Abstract

This program is designed to improve causal inference via a method of matching that is widely applicable in observational data and easy to understand and use (if you understand how to draw a histogram, you will understand this method). The program implements the coarsened exact matching (CEM) algorithm, described below. CEM may be used alone or in combination with any existing matching method. This algorithm, and its statistical properties, are described in Iacus, King, and Porro (2008).

Keywords: causal inference, matching, treatment effect estimation.

1. Introduction

1.1. Properties

Iacus et al. (2008) show that CEM is a monotonoic imbalance bounding (MIB) matching method — which means both that the maximum imbalance between the treated and control groups may be chosen by the user ex ante, rather than discovered through the usual laborious process of ex post checking and repeatedly reestimating, and that adjusting the maximum imbalance on one variable has no effect on the maximum imbalance of any other. This paper also shows that CEM bounds through ex ante user choice both the degree of model dependence and the average treatment effect estimation error, eliminates the need for a separate procedure to restrict data to common empirical support, meets the congruence principle, is robust to measurement error, works well with multiple imputation and other methods for missing data, can be completely automated, and is fast computationally even with very large data sets. After preprocessing data with CEM, the analyst may then use a simple difference in means, or whatever matching method or statistical model they would have applied to the raw data. CEM also works for multicategory treatments, creating randomized blocks in experimental designs, and evaluating extreme counterfactuals.
1.2. Goal

Matching is not a method of estimation; it is a way to preprocess a data set so that estimation of SATT based on the matched data set will be less “model-dependent” (i.e., less a function of apparently small and indefensible modeling decisions) than when based on the original full data set. Matching involves pruning observations that have no close matches on pre-treatment covariates in both the treated and control groups. The result is typically less model-dependence, bias, and (by removing heterogeneity) inefficiency (King and Zeng 2006; Ho, Imai, King, and Stuart 2007; Iacus et al. 2008). If used for analyzing observational data, applications of CEM (and all other methods of causal inference) require an assumption of ignorability (a.k.a. “no omitted variable bias” or “no confounding”).

The specific statistical goal is to estimate some version of a causal effect, such as the sample average treatment effect on the treated (the “SATT”). Thus, let \( Y_i \) be the dependent variable for unit \( i \), \( T_i \) be a treatment variable, and \( X_i \) be a vector of pre-treatment control variables. Although CEM works as easily with multicategory treatment variables, we simplify this introductory description by assuming that \( T_i \) is dichotomous and takes on the value 1 for “treated” units and 0 for “control” units. Then define the treatment effect for treated units as the difference between two potential outcomes: \( \text{TE}_i = Y_i(T_i = 1) - Y_i(T_i = 0) \), where \( Y_i(T_i = 1) = Y_i \) is always observed and \( Y_i(T_i = 0) \), the value that \( Y_i \) would have taken on if it were the case that \( T_i = 0 \), is always unobserved. Then \( Y_i(T_i = 0) \) is estimated with \( Y_j \) from matched controls (i.e., among units for which \( X_i \approx X_j \)), either directly, \( \hat{Y}_i(T_i = 0) = Y_j(T_j = 0) \), or via a model, \( \hat{Y}_i(T_i = 0) = \hat{g}(X_j) \). Then SATT can be computed as a simple average: \( \text{SATT} = \frac{1}{n_T} \sum_{i \in \{T_i = 1\}} \text{TE}_i \).

1.3. Algorithm

The CEM algorithm then involves three steps:

1. *Temporarily* coarsen each control variable in \( X \) as much as you are willing, for the purposes of matching. For example, years of education might be coarsened into grade school, middle school, high school, college, graduate school. Most researchers are intimately familiar with the concept and practice of coarsening, as it is widely used in applied data analyses in many fields, although unlike its present use coarsening for data analysis involves a permanent removal of information from the analysis and ultimate estimates.

2. Sort all units into strata, each of which has the same values of the coarsened \( X \).

3. Prune from the data set the units in any stratum that do not include at least one treated and one control unit.

Following these three steps, the researcher can apply any method to the matched data that they might have to the raw data to estimate the causal effect, with the addition of a weight that equalizes the number of treated and control units within each stratum. Thus, any existing method of matching may be used within CEM strata to further prune the data in other ways, in which case the combined approach still inherits all of CEM’s properties. Whether or not another method of matching is applied, one must compute the causal effect, either by a (weighted) difference in means in \( Y \) among the treated and control units, or with the application of a statistical model.
If the coarsened bins are set to zero width, then CEM returns the exact matching solution, in which case model dependence will be eliminated (other than the ignorability assumption), but too few observations may be left. If instead the coarsened bins are set too wide, then few observations will be discarded, but differences within the large strata must be spanned with a statistical model, in which case model dependence may be an issue.

