Abstract

Objective: The role of adjuvant chemotherapy in addition or alternative to radiotherapy for early-stage high-risk endometrioid endometrial cancer is controversial. The study aimed to investigate the role of adjuvant chemotherapy in early-stage high-risk endometrioid endometrial cancer.

Methods: We identified patients with stage I or II endometrioid grade 2 or 3 endometrial cancer with myometrial invasion >50% and negative lymph nodes after pelvic with or without para-aortic lymphadenectomy at four institutions (United States and Italy). Associations between chemotherapy and cause-specific and recurrence-free survival were assessed with Cox proportional hazards models. Hematogenous, peritoneal, and lymphatic recurrences were defined as “nonvaginal”.

Results: We identified 329 patients; mean age 66.4 (standard dviation, 9.8) years. The median follow-up among those alive was 84 (interquartile range, 44-133) months. Five-year cause-specific survival was 86.1% (95% confidence interval [CI], 82.0%-90.4%) and the 5-year recurrence-free survival, 82.2% (95%CI, 77.9%-86.8%). Stage II (vs. stage IB) was associated with poorer cause-specific and recurrence-free survival. A total of 58 (90.6%) of 64 patients who had chemotherapy had 4 to 6 cycles of platinum-based regimen. In adjusted analysis, we did not observe a statistically significant improvement of cause-specific survival (hazard ratio [HR], 0.34; 95%CI, 0.11-1.03; P=.06) and nonvaginal recurrence-free survival (HR, 0.36; 95%CI, 0.12-1.08; P=.07) with adjuvant chemotherapy. Sixteen of 18 lymphatic recurrences (88.9%; 3 of 5 pelvic, all 13 para-aortic) were observed in the 265 patients who did not receive adjuvant chemotherapy. Among stage II patients, no deaths (100% 5-year recurrence-free survival) were observed in the 8 patients who received adjuvant chemotherapy, compared to 66% 5-year recurrence-free survival in the 34 patients who did not.

Conclusion: Although we observed that adjuvant chemotherapy was associated with improved oncologic outcomes in early-stage high-risk endometrioid endometrial cancer, the associations did not meet conventional levels of statistical significance. Further research is warranted in this relatively uncommon subgroup of patients.

Precis

Although we observed adjuvant chemotherapy was associated with improved outcomes in early-stage/high-risk endometrioid endometrial cancer, the associations did not meet conventional levels of statistical significance.

Keywords

adjuvant treatment; chemotherapy; early-stage; endometrial cancer; high-risk

Introduction

In 2020, a total of 65,620 new endometrial cancer cases and 12,590 deaths were estimated in the United States.[1] Apparent early-stage endometrial cancer comprises most cases at diagnosis, and primary surgery with total hysterectomy, bilateral salpingo-oophorectomy, and lymph node assessment is the standard of care.[2] Conversely, postoperative management of confirmed early-stage endometrioid endometrial cancer is not standardized.[2]

Adjuvant external beam radiotherapy and vaginal brachytherapy have improved locoregional control in early-stages,[3-5] but have not improved distant recurrence or overall survival.[3] Therefore, chemotherapy has been investigated as an additional or alternative adjuvant treatment[3, 6] particularly for high-risk early-stage endometrioid endometrial cancer.[7-12] However, randomized trials investigating adjuvant chemotherapy [13-15] or chemoradiotherapy [6, 15-18] reported conflicting results. Therefore, it is unclear which patients with early-stage endometrioid endometrial cancer, if any, would benefit from adjuvant chemotherapy.

