Low Prevalence of *GSC* Gene Mutations in a Large Cohort of Predominantly Caucasian Patients with Hidradenitis Suppurativa

Journal of Investigative Dermatology (2020) **140,** 2085–2088; doi:10.1016/j.jid.2019.10.025

TO THE EDITOR

Hidradenitis suppurativa (HS) is a chronic dermatosis characterized by nodules and abscesses in apocrine gland–bearing sites. Mutations in three *GSC* genes have been identified in autosomal dominant forms of HS (Frew et al., 2017) (Supplementary Tables S1 and S2). *NCSTN, PSEN1,* and *PSENEN* mutations have been reported in 41 patients with unrelated HS, one Chinese family with HS, and 21 patients with unrelated HS with or without Dowling-Degos disease, respectively (Frew et al., 2017). The functional consequences of these mutations are yet to be elucidated. In the absence of segregation analysis and functional studies supporting their causality, it is possible that some reported variants are benign (Supplementary Table S2).

A total of three studies investigated *GSC* gene mutations in small patient cohorts (Supplementary Table S1). One of these studies explored *NCSTN, PSEN1,* and *PSENEN* in 48 British patients (Pink et al., 2012). A second study analyzed the six *GSC* genes (*NCSTN, PSEN1, PSENEN, PSEN2, APH1A,* and *APH1B)* in 20 patients from South Wales (Ingram et al., 2013). The third study investigated *NCSTN* in 95 Caucasian patients (Liu et al., 2016).

In contrast to our previous studies that focused on multiplex kindreds or on patients with syndromic HS and led to the identification of four *NCSTN* mutations (Duchatelet et al., 2019, 2015; Miskinyte et al., 2012; Sonbol et al., 2018), the recent study aimed at determining the prevalence of *GSC* gene mutations among a large cohort involving 169 unrelated patients who were mostly Caucasian with isolated or syndromic HS. This study was approved by the institutional review board (CPP Ile-de-France, Paris). Participants provided written informed consent and consented to the publication of their images. The characteristics of the cohort are detailed in Table 1 and Supplementary Table S3. We performed mutational analysis of the six *GSC* genes using a targeted next-generation sequencing gene panel, which also included *PSTP1P1* involved in a combination of pyoderma gangrenosum, acne, and HS and a combination of pyogenic arthritis, acne, pyoderma gangrenosum, and HS syndromes. Mutational analysis of the six *GSC* genes using a targeted next-generation sequencing gene panel also included *FGFR2* and *POFUT1* possibly implicated in HS (Calderón-Castrat et al., 2016; González-Villanueva et al., 2018; Higgins et al., 2017).

We identified two unreported *NCSTN* (NM_015331) mutations, p.Gly61Val (c.182G>T) and p.Gly576Val (c.1727G>T), in two unrelated familial cases (patients 111 and 150), predicted to be damaging by computational tools (Supplementary Table S4). The first mutation cosegregated with HS in the family (Figure 1 and Supplementary Figure S1). The proband's daughter carrying the familial mutation had an atypical presentation with multiple comedones outside HS predilection sites, suggesting the involvement of modifier genes and epigenetic and/or environmental factors. Cosegregation of the second mutation with the disease was not studied, as no additional family member was available. We also identified a previously reported *NCTSN* variant, c.996+7G>A, in a sporadic patient (patient 2) (Pink et al., 2012). However, this variant was inherited from the unaffected father and the study of the subject's keratinocytes mRNA did not detect *NCSTN* splicing nor expression anomaly, suggesting it was a nondeleterious change. In a familial HS case (patient 30), we identified a previously unreported *PSEN1* (NM_000021) mutation p.Ser390Glufs*20 (c.1167_1168insGA), inherited from the mother with Crohn's disease and spondylarthropathy (Figure 1 and Supplementary Figure S1). We found *PSENEN* (NM_172341) mutations in five patients with HS with Dowling-Degos disease (Figure 1 and Supplementary Figure S1). In patient 157, we identified the previously reported c.168T>G p.Tyr56* Jewish Ashkenazi founder mutation inherited from the mother with Jewish Ashkenazi ancestry. Three *PSENEN* mutations were not previously described: c.304T>A p.*102Argext*50 (patient 158), c.166+2T>C (patients 159 and 160), and c.66dup p.Phe23Valfs*98 (patient 161). Haplotype analysis for patients 159 and 160 did not reveal a common haplotype, arguing against a founder mutation (Figure 1). The c.166+2T>C mutation is predicted to abolish the splicing donor site (Supplementary Table S4). No causal mutation was identified in the remaining 160 patients.