What if the level of coarsening is set as large as the researcher finds reasonable, but the number of observations is still too small? This of course may happen with a single continuous covariate with little or no coarsening or due to higher order interactions among a large set of discrete covariates. We offer below a “progressive coarsening” procedure that may help you rethink some of your coarsening choices by indicating how many more observations you would recover by loosening up the coarsening level for each variable. But if the remaining sample is still too small, the only possibilities involve collecting more data; setting the coarsening level artificially large and relying on theory to rule out some of the model dependence; or living with the model dependence and increasing the uncertainty with which you draw your inferences and represent your conclusions. To be clear, in this situation, you are in a bind and no method of matching or analysis is likely to save you. Statistics of course is not magic and can only get you so far given limited information. When in this situation, it is best to recognize the limits of your data relative to the question you are asking, and decide whether to devote whatever resources at your disposal to collecting more data, developing better theory, dealing with the uncertainty, or choosing a different research project.

1.4. Measuring Balance

Although CEM is MIB, the actual degree of imbalance achieved in the matched sample may be lower than the chosen maximum, and so we also introduce a simple and comprehensive multivariate imbalance measure (Iacus et al. 2008). The measure is based on the $L_1$ difference between the multidimensional histogram of all pretreatment covariates in the treated group and that in the control group. To do this, we first choose the number of bins for each continuous variable via standard automated univariate histogram methods and with categorical variables left as is. These bin sizes must be defined separately from and prior to the coarsening levels chosen for CEM. Although this initial choice poses all the usual issues and potential problems when choosing bins in drawing histograms, we use it only as a fixed reference to evaluate pre and post matching imbalance. Our functions compute these bin sizes automatically using automated histogram methods (and with smaller bins than would typically be chosen in running CEM), or they can optionally be set by the user, so long as this level is fixed through all subsequent matching. Then, we cross-tabulate the discretized variables as $X_1 \times \cdots \times X_k$ for the treated and control groups separately, and record the $k$-dimensional relative frequencies for the treated $f_{\ell_1,\ldots,\ell_k}$ and control $g_{\ell_1,\ldots,\ell_k}$ units. Finally, our measure of imbalance is the absolute difference over all the cell values:

$$L_1(f, g) = \frac{1}{2} \sum_{\ell_1,\ldots,\ell_k} |f_{\ell_1,\ldots,\ell_k} - g_{\ell_1,\ldots,\ell_k}|$$

and where the summation is over all cells of the multivariate histogram, but is feasible to compute because it contains at most $n$ nonzero terms. The $L_1$ measure\(^1\) varies in $[0,1]$. Perfect (up to discretization) global balance result in $L_1 = 0$, and $L_1 = 1$ indicates complete

\(^{1}\)Prior to version 1.0.90 of the cem package the $L_1$ measure did not include the factor $\frac{1}{2}$. 

separation of the multimensional histograms. Any value in the interval (0, 1) indicates the amount of difference between \( k \)-dimensional frequencies of the two groups. CEM also offers several other measures of imbalance such as the global difference in means and the difference in means within the strata that are defined by every matching method.

2. Setup

2.1. Software Requirements

CEM works in conjunction with the R Project for Statistical Computing, and will run on any platform where \( R \) is installed (Windows, Linux, or Mac). \( R \) is available free for download at the Comprehensive R Archive Network (CRAN) at \texttt{http://cran.r-project.org/}. CEM has been tested on the most recent version of \( R \).

CEM may be run by installing the program directly, as indicated below, or by using the alternative interface to CEM provided by \texttt{MatchIt} (\texttt{http://gking.harvard.edu/matchit.} (Ho, Imai, King, and Stuart Forthcoming)). Using CEM directly is faster. The \texttt{MatchIt} interface is easier for some applications and works seamlessly with \texttt{Zelig} (\texttt{http://gking.harvard.edu/zelig}) for estimating causal effects after matching, but presently only offers a subset of features of the \( R \) version. A \texttt{Stata} version of CEM is also available at the CEM web site, \texttt{http://gking.harvard.edu/cem}.

2.2. Installation

To install \texttt{cem}, type at the \( R \) command prompt,

\[ \texttt{install.packages("cem"}) \]

and CEM will install itself onto your system automatically from CRAN. You may alternatively load the beta test version as

\[ \texttt{install.packages("cem",repos="http://gking.harvard.edu")} \]

2.3. Loading CEM

You need to install CEM only once, but you must load it prior to each use. Do this at the \( R \) prompt:

\[ \texttt{library(cem)} \]

2.4. Updating CEM

We recommend that you periodically update CEM at the \( R \) prompt by typing:

\[ \texttt{update.packages()} \]

which will update all the libraries including CEM and load the new version of the package with
We show here how to use CEM through a simple running example: the National Supported Work (NSW) Demonstration data, also known as the Lalonde data set (Lalonde 1986). This program provided training to selected individuals for 12-18 months and help finding a job in the hopes of increasing their earnings. The treatment variable, treated, is 1 for participants (the treatment group) and 0 for nonparticipants (the control group). The key outcome variable is earnings in 1978 (re78).

