Abstract

Cancer burden can be reduced by controlling modifiable risk factors, including diet. We provided an evidence-based assessment of cancer cases and deaths attributable to diet in Italy in 2020. We considered dietary factor-cancer type pairs for which the World Cancer Research Fund/American Institute for Cancer Research – Continuous Update Project reported either ‘convincing’ or ‘probable’ evidence of causal association. Relative risks were retrieved from recent meta-analyses and dietary intakes (around 2005) from a national food consumption survey. Sex-specific population attributable fractions (PAFs) were computed by comparing the distribution of dietary intakes in the Italian population against counterfactual scenarios based on dietary recommendations. Using data from national cancer and mortality registries in 2020, we estimated the number of attributable cancer cases and deaths, assuming ~15-year lag period. Unhealthy diet accounted for 6.3% (95% CI: 2.5%–9.9%) of all cancer cases in men and 4.5% (95% CI: 1.7%–7.4%) in women. PAFs of colorectal cancer were 10.5% and 7.0% for any intake of processed meat, 3.3% and 2.0% for high red meat, 4.8% and 4.3% for low dairy products, and 7.9% and 9.0% for low fiber intakes in men and women, respectively. PAFs for low intake of non-starchy vegetables and fruit ranged from 0.8% to 16.5% in men and 0.6%–17.8% in women for cancers of the aerodigestive tract. The estimated cancer burden associated with unfavorable dietary habits in Italy is considerable, but appears lower than for other high-income countries, reflecting the typically Mediterranean diet.

KEYWORDS

attributable cancer cases, attributable cancer deaths, dietary factors, population attributable fraction

What's New?

The Italian diet is primarily Mediterranean, being based on plant foods and on relatively low intake of red and processed meat. The impact of this diet on cancer burden, however, remains uncertain. Here, the authors examined cancer cases and deaths linked to diet in the Italian population. Analyses indicate that 6.3 percent of cancers in men and 4.5 percent in women can be attributed to unhealthy diet. Risk was highest for colorectal cancer. Relative to other high-income countries, Italy has a lower estimated cancer burden attributable to unhealthy diet. The findings may inform interventions to reduce diet-related cancer burden.

1 | INTRODUCTION

Lifestyle and environmental factors play a major role on cancer risk, offering important avenues for prevention.¹⁻³ In particular, a large body of epidemiological evidence indicates poor diet as an amenable risk factor for cancer.⁴ Several studies reported a direct relationship between high processed and red meat intakes and digestive tract cancers, especially colorectal cancer.⁵⁻⁸ An inverse association was reported for dairy products and colorectal cancer as well.^{8,9} Multiple studies found reduced risks of cancers mainly of the upper aerodigestive tract for diets rich in vegetables and fruit, and their related compounds (e.g., fibers and antioxidants).^{5,10}

The population attributable fraction (PAF) is an epidemiological measure which quantifies the proportion of cases that would have not occurred in the absence of the exposure. It depends on both the strength of the association between the exposure and the disease and the prevalence of the exposure.¹¹ PAF estimates of cancer due to diet have been calculated for various countries, including France,¹² Switzerland,¹³ Denmark,¹⁴ UK,¹⁵⁻¹⁸ Brazil,¹⁹ China,²⁰⁻²³ Japan,^{24,25} Korea,²⁶ the US,^{27,28} Canada,²⁹⁻³¹ and Australia.^{32,33} A systematic contemporary assessment for Italy is, however, lacking. Quantifying the contribution of unhealthy dietary habits to the cancer burden at the country level is crucial to guide public health recommendations aiming at improving diet and, in turn, population's health.

The aim of our study is to conduct an evidence-based evaluation of the PAF of cancer due to a poor diet in the Italian population. The Italian diet, which is typically Mediterranean, based on plant foods and characterized by relatively low amounts of red and processed meat, makes this assessment of particular interest.