Functional studies on primary keratinocytes from *PSENEN*-mutated patients 157 and 158 showed a 2-fold reduction in *PSENEN* transcript levels in patient 157 compared with controls and a 25% reduction in patient 158 (Supplementary Figure S2). Western blot analysis revealed no mutated PEN2 protein in both patients, a low level of wild-type protein (~13%) in patient 157 but a normal level of wild-type protein in patient 158 (Supplementary Figure S3). We could show impaired NCSTN maturation and stability of PSEN1 protein fragments and a reduction in *HES1* (Notch target) transcript levels in patient 157 compared with controls (Supplementary Figures S2 and S3), suggesting impaired gamma-secretase complex (GSC) function and Notch signaling. In contrast, patient 158 displayed no detectable

Abbreviations: GSC, gamma-secretase complex; HS, hidradenitis suppurativa

Abbreviations: HS, Hidradenitis suppurativa; PAPASH, pyogenic arthritis, acne, pyoderma gangrenosum and suppurative hidradenitis; PASH, pyoderma gangrenosum, acne and suppurative hidradenitis; PASS, pyoderma gangrenosum, acne vulgaris, hidradenitis suppurativa, and ankylosing spondylitis.

There was a bias in the recruitment of patients with HS in this cohort because the enrollment mainly involved patients with severe forms of HS.

[1]False sporadic cases had in fact first- or second-degree relatives who presented either a few abscesses and/or cysts localized to HS predilection sites or isolated pilonidal sinus without completely fulfilling criteria for HS and/or had inflammatory bowel disease, rheumatologic inflammatory disease, or severe acne.

abnormality at the protein nor the RNA levels (Supplementary Figures S2 and S3), although previous studies reported the critical role of the length and sequence of the C-terminus of PEN2 for GSC activity (Prokop et al., 2005). Previous studies reported that some *NCSTN* mutations did not impair GSC activity nor Notch signaling (Zhang and Sisodia, 2015), that the *PSEN1* p.Pro242Leufs*11 mutation may lead to enhanced Notch signaling in zebrafish (Newman et al., 2014), and that the total number of mature GSC was unaltered in fibroblast solubilized membrane fractions harboring *NCSTN* p.Glu333_Gln367del or *PSENEN* p.Phe23Valfs*98 mutations (Pink et al., 2016) (Supplementary Table S2).

To date, Notch was used as a hallmark for GSC function, hypothesizing that Notch signaling was involved in HS pathogenesis. However, these findings suggest that the disease mechanisms are complex and that these mutations, together with the p.*102Argext*50 *PSENEN* mutation, may act through the alteration of a GSC catalytic activity independent mechanism and/or impaired Notch-independent downstream signaling. Alternatively, mutations may become deleterious only in particular cells or conditions such as temperature, pH, or salt concentrations. Therefore, the cells which were investigated (fibroblasts or epidermal keratinocytes) may not be appropriate and other cell types such as follicular keratinocytes or sebocytes could be more suitable to investigate HS pathophysiology. Further experiments to elucidate the functional consequences of these mutations on GSC activity and downstream pathways are required.

In summary, in this study as well as the previous ones, we have examined *GSC* gene mutations in a total of 188 patients with unrelated HS and identified mutations in 8 of 169 patients in the recent study and in 4 of 19 patients in our previous studies. Our findings confirm that *GSC* gene mutations are uncommon in the largest HS cohort investigated so far (12 mutations per 188 patients, 6.4%), further document *PSENEN* mutations in patients with HS with Dowling-Degos disease, report a European case of HS owing to a *PSEN1* mutation, and expand the spectrum of *NCSTN*-associated clinical manifestations.