Since participation in the program was not assigned strictly at random, we must control for a set of pretreatment variables by the CEM algorithm. These pre-treatment variables include age (age), years of education (education), marital status (married), lack of a high school diploma (nodegree), race (black, hispanic), indicator variables for unemployment in 1974 (u74) and 1975 (u75), and real earnings in 1974 (re74) and 1975 (re75). Some of these are dichotomous (married, nodegree, black, hispanic, u74, u75), some are categorical (age and education), and the earnings variables are continuous and highly skewed with point masses at zero. We modify these data by adding a (fictitious) variable to illustrate discrete responses called q1, the answer to a survey question asking before assignment for an opinion about this job training program, with possible responses strongly agree, agree, neutral, strongly disagree, disagree, and no opinion; note that the last category is not on the same ordered scale as the other responses. Ten percent of the observations have missing data (added randomly by us to illustrate how CEM deals with missingness). We call this new data set the LeLonde (intentionally misspelling Lalonde); the original, unmodified Lalonde (1986) data are contained in data set LL.

We begin with a naive estimate of SATT— the simple difference in means — which would be useful only if the in-sample distribution of pre-treatment covariates were the same in the treatment and control groups:

```r
> require(cem)
> data(LeLonde)
```

We remove missing data from the the data set before starting the analysis (we show better procedures for dealing with missing data in Section 3.6).

```r
> Le <- data.frame(na.omit(LeLonde))
```

and then compute the size of the treated and control groups:
Thus, the data include 258 treated units and 392 control units. The (unadjusted and therefore likely biased) difference in means is then:

```r
> mean(Le$re78[tr]) - mean(Le$re78[ct])
```

[1] 759

Because the variable `treated` was not randomly assigned, the pre-treatment covariates differ between the treated and control groups. To see this, we focus on these pre-treatment covariates:

```r
> vars <- c("age", "education", "black", "married", "nodegree", + "re74", "re75", "hispanic", "u74", "u75", "q1")
```

The overall imbalance is given by the $L_1$ statistic:

We compute $L_1$ statistic, as well as several unidimensional measures of imbalance via our `imbalance` function. In our running example:

```r
> imbalance(group = Le$treated, data = Le[vars])
```

</table>

Only the overall $L_1$ statistic measure includes imbalance with respect to the joint distribution, including all interactions, of the covariates; in the case of our example, $L_1 =0.902$. The unidimensional measures in the table are all computed for each variable separately.
The first column in the table of unidimensional measures, labeled statistic, reports the difference in means for numerical variables (indicated by the second column, type, reporting (diff)) or a chi-square difference for categorical variables (when the second column reports (Chi2)). The second column, labeled L1, reports the \( L^j_1 \) measure, which is \( L_1 \) computed for the \( j \)-th variable separately (which of course does not include interactions). The remaining columns in the table report the difference in the empirical quantile of the distributions of the two groups for the 0th (min), 25th, 50th, 75th, and 100th (max) percentiles for each variable. When the variable type is Chi2, the only variable-by-variable measure that is defined in this table is \( L^j_1 \); others are reported missing.

This particular table shows that variables re74 and re75 are imbalanced in the raw data in many ways and variable age is balanced in means but not in the quantiles of the two distributions. This table also illustrates the point that balancing only the means between the treated and control groups does not necessarily guarantee balance in the rest of the distribution. Most important, of course, is the overall \( L_1 \) measure, since even if the marginal distribution of every variable is perfectly balanced, the joint distribution can still be highly imbalanced.

As an aside, we note that for convenience that the function imbalance allows you to drop some variables before computation:

```r
todrop <- c("treated", "re78")
imbalance(group=Le$treated, data=Le, drop=todrop)
```

3.2. Coarsened Exact Matching

We now apply the coarsened exact matching algorithm by calling the function cem. The CEM algorithm performs exact matching on coarsened data to determine matches and then passes on the uncoarsened data from observations that were matched to estimate the causal effect. Exact matching works by first sorting all the observations into strata, each of which has identical values for all the coarsened pre-treatment covariates, and then discarding all observations within any stratum that does not have at least one observation for each unique value of the treatment variable.

To run this algorithm, we must choose a type of coarsening for each covariate. We show how this is done this via a fully automated procedures in Section 3.2.1. Then we show how to use explicit prior knowledge to choose the coarsening in Section 3.2.2, which is normally preferable when feasible.