One reason the evidence is unclear is that early-stage endometrioid endometrial cancer is heterogeneous in a continuum for risk of recurrence and cancer-related death.[2] Risk has been associated with specific factors, including age, International Federation of Gynecology and Obstetrics (FIGO) stage, myometrial invasion depth, tumor grade, and lymphovascular space invasion.[9] These factors are present in varying degrees in selected populations, defining different subgroups with various risk levels and potential benefit from chemotherapy. The low prevalence of every single subgroup defined by each unique combination of risk factors limits the power of previous studies to exclude the role of adjuvant chemotherapy in those at high risk, which are investigated merged with subgroups at lower risk to achieve sufficient study power [6, 13-18] On that basis, we specifically focused on a restricted group of patients with high-risk early-stage endometrioid endometrial cancer characterized by myometrial invasion >50% and grade 2 or 3. High-grade early-stage endometrioid endometrial cancer with deep myometrial invasion was reported potentially benefit from adjuvant chemotherapy.[14]

We performed a multicenter retrospective study of patients with stage I or II endometrioid grade 2 or 3 endometrial cancer who had myometrial invasion >50% and negative lymph nodes. We aimed to compare oncologic outcomes between patients who received adjuvant chemotherapy and those who did not.

Methods

We retrospectively identified all patients with FIGO stage I or II endometrioid endometrial cancer, grade 2 or 3, and myometrial invasion >50% who underwent pelvic ± para-aortic lymphadenectomy and had negative lymph nodes. Patients were identified from the endometrial cancer databases at four large institutions in the United States (Mayo Clinic in Rochester, Minnesota) and Italy (University of Pisa, University of Turin, and University of Brescia). At Mayo Clinic, patients were treated from January 1984 to December 2012; at the three Italian institutions, from January 1987 to December 2012. We excluded patients with synchronous invasive cancer, patients who underwent neoadjuvant therapy, patients with unknown adjuvant therapy status, and patients who did not consent. Details regarding excluded patients among those identified at Mayo Clinic are shown in Supplementary Figure 1.

The variables collected for analysis were patient age, FIGO grade and stage, lymphovascular space invasion, the extent of lymphadenectomy, type of adjuvant therapy, date and site of the first recurrence, vital status, date and cause of death, and date of the last follow-up. The first recurrence site was classified as *vaginal* if recurrence involved the vaginal cuff or as *nonvaginal* if recurrence was localized to the lymph node basins or peritoneum or was distant through hematogenous spread.

The inclusion criteria required that patients had undergone hysterectomy, bilateral salpingo-oophorectomy, and pelvic ± para-aortic lymphadenectomy. No patient underwent sentinel lymph node biopsy due to the fact that it was not standard of care at the time. The para-aortic area was evaluated according to institutional guidelines and the surgeon's discretion. Adjuvant therapy was administered following institutional guidelines and the preferences of physician and patient. Pelvic external beam radiotherapy was performed with a beam of 15 to 18 mV and a daily fraction of 1.8 Gy up to a dose of 45 to 50.4 Gy given in 5 to 6 weeks. The sequential protocol for combined regimens (chemotherapy before radiotherapy) was used at the Italian centers and Mayo Clinic, the sandwich protocol (3 cycles of chemotherapy, radiotherapy, 3 cycles of chemotherapy) only at Mayo Clinic.

Patient and pathologic characteristics and adjuvant therapy use were summarized with standard descriptive statistics and compared between Mayo Clinic and Italian centers. Primary outcomes were cause-specific survival (event = death due to disease), recurrence-free survival (event = first recurrence at any site), and nonvaginal recurrence-free survival (event = first recurrence is *nonvaginal*). Each outcome was estimated with the Kaplan-Meier method restricting follow-up to the first 5 years after surgery. Univariate Cox proportional hazards regression models were fit to evaluate the association of each characteristic with each outcome. Cox models were stratified by center (Mayo Clinic vs. Italian centers) to accommodate a separate hazard function.

Given the absent random assignment of adjuvant therapy, we evaluated the association of chemotherapy receipt with primary outcomes by fitting Cox proportional hazards models weighted using the inverse probability of treatment weighting. The propensity score values for the inverse probability of treatment weighting were estimated using as covariates age,

grade, FIGO stage, lymphovascular space invasion, and para-aortic lymphadenectomy. Detailed inverse probability of treatment weighting analysis is available in Supplementary Material.