2 | METHODS

Within the framework of a global analysis of the cancer burden attributable to modifiable risk factors in Italy,³⁴⁻³⁸ we estimated here PAFs due to unhealthy dietary habits. We selected dietary factors and the corresponding related cancer sites (Table 1) for which the World Cancer Research Fund/American Institute for Cancer Research – Continuous Update Project (WCRF/AICR-CUP) reported ‘convincing’ (i.e., processed meat for colorectal cancer)⁸ or ‘probable’ evidence (i.e., red meat, dairy products, and fiber for colorectal cancer; citrus fruit for cardia stomach cancer; coffee for liver and endometrial cancers)^{5,8,10,39} for a causal association. We did not consider aflatoxin, arsenic in water, and high-dose beta carotene supplements among factors with a ‘convincing’ association, and salt-preserved foods, cantonese-style salted fish, mate, fast foods, and calcium supplements among those with a ‘probable’ association because these dietary factors are not relevant exposures in our population, or we could not identify reliable estimates of intake. In addition, we did not consider wholegrains for colorectal

TABLE 1 Relative risk (RR) and corresponding 95% confidence interval (CI) used for each dietary factor-cancer type pair.

Dietary factor	Cancer type	RR (95% CI), increase in amount	References
‘Convincing’ association ^a			
Processed meat	Colon and rectum	1.16 (1.10–1.28), 50 g/day	Viera et al. ⁴⁰
‘Probable’ association ^a			
Red meat	Colon and rectum	1.12 (1.00–1.25), 100 g/day	Viera et al. ⁴⁰

^bWCRF/AICR evidence on non-starchy vegetables or fruit intake is restricted to former and current smokers. Data on non-starchy vegetables or fruit intake in Italy are available for smokers and non-smokers combined. We extracted RRs of lung cancer for non-starchy vegetables and fruit intake among smokers and non-smokers combined.

TABLE 2 Distribution of dietary intakes by sex in Italy in 2005–2006^a.

Dietary factor	Men		Women	
	Prevalence of consumers (%)	Mean (SD) intake among consumers (g/day)	Prevalence of consumers (%)	Mean (SD) intake among consumers (g/day)
Processed meat	87	40.7 (31.0)	80	29.3 (22.4)
Red meat	83	75.0 (51.4)	80	60.3 (37.8)
Fiber	100	19.6 (7.3)	100	17.7 (6.3)
Dairy products	99	178.5 (126.0)	99	194.5 (117.0)
Non-starchy vegetables	~100	232.9 (120.2)	~100	213.3 (102.6)
Fruit	93	214.7 (157.8)	95	228.2 (143.8)
Citrus fruit	45		51	
Coffee	91		88

cancer ('probable' association) since we included fiber, which strongly correlate with the former, and no adequate data on whole-grain intake for the Italian population were available. Likewise, no data on glycemic load ('probable' association with endometrial cancer) were available, and therefore we did not include it in our analysis. The WCRF/AICR judged as 'probable' the association between non-starchy vegetables and fruit and aerodigestive tract cancers, considering that, although the evidence for single cancer sites is 'limited-suggestive', the pattern of association is consistent and in the same direction.¹⁰ We considered cancer sites as follows: mouth, pharynx, larynx, nasopharynx, esophagus (adenocarcinoma and squamous cell carcinoma), colorectum and lung for non-starchy vegetables; and esophagus (squamous cell carcinoma), stomach and lung for fruit; since available epidemiological evidence for vegetable/fruit-cancer associations has focused mainly on single cancer sites and considered separately the effect of vegetables and fruit, as reported in the WCRF/AICR-CUP.¹⁰

2.1 | RR data

The RRs for the association between the increase in amount of intakes (expressed in g/day) and the corresponding cancer types were obtained from meta-analyses and pooled analyses^{8,40–42} and, in one case, from a cohort study.⁴³ For citrus fruit and coffee, we extracted the RRs for any versus no intake from metanalyses.^{44–46} Original data from an Italian case-control study⁴⁷ were used to estimate the odds ratio between non-starchy vegetables and nasopharyngeal cancer risk by means of a logistic regression model adjusted for area of residence, sex, age, education, smoking, and total energy intake. The RRs for each pairwise association are reported in Table 1.