Data availability statement

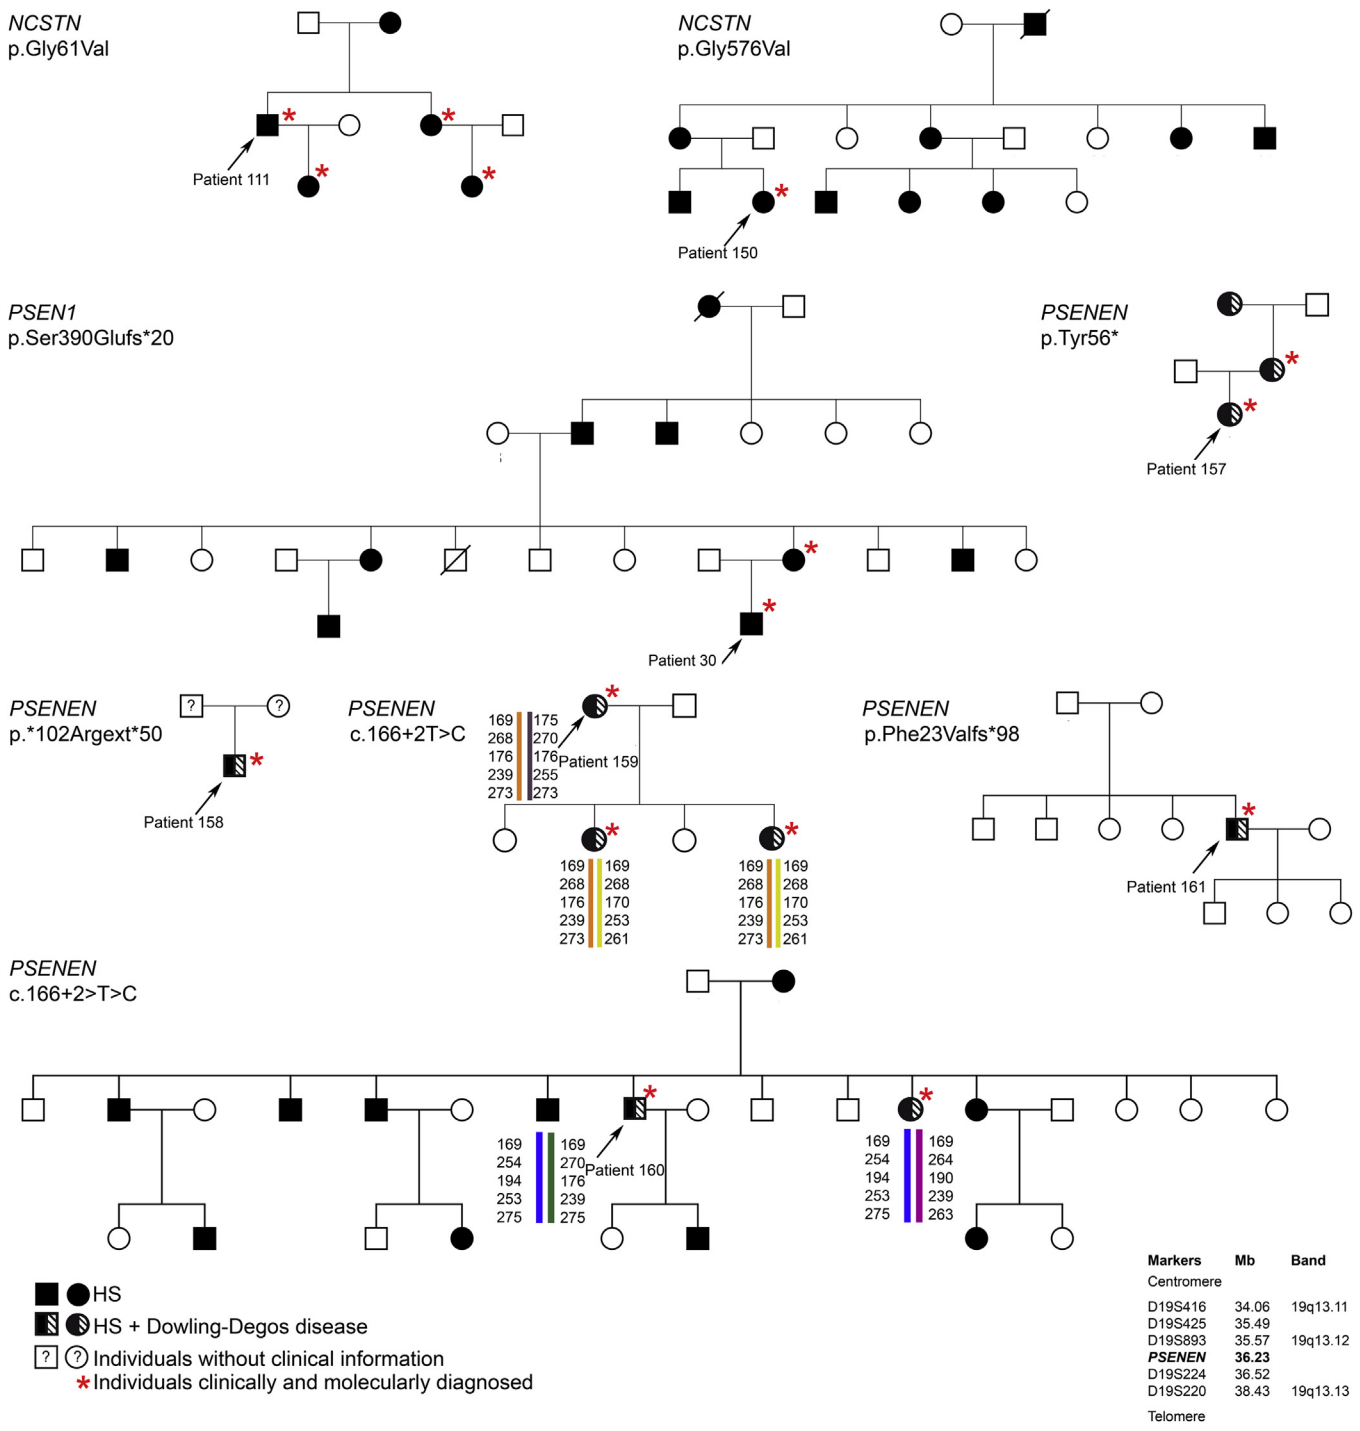

Figure 1. Genealogical trees of patients harboring mutations in *NCSTN*, *PSEN1*, or *PSENEN* genes. Arrows indicate the probands. Haplotype reconstruction with informative microsatellites markers D19S416, D19S425, D19S893, D19S224, and D19S220 on chromosome 19q13.11-q13.13 flanking *PSENEN* was performed for patient 159 and her two affected daughters and for patient 160 and one of his affected sisters, as illustrated. No common haplotype for these two families was identified. Patient 160 belongs to a family in which some patients presented only HS and were unavailable for the genetic study. Patient 2 *NCSTN* variant was excluded as there was no cosegregation of this splicing variant with HS and no effects on mRNA expression or splicing, arguing against a causal mutation. HS, Hidradenitis suppurativa.

SUPPLEMENTARY MATERIALS AND METHODS

Clinical diagnostic criteria

Diagnosis of hidradenitis suppurativa was made according to European guidelines (Zouboulis et al., 2015a, 2015b), including recurrent or suppurating typical lesions (nodules, abscesses, sinus tracts, or hypertrophic scars) in typical localizations (axillae, inguinal folds, anal cleft, and submammary regions) occurring more than twice in six months.

Study subjects

The DNA bioresources originated from three protocols dedicated to studies of hidradenitis suppurativa, which were all approved by French Ethical Committee (CPP Ile-de-France I, CPP Ile-de-France 3). All protocols were parallelly approved by the French drug agency (AFFSSAPS/ANSM). Written informed consents