In an exploratory analysis to identify a subgroup of patients who may benefit more from chemotherapy, we evaluated the association between adjuvant chemotherapy and outcomes separately, according to the presence of risk factors, by fitting inverse probability of treatment weighting-adjusted Cox proportional hazards models stratified by center and using robust sandwich covariance estimates. Risk factors were those identified according to univariate analysis.

Analyses were performed with Statistical Analysis System (SAS) version 9.4 (SAS Institute Inc); statistical significance was set at a 2-tailed α level of .05. The study was approved by the Institutional Review Board of all centers, which waived the requirement for written informed consent. In accordance with the journal's guidelines, we will provide our data for the reproducibility of this study in other centers if such is requested.

Results

We included 329 patients who met inclusion criteria: 141 patients were treated at Mayo Clinic, and 188 at the three Italian institutions. Table 1 summarizes characteristics of patients and tumors, the extent of surgical staging, and adjuvant therapy administration. Adjuvant chemotherapy was used in 19.5% (64/329) of patients. Details of chemotherapy regimens are reported in Supplementary Table 1. Of the 64 patients who received chemotherapy, most (98.4%) had platinum-based regimen; 44 (68.8%) patients had chemotherapy ± vaginal brachytherapy, and 20 (31.2%) patients had chemotherapy and external beam radiotherapy ± vaginal brachytherapy. A total of 58 patients (90.6%) had 4 to 6 cycles of chemotherapy. Distribution over time of patient inclusion, rate of para-aortic lymphadenectomy, and adjuvant chemotherapy is reported in Supplementary Table 2.

Of the 329 patients, 59 patients died (37 patients died of disease) within the first 5 years. Among the remaining 270 patients, the median follow-up was 84 (interquartile range, 44-133) months. Disease recurred in 51 patients (15.5%) within 5 years after surgery; the first recurrence was vaginal *only* in 9 patients and nonvaginal in 42 (hematogenous or peritoneal only [or both] in 23; lymphatic only in 10 [all para-aortic]; lymphatic and hematogenous or peritoneal in 7 [4 pelvic and 3 para-aortic]; hematogenous and vaginal in 1; and lymphatic [pelvic], hematogenous, and vaginal in 1). Overall, 18 (5.5%) patients had lymphatic recurrence: 5 pelvic, 13 para-aortic. All 10 isolated lymphatic failures were para-aortic.

The 5-year cause-specific survival was 86.1% (95% confidence interval [CI], 82.0%-90.4%) and the 5-year recurrence-free survival, 82.2% (95%CI, 77.9%-86.8%). With univariate analysis, FIGO stage II (vs. stage IB) was significantly associated with poorer cause-specific and recurrence-free survival, and older age with poorer recurrence-free survival; no other variable was significantly associated (Table 2).

Standardized differences of covariates in the adjusted cohort were less than the 0.20 threshold of desirability for 4 of the 5 characteristics (Supplementary Table 3). To address the residual imbalance in age between groups, outcomes were compared between the group that received chemotherapy (± external beam radiotherapy ± vaginal brachytherapy) and the group that did not by fitting the Cox models with age as the time scale. Moreover, the analysis was stratified by the center groups (Mayo Clinic vs. Italian centers) to accommodate a separate hazard function because of observed differences (Table 1). The inverse probability of treatment weighting-adjusted analysis of outcomes did not show a statistically significant association between the administration of adjuvant chemotherapy and cause-specific survival (hazard ratio [HR], 0.34; 95%CI, 0.11-1.03; P=.06), recurrence-free survival (HR, 0.57; 95%CI, 0.24-1.37; P=.21), and nonvaginal recurrence-free survival (HR, 0.36; 95%CI, 0.12-1.08; P=.07) (Table 3 and Figure 1).