2.2 | Dietary intake data

Dietary intake data were obtained from the Italian National Food Consumption Survey INRAN-SCAI 2005–06, conducted between

2005 and 2006 on 3323 subjects belonging to 1329 households using consecutive 3-day food records.^{48–51} For each dietary factor, we extracted the proportion of non-consumers and consumers among subjects aged 18–65 years (men = 1068 and women = 1244), and for consumers, we extracted the mean and standard deviation of intake (Table 2).

In consumers, we estimated the intake distribution for each dietary factor by means of a gamma distribution⁵² with shape and scale parameters based on the observed mean and standard deviation of intake (i.e., by the INRAN-SCAI 2005–06). The gamma distribution is a flexible two-parameter distribution that allows to fit a variety of shapes, including both symmetric and highly skewed ones. We used the method of moments to estimate gamma parameters, assuming means and standard deviations from the INRAN-SCAI 2005–06 as population means and standard deviations of dietary intakes. The overall distribution of dietary intake for men and women separately was obtained by combining the prevalence of non-consumers with the gamma-derived intervals of intakes among consumers. In particular, we considered 11 exposure categories, i.e., no intake category and 10 categories of intake with the same frequency of consumers according to the estimated gamma quantiles (Figures S1 and S2).

2.3 | Recommended intake

PAFs were calculated against counterfactual scenarios based on recommended dietary intakes by the WCRF/AICR or other Institutions (Table 3).^{53–55} Specifically, the WCRF/AICR recommends consuming very little, if any, processed meat; no more than about three portions/week of red meat (i.e., <~350–500 g/week); and at least 30 g/day of fibre.⁵³ Thus, our counterfactual scenarios were as follows: 0 g/day of processed meat, <50 g/day of red meat (lower cut-off of the recommended intake), and ≥30 g/day of fiber. The WCRF/AICR, the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO) recommend the intake of at least five servings/day of fruit and vegetables (i.e., ≥400 g/day; one serving ~80 g).^{53–55} We set counterfactual scenarios

TABLE 3 Population attributable fraction (PAF), observed and attributable cancer cases in 2020, and corresponding 95% confidence interval (CI) for each dietary factor–cancer type pair by sex in Italy.

All cancers ^f							

^aDefined according to dietary intake recommendations of the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) or other institutions. ^{53–55}

^bDefined according to the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR). ^{5,8,10,39}

^cNasopharyngeal cancer cases were estimated as 8.7% and 6.9% of the total oral and pharyngeal cancers in men (n = 4839) and women (n = 1716), respectively, according to a previously defined algorithm. ³⁴

^dAdenocarcinomas and squamous cell carcinomas of the esophagus were estimated as 33% and 67% of the total esophageal cancers, respectively, according to a previously defined algorithm. ³⁴

^eDiet-related cancers included the following cancer sites: mouth, pharynx, larynx, nasopharynx, esophagus (adenocarcinoma and squamous cell carcinoma), stomach, colorectum, liver, lung, and endometrium.

^fAll cancers excluding non-melanoma skin cancer.

separately for non-starchy vegetables and fruit of, respectively, ≥ 240 g/day and ≥ 160 g/day based on most country-specific guidelines suggesting at least three servings/day should come from vegetables.⁵⁶ No WCRF/AICR recommendation exists for dairy products; we set the corresponding counterfactual scenario as ≥ 300 g/day since more than half of European dietary guidelines recommend 2–4 servings of dairy products per day (i.e., ~ 300 – 450 g/day).⁵⁷ No recommendation is provided for citrus fruit and coffee, and we considered any intake as counterfactual scenario.