were obtained from all included subjects. Samples and associated data were managed by the ICAReB platform at Pasteur Institute, Paris, France, or by Necker Imagine DNA biobank, Paris, France, following all applicable regulations and standards. The probands and their relatives provided blood samples. Patients 2, 157, and 158 provided punch biopsies of skin. De-identified normal skin from surgical margins was obtained for controls.

Targeted next-generation sequencing

A custom SureSelect gene panel was designed using the SureDesign software (*Homo sapiens*, hg19, GRCh37, February 2009, Agilent Technologies, Santa Clara, CA). The target regions covered 751.97 kb (panel v1) or 866.10 kb (panel v2), including coding exons and splice junctions of the 185 genes (panel v1: 2613 exons) or 210 genes (panel v2: 2803 exons), respectively. Illumina compatible precapture barecoded genomic DNA libraries were constructed according to the manufacturer's protocol (Ovation Ultralow, Nugen Technologies, Redwood city, CA). Briefly, genomic DNA (1−3 μg) was mechanically fragmented by sonication with a Covaris S2 Ultrasonicator (Covaris, Woburn, MA), ligated to multiplexing Illumina compatible paired-end adapters, amplified by PCR with indexed (barcoded) primers for sequencing, and hybridized to biotinylated complementary 120-bp RNA custom−designed capture probes in a solution-based reaction. Hybridization was performed at 65 °C for at least 16 hours, followed by paired-end sequencing on the Illumina HiSeq 2500 (130 × 130 bases) or on a NovaSeq 6000 (100 × 100 bases) at the Genomics Core Facility at the Imagine Institute.