In CEM, the treatment variable may be dichotomous or mutichotomous. Alternatively, cem may be used for randomized block experiments without specifying a treatment variable; in this case no strata are deleted and the treatment variable is (randomly) assigned to units within each strata to ensure that each has at least one observation assigned each value of the treated variable.

**Automated Coarsening**

In our running example we have a dichotomous treatment variable. In the following code, we match on all variables but re78, which is the outcome variable and so should never be included. Hence we proceed specifying "re78" in argument drop:
The output object `mat` contains useful information about the match, including a (small) table about the number of observations in total, matched, and unmatched, as well as the results of a call to the `imbalance` function for information about the quality of the matched data (unless `eval.imbalance` is set to `FALSE`). Since `cem` bounds the imbalance ex ante, the most important information in `mat` is the number of observations matched. But the results also give the imbalance in the matched data using the same measures as that in the original data described in Section 3.1. Thus,

```r
> mat

          G0  G1
All      392 258
Matched  95  84
Unmatched 297 174

</tbody>
</table>

We can see from these results the number of observations matched and thus retained, as well as those which were pruned because they were not comparable. By comparing the imbalance results to the original imbalance table given in the previous section, we can see that a good match can produce a substantial reduction in imbalance, not only in the means, but also in the marginal and joint distributions of the data.

The function `cem` also generates weights for use in the evaluation of imbalance measures and estimates of the causal effect (stored in `mat$w`).

**Coarsening by Explicit User Choice**
The power and simplicity of CEM comes from choosing the coarsening yourself rather than using the automated algorithm as in the previous section. Choosing the coarsening enables you to set the maximum level of imbalance ex ante, which is a direct function of the coarsening you choose. By controlling the coarsening, you also put an explicit bound on the degree of model dependence and the SATT estimation error.

Fortunately, the coarsening is a fundamentally substantive act, almost synonymous with the measurement of the original variables. In other words, if you know something about the data you are analyzing, you almost surely have enough information to choose the coarsening. (And if you don’t know something about the data, you might ask why you are analyzing it in the first place!)

In general, we want to set the coarsening for each variable so that substantively indistinguishable values are grouped and assigned the same numerical value. Groups may be of different sizes if appropriate. Recall that any coarsening during CEM is used only for matching; the original values of the variables are passed on to the analysis stage for all matched observations.

The function \texttt{cem} treats categorical and numerical variables differently. For \textit{categorical} variables, we use the \texttt{grouping} option. For example, variable \texttt{q1} has the following levels:

\begin{verbatim}
> levels(Le$q1)
[1] "agree" "disagree" "neutral"
[4] "no opinion" "strongly agree" "strongly disagree"
\end{verbatim}

Notice that the levels are not ordered in the original data set. One can possibly transform the variable \texttt{q1} from \texttt{factor} to ordered factor using the command \texttt{ordered} in R or may want to group them in three groups as follows:

\begin{verbatim}
> q1.grp <- list(c("strongly agree", "agree"), c("neutral", "no opinion"),
+                c("strongly disagree", "disagree"))
\end{verbatim}

For \textit{numerical} variables, we use the \texttt{cutpoints} option. Thus, for example, in the US educational system, the following discretization of years of education corresponds to different levels of school

- Grade school: 0–6
- Middle school: 7–8
- High school: 9–12
- College: 13–16
- Graduate school: >16

Using these natural breaks in the data to create the coarsening is generally a good approach and usually better than caliper matching in this context, as it would disregard these meaningful breaks. (The venerable technique of caliper matching of course may be useful for certain other types of data.) Because in our data, no respondents fall in the last category,

\begin{verbatim}
> table(Le$education)
\end{verbatim}
we define the cutpoints as:

```r
> educut <- c(0, 6.5, 8.5, 12.5, 17)
```

and run `cem` adding only the `grouping` and `cutpoints` options, leaving the rest unchanged:

```r
> mat1 <- cem(treatment = "treated", data = Le, drop = "re78",
+ cutpoints = list(education = educut), grouping = list(q1.grp))
> mat1

```

```
G0  G1

```

As we can see, this matching solution differs from that resulting from our automated approach in the previous section. For comparison, the automatic cutpoints produced by `cem` are stored in the output object in slot `breaks`. So, for example, our automated coarsening produced:

```r
> mat$breaks$education

[1] 3.0 4.2 5.4 6.6 7.8 9.0 10.2 11.4 12.6 13.8 15.0
```

whereas we can recover our personal choice of cutpoints as