Sixteen of 18 lymphatic recurrences (88.9%; 3 of 5 pelvic and all 13 para-aortic) were observed in the 265 patients who did not receive adjuvant chemotherapy; 6% of patients (16 of 265) had lymphatic recurrences versus 3.1% (2 of 64) of patients who received chemotherapy (Table 3). Eleven of 13 para-aortic recurrences (84.6%) were observed in the 194 patients who had neither para-aortic lymphadenectomy nor adjuvant chemotherapy. Two para-aortic recurrences were reported in the 71 patients who had para-aortic lymphadenectomy but did not receive adjuvant chemotherapy (Supplementary Table 4). Conversely, no para-aortic recurrences were observed among the 32 patients who did not undergo para-aortic lymphadenectomy but received chemotherapy (Supplementary Table 4).

We evaluated the association between adjuvant chemotherapy and outcomes, stratifying according to the presence of significant (P<.05) risk factors (stage II for cause-specific survival; stage II and older age for recurrence-free survival; Table 2). Supplementary Table 5 reports the Kaplan-Meier estimate of 5-year cause-specific survival and 5-year recurrence-free survival for the inverse probability of treatment weighting-adjusted cohort according to the presence of risk factors and receipt of adjuvant chemotherapy. Among the 42 patients with stage II, no deaths (100% 5-year cause-specific survival) were observed in the 8 patients who received adjuvant chemotherapy, compared to 66% 5-year cause-specific survival in the 34 stage II patients without adjuvant chemotherapy (Figure 2B).

Discussion

Summary of Main Results

Although we observed that adjuvant chemotherapy was associated with improved cause-specific survival and nonvaginal recurrence-free survival in stage I or II endometrioid grade 2 or 3 endometrial cancer with myometrial invasion >50%, the associations did not meet conventional levels of statistical significance. Stage II and advanced age were the strongest risk factors for poor prognosis in early-stage grade 2 and 3 endometrioid endometrial cancer with deep myoinvasion.

Results in the Context of Published Literature

Although adjuvant external beam radiotherapy is commonly used in high-intermediate-risk and high-risk early-stage endometrial cancer,[19] it does not impact rates of distant recurrence and overall survival.[3] For this reason, adjuvant chemotherapy and chemoradiotherapy have been investigated in endometrial cancer subgroups with a higher rate of distant recurrence and cancer-related mortality[3, 6] Nevertheless, previous studies including high-risk early-stage endometrial cancer patients reported conflicting results[6, 13-18]

Concerning adjuvant chemotherapy versus external beam radiotherapy, Maggi et al.[13] and the Gynecologic Oncology Group (GOG)-249 trial [16] included patients who had high-risk early-stage endometrial cancer similar to patients in our study and observed comparable overall and recurrence-free survival. Similarly, Susumu et al.[14] confirmed these results in patients with stage I, II, or IIIA endometrioid endometrial cancer with myometrial invasion >50%. Nevertheless, when they excluded stage I patients that were not high- intermediate risk as per the GOG-99 trial,[5] chemotherapy significantly improved overall and recurrence-free survival. Noteworthy, chemotherapy seemed to prevent distant relapses more than external beam radiotherapy in Maggi et al.[13] Moreover, including patients with either grade 1 or myometrial invasion ≤50% and administering only 3 cycles of chemotherapy may have obscured the benefit of chemotherapy in the GOG-249 trial.[16]

Regarding chemoradiotherapy versus external beam radiotherapy, the Post-Operative Radiation Therapy in Endometrial Carcinoma (PORTEC)-3 trial observed improved 5-year overall and recurrence-free survival in the chemoradiotherapy group.[6] However, the exploratory analysis did not confirm these results in stage I or II diseases. Similarly, Kuoppala et al.[18] did not report improved 5-year overall and recurrence-free survival. Conversely, the study by Hogberg et al.[17] showed significantly improved recurrence-free and cause-specific survival among patients with stage I or II endometrioid endometrial cancer who received chemoradiotherapy,[17] These benefits were confirmed in a subsequent meta-analysis, including 5 randomized controlled trials.[15]