Data analysis was performed with Paris Descartes University and/or Imagine Institute's Bioinformatics Core facility. After demultiplexing, sequences were aligned to the reference human genome hg19 using the Burrows-Wheeler Aligner. Downstream processing was carried out with the Genome Analysis Toolkit, SAMtools, and Picard, following documented best practices (http://www.broadinstitute.org/gatk/guide/topic?name=best-practices). Variant calls were made with the Genome Analysis Toolkit, Unified Genotyper, freebayes, and SAMtools on the basis of the 72nd version of ENSEMBL database. Variants were annotated and analyzed using the in-house PolyDiag software interface that filtered out irrelevant and common polymorphisms on the basis of frequencies extracted from public databases (dbSNP, Exome Variant Server, and Exome Aggregation Consortium). Consequences of mutations on protein function were predicted using Polyphen2 (http://genetics.bwh.harvard.edu/pph2), SIFT (https://sift.bii.a-star.edu.sg/), and MutationTaster (www.mutationtaster.org). Mutations were then ranked on the basis of the predicted impact of each variant by combined annotation-dependent depletion (Kircher et al., 2014) and compared with the mutation significance cutoff, a gene-level specific cutoff for combined annotation-dependent depletion scores (http://pec630.rockefeller.edu:8080/MSC) (Itan et al., 2016). To evaluate copy number variations (i.e., duplication and large deletion events for each individual), the relative read count for each targeted region was determined as the ratio of the read count for that region divided by the total absolute read counts of all targeted regions of the design. The ratio of the relative read count of a region in a given individual over the average relative read counts in other individuals of the run resulted in the estimated copy number for that region in that individual (method adapted from Goossens et al., 2009).

The mean depth of coverage per sample was >300× (except for patients 51, 148, 150, 152, and 155 for whom it comprised between 267× and 298×) allowing the maximization of detection of variant in regions with less coverage and to enable accurate copy number variant analysis of the exons of the panel. In average, 99% of the targeted exonic bases were covered at least with 30 independent reads.

Prioritization of the variants was performed by PolyDiag interface. We excluded known variants with a minor allele frequency ≥5% listed in databases or variants previously identified in in-house exomes. We subsequently selected for variants affecting splice sites or coding regions (nonsynonymous, nonsense, frameshift, and start and/or stop gain or loss) and predicted to be damaging by in silico prediction tools. Additional prediction tools were then used to predict the pathogenicity of candidate missense variants identified (Panther, MutationAssessor, AlignGVGD, SNAP2, SNP&GO, Condel, FATHMM, Provean, and MutPred2). Other computational tools were also used (VEST-4, MutPred-LOF, DDIG, and ENTPRISE-X). To evaluate the consequence of the splicing-site mutation, we used in silico prediction tools (SSF, MaxEnt, NSPLICE, GeneSplicer, and HSF).

Microsatellites genotyping

Primers sequences of microsatellite markers (available at the Working Draft of the Human Genome available at University of California Santa Cruz, Human Assembly [GRCh37/hg19]) used for haplotype analysis at *PSENEN* locus (19q13.12) are as follows;

D19S416 (AFM304XF5): Forward 5′-CCTGTCCCAGAGAGACCCTA-3′, Reverse 5′-AAGAGAGTGTGCCATTTGCT-3′;

D19S425 (AFMA139WE9): Forward 5′-CCACAGGTGTGCATAAAAG-3′; Reverse 5′-GCCATGTGACTGTAGCAGA-3′;

D19S893 (AFMB004WH1): Forward 5′-AATCCTGAGACTGGGGG-3′, Reverse 5′-TGGTGACACACTGGTGAC-3′;

D19S224 (AFM240VC1): Forward 5′-AACACCATTCCTCATCTTCC-3′, Reverse 5′-CCCAGGCCCTATCTGA-3′;

D19S220 (AFM214YF12): Forward 5′-ATGTTCAGAAAGGCCATGTCATTTG-3′, Reverse 5′-TCCCTAACGGATACACAGCAACAC-3′.