2.4 | Population attributable fractions

For each pair of dietary factor and cancer type, sex-specific PAFs were estimated by comparing the distributions of dietary intakes in the Italian population against the corresponding counterfactual distributions (recommended intakes) using the same methodology as described in Parkin and Boyd 2011.¹⁶ Specifically, PAFs were calculated by:

$$PAF = \frac{\sum_{k=1}^K (ERR_k \cdot Pr_k)}{1 + \sum_{k=1}^K (ERR_k \cdot Pr_k)}$$

where Pr_k is the proportion of subjects in the k -th intake category, and ERR_k is the excess RR in the k -th intake category expressed by:

$$ERR_k = \{ \exp[\ln(RR_{1g}) \cdot Dev_k] - 1 \}$$

where $\ln(RR_{1g})$ is the natural logarithm of the RR for an increment of 1 g/day in dietary factor intake and Dev_k is the deviation (excess or deficit) from the counterfactual scenario in the k -th intake category. We defined Dev_k as the difference between the midpoint of each intake category and the recommended intake. For protective dietary factors, we used the reciprocal of the RR and therefore the $\ln(1/RR_{1g})$ represents the increase in risk (log-scale) for a deficit of 1 g/day in dietary factor intake.

According to the counterfactual distribution considered for citrus fruit and coffee consumption, the above formulation of PAF collapses to the Levin's formula⁵⁸ for a dichotomous exposure:

$$PAF = \frac{(RR - 1) \cdot Pr}{1 + [(RR - 1) \cdot Pr]}$$

where RR is the relative risk for consumption versus no consumption and Pr is the proportion of consumers.

To compute the 95% confidence intervals (CIs) for PAFs, we performed 10,000 Monte Carlo simulations⁵⁹ considering both the variability of RRs and dietary factors. In particular, we simulated asymptotic distributions for RRs and each dietary factors considering a normal distribution for the logarithm of the RR; a normal distribution for the mean intake of continuous dietary factors (in order to generate gamma distributions with simulated means and the observed standard deviation); and the normal approximation of the binomial distribution for the proportion of consumers for dichotomous dietary factors. For

each simulation, we calculated PAFs and used the 2.5th and 97.5th quantiles of the PAF distribution as the approximate 95% CI. When the lower bound of 95% CI was negative, we set it to zero.

2.5 | Cancer data and attributable cancers

Attributable cancer cases and deaths were estimated by multiplying sex- and cancer-specific PAFs by the number of incident cases and deaths occurred in Italy in 2020, respectively (ICD-10 codes are reported in Table S1). The estimated number of cancer diagnoses in 2020 (projected data on diagnoses registered until 2016) was extracted from the Italian Association of Cancer Registries⁶⁰; the number of cancer deaths that occurred in 2020 was extracted from the national vital statistics on causes of death.⁶¹ From these sources, data on cancer cases and deaths were not available for some cancer subtypes and, therefore, these were estimated as follows³⁴: cardia gastric cancers (cases and deaths) were estimated as 33% of all gastric cancers; adenocarcinomas and squamous cell carcinomas of the esophagus (cases and deaths) as, respectively, 33% and 67% of all esophageal cancers; and nasopharyngeal cancers (cases and deaths) as 8.7% of oral and pharyngeal cancers.

Using dietary data in 2005–2006 and cancer data in 2020 we accounted for a ~ 15 -year lag period between dietary exposure and cancer diagnosis/death. The 95% CIs for attributable cases and deaths were calculated by using the 95% CI limits of PAFs. All analyses were conducted using R version 4.3.1 (R Core Team, 2023).

