}$ the increasing

sequence of stopping times exhausting the intervention times of both players. Since the optimal impulses $(\xi_i^*)_{i \geq 1}$ are uniformly bounded by some positive constant, say κ , we have

$$\begin{aligned} \mathbb{E} \left[\left(\sum_{i \geq 1} \xi_i^* e^{-\beta \tau_i} \right)^2 \right] &\leq \kappa^2 \mathbb{E} \left[\left(\sum_{k \geq 1} e^{-\beta \tau'_k} \right)^2 \right] \leq \lim_{m \rightarrow \infty} 2 \mathbb{E} \left[\sum_{1 \leq k \leq r \leq m} e^{-\beta(\tau'_r + \tau'_k)} \right] \\ &\leq \lim_{m \rightarrow \infty} 2\kappa^2 \mathbb{E} \left[\sum_{1 \leq k \leq m} e^{-2\beta \tau'_k} \right] = 2\kappa^2 \mathbb{E} \left[\sum_{k \geq 1} e^{-2\beta \tau'_k} \right], \end{aligned}$$

hence it suffices to prove that $\sum_{k \geq 1} e^{-2\beta \tau'_k} \in L^1(\mathbb{P})$. Now, notice that $\tau'_k, k \geq 1$, can be represented as $\sum_{r=1}^k \zeta_r$, where ζ_r is a sequence of independent random variables distributed as the exit time, say $\zeta^{z, \mu}$, of one of the processes $z + \mu t + \sigma W_t$ with

$$(z, \mu) \in \mathcal{Z}^\pm := \{(y_h, \mu_+), (y_\ell, \mu_-), (x_h^-, \mu_-), (x_\ell^+, \mu_+)\},$$

from the respective intervals

$$(-\infty, y_h), (y_\ell, +\infty), (-\infty, x_h^-), (x_\ell^+, +\infty).$$

Due to the independence of the sequence ζ_r we have

$$\mathbb{E} \left[\sum_{k \geq 1} e^{-2\beta \tau'_k} \right] = \sum_{k \geq 1} \prod_{r=1}^k \mathbb{E} [e^{-2\beta \zeta_r}] \leq \sum_{k \geq 1} \left(\mathbb{E} [e^{-2\beta \min_{(z, \mu) \in \mathcal{Z}^\pm} \zeta^{z, \mu}}] \right)^k,$$

which is a convergent geometric series, due to $\beta > 0$ and the fact that $\zeta^{z, \mu} > 0$ almost surely for all $(z, \mu) \in \mathcal{Z}^\pm$. This shows that $(\tau_i^*, \xi_i^*)_{i \geq 1}$ is an admissible producer’s impulse strategy and concludes the proof. \square

Proof of Proposition 4 Here, notice that $x_h^+ = y_h$ so that, given producer’s priority in case of simultaneous interventions (cf. Remark 2), the drift is always equal to μ_+ (recall that we are in the case $\mu_{0-} = \mu_+$). Hence, this proof can be performed as the one of Proposition 3, by ignoring the intervals where the drift is μ_- so that the second half in the RHS of inequality (70) is zero. The admissibility is proved in the same way. The details are therefore omitted. \square

7.4 Equilibrium Dynamics Computation

Let (a, b) be an arbitrary interval and $x \in (a, b)$ be an interior starting location. We define $\delta_+(x; a, b)$ to be the first passage time associated with the interval (a, b) of a Brownian Motion with drift μ_+ starting from x and $P_+(x; a, b)$ to be the probability that this BM hits a before b (similarly for $\delta_-(x; a, b)$ and $P_-(x; a, b)$ associated with drift μ_-). These quantities admit explicit expressions, see [6].

The expected time $\tau_- := \inf\{t : \mu_t = \mu_-\}$ for μ_t to switch from μ_+ to μ_- within a double-switch and one-sided impulse equilibrium is then

$$\mathbb{E}[\tau_-] = \mathbb{E}[\delta_+(x_0; x_\ell^+, y_h)] + \frac{P_+(x_0; x_\ell^+, y_h)}{\mathbf{P}_{I_h^+, S_-}} \mathbb{E}_+[\delta(x_\ell^{+*}; x_\ell^+, y_h)], \tag{71}$$

where \mathbf{P} is the transition matrix of M_h^* . Above, the first term denotes the time to either reach x_ℓ^+ (producer impulses up) or y_h (switch to contraction); the second term counts the additional

time if x_ℓ^+ is reached first multiplied by the respective probability $P_+(x_0; x_\ell^+, y_h)$. Let $\vec{\zeta}$ be the resulting vector of expected sojourn times. Then, the long-run proportion of time that X^* carries a positive drift (μ_+) is

$$\rho_+ = \frac{\Pi_{S_+} \zeta_{S_+} + \Pi_{I_\ell^+} \zeta_{I_\ell^+} + \Pi_{I_h^+} \zeta_{I_h^+}}{\vec{\Pi} \cdot \vec{\zeta}^\dagger}, \quad (72)$$

and similarly the long-run proportion associated with a negative drift (μ_-) is $\rho_- = 1 - \rho_+$.