These conflicting results may be related to the heterogeneity of study populations, differences in treatment protocols, and a study power calculated for the entire study population but not for each subgroup of endometrial cancer.[20,21] Moreover, many trials are designed to detect a minimum improvement of 10%, but less may be acceptable.[22] A Cochrane systematic review reported an absolute reduction of 4% for death and 5% for distant recurrence after chemotherapy.[15]

Nevertheless, conversely to that suggested by Susumu et al.[14] and Hogberg et al.[17], our study results did not show a statistically significant benefit of adjuvant chemotherapy in patients with stage I or II endometrioid grade 2 or 3 endometrial cancer with myometrial invasion >50% and negative nodes in improving cause-specific survival (HR, 0.34; 95%CI, 0.11-1.03; P=.06), recurrence-free survival (HR, 0.57; 95%CI, 0.24-1.37; P=.21), and nonvaginal recurrence-free survival (HR, 0.36; 95%CI, 0.12-1.08; P=.07). This study is the first to focus on this specific subgroup of early-stage high-risk endometrial cancer. The multicenter design allowed identifying a high number of patients with homogeneous risk,

with a higher number of recurrences than the previous series[9, 10] Moreover, more than 90% of patients who received chemotherapy had platinum-based regimens with 4 to 6 cycles.

Nevertheless, although our study aimed to overcome the limitations of previous evidence and provide targeted indications for clinical practice, the sample size was not sufficient to confirm a protective effect with the chosen level of statistical significance. In fact, stage I and II, grade 2 and 3 endometrioid endometrial cancer with myometrial invasion > 50% is a relatively rare subgroup of patients. Thus, consistent with previous studies[13, 14] only a small percentage of patients treated each year met the inclusion criteria for this investigation, thus leading to study nearly 30 years. This subgroup accounted for 5.2% of the overall Mayo Clinic population who underwent surgical treatment for endometrial cancer (170 out of 3267, before applying exclusion criteria), which is consistent with an estimated prevalence in the literature of 6.1 %.[23] The low prevalence explains the relatively limited number of such patients reported in the literature. Noteworthy, the sample size is further restricted when focusing only on patients with surgical staging, as in our study. Surgical staging with lymph node assessment is essential to classify these patients appropriately.

Regarding nonvaginal recurrences, the limited numbers do not allow us to draw definitive conclusions on a possible protective effect of chemotherapy for specific recurrence sites, such as para-aortic recurrences. Concerning the exploratory analysis, we did not identify a subgroup that may benefit from adjuvant chemotherapy. However, adjuvant chemotherapy may deserve further investigation in our stage II subgroup. Indeed, in stage II endometrial cancer, distant recurrences and overall survival are not improved by external beam radiotherapy; however, it is still unclear which subgroup of stage II may benefit from adjuvant chemotherapy.[24]

Strengths and Weaknesses

Despite the advantages, a multicenter design also has some limitations. Adjuvant chemotherapy remains heterogeneous, impeding definitive conclusions on the most appropriate regimen. The long-time interval and the multicenter origin of data did not allow a complete centralized pathology review, although it was conducted at each center to confirm diagnoses. Differences in adopting para-aortic lymphadenectomy between Italian centers and Mayo Clinic prohibit definitive conclusions regarding the impact on prognosis (9.6% of patients underwent para-aortic lymphadenectomy at Italian centers and 60.3% at Mayo Clinic). Therefore, the trend in improved outcomes related to para-aortic lymphadenectomy may reflect other differences between centers. Moreover, the observed effect of para-aortic lymphadenectomy may be partly due to selection bias: patient and tumor characteristics may have influenced the surgeon’s decision. Finally, treatment trends over time have to be considered (Supplementary Table 2). The use of para-aortic lymphadenectomy at Mayo Clinic increased in the last years of the study period due to a more standardized surgical approach introduced in 2004. Chemotherapy was administered, particularly at Mayo Clinic, mostly in the second half of the time interval. This distribution may reduce selection bias, being associated more with a change in clinical practice than patients’ characteristics. However, simultaneously, it may introduce unknown confounders associated with oncologic outcomes. Nonrandom assignment of patients to adjuvant therapy

introduces potential selection bias and possible confounders. However, the propensity score methodology allowed for a reduction in the imbalance of measured covariates between the two groups, limiting the risk of biases and strengthening results.