3 | RESULTS

Table 3 reports sex-specific PAFs and attributable cases with the corresponding 95% CIs. Overall, the dietary factors considered in this study were responsible for 12,179 (95% CI: 4887–19,288) incident cancer cases among men in 2020 in Italy, corresponding to a PAF of all cancers of 6.3% (95% CI: 2.5%–9.9%). The fraction of colorectal cancers attributable to processed meat intake (the only ‘convincing’ association reported by the WCRF/AICR) was 10.5% (95% CI: 5.0%–16.3%) with a burden of cases of 2459 (95% CI: 1171–3817). Among the ‘probable’ associations suggested by WCRF/AICR, the fraction of colorectal cancer cases attributable to high intake of red meat and low intake of dairy products were 3.3% (95% CI: 0.1%–7.0%) and 4.8% (95% CI: 3.6%–5.9%), respectively. Low fiber intake accounted for 7.9% (95% CI: 0.4%–14.5%) of colorectal cancer cases. PAFs for low non-starchy vegetable consumption ranged from 1.1% (95% CI: 0.3%–1.8%) for colorectal cancer to 16.5% (95% CI: 5.2%–26.8%) for nasopharyngeal cancer. Low fruit intake was responsible for 7.3% (95% CI: 2.8%–11.4%) of squamous cell carcinomas of the esophagus, 3.4% (95% CI: 2.3%–4.5%) of lung cancers, and 0.8% (95% CI: 0.0%–2.3%) of gastric cancers. No consumption of citrus fruit resulted in a fraction of cardia gastric cancers of 6.3% (95% CI: 0.4%–13.0%), and no coffee consumption in a fraction of liver cancers of 31.9% (95% CI: 19.7%–42.8%).

Among women, a poor diet accounted for 8262 (95% CI: 3008–13,415) diagnoses of all cancers in 2020 in Italy corresponding to a PAF of 4.5% (95% CI: 1.7%–7.4%). The share of colorectal cancers attributable to processed meat was 7.0% (95% CI: 3.4%–11.0%); in absolute numbers, it translated into 1420 (95% CI: 690–2231) cases. Regarding the ‘probable’ associations, PAFs for colorectal cancer due to high red meat and low dairy product intakes were 2.0% (95% CI: 0.1%–4.2%) and 4.3% (95% CI: 3.2%–5.3%), respectively. The fraction of colorectal cancer cases attributable to low fiber intake was 9.0% (95% CI: 0.5%–16.8%). PAFs for low intake of non-starchy vegetables ranged from 1.2% (95% CI: 0.3%–2.0%) for colorectal cancer to 17.8% (95% CI: 5.7%–29.0%) for nasopharyngeal cancer. Low fruit consumption was responsible for 5.6% (95% CI: 2.1%–8.8%) of squamous cell carcinomas of the esophagus, 2.6% (95% CI: 1.7%–3.4%) of lung cancer cases, and 0.6% (95% CI: 0.0%–1.8%) of gastric cancer cases. The share of cardia stomach cancer cases due to no consumption of citrus fruit was 7.1% (95% CI: 0.4%–14.5%). The lack of coffee consumption accounted for 31.2% (95% CI: 19.2%–42.0%) and 11.6% (95% CI: 4.1%–19.0%) of liver and endometrial cancer cases, respectively.

Attributable cancer deaths are reported in Table S2. A poor diet was associated with over 10,000 cancer deaths, i.e., 6674 (95% CI: 2815–10,412) in men and 4074 (95% CI: 1573–6509) in women.

4 | DISCUSSION

The present study provides a comprehensive assessment of the fraction and number of cancer cases and deaths attributable to diet in the Italian population. The dietary factors considered in our analysis were responsible for 6.3% and 4.5% of all cancer cases in Italy in 2020 among men and women, respectively. For cancer-specific PAFs, no major differences were observed according to sex, reflecting similar dietary intakes in men and women. Specifically, PAFs of colorectal cancer due to processed meat intake were 10.5% for men and 7.0% for women. Among other dietary factors considered, PAFs of colorectal cancer were 3.3% (men) and 2.0% (women) for high red meat intake; 4.8% (men) and 4.3% (women) for low intake of dairy products; and 7.9% (men) and 9.0% (women) for low fiber intake. The fractions of cases due to low non-starchy vegetables and fruit intake ranged from less than 1% for colorectal cancer to approximately 17% for nasopharyngeal cancer in both sexes.