```r
> mat1$breaks$education
```
3.3. Progressive coarsening

Although the maximum imbalance is fixed ex ante by the user’s coarsening choices, the number of observations matched is determined as a consequence of the matching procedure. If you are dissatisfied with the number of observations available after matching, and you feel that it is substantively appropriate to coarsen further, then just increase the coarsening (by using fewer cutpoints). The result will be additional matches and of course a concommitant increase in the maximum possible imbalance between the treated and control groups. This is easy with CEM because CEM is a monotonic imbalance bounding (MIB) method, which means that increasing the imbalance on one variable (by widening the coarsened bin sizes) will not change the maximum imbalance on any other variable. MIB thus enables you to tinker with the solution one variable at a time to quickly produce a satisfactory result, if one is feasible.

If, however, you feel that additional coarsening is not appropriate, than too few obserations may indicate that your data contains insufficient information to estimate the causal effects of interest without model dependence; in that situation, you either give up or will have to attempt adjusting for the pre-treatment covariates via modeling assumptions.

Suppose, instead, that you are unsure whether to coarsen further or how much to coarsen, and are willing to entertain alternative matching solutions. We offer here an automated way to compute these solutions. The idea is to relax the initial cem solution selectively and automatically, to prune equivalent solutions, and to present them in a convenient manner so that users can ascertain where the difficulties in matching in these data can be found and what choices would produce which outcomes in terms of the numbers of observations matched.

For categorical variables, the algorithm considers the numerical values associated to each level of the variable. In R the numerical values associated to the levels go from 1 to the number of levels, say $k$. The coarsening occurs by partitioning the interval $[1, k]$ into intervals of growing size starting from, say, $\epsilon = 1$. So in all cases, coarsening occurs by grouping adjacent levels from “left” to “right”. This is of course not completely appropriate for pure unordered categorical variables, but to treat them in a proper way additional combinatorics would be necessary. The progressive coarsening is instead intended as an instrument which gives a feeling on which variable is more likely to prevent matching for a given data set.

We start by illustrating what happens when we relax a CEM solution “by hand”. The following three runs show the effect on the matching solution (in terms of the number of observations and imbalance) when the coarsening for one variable (age) is relaxed from 10 to 6 to 3 bins.

As can be seen, fewer cutpoints (which means larger bins) produces more matched units and high maximum (and in this case actual) imbalance:

```r
> cem("treated", Le, cutpoints = list(age = 10), drop = "re78",
+ grouping = q1.grp)

          G0  G1
All     392 258
Matched  87  77
Unmatched 305 181
```

We automate this progressive coarsening procedure here in the `relax.cem` function. This function starts with the output of `cem` and relaxes variables one (depth=1), two (depth=2), or three (depth=3) at a time, while optionally keeping unchanged a chosen subset of the variables which we know well or have important effects on the outcome (fixed). The function also allows one to specify the minimal number of breaks of each variable (the default limit being 1). We begin with this example (the argument `perc=0.3` is passed to the plot function and implies that only the solutions with at least 30% of the units are matched)

> tab <- relax.cem(mat, Le, depth = 1, perc = 0.3)

Executing 47 different relaxations

[20%] ....[40%] .....[60%] .....[80%] .....[100%]

After all possible coarsening relaxations are attempted, the function returns a list of tables, one per group (i.e. treated and control). Each row of the tables contain information about the number of treated and control units matched, the value of the $L_1$ measure, and the type of relaxation made. Each table is the sorted according to the number of treated (or control) units matched.

The user may want to see the output of `tab$G1` or `tab$G0` but these tables may be very long, and so we provide a method `plot` to view these tables more conveniently. The output
of plot(tab) is plotted in Figure 1 from which it is seen that the most difficult variables to match are age and education. On the x-axis of the plot the variable and the number of equally sized bins used for the coarsening are used (color-coded by variable). On the y-axis on the right is the absolute number of treated units matched, while the left side y-axis reports the same number in percentages. The numbers below the dots in the graphs represent the $L_1$ measure corresponding to that matching solution. This graph also gives a feeling of the MIB behaviour of cem. When the tables produced by relax.cem are too large, the plot function, allows for some reduction like printing only the best matching solutions (in the terms of number of treated units matched), removing duplicates (i.e. different coarsenings may lead to the same matching solution), or printing only solution where at least some percentage of treated units, have been matched, or a combination of these. For more information refer to the reference manual for the function relax.plot which can be called directly instead of plot.

Here is one example of use of plot in which we specify that only solutions with at least 60% of the treated units are matched and duplicated solutions are removed. The output can be seen in Figure 2