Implications for Practice and Future Research

Our study results do not conclusively support the use of adjuvant platinum-based chemotherapy in patients with stage I or II endometrioid grade 2 or 3 endometrial cancer and myometrial invasion >50%, given that the p-value did not meet the conventional level of statistical significance. However, we do feel that our study is not without merit, and studies involving cohorts from other institutions are warranted to evaluate the reproducibility of our findings. Increasing the sample size may help to achieve statistically significant results, however the effect size (i.e., hazard ratio) may change in a larger or different cohort and as a consequence statistical significance may still not be obtained. Therefore a post-hoc power calculation using the currently observed effect size does not add useful information to our analysis and was not conducted.[25] In particular, in this cohort, there is a suggestion that especially women with stage II endometrial cancer may warrant more investigations on the role of adjuvant chemotherapy. In the future, additional information provided by integrated clinicopathologic and molecular risk profiling may further guide the adjuvant treatment.[26, 27]

Conclusion

The role of adjuvant chemotherapy, as an addition or alternative to radiotherapy, is controversial in early-stage high-risk endometrioid endometrial cancer. In our study, although the numbers were relatively large for a highly selected subgroup of patients, we still did not observe a statistically significant improvement of oncologic outcomes with the use of adjuvant chemotherapy in stage I or II endometrioid grade 2 or 3 endometrial cancer with deep myoinvasion and negative lymph nodes. Further research is warranted in this relatively rare subgroup of patients.

Research Highlights

Adjuvant chemotherapy was associated with improved oncologic outcomes, but the associations did not meet statistical significance.

Stage II and advanced age were the strongest risk factors for poor prognosis.

Adjuvant chemotherapy needs further investigation especially in grade 2-3 stage II endometrial cancer with myometrial invasion >50%

