Variations in clinical presentation, frequency of hemophagocytosis and clinical behavior of intravascular lymphoma diagnosed in different geographical regions

Background and Objectives
This study explored variations in the clinical manifestations of intravascular lymphoma (IVL) on the bases of the association with hemophagocytosis and the country where the diagnosis was made.

Design and Methods
The clinical features of 50 Western patients with IVL were compared with those of 123 patients with IVL diagnosed in Eastern countries (87 diagnosed in Japan and 36 in other Asian countries), previously reported in English literature, and collected by an electronic bibliographic search.

Results
Hemophagocytosis was absent in Western patients, but reported in 38 (44%) Japanese patients (p=0.00001) and in seven (19%) patients from other Asian countries (p=0.002). No clinical differences were evident between patients with hemophagocytosis-negative IVL diagnosed in Western countries, Japan and other Asian Countries. Conversely, Japanese and non-Japanese patients with hemophagocytosis-related IVL more frequently had stage IV disease, fever, hepato-splenic involvement, marrow infiltration, dyspnea, anemia, and thrombocytopenia, and rarely exhibited cutaneous or central nervous system involvement. Lymph node and peripheral blood involvement was uncommon in all subgroups. In Western patients, anthracycline-based chemotherapy was associated with a 52% remission rate, and a 2-year overall survival of 46%.

Interpretation and Conclusions
The clinical features of IVL vary according to the association with hemophagocytosis, regardless of the country in which the diagnosis is made. Western, Japanese and other Asian patients with hemophagocytosis-negative IVL display similar clinical characteristics and should be considered as having classical IVL. Patients with hemophagocytosis-related IVL show significantly different clinical features. Both forms have a poor prognosis. Extensive molecular studies are needed to explore whether these clinical differences might reflect discordant biological entities within IVL.

Keywords: intravascular lymphoma, hemophagocytosis, cutaneous lymphoma, brain lymphoma.
Intravascular lymphoma (IVL) is a rare entity characterized by exclusive or predominant growth of neoplastic cells within the lumen of blood vessels. This disorder was recently recognized as a subtype of diffuse large B-cell lymphoma by the World Health Organization (WHO) Classification, although rare forms with a T-cell phenotype also occur. The understanding of IVL is very limited considering that, with a few exceptions, literature on this malignancy is almost exclusively represented by case reports and small case series. IVL is considered to be a rapidly aggressive and disseminated disease, usually affecting elderly patients, and is associated with a poor performance status (PS), B symptoms, anemia, and elevated serum lactate dehydrogenase (LDH) levels. However, the clinical presentation, behavior and therapeutic outcome are extremely variable; in particular, it has been suggested that there are some differences in clinical and histopathological characteristics between patients diagnosed in Asian and Western countries. A large Japanese study concluded that IVL associated with hemophagocytosis (HPC) is the equivalent of the Asian variant of IVL. In Western patients, a cutaneous variant, with a favorable clinical behavior, has been described. However, a comprehensive and detailed comparison between relatively large series from Western and Eastern countries has not previously been performed, and clinical and biological differences among these cohorts of patients are still debated. The acknowledgement of the existence of different clinical forms may have diagnostic, prognostic and therapeutic implications and constitutes the rationale for further investigations into the mechanisms of lymphomagenesis, adhesion and dissemination. This paper reports a comparison of presenting symptoms, clinical features, behavior, and therapeutic management of the largest series of patients with IVL diagnosed in Western countries with three potentially different subgroups of previously reported cases of IVL diagnosed in Asian countries, in order to assess whether apparent clinical differences may be driven by the geographical distribution of IVL patients.

**Design and Methods**

**Study group (Western-IVL series)**

A questionnaire requesting information about patients’ characteristics, clinical presentation, diagnosis, staging, sites of disease, laboratory findings, treatment, objective response, site and date of relapse, second line treatment, survival, salient morphologic features, and autopsy findings was sent to each participating center of the International Extranodal Lymphoma Study Group (I.E.L.S.G.). Criteria for including patients were a histological diagnosis of IVL (from 1985 to 2006), which constituted the Western-IVL series. Preliminary data of a part of this series have been reported previously.