```r
> plot(tab, group = "1", perc = 0.35, unique = TRUE)
```

### 3.4. Restricting the Matching Solution to a $k$-to-$k$ Match

By default, CEM uses maximal information, resulting in strata that may include different numbers of treated and control units. To compensate for the differential strata sizes, cem also returns weights to be used in subsequent analyses. Although this is generally the best option, a user with enough data may opt for a $k$-to-$k$ solution to avoid the slight inconvenience of needing to use weights.
Figure 2: Example of reduced graphical output of relax.cem.

The function k2k accomplishes this by pruning observations from a cem solution within each stratum until the solution contains the same number of treated and control units in all strata. Pruning occurs within a stratum (for which observations are indistinguishable to cem proper) by using nearest neighbor selection using a distance function specified by the user (including euclidean, maximum, manhattan, canberra, binary, or minkowski). By default method is set to NULL, which means random matching inside cem strata, an option that may reduce the chance for bias. (For the Minkowski distance the power can be specified via the argument mpower. For more information on method != NULL, refer to dist help page.)

Here is an example of this approach. First, by running cem:

```r
> mat <- cem(treatment = "treated", data = Le, drop = "re78")
> mat

          G0   G1
All   392 258
Matched  95  84
Unmatched 297 174

Multivariate Imbalance Measure: L1=0.605
Percentage of local common support: LCS=30.5%

Univariate Imbalance Measures:

    statistic type L1  min 25% 50%    75% max
```
and now pruning to a $k$-to-$k$ solution, using the euclidean distance within CEM strata:

```r
> mat2 <- k2k(mat, Le, "euclidean", 1)
> mat2

   G0   G1
All 392 258
Matched 70 70
Unmatched 322 188
```

Multivariate Imbalance Measure: L1=0.605
Percentage of local common support: LCS=30.5%

Univariate Imbalance Measures:

```
              statistic type     L1  min 25%  50%  75%  max
age  9.405e-02 (diff) 0.000e+00  0  0  1.0  0.0  0.0
education -2.222e-02 (diff) 2.222e-02  0  0  0.0  0.0  0.0
black  1.110e-16 (diff) 0.000e+00  0  0  0.0  0.0  0.0
married  0.000e+00 (diff) 0.000e+00  0  0  0.0  0.0  0.0
nodegree  0.000e+00 (diff) 0.000e+00  0  0  0.0  0.0  0.0
re74  1.496e+02 (diff) 0.000e+00  0  0  0.0  463.3 889.5
re75  1.588e+02 (diff) 0.000e+00  0  0  0.0  165.2 843.7 -640.9
hispanic  0.000e+00 (diff) 0.000e+00  0  0  0.0  0.0  0.0
u74  0.000e+00 (diff) 0.000e+00  0  0  0.0  0.0  0.0
u75  0.000e+00 (diff) 0.000e+00  0  0  1.0  0.0  0.0
q1  2.083e+00 (Chi2) 1.388e-17  NA  NA  NA  NA  NA
```

```r
> mat2$k2k

[1] FALSE
```
[1] TRUE

Alternatively, we can produce the same result in one step by adding the `k2k=TRUE` option to the original `cem` call.

### 3.5. Estimating the Causal Effect from CEM output

Using the output from `cem`, we can estimate SATT via the `att` function. The simplest approach requires a weighted difference in means (unless `k2k` was used, in which case no weights are required). For convenience, we compute this as a regression of the outcome variable on a constant and the treatment variable,

```r
> data(LL)
> mat <- cem(treatment = "treated", data = LL, drop = "re78")
> est <- att(mat, re78 ~ treated, data = LL)
> est

     G0  G1
All  425 297
Matched 222 163
Unmatched 203 134

Linear regression model on CEM matched data:

SATT point estimate: 550.962564 (p.value=0.368242)  
95% conf. interval: [-647.777701, 1749.702830]

where the SATT estimate is the coefficient on the `treated` variable, in our case 550.96. The function `att` allows for R’s standard `formula` interface and, by default, uses a linear model to estimate the att using the weights produced by `cem`.

If exact matching (i.e., without coarsening) was chosen this procedure is appropriate as is. In other situations, with some coarsening, some imbalance remains in the matched data. The remaining imbalance is strictly bounded by the level of coarsening, which can be seen by any remaining variation within the coarsened bins. Thus, a reasonable approach in this common situation is to attempt to adjust for the remaining imbalance via a statistical model. (Modeling assumptions for models applied to the matched data are much less consequential than they would otherwise be because CEM is known to strictly bound the level of model dependence.) To apply a statistical model to control for the remaining imbalance, we use the `formula` interface in `att`. For example:

```r
> est2 <- att(mat, re78 ~ treated + re74, data = LL)
> est2

     G0  G1
All  425 297
Matched 222 163
Unmatched 203 134
```
Linear regression model on CEM matched data:

SATT point estimate: 553.113736 (p.value=0.362760)
95% conf. interval: [-636.606542, 1742.834014]