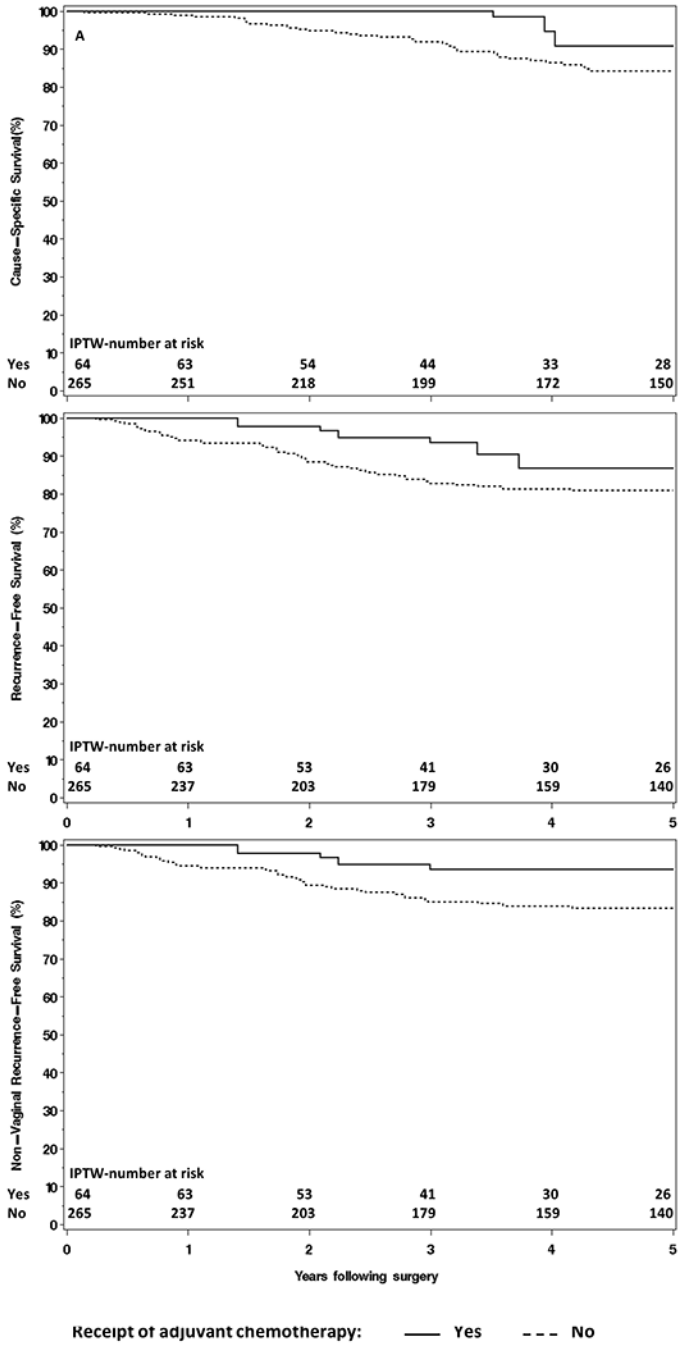

Figure 1.

Inverse Probability of Treatment Weighting (IPTW) for Survival According to Receipt of Adjuvant Chemotherapy. A, Cause-specific survival. B, Recurrence-free survival. C, Nonvaginal recurrence-free survival.

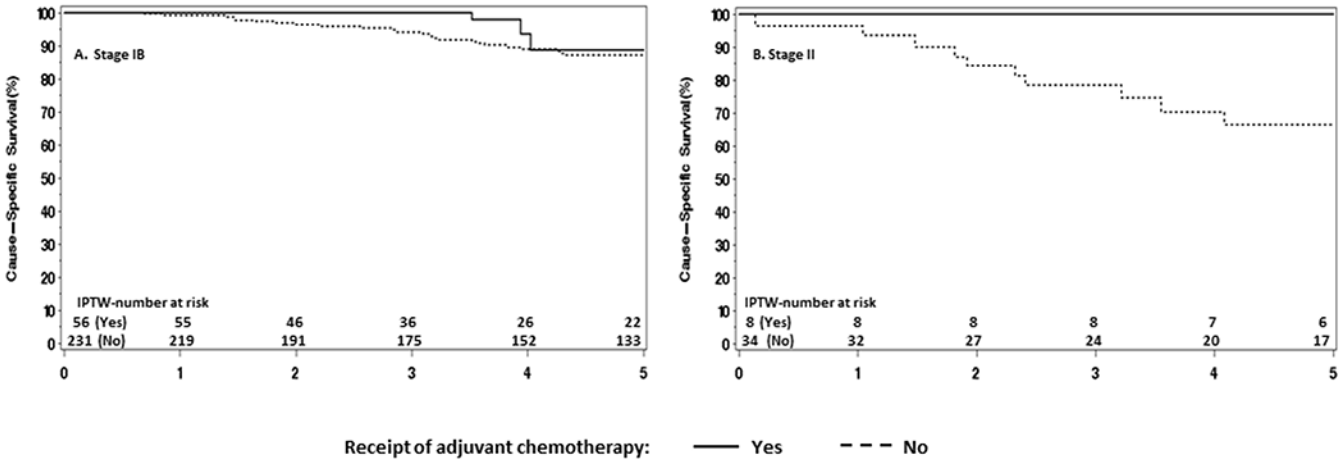

Figure 2.

Inverse Probability of Treatment Weighting (IPTW) for Cause-Specific Survival According to Receipt of Adjuvant Chemotherapy. A, Patients with FIGO stage IB. B, Patients with FIGO stage II.

Table 1.