**Eastern cases**

Features of the Western-IVL series were compared with those of cases of IVL diagnosed in Eastern countries and previously reported in English literature. An electronic search of Medline, Current Contents and Pubmed, updated to March 2006, was performed, including as key words intravascular lymphoma, intravascular lymphomatosis, angiotropic lymphoma, angioendotheliomatosis, and hemophagocytosis. Each full paper was reviewed and duplicate reports describing the same patients were included just once. We found 123 previously reported cases of IVL diagnosed in Japan (n=87) and other Asian countries (n=36) [see references in the linked file]. These groups were divided accordingly to the country in which the diagnosis was made and to the presence of HPC, which was defined by the morphologic recognition of an excess of mature benign-looking histiocytes with phagocytosis of erythroblasts, granulocytes and platelets in histopathological specimens. Therefore, three main comparator groups were considered: 1) Japanese patients with IVL and HPC (J-HPC), 2) Japanese patients with IVL but without HPC (J-IVL), and 3) patients with IVL without HPC diagnosed in Asian countries other than Japan (Eastern-IVL). Additionally, a small subgroup of patients with IVL and HPC diagnosed in Western and Asian countries other than Japan and previously reported in English literature was considered for analysis [see references in the linked file].

**Statistical considerations**

The distributions of clinical variables among the subgroups of patients were assessed by Fisher’s exact test for categorical variables. Survival curves were generated by the Kaplan-Meier method. Overall survival (OS) was calculated from the date of pathologic diagnosis to death or to the last date of follow-up, while event-free survival (EFS) was calculated from the first day of treatment to relapse, progression or death, or to the last date of follow-up. The impact of clinical and therapeutic variables on survival was evaluated using the log-rank test. All the probability values were two-sided, with an overall significance level of 0.05. Analyses were carried out using the Statistica 4.0 statistical package for Windows (Statsoft Inc., 1993, Tulsa, OK 74104, USA).

**Results**

**Study Population**

HPC was absent in the 50 Western-IVL cases, but was reported in 38 (44%) of the 87 Japanese patients (p=0.00001) and in seven of the 36 patients (19%) diagnosed in other Asian countries (p=0.002). Accordingly, the three main groups against which to compare the Western-
IVL series consisted of 38 J-HPC patients, 49 J-IVL patients and 29 Eastern-IVL patients. Additionally, a small subgroup of patients with IVL and HPC diagnosed in Western (n=5) and Asian countries other than Japan (n=7) and previously reported in English literature was considered for analysis.

**Clinical presentation**

Comparisons of the patients’ characteristics at diagnosis between the Western-IVL series and the three main groups of Asian patients are summarized in Table 1. The number of patients with an in vivo diagnosis was 38 (76%) Western-IVL, 35 (92%) J-HPC, 36 (74%) J-IVL, and 16 (55%) Eastern-IVL. No significant differences in age and gender were observed among the subgroups. The clinical presentation was heterogeneous in Western-IVL patients, with a remarkable deterioration in PS, with an ECOG score ≥2 in 52 cases (64%). PS was rarely reported in Asian series, but the constant presence of systemic symptoms and multi-organ involvement in reported cases suggests that IVL is associated with a poor PS also among Asian patients. As reported in Table 1, with a few exceptions, no significant differences in clinical features were observed among Western-IVL, J-IVL and Eastern-IVL subgroups. Conversely, several significant differences were observed between these three subgroups and patients with J-HPC. Thirty Western-IVL patients (60%) had systemic symptoms, mostly represented by fever, which was present in 21 cases (42%), and associated with other B symptoms in 12 cases. Fever as well as fatigue and jaundice were significantly more common among J-HPC patients (Table 1). Significant differences in terms of Ann Arbor stage of disease and sites of disease were observed. A large majority of J-HPC patients had stage IV disease, which was observed in 76-82% of cases in the other subgroups (Table 1). The most common sites of disease in the Western-IVL series, i.e., skin (38%) and central nervous system (42%), were involved in a significantly lower proportion of cases in J-HPC patients (3% and 21%, respectively). In the J-IVL and Eastern-IVL subgroups, the percentages of involvement of skin and central nervous system were similar to those observed in the Western series (Table 1). Cutaneous lesions were the sole pathologic finding in 12 (24%) Western cases; these patients were considered as having a cutaneous variant of IVL. The cutaneous variant was diagnosed in 0%, 6% and 0% of J-HPC (p=0.0004), J-IVL (p=0.01) and Eastern-IVL (p=0.002) subgroups, respectively. Involvement of hemolymphatic organs was significantly more common in J-HPC cases: 66%, 77% and 74% of these patients showed liver, spleen and marrow involvement, respectively, which was present in 26%, 26% and 30% of Western-IVL patients (p=0.0002, 0.0001 and 0.0001, respectively). With the exception of slightly more common involvement of liver in Eastern-IVL patients, no significant differences in the involvement of hemolymphatic organs were observed among Western-IVL, J-IVL and Eastern-IVL subgroups (Table 1). There were no signifi-