Italian dietary habits at least in part reflect the Mediterranean diet, characterized by a low intake of processed and red meat; a moderate intake of dairy products (mostly cheese and yogurt), poultry and fish; high intake of vegetables, fresh fruits, legumes, bread and other cereals (generally minimally refined), potatoes, and nuts; and a high intake of olive oil (especially virgin and extra-virgin) used as the main source of fats.⁶² The Mediterranean diet has been extensively associated with a portfolio of health benefits including a reduced risk of developing several cancer types, as well as a lower cancer-specific and overall mortality.^{63–65} Consistent with Italian dietary habits, PAFs

for cancer due to dietary factors in this population are expected to be lower than those among populations with less healthy dietary patterns. However, PAF depends not only on the population's dietary habits but also on the choice of the RRs and counterfactual scenarios, making results across studies not directly comparable. In addition, different tools used to estimate population dietary intakes (e.g., 24-h dietary recall, food frequency questionnaires, and food records) may further hamper the comparison of results across studies.

Nearly all previous studies^{12,14,18,19,23,25,27,29,31,66} assessing the PAF of colorectal cancer for processed meat intake used an analytical approach similar to the one used in this study, including similar RRs (from 1.11 to 1.24 for an intake of 50 g/day) and counterfactual scenarios (i.e., 0 g/day for the majority of the studies). Therefore, the higher PAFs observed in France (12.7% for men and 8.8% for women),¹² Switzerland (13.8% for men and 8.1% for women),¹³ UK (16.1% for men and 8.6% for women),¹⁸ and Denmark (15.8% for men and 8.0% for women)¹⁴ largely reflect higher processed meat intakes in these populations (mean intakes ranged from 43.9 to 74.0 g/day for men and from 29.5 to 37.0 g/day for women) than the Italian one (40.7 g/day and 29.3 g/day for men and women, respectively). Likewise, the lower PAFs reported in Brazil (6.6% for men),¹⁹ Canada (from 3.8% to 4.9% for men; from 1.6% to 3.4% for women),^{29,31} Eastern Mediterranean Region Countries (3.1% for men and 3.0% for women),⁶⁶ Japan (4.3% for men and 3.3% for women),²⁵ and China (1.0% for men and 0.9% for women)²³ derived mainly from a lower processed meat consumption in these Countries, with mean intakes of <19.5 g/day for men and <10.5 g/day for women.

Compared to our study, similar fractions of colorectal cancer cases attributable to red meat were observed for populations in Eastern Mediterranean Region (2.2% for men and 2.1% for women),⁶⁶ likely explained by comparable dietary intakes in these countries (mean intake of 55.9 g/day for men and women combined) and Italy. Studies conducted in the US (6.6% for men and 3.9% for women),²⁷ Canada (5.8% for men and 4.6% for women),³¹ France (5.8% for men and 3.3% for women),¹² and Switzerland (5.2% for men)¹³ reported higher PAFs for red meat intake than our estimates. Different counterfactual scenarios, RRs, and intake levels all likely contributed to such differences. Regarding dairy products, the higher consumption in France resulted in lower estimates of colorectal cancer cases avoidable by optimal consumption (2.1% for men and 2.7% for women)¹² compared to those in Italy.

As for fiber intake, previous investigations relied on intake levels (mean intake ~18–24 g/day for men and ~15–20 g/day for women) and counterfactuals (≥ 30 g/day in the majority of the studies) similar to those used here. Thus, the large variability in PAFs (from 5.7% in France¹² to 24.6% in UK¹⁸ for men and from 7.1% in Japan⁶⁷ to 31.0% in UK¹⁸ for women) was mainly due to the different RR estimates used. Similarly, PAFs for inadequate fruit and vegetable consumption were heterogeneous across populations. For most cancer types included in the present analysis (i.e., mouth, pharynx, and larynx; nasopharynx; squamous cell carcinoma of the esophagus; colon and rectum; lung; and stomach), our PAFs were

lower than those of other studies.^{12,13,17,20–23,27,30,32,66,68} This may be largely ascribable to the higher intake of fruit and vegetables in Italy; still, the choice of RRs and counterfactual scenarios may have played a role.