Stages I and II Endometrioid Grade 2 or 3 Endometrial Cancer With Myometrial Invasion >50%: Patient and Tumor Characteristics, Extent of Surgical Staging, and Adjuvant Therapy

Characteristic	Mayo Clinic (n=141)	Italian centers(n=188)	Total (N=329)
Age at surgery, mean (SD), y	69.1 (9.9)	64.4 (9.1)	66.4 (9.8)
Grade, No. (%)			
2	99 (70.2)	107 (56.9)	206 (62.6)
3	42 (29.8)	81 (43.1)	123 (37.4)
FIGO stage,[a] No. (%)			
IB	127 (90.1)	158 (84.0)	285 (86.6)
II	14 (9.9)	30 (16.0)	44 (13.4)
LVSI, No. (%)			
No	94(66.7)	89 (47.3)	183 (55.6)
Yes	35 (24.8)	61 (32.4)	96 (29.2)
Unknown	12 (8.5)	38 (20.2)	50 (15.2)

EBRT ± VB (n=141)	0.91 (0.42-1.97)		0.84 (0.42-1.66)		0.99 (0.46-2.13)	
Chemotherapy ± VB (n=44)	0.34 (0.08-1.57)		0.50 (0.16-1.55)		0.32 (0.07-1.47)	
Chemotherapy and EBRT ± VB (n=20)	0.35 (0.05-2.79)		0.49 (0.11-2.18)		0.66 (0.14-3.05)	

Abbreviations: EBRT, external beam radiotherapy; FIGO, International Federation of Gynecology and Obstetrics; HR, hazard ratio; LND, lymphadenectomy; LVSI, lymphovascular space invasion; ±, with or without; VB, vaginal brachytherapy; CI, confidence interval.

[a]Each characteristic was evaluated in a separate univariate stratified Cox proportional hazards regression model, stratified by the 2 center groups (Mayo Clinic and 3 Italian centers), to accommodate a separate hazard function for each of the 2 center groups because of their different patient populations.

[b]Hazard ratio per 10-year increase in age.

[c]According to the 2009 FIGO staging system.

[d]The 50 patients with unknown information for LVSI were included in the univariate analysis.

Table 3.

Comparison of Outcomes Between Patients Who Did or Did Not Receive Chemotherapy

Outcome	Received chemotherapy	No. of events within 5 y	Without IPTW adjustment[a]		With IPTW adjustment[a]	
			HR (95%CI)	*P*	HR (95%CI)	*P*
Death due to disease	No (n=265)	34	Reference		Reference	
	Yes (n=64)	3	0.30 (0.09-1.01)	.05	0.34 (0.11-1.03)	.06
Recurrence						
Any	No (n=265)	45	Reference		Reference	
	Yes (n=64)	6	0.54 (0.22-1.33)	.18	0.57 (0.24-1.37)	.21
Nonvaginal	No (n=265)	38	Reference		Reference	
	Yes (n=64)	4	0.39 (0.14-1.13)	.08	0.36 (0.12-1.08)	.07
Lymphatic	No (n=265)	l6	Reference		Refersence	
	Yes (n=64)	2	0.40 (0.09-1.82)	.23	0.34 (0.07-1.71)	.19
Para-aortic	No (n=265)	13	Reference		Reference	
	Yes (n=64)	0	0.10 (0.01-2.09)	.14	0.11 (0.01-2.21)	.15
HP	No (n=265)	28	Reference		Reference	
	Yes (n=64)	4	0.54 (0.18-1.61)	.27	0.52 (0.17-1.58)	.25

Abbreviations: HP, hematogenous and/or peritoneal; HR, hazard ratio; IPTW , inverse-probability of treatmentweights; CI, confidence interval.

[a]Each Cox proportional hazards regression model was fit using age as the time scale in order to more completely adjust for age and stratified by the 2 center groups (Mayo Clinic and 3 Italian centers) to accommodate a separate hazard function for each country given the different patient populations.