NS: not significant; NR: not reported; LDH: lactate dehydrogenase; ESR: erythrocyte sedimentation rate; ALT: alanine amino transferase; *Relationship between number of positive cases and number of assessed cases; †p values for comparisons between the Western series and the other subgroups.

Figure 1. Intravascular lymphoma of the cardiac muscle (hematoxylin and eosin). The growth of neoplastic large cells (arrows) occurs within the lumen of blood vessels. Neoplastic lymphocytes show large nuclei with one or more nucleoli and scant cytoplasm.

Significant differences in lymph-node and peripheral blood involvement among the four studied subgroups, infiltration rates ranged between 4% and 17% and between 0% and 13%, respectively (Table 1).

**Histopathological and laboratory findings**

In the 38 Western-IVL patients with an in vivo diagnosis, the histopathological diagnosis was performed on tissue samples obtained by partial surgical biopsy in 29 cases (skin in 18 cases, central nervous system in five, lung in two, uterus in two, gallbladder in one, and liver in one), visceral resection in six (kidney in three, prostate in two and spleen in one) and bone marrow biopsy in three cases. By definition, all cases from the four subgroups showed large lymphoid cells within vessel lumina (Figure 1). Lymphomatous lesions with infiltration of extravascular tissues (called extravascular component) were observed in ten (20%) Western cases, and was significantly more common in samples from lung and kidney of J-HPC cases. All Western-IVL cases but one displayed a B-cell immunophenotype. T-cell immunophenotype was observed in one (2%) Western-IVL case, in one (3%) J-HPC case, in one J-IVL (2%), and in five (17%) Eastern-IVL cases (p≤0.03 between Eastern-IVL cases and the other three groups; not significant differences among the others).

As reported in Table 2, no significant differences in laboratory findings were noted among Western-IVL, J-IVL and Eastern-IVL subgroups; while a different biochemical profile was observed in J-HPC patients. In fact, anemia (84%) and thrombocytopenia (74%) were significantly more common in J-HPC cases than in the other three subgroups. Thrombocytopenia was associated with anemia, bone marrow infiltration and hepatosplenic involvement in each subgroup. Increased serum LDH levels were observed in all J-HPC patients and in 85%-94% of cases in the other subgroups (Table 2). Increased levels of β2-microglobulin and elevated erythrocyte sedimentation rates were observed in, respectively, 84% and 48% of Western-IVL cases, while these parameters were not reported for patients in the other subgroups. A monoclonal serum component was reported in 5% - 16% of cases in the studied subgroups (p= not significant). Elevated transaminases and total bilirubin levels were significantly more common among J-HPC cases than in the other subgroups (Table 2).