Fluorescein amidites–labeled amplified fragments were electrophoresed on an Applied Biosystems 3500XL genetic analyzer using GeneScan 400 HD ROX Size Standard (Life technologies, Carisbad, CA) and analyzed using the Gene-Mapper Software 5 (Applied Biosystems, Foster City, CA).

Cell culture

The 4-mm punch biopsies were explanted to isolate primary epidermal keratinocytes, which were maintained in Green medium on a feeder layer of lethally irradiated 3T3 mouse fibroblasts as described previously (Barrandon and Green, 1987). For experiments, keratinocytes were grown in 0.06 mM $CaCl_2$ EpiLife medium (Invitrogen, Carisbad, CA) to 70–80% confluence.

RNA isolation from primary human epidermal keratinocytes and RT-PCR

Subconfluent cultured keratinocytes were harvested, RNA was prepared through RNeasy Mini (Qiagen, Hilden, Germany), and cDNA was prepared with random hexamer priming and SuperScript IV reverse transcriptase (Life-Technologies). PCR was performed in triplicate for each sample with qPCR MesaGreen Mastermix (Eurogentec, Liège, Belgium) on a 7500 Sequence Detection (Applied Biosystems). Six control subjects were used, giving similar results. The experiment was replicated at least three times. PGK1 was used as an endogenous control.

RT-PCR primers

Quantitative PCR was performed with *PSENEN or HES1* and normalization to *PGK1*.

PSENEN: Forward 5′-ATGAACCTGGAGCGAGTGTC-3′, Reverse 5′-GTGTAGGCTGGGACAAGGAA-3′;

HES1: Forward 5′-CCAAAGACAG CATCTGAGCA-3′, Revrse 5′-AGAATG TCCGCCTTCTCCA-3′;

PGK1: Forward 5′-CTGTGGCTTC TGGCATACCT-3′, Reverse 5′-AATC TGCTTAGCCCGAGTGA-3′.

Protein isolation from primary human epidermal keratinocytes and immunoblotting

Keratinocytes were lysed in buffer (50 Mm, pH: 8, Tris-HCl, 150 mM NaCl; 1% Nonidet P-40, 5 Mm, pH: 8, EDTA pH: 8; Complete protease inhibitors [Roche, Basel, Switzerland]), incubated on ice for 30 minutes and sonicated for 2 minutes. Protein extracts were isolated by centrifugation at 13,000*g* at 4 °C for 20 minutes. 30 μg samples were loaded in Laemmli buffer (62.5 Mm, pH: 6.8, Tris-HCl, 5% β-mercaptoethanol, 2% SDS, 10% glycerol, 0.002% bromophenol blue), separated by SDS-PAGE, transferred onto Nitrocellulose membrane (Trans-Blot Turbo Nitrocellulose, Bio-Rad, Hercules, CA), and incubated with primary and secondary antibodies, with chemiluminescence detection (ECL Plus Western Blotting Substrate, Pierce) using the ChemiDoc Imaging System (Bio-Rad). β-Actin served as loading control. Experiments were replicated three times. Two control subjects were used, giving similar results.

Antibodies. Primary antibodies included rabbit polyclonal anti-PEN2 (Enzo ADI-905-736), rabbit polyclonal anti-NCSTN (N1660, Sigma, St. Louis, MO), and mouse monoclonal anti-PSEN1 (MAB5232, Chemicon International, Temecula, CA). Secondary antibodies were HRP-linked anti-rabbit or anti-mouse IgG antibodies (#7074 and #7076, Cell Signaling, Danvers, MA).

Statistical analyses. Statistical significance of observed differences was assessed by two-tailed Mann–Whitney *U* tests. Means with SEM are shown.