The user can also specify the option model which accepts one of the following string arguments

- **linear** or **lm** (the default) for linear model, when the treatment effect is supposed to be homogeneous

  \[ \texttt{> att(mat, re78} \sim \texttt{treated + re74, data = LL, model = "linear")} \]

  \[
  \begin{array}{ll}
  \text{G0} & 425 \\
  \text{G1} & 297 \\
  \text{Matched} & 222 \\
  \text{Unmatched} & 163 \\
  \end{array}
  \]

  Linear regression model on CEM matched data:

  SATT point estimate: 553.113736 (p.value=0.362760)
  95% conf. interval: [-636.606542, 1742.834014]

- **linear-RE** or **lme** for linear model with random effects in cem strata, for non-homogeneous treatment effect

  \[ \texttt{> att(mat, re78} \sim \texttt{treated + re74, data = LL, model = "linear-RE")} \]

  \[
  \begin{array}{ll}
  \text{G0} & 425 \\
  \text{G1} & 297 \\
  \text{Matched} & 222 \\
  \text{Unmatched} & 163 \\
  \end{array}
  \]

  Linear random effect model on CEM matched data:

  SATT point estimate: 552.448961 (p.value=0.000000)
  95% conf. interval: [364.067068, 740.830853]

- **logistic** or **logit** for dichotomous response variable\(^2\), for homogeneous treatment effect.

- **forest** or **rf** for random forest model, also for non-homogeneous treatment effect. It accepts continuous, dichotomous or counting outcomes.

  \[ \texttt{> att(mat, re78} \sim \texttt{treated + re74, data = LL, model = "forest")} \]

\(^2\)We do not provide an example here, model the syntax is the same for the other models.
All the above models run on the CEM matched subsamples, so the quantity of interest may change in case of non-homogeneous treatment effect. The option `extrapolate`, if set `TRUE`, extrapolates each of the above models also to the set of treated units not matched. In this case the quantity of interest is kept fixed but the estimation is more model dependent.

```r
> att(mat, re78 ~ treated + re74, data = LL, model = "linear",
+       extra = TRUE)
```

Linear regression model with extrapolation:

SATT point estimate: 674.337762 (p.value=0.347286)
95% conf. interval: [-236.091964, 1584.767489]

```r
> att(mat, re78 ~ treated + re74, data = LL, model = "linear-RE",
+       extra = TRUE)
```

Linear random effect model with extrapolation:

SATT point estimate: 902.087484 (p.value=0.000000)
95% conf. interval: [816.567245, 987.607724]

```r
> att(mat, re78 ~ treated + re74, data = LL, model = "rf", extra = TRUE)
```
Random forest model with extrapolation:

SATT point estimate: 91.560670 (p.value=0.889157)
95% conf. interval: [-1196.056058, 1379.177399]

As Figure 3 shows, it is also possible to plot the results of the SATT estimation as follows

```r
> est3 <- att(mat, re78 ~ treated + re74, data = LL)
> est3
   G0   G1
All  425  297
Matched 222  163
Unmatched 203  134
```

Linear regression model on CEM matched data:

SATT point estimate: 553.113736 (p.value=0.362760)
95% conf. interval: [-636.606542, 1742.834014]

```r
> plot(est3, mat, LL, vars = c("education", "age", "re74", "re75"))
```

For more information, see the reference manual entry for `att`.

### 3.6. Matching and Missing Data

Almost all previous methods of matching assume the absence of any missing values. In contrast, CEM offers two valid approaches to dealing with missing values (item nonresponse). In the first, where we treat missing values as one of the values of the variables, is appropriate when "NA" is a valid value that is not really missing (such as when "no opinion" really means no opinion); see Section 3.6.1. The other is a special procedure to allow for multiply imputed data in CEM, as described in Section 3.6.2.

#### Matching on Missingness

In the next example, we use our original LeLonde data with missing values and we compare the result with Le from which we dropped the NA values. For comparability, we use the same cutpoints we used in Section 3.2 on the Le data. The cutpoints are contained in `mat$breaks`

```r
> mat3 <- cem("treated", LeLonde, drop = "re78", cutpoints = mat$breaks,
+   grouping = list(q1 = q1.grp))
```

Missing values exist in the data!

```r
> mat3
```

</table>

and, as expected, the two solutions differ somewhat. The gain (in terms of number of matched units) decreases as the number of covariates increases.

**Matching Multiply Imputed Data**

Consider a data set to be matched, some of which is missing. One approach to analyzing data with missing values is *multiple imputation*, which involves creating $m$ (usually about $m = 5$) data sets, each of which is the same as the original except that the missing values have been imputed in each. Uncertainty in the values of the missing cells is represented by variation in the imputations across the different imputed data sets (King, Honaker, Joseph, and Scheve 2001).