**Comparison with patients with HPC-related IVL diagnosed outside Japan**

The Western-IVL series was also compared with the small group (n=12) of patients with HPC-related IVL diagnosed in Western (n=5) or Eastern (n=7) countries other than Japan and previously reported in English literature.
[see references in the linked file] to better understand whether clinical features are related to HPC independently of the country of origin of the patient. As reported in Table 3, these patients exhibited similar characteristics to J-HPC patients, while displaying many differences compared to Western-IVL patients. Similarly to J-HPC patients, patients with HPC-positive IVL diagnosed outside Japan more commonly had stage IV disease, fever, thrombocytopenia, and involvement of liver, spleen and bone marrow. A higher prevalence of cutaneous lesions in non-Japanese patients with HPC-positive IVL was the only distinctive feature in comparison with J-HPC patients (Table 3).

**Therapeutic outcome**

In Western-IVL series, *in vivo* diagnosis was possible in 38 patients, 36 of whom received at least one line of treatment. Seventeen (47%) achieved a complete remission (CR) and four had a partial response (PR), for an overall response rate of 58%; nine patients experienced progressive disease (PD), two had stable disease, and four died of toxicity. There were 23 treatment failures: 11 PD, eight relapses after response and four toxic deaths. All treatment failures but one occurred within the first year of follow-up. Anthracycline-based chemotherapy was administered as initial treatment to 25 patients, resulting in a CR rate of 52%, a median OS of 10+ months and a 2-year OS of 46±10%. The median EFS for the 38 patients with an *in vivo* diagnosis was 6 months (range 1-81), with a 2-year EFS of 32±8%. Seventeen patients are alive at a median follow-up of 28 months, with a 2-year OS of 39±8%. Considering the entire series (including patients with a *post-mortem* diagnosis), the 2-year EFS and OS were 24±6% and 30±7%, respectively.

**Discussion**

The comparison of our series, the largest one of IVL patients diagnosed in Western countries, with IVL cases from Asian countries strongly suggests the existence of different clinical forms of IVL. This issue does not seem simply to reflect regional differences since IVL cases with similar clinico-pathological characteristics have been reported in Western countries, in Japan and in other Asiatic countries (the Western-IVL, J-IVL and Eastern-IVL groups in this study). Patients from these three subgroups could be comprehensively considered as having the *classical form* of IVL. By contrast, patients with IVL associated with HPC, who have been mostly reported in Japan (the J-HPC group in this study), display clinical features distinct from those observed in the patients with the *classical form*. Patients with IVL and HPC diagnosed in countries other than Japan display similar characteristics to those of J-HPC patients, while Japanese patients with IVL without HPC (the J-IVL group) show similar features to those of Western patients. Taken together, these data suggest that differences in clinical presentation and behavior in IVL

might be more related to the concomitant presence of
HPC rather than the geographical distribution of the dis-
ease per se.