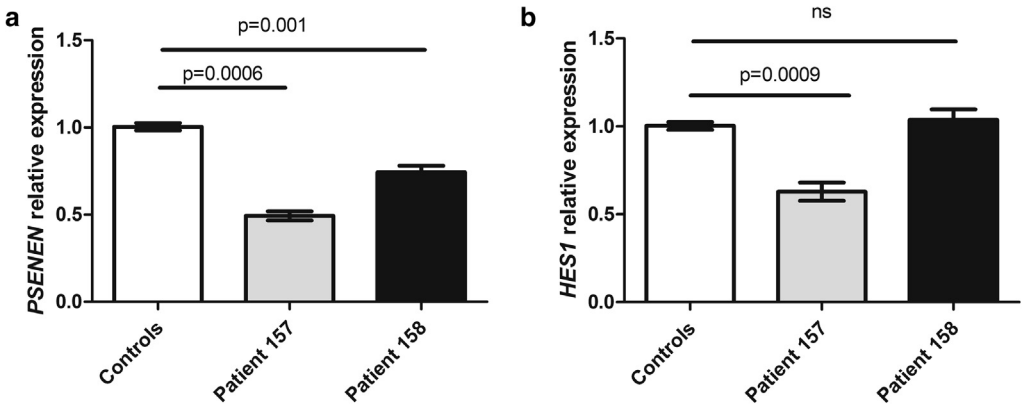
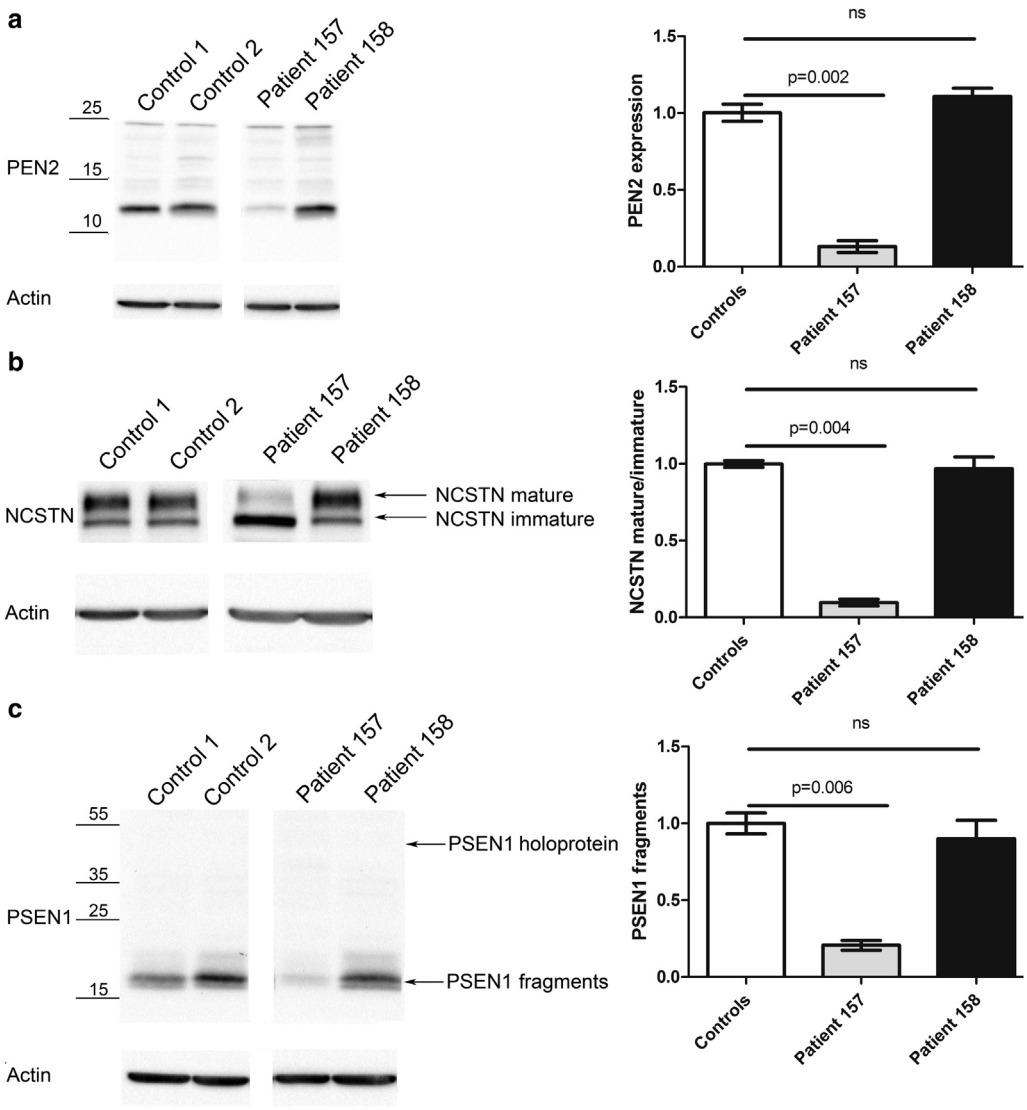
Supplemental Figure S1. Histopathological and clinical features of patients with HS with identified mutations. H&E staining of affected skin from patient 158 with HS and Dowling-Degos disease carrying a *PSENEN* mutation showed epidermal hyperplasia with elongated and hyperpigmented rete ridges. Hyperpigmentation and numerous multipore comedones in the groin of patient 30's affected mother (harboring *PSEN1* mutation and presenting with HS associated with Crohn's disease and ankylosing spondylitis). Nodules of the groin and the buttocks in patient 111's affected niece (carrying *NCSTN* mutation). Hyperpigmentation of the intergluteal fold, the groin, and the axillary regions in patient 157 (affected with HS and Dowling-Degos disease, harboring a *PSENEN* mutation). Subjects consented to the publication of their images. HS, Hidradenitis suppurativa.