Few studies^{13,69,70} quantified the burden of liver and endometrial cancer cases due to coffee consumption. For both cancer types, our PAFs were higher than those reported in the US,^{69,70} due to the different prevalence of coffee consumers and RRs used. A Swiss study¹³ showed PAF estimates of liver and endometrial cancers similar to those presented here, reflecting a similar pattern of coffee consumption.

Primary prevention by controlling modifiable risk factors is the best option to reduce cancer burden. Although strategies for reducing smoking, alcohol, overweight, and cancer-related infections remain the cornerstone of cancer prevention, according to our findings the adoption of healthy dietary habits would result in a considerable fraction of avoidable cancer cases in Italy (6.3% in men and 4.5% in women). We considered dietary factors and corresponding cancer types according to the updated guidelines of the WCRF/AICR. Other studies, however, considered different sets of dietary factor-cancer type pairs suggesting major uncertainties about the causal relationship between diet and cancer risk.

Among study's strengths, we used nationally representative data for dietary intakes, large meta-analyses and pooled analyses for RRs, and common methodologies for estimating PAFs and corresponding 95% CIs. We also accounted for a plausible latency period (i.e., ~15-year) between dietary intakes (i.e., around 2005) and cancer diagnosis (i.e., 2020), and provided a measure of variability of our PAF estimates.

In the national survey used as data source, dietary intakes were self-recorded potentially leading to inaccurate measurement of food consumption. In addition, our estimated intakes deriving from a probability distribution may not be accurate for all dietary factors considered. However, the gamma distribution was used in several previous studies and in similar contexts.^{28,71,72} Furthermore, our PAF estimates are consistent with those from other studies which do not use a probability distribution for dietary intakes. In addition, it has been argued that in case of confounding in the relationship between risk factor and disease, the Levin's formula is asymptotically biased and Miettinen's formula is more accurate.⁷³ Nevertheless, Miettinen's formula requires prevalence data among cases that were not available. As in most prior studies on PAF, we applied the Levin's formula plugging-in adjusted RRs. However, residual confounding by lifestyle, if any, would have led to overestimation of PAFs. Most RR estimates were derived from studies on cancer incidence. Despite this, we used the same RRs for incidence and mortality, thus assuming no effect of diet on cancer survival, possibly introducing bias in estimated attributable deaths. In addition, cancer mortality in 2020 may be affected by COVID-19 pandemic; however, no relevant temporal difference emerged comparing national cancer mortality data in the years around 2020.^{61,74} This issue is not relevant for incidence data, since we extracted cancer cases estimated to have occurred in 2020 based on available registered cancer data until 2016. Our estimates provide fractions of cancer cases/deaths attributable to dietary factors acting

in isolation, without considering potential interactions among dietary factors. We could not consider interactions in our calculation, as no national information on the combined intakes of multiple dietary factors was available. Likewise, we could not account for the possible role of the substitution effect, for instance, of increasing vegetables and fruit at the expense of red meat intake. Recently, an approach based on pathway-specific PAFs has been proposed⁷⁵ to address this issue, but it requires individual-level data. Furthermore, we could not compute age-specific PAFs because of missing data on dietary intake in strata of age. Lastly, the 'overall' estimates may be overestimated since they resulted from summing up the contributions of the individual dietary factors, ignoring their possible overlapping effects on the same cancer site. Alternatively, the overall impact of diet on cancer burden could be greater than estimated since other dietary aspects (e.g., salted-preserved foods, fast foods, and foods with high glycemic index) may influence the risk of selected cancers as well.

5 | CONCLUSIONS

This analysis offers robust data to inform interventions aimed at reducing the burden of cancer related to dietary factors in Italy. We found that unfavorable dietary habits cause a considerable proportion of cancers in the country. Despite challenges in comparisons across studies, PAFs due to poor diet in Italy appear lower than for other high-income countries, likely reflecting the healthier (Mediterranean) dietary pattern of the Italian population.