This study is the first one comparing large series of IVL
patients diagnosed in different geographical regions. The
study of cumulative retrospective series and comparison
with previously reported cases is so far the only strategy
available for studying IVL given the extreme rarity of this
disease and the diagnostic difficulties. Conclusions from
this study should be viewed with caution, not only because
of the intrinsic caveats regarding the methods
used, but also considering that cases published in non-
English literature were not included in this analysis, which
may have introduced some interpretation biases. Neverthe-
less, the size of the studied subgroups, the high propor-
tion of patients with an in vivo diagnosis and the quality
of reports in English literature support our conclu-
sions. Moreover, the clinical features observed in the J-
HPC and J-IVL subgroups have been confirmed by a
recently reported study including the largest series of
Japanese patients with IVL (n=96).11 Our observations
suggest that, unlike in Japanese patients,8 HPC is rarely
observed in IVL cases diagnosed in Western countries.
Among 321 cases of IVL diagnosed in Western countries,
and published in English literature, morphologically con-
firmed HPC has been reported in only five cases (1.5%).12
However, two of these patients showed HPC features
only at relapse and not at initial diagnosis.1415 and two oth-
ers were of Caribbean and Vietnamese origin.12,16
Comprehensively, the rare cases of HPC-associated IVL
diagnosed outside Japan exhibited clinical features similar
to those displayed by patients with HPC-associated IVL
diagnosed in Japan (J-HPC), i.e., significantly higher rates
of advanced disease, fever, hepatosplenic involvement,
bone marrow infiltration, fatigue, jaundice, dyspnea, ane-
mia, thrombocytopenia, and altered liver function tests. In
contrast, the skin and central nervous system, the most
common sites of disease in the classical form of IVL, were
rarely involved in J-HPC patients. To the best of our
knowledge, there is a single case of cutaneous involve-
ment in J-HPC patients, which was represented by a cuta-
aneous lesion on the torso reported as a cutaneous indura-
tion without histological confirmation.17 Our analysis
demonstrates that other characteristics, such as age, gen-
der and rates of lymph-node involvement, peripheral
blood dissemination and increased serum LDH levels,
overlap substantially between classical and HPC-related
forms. Both forms share B-cell immunophenotype in
>97% of cases, in contrast to other non-Hodgkin’s lym-
phomas associated with HPC, which are mostly of T-cell
lineage.18 As reported for other hematologic malignan-
cies,19 the presence of HPC has been proposed as a nega-
tive prognostic factor in IVL patients. Unfortunately, the
comparison of therapeutic outcomes among the studied
subgroups was limited by the fact that data from Asian
patients were collected from case reports written by
physicians with different expertise and specializations,
sometimes with incomplete therapeutic data (complete
therapeutic data for 94% of previously reported J-HPC
patients, 70% of J-IVL patients and 88% of Eastern-IVL
patients) and minimal follow-up. In the largest cumulative
series of Japanese patients with IVL,11 the use of anthracy-
cline-based chemotherapy, the standard strategy against
IVL,19 resulted in a 55% complete remission rate and a
median OS of 13 months, which are very similar out-
comes to those of the current series of Western-IVL
patients. In the largest reported series of patients with the
so-called Asian variant of IVL, anthracycline-based
chemotherapy was associated with a complete remission
rate of 53%, and a median OS of 10 months.3 At the time
of analysis, the combination of rituximab and chemother-
apy has been reported to have been used in 15 patients
(six in our series), resulting in complete remission in 11 of
12 evaluable patients, and no relapses at a median follow-
up of 15 months; this combined strategy seems to be
advisable in patients with CD20-positive IVL. Con-
solidation with high-dose chemotherapy supported by
autologous stem cell transplantation may improve current
outcomes,2123 even among J-HPC patients.3 The applica-
tion of such a strategy is, however, greatly limited by the
high median age and poor PS of IVL patients. Thus, the
identification of reliable high-risk predictors constitutes a
relevant issue in the management of patients with IVL.

The virtually selective geographical distribution of the
HPC-related form of IVL as well as its differences from the
classical form could have environmental causes. In fact, IVL
occurs in rural areas of Southwestern Japan, where human
T-cell lymphotropic virus type-1 (HTLV-1) is endemic,4
and associations with some helminthic infections have
been proposed in J-HPC patients.24 Associations between
IVL and HTLV-1, Epstein-Barr virus, cytomegalovirus, her-
pes simplex virus, varicella-zoster virus and human herpes
virus-6 have not been detected.25 In conclusion, differ-
ences in clinical features of IVL seem to be correlated to
the concomitant presence of HPC rather than to the geo-
graphical area where the lymphoma is diagnosed. At least
two different clinical forms of IVL seem to exist: a classical
form, which is the most common presentation in Western
countries, with frequent involvement of the skin and cen-
tral nervous system and less common infiltration of
hemolymphoid organs; and a HPC-related form, which is
remarkably more common in Japan, with an almost con-
tant involvement of hemolymphoid organs, higher rates
of advanced disease, fever, respiratory symptoms, ane-
mia, and thrombocytopenia, and virtually always sparing
the skin. Despite these clinico-pathological differences,
patients with both forms have a poor prognosis when
treated with anthracycline-based chemotherapy, and
treatment intensification and the addition of rituximab
appear advisable. Extensive phenotypic and molecular
characterization is needed to test whether these different
clinical forms may also have a different biological back-
grounds, and, therefore, international co-operative studies
are warranted.