Supplemental Figure S2. Relative *PSENEN* and *HES1* transcripts abundance in *PSENEN*-mutated patients versus control primary human epidermal keratinocytes. Quantitative RT-PCRs of keratinocyte RNA from patients 157 (p.Tyr56*) and 158 (p.*102Argext*50) show (**a**) decreased *PSENEN* expression level in both patients compared with control RNA, suggesting nonsense-mediated mRNA decay and unstable mutant mRNA degradation, respectively, and (**b**) reduction in *HES1* (used as a hallmark for Notch signaling activation) expression level in patient 157. *PGK1* was used as an endogenous control.



Supplemental Figure S3. Immunoblot of PEN2, NCSTN, and PSEN1 in *PSENEN*-mutated patients and control primary human epidermal keratinocytes. Western blot analysis of keratinocyte lysates from control subjects and patients 157 and 158 probed for (**a**) PEN2, (**b**) NCSTN, and (**c**) PSEN1 show decreased PEN2 levels, a significant reduction in mature NCSTN expression and in PSEN1 fragments in patient 157, but no abnormality for patient 158. No mutated PEN2 protein was observed in patients 157 and 158 (size prediction ~7 kDa for p.Tyr96* and ~17 kDa for p.*102Argext*50). Unaltered PSEN1 endoproteolysis was noted in both patients. Actin was used as a loading control.

Gene	Mutation		Familial Segregation	Functional Studies	Reference
	Nucleotide	Protein			
PSENEN	c.168T>G[10]	p.Tyr56*	Yes	mRNA study from keratinocytes: decreased *PSENEN* expression; Notch-responsive reporter assay in primary keratinocytes: decreased Luciferase activity	Pavlovsky et al. (2018)
	c.194T>G[10]	p.Leu65Arg	Yes/Yes	None	Zhou et al. (2016) / Li et al. (2017)
	c.229_230insCACC[10]	p.Ile77Thrfs*45[11]	Yes	None	Li et al. (2017) (Zhang et al. unpublished data)
	c.279delC	p.Phe94Serfs*51[11]	Yes	None	Wang et al. (2010)

Abbreviations: HS, Hidradenitis suppurativa; PASH, pyoderma gangrenosum, acne, and suppurative hidradenitis; N/A, not applicable; NR, not reported.

Mutations are numbered according to the nomenclature of the Human Genome Variation Society, such that +1 is the A of the start codon (ATG) of the cDNA sequences of *NCSTN* (Genbank accession number NM_015331), *PSEN1* (NM_000021), and *PSENEN* (NM_172341).

[1]This mutation was initially reported as p.Thr70fsX18.

[2]This mutation was initially reported as p.Pro73Leufs*15.

[3]PASH syndrome.

[4]This mutation was initially reported as c.687insCC p.Cys230Profs*31.

[5]This mutation was initially reported as c.1125+1G>A.

[6]This variant is unlikely to be causal according to our findings (absence of cosegregation with the disease and no effect on *NCSTN* splicing or expression).

[7]This variant was reported to be unlikely pathogenic on the basis of mRNA study results.

[8]This mutation was initially reported as c.1799delTG p.Leu600X.

[9]These variants were reported to be unlikely pathogenic (absence of cosegregation with the disease, observed in healthy controls, predicted to be benign).

[10]HS associated with Dowling-Degos disease or hyperpigmentation.

[11]Mutations predicting an altered and elongated protein.

[12]Patients with this mutation presented Dowling-Degos disease associated or not with HS.

[13]This mutation was initially reported as g.1412T>C.

Supplementary Table S3. Clinical Information for the 169 Patients with HS from the Cohort