As an example we take the original LeLonde data with missing values

```r
> summary(LeLonde)
```

<table>
<thead>
<tr>
<th>treated</th>
<th>age</th>
<th>education</th>
<th>black</th>
<th>married</th>
</tr>
</thead>
<tbody>
<tr>
<td>Min. :0.000</td>
<td>Min. :17.0</td>
<td>Min. :3.0</td>
<td>Min. :0.0</td>
<td>Min. :0.000</td>
</tr>
</tbody>
</table>
Now we use `Amelia` package (Honaker, King, and Blackwell 2006) to create multiply imputed data sets:

```r
> require(Amelia)

## Amelia II: Multiple Imputation
## (Version 1.2-0, built: 2009-04-09)
## Copyright (C) 2005-2009 James Honaker, Gary King and Matthew Blackwell
## Refer to http://gking.harvard.edu/amelia/ for more information
##
> set.seed(123)
> imputed <- amelia(Lelonde, noms = c("black", "hispanic", "treated",
+    "married", "nodegree", "u74", "u75", "q1"))

-- Imputation 1 --

1 2 3

-- Imputation 2 --

1 2 3 4
Now `imputed` contains a list of 5 multiply imputed versions of `LeLonde`. We pass this list to the `cem` function in the argument `datalist` and `cem` produces a set of multiply imputed solutions, as usual with the original uncoarsened values of the variables, but now assigning each multiply imputed observation to the strata where it falls most frequently. The output of `cem` is a list of `cem.match` solutions (named `match1, match2,..., match5`). (Be sure to also name the original data frame in option `data` or `cem` will merely run the basic algorithm five separate times on each of the input data sets, a procedure that can be useful for batch processing of data to be matched, but is not recommended for multiply imputed data sets since the strata will not be the same across the data sets.) For example:

```r
> mat2 <- cem("treated", datalist = imputed, drop = "re78", data = LeLonde,
+ grouping = list(q1 = q1.grp))
> mat2

   G0  G1
All 425 297
Matched 132 98
Unmatched 293 199

Multivariate Imbalance Measure: L1=0.703
Percentage of local common support: LCS=28.3%

Univariate Imbalance Measures:

<table>
<thead>
<tr>

<td></td>
<td>99.066521 (diff)</td>
<td>0.000000</td>
<td>-250.6</td>
<td>0</td>
<td>0</td>
<td>252.3</td>
</tr>
<tr>
<td>re75</td>
<td></td>
<td>44.619415 (diff)</td>
<td>0.000000</td>
<td>0.0</td>
<td>0</td>
<td>-128.5</td>
<td>640.9</td>
</tr>
</tbody>
</table>
Now we estimate SATT via the usual multiple imputation combining formulas (averaging the point estimates and within and between variances, as usual; see (King et al. 2001)). The function att implements these procedures:

```r
> out <- att(mat2, re78 ~ treated, data = imputed)
> out

Linear regression model on CEM matched data:

SATT point estimate: 1177.182780 (p.value=0.123993)
95% conf. interval: [-322.747427, 2677.112987]

3.7. Creating paired samples

In some cases, it is useful to apply CEM so some data to create paired matched samples. Given an output of cem, the function pair produces two sets of indexes corresponding to pair matched units.

```r
> data(LL)
> mat <- cem(data = LL, drop = "re78")
> psample <- pair(mat, data = LL)
```

Total number of units paired in CEM strata: 352
Total number of units matched: 722

each pair of observation has a different strata number

```r
> table(psample$paired)[1:50]

 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26
2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2
27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50
2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2 2

not all observations can be matched in cem strata

```r
> psample$paired[1:50]

15993 15994 15995 15996 15997 15998 16000 16001 16002 16003 16004 16005
NA NA NA NA NA NA NA NA NA NA NA NA
16006 16007 16008 16009 16010 16011 16012 16013 16014 16015 16016 16017 16018
```
the remaining observations are then matched and the final list of all paired units is contained in the field `full.paired`

```r
> table(psample$full.paired)[1:50]
   1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26
  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2
```

```r
> psample$full.paired[1:10]
15993 15994 15995 15996 15997 15998 15999 16000 16001 16002
265 268 240 189 196 195 267 177 227 232
```

When the data contain an even number of units, all units can be paired; if they cannot be paired, the function indicates which units are left without a mate.

```r
> mat1 <- cem(data = LL[-1, ], drop = "re78")
> psample <- pair(mat1, data = LL[-1, ])
```

Total number of units paired in CEM strata: 352
Total number of units matched: 720
Unit corresponding to row `15994`, not paired

```r
> table(psample$full.paired)[1:50]
   1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26
  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2  2
```